Abstract

In autumn 2005 the artificial catchment Chicken Creek was completed in an open-cast lignite mine in Lusatia, Germany. The 6 ha area has been constructed as a two-layer system consisting of a clay aquiclude and a sandy aquifer at the top. After construction the site was left to an unrestricted and unmanaged succession. A comprehensive environmental monitoring program started immediately after the site was completed. Time series of essential environmental parameters were recorded with high temporal and spatial resolution. This paper presents selected time series of the past six-year ecosystem development. Important changes registered in this period allow for the definition of distinctive phases of the still ongoing initial ecosystem evolution. A primary, short but pronounced geo-phase – characterized by surface runoff, excessive erosion and sedimentation as well as very rapid immigration of biota – was followed by a hydrological dominated phase with processes such as groundwater recharge. At the end of the study period biotic processes became more evident. It can be concluded that the artificial catchment offers unique opportunities for

interdisciplinary research on the establishment of an ecological system with rapidly growing complexity. The highly dynamic development of the Chicken Creek catchment provides the possibility to observe manifold changes within short time and to detect feedbacks and their modifications between different ecosystem compartments.

Keywords

initial stage, environmental monitoring, erosion, groundwater recharge, soil development, primary succession

1. Introduction

1
2
3 Watersheds as the only landscape unit with naturally defined boundaries are often
4 used in interdisciplinary ecological studies for very different purposes and at
5 different scales. Prominent examples for large-scale ecological research are the
6 Hubbard Brook Experimental Forest (Campbell et al. 2007) or the Walnut Gulch
7 Experimental Watershed (Stone et al. 2008). Both sites are naturally developed
8 catchments observed to understand the ecological response of forest ecosystems to
9 various disturbances and manipulations or rainfall-runoff processes, respectively.

10
11
12
13
14 **In Germany, e.g., hydrological research in the Schäfertal catchment already**
15 **started in the 1960ies (Reinstorf et al. 2013).** Generally, the number of
16 instrumented watersheds worldwide is large and it is still growing, as the problem
17 of global change is often investigated using such experimental landscape units.
18
19 Whereas many of these sites deal with specific disciplinary, often hydrological
20 oriented objectives, interdisciplinary approaches are of growing importance. Lin
21 (2011) pointed out that “processes occurring at and near the Earth’s surface do not
22 operate independently”. In his opinion recently postulated new sub disciplines of
23 hydrology such as hydropedology, ecohydrology or hydrogravimetry are of
24 increasing importance as they clearly demand the interdisciplinary exchange with
25 other areas of ecological research and geosciences.

26
27
28
29
30
31
32
33
34
35
36 Such multidisciplinary approaches are the background for recently established
37 networks such as the Critical Zone Exploration Network in the USA (Brantley et
38 al. 2006). In Germany a network of terrestrial environmental observatories
39 (TERENO) was launched in 2008 (Bogena et al. 2012, Zacharias et al. 2011).

40
41
42
43 **Another example for interdisciplinary catchment research is the Water & Earth**
44 **Science Competence Cluster (WESS) considering several different catchments of**
45 **different scales in Germany (Grathwohl et al. 2013).** In TERENO, long-term
46 integrated observation platforms are operated as a joint research network activity
47 between several institutes of the Helmholtz-Association and in close cooperation
48 with university partner institutions with the aim to investigate consequences of
49 global change for terrestrial landscapes and ecosystems. **Measured data from the**
50 **TERENO sites are provided by the TEODOOR portal (Kunkel et al. 2013).**

1 research stations and activities and complementing them with dedicated new
2 infrastructure for long-term integrated environmental monitoring and observation.
3 The TERENO Northeast German Lowland Observatory (Bens et al. 2012) has
4 been established in close vicinity to the artificial catchment Chicken Creek. These
5 investigations are also based on catchments as spatial units. However, the
6 expected response of the monitored ecosystems to global change processes is
7 supposed to be very subtle and difficult to observe in the short term.

8
9
10
11
12 In contrast, highly dynamic conditions are found **when** investigating ecosystems
13 in their initial state of development. This initial stage can be defined as the time
14 period between the start of ecosystem development (“point zero”) and the
15 quantitative establishment of a first dynamic equilibrium of element cycling of an
16 ecosystem (Schaaf et al. 2011). The duration of this initial stage differs with the
17 type of ecosystem and, for example, **climatic** conditions. According to Schaaf et
18 al. (2011), the initial stage can be characterized as a sequence of development
19 phases taking into account that the number of ecosystem patterns and related
20 structural complexity are growing with ecosystem development. This assumption
21 is consistent with ecosystem development models, e.g., provided by Odum
22 (1969), or more recently discussed by Fath et al. (2004). In most cases such initial
23 systems are far less structured and less heterogeneous than mature systems (e.g.,
24 **Huggenberger et al. 2013**) which have undergone an evolution of several centuries
25 or millennia. During ecosystem development both the complexity of structures
26 and their interactions increases as additional patterns (e.g., surface and subsurface
27 flow paths, humus layers and soil horizons, rooting channels and worm burrows)
28 and processes (e.g., erosion and sedimentation, C-accumulation and pedogenesis,
29 effects of biota) appear. These initial processes determine and control **evolving**
30 properties and functions of the system (Schaaf et al. 2011). Thus, the analysis of
31 young ecosystems in their initial stage of development seems to be a fundamental
32 approach and essential requirement to disentangle the complex web of processes,
33 and help to better understand both ecosystem functioning as well as ecosystem
34 reactions to alterations of structural properties. Interactions between newly
35 emerging structures and related processes, including feedback processes between
36 existing and new structures, should be much more visible if initial ecosystems are
37 investigated.

The objective of this paper is, therefore, to introduce a promising scientific method and a category of watersheds, which is supplemental to approaches such as TERENO – the specific use of artificial catchments with evolving initial ecosystems. Prominent examples for other artificial watersheds are Hydrohill in China (Kendall et al. 2001) or the Biosphere 2 project in Arizona, USA (Hopp et al. 2009) with clearly disciplinary, but mostly hydrological, emphases. This paper presents a unique new research site that has been launched for interdisciplinary ecological research in autumn 2005. The artificial catchment Chicken Creek (the German name is “Hühnerwasser”) offers the opportunity to investigate linkages between abiotic site development and biotic responses and vice versa in a well-defined, constructed system at the landscape scale. The evolution of such initial ecosystems is rapid and highly dynamic so that short-term feedback processes and changes of ecosystem behavior can be studied directly. The main focus of the Chicken Creek project is on the multidisciplinary study of ecosystem and landscape functioning (Gerwin et al. 2011). Thus, the project addresses the problem of co-evolution of ecosystems and landscapes which had been postulated as one of the central questions of ecosystem research (Reinhardt et al. 2010). The Chicken Creek catchment is equipped with a comprehensive ecological monitoring network observing hydrological, pedological, limnological and biological compounds and processes. In this paper results of the first more than six years of intensive monitoring of ecosystem evolution in the Chicken Creek catchment are presented demonstrating the dynamic evolution of the system as well as the occurrence of first feedback processes. Time series of geomorphic, hydrologic, soil and water chemistry as well as biotic parameters have been recorded in high temporal and spatial resolution. The different monitored components are discussed as parts of the developing system as a whole and already existing and evident feedback controls between single compartments are presented.

2. Artificial catchment and monitoring program

2.1 Artificial catchment

The Chicken Creek catchment was constructed as part of the post-mining landscape of the Lusatian lignite mine Welzow-Süd in the State of Brandenburg,

1 in Northeast Germany, about 150 km southeast from Berlin (Fig. 1). The site was
2 built as the headwater of a small stream of the same name and consists of an area
3 with clear boundary conditions at the surface and in the underground and has both
4 terrestrial and aquatic parts. Detailed descriptions of its internal structures and
5 also of the construction works are summarized by Gerwin et al. (2009, 2010 and
6 2011); the most important properties are introduced below.

7
8
9
10 Generally, the site is constructed as a two-layer system with a clay layer as the
11 aquiclude and an overlying sandy layer as the aquifer. The watershed covers an
12 area of 6 ha (see Fig. 2 for site dimensions and inner structures). As a unique
13 feature this site was left to an unrestricted and unmanaged succession after the
14 construction work was completed in 2005. Faunistic and floristic patterns are
15 allowed to evolve according to the initial site conditions, which are also subject to
16 natural modifications during the further ecosystem development. Generally, the
17 site can be divided into three major sections: (i) the backslope area, (ii) the
18 footslope, and (iii) the pond basin. **A subsurface clay dam in the footslope area
19 was constructed as a barrier for groundwater fluxes and for geo-mechanical
20 reasons.** The site is completely fenced off to avoid disturbances by human visitors
21 or the abundant game animals.

33 **2.2 Ecosystem monitoring**

34
35
36 A comprehensive description of the monitoring configuration and methods in use
37 as well as of preliminary results can be found in previous “Ecosystem
38 Development” publications by Gerwin et al. (2010), Schaaf et al. (2010) and
39 Elmer et al. (2011) (the volumes of this project series are available online via their
40 URN given in the list of references). Basic monitoring installations - such as
41 groundwater gauges, atmospheric deposition samplers, soil moisture probes - are
42 oriented along a regular network of grid points, which were defined at the start of
43 observations in autumn 2005. Several new measuring devices were installed
44 during the following years at evolving structures of the system which are of
45 specific interest (weirs and flumes for runoff measurement in erosion gullies,
46 additional groundwater gauges). In this paper results of the following monitoring
47 investigations are introduced.

2.2.1 Meteorology

Two weather stations operate in the catchment. Weather station 1 is used for the registration of basic data, whereas weather station 2 provides more detailed data. Data obtained at station 1 are presented here. This station measures basic meteorological parameters with time resolution of one hour since September 2005 and is located in the upper eastern part of the catchment. Details of the installed techniques are published by Biemelt and Nenov (2010). **Measured annual precipitation and average temperature values as well as long term data for comparison are given in Tab. 1.**

2.2.2 Remote sensing

A micro drone (MD4-200, microdrones GmbH) equipped with a digital camera is in use to take aerial photographs of the whole catchment with a high spatial resolution (terrain resolution of 3 cm x 3 cm). Photographs **have been** taken regularly in spring (April), summer (June/July) and autumn (September). Technical details of the drone and details of picture processing are published by Veste et al. (2010). The aerial photographs together with digital elevation models (DEMs provided by Vattenfall Europe Mining AG) are used to identify and quantify surface structures such as erosion rills or vegetation cover. The vegetation cover within the catchment was calculated on the basis of these aerial photographs using ArcGIS (ESRI, version 9.3). A supervised classification was conducted to identify areas with vegetation cover. To calculate the vegetation cover within the erosion rills, these maps were superimposed with maps of the gully network, which were also derived from aerial photographs.

2.2.3 Hydrology

A total of 30 groundwater gauges are installed in the catchment area. Nine of them register groundwater levels automatically; the levels at the other gauges are measured manually every two weeks. Biemelt et al. (2010) describes details of the measuring arrangement. Within three larger erosion rills, **flumes were** installed to measure surface runoff. In this paper data from the central erosion gully are presented, which provides the streambed for the most important stream of the site. Permanent base flow is found here in the lower parts whereas periodic peak flow occurs after heavy rainfall events. The measuring techniques used in this gully to

1 quantify runoff (“flume 2”: stainless steel H-flume made by Umwelt-Geräte-
2 Technik GmbH) are described by Biemelt et al. (2010). The same holds true for
3 the subsurface drainage gutter, measuring the baseflow in the main eastern gully
4 since June 2009. Two weirs are operating within the catchment: The inflow to the
5 pond from the artificial spring area (Fig. 2) is determined by means of weir 1
6 (upper weir), whereas total catchment runoff is measured at the outlet of the pond
7 by means of weir 2 (lower weir). The discharge from the pond is controlled by its
8 water level, which is automatically recorded by two pressure transducers.
9

2.2.4 Water and soil solution chemistry

Bulk **aerial** deposition was sampled initially at 18 grid points. Since the data of bulk precipitation and rainwater composition showed no consistent spatial trend over the catchment area, sampling points were reduced to 9 in November 2009 (Schaaf and Elmer 2011). Both weirs and the flume in the central gully were equipped with automated water sampling units (ISCO 6712, ISCO 3700). Daily water samples were taken and collected every two weeks. Sampling started in June 2007 at both weirs and in May 2008 at the flume. Daily samples were measured for pH and electrical conductivity (EC) and biweekly mixed samples were used for further analysis. Soil solution was sampled from four permanent soil pits from October 2007 in two depths (30 cm, 80 cm) using boron silicate glass suction plates (\varnothing 10 cm) with permanent pressure of -10 kPa. Samples were taken every two weeks. All solution samples were analyzed for pH (Beckmann pH34 glass electrode and WTW pH537) and electrical conductivity (EC; Hanna HI 8733 and WTW LF537), concentrations of cations (ICP-OES Unicam 701 and Thermo Scientific iCAP 6000), anions (IC Dionex 5000), NH_4 (Rapid Flow Analyzer Alpkem), DOC, TOC, TIC and TN (Shimadzu TOC-5000 and VCPH+TNM-1).

2.2.5 Vegetation

Since 2005, the developing vegetation of the study site has been recorded in July and August each year. Assessment plots are assigned to the regular grid (20 m x 20 m). Each grid point is permanently marked by a flag denoting the centre of a quadrat plot of 25 m², with additional plots of 1 m² at each corner. The

1 monitoring program is, therefore, based on a nested plot design with one 25 m²
2 plot at each grid point including four 1 m² plots (Zaplata et al. 2010).
3

4 **2.2.6 Soil fauna**

5

6
7 Sampling of soil fauna began in October 2005, and from then on has taken place
8 at usual times of peak abundances of the soil fauna, namely in April/May and
9 October. A total of 27 soil cores for both microfauna (Nematoda, Tardigrada) and
10 mesofauna (Collembola, Acari) were taken on the respective sampling dates. Soil
11 cores for microfauna (3.5 cm in diameter) and mesofauna (6.4 cm in diameter)
12 were always taken to a depth of 5 cm and directly adjacent to one another (Elmer
13 et al. 2010). The “weighted faunal analysis” concept was applied, where
14 functional guilds of nematodes are indicators of food web complexity and
15 nutritional status of the post-mining soils (Hohberg 2003).

19
20
21
22
23

24 **3. Time series of ecosystem development**

25 **3.1 Geomorphic development**

26

27
28 During the first two years (until 2007), development of the Chicken Creek
29 catchment was dominated by intensive surface runoff processes, e.g., after
30 episodic heavy precipitation events or snow melt, resulting in severe sheet and
31 gully erosion causing considerable changes of the initial surface structure. Visual
32 observations in the first years also indicated a noticeable contribution of wind
33 erosion to the total sediment balance. Wind erosion modeling and aerial image
34 analysis suggested that aeolian sediment relocation was about two magnitudes
35 lower than that caused by water erosion (Maurer and Gerke 2011). Further hydro-
36 geomorphic development was characterized by an increasing vertical incision and
37 lateral extension of the gully network. Width and depth of these channels were
38 highly influenced by the varying textural composition of the initial substrate. As a
39 consequence, overall length and area of active streambeds within erosion rills
40 increased rapidly until mid of 2007 (Fig. 3). Sediment relocation and the
41 emergence of erosional and depositional structures resulted in rapid surface
42 differentiation.

58 **Biological colonization of the site started immediately and became obvious in**
59 **2009 when the vegetation cover rapidly increased to more than 30 % (Fig. 7). This**
60
61
62
63
64
65

1 development changed geomorphic development clearly. After the first phase of
2 rapid growth and vertical incision, the general evolution of the erosion rill
3 network was apparently completed and the prevailing processes changed. With
4 the development of biological soil crusts (Fischer et al. 2010, Spröte et al. 2010)
5 and an increasingly denser vegetation cover the growth of the rill length and
6 stream bed area was disrupted and both length and area of actively eroding rills
7 decreased. This corresponds to the establishment of vegetation in formerly more
8 unstable regions in combination with vegetation growing preferably along the
9 former stream beds within the rills. In fact, plants started invading notably into the
10 erosion rills (Fig. 4) and it is assumed that they could benefit from the sediment
11 structures formed by the ephemeral small streams. As a consequence, the erosion
12 gullies became paths of vegetation dispersal for some species that had been
13 immigrated early to these structures. Once the vegetation cover reached high
14 values in 2010 and 2011, the analysis of stream length and area using aerial
15 photographs was no longer possible.

16 The Chicken Creek catchment offers the unique opportunity to investigate the
17 influence of developing structures in the terrestrial parts of an initial ecosystem on
18 a young aquatic system. The described geomorphic development in the terrestrial
19 part of the catchment is mirrored by the evolution of an extensive sediment body
20 in the pond basin during the first years of development, which reduced depth and
21 volume of the pond and increased turbidity. Longer rainy periods and episodic
22 precipitation events contributed to an enhanced material input as revealed by the
23 annual sedimentation rate of up to 30 cm yr⁻¹ in the inflow area of the pond.
24 Hence, already in 2008 19.7 % of the original pond volume was filled with
25 sediments from the catchment (Kleeberg et al. 2010) and a pronounced alluvial
26 fan established in the inflow region of the pond. In the following years, sediment
27 transport into the pond was considerably reduced as shown by measurements of
28 the sediment structures in the pond in 2010 and 2011. Sedimentation traps
29 revealed that most sediment was retained by the growing reed belt around the
30 pond and the sedimentation rate decreased to about 17 cm yr⁻¹ (Kleeberg 2011).

3.2 Hydrologic development

31 Surface runoff and the primary groundwater recharge were the most important
32 hydrologic processes during the first stage of development of the catchment

1 (Mazur et al. 2011). **Substrate saturation** and the establishment of a groundwater
2 body above the clay layer proceeded over several years. This groundwater
3 recharge period **between 2005 and 2009** is defined by a trend of increasing
4 groundwater levels overlain by typical seasonal fluctuations due to prevailing
5 natural discharge and recharge processes in summer and winter, respectively (Fig.
6 **5**). This period of groundwater filling was apparently completed in 2009 when the
7 overall increasing trend of the groundwater table ended and only the seasonal
8 fluctuations remained. However, exceptional high amounts of rainfall in 2010 led
9 to a temporary increase of groundwater levels up to the surface, indicating the
10 almost complete saturation of the sediment body. In contrast, in 2011 with
11 “normal” precipitation amounts, groundwater tables declined again to the level of
12 2009 when the equilibrium between discharge and recharge was reached for the
13 first time.
14

15 The amount of runoff registered in the two main erosion gullies increased over the
16 observation period, particularly visible at the central erosion gully as shown in
17 Fig. 5. A constant but relatively low base flow has been observed in both streams
18 since 2007 and has been measured since 2008. As of 2010 a marked increase in
19 runoff with pronounced peaks after rainfall events was detected.
20

21 The pond integrates most of the hydrological processes occurring in the terrestrial
22 parts of the system. A close relationship between the temporal patterns of rainfall
23 and discharge at the pond weir (Fig. 5) demonstrates the still initial conditions of
24 the catchment: With very short delay, the pond level increases after rainfall starts.
25 The very sudden, complete filling of the pond basin with water in winter 2005/06
26 was the result of specific meteorological conditions demonstrating the importance
27 of surface runoff in this initial system: Melting snow combined with rainfall on
28 frozen soil led to very high surface runoff into the basin. Even if this
29 extraordinary event was promoted by the bare sediment surface, physical soil
30 crusting and the described weather conditions, the importance of surface runoff
31 with regard to the hydrological behavior of the catchment is still obvious. Large
32 amounts of water from precipitation still directly flow into the pond, causing
33 sudden changes of the pond level. In August 2010, permanent discharge from the
34 pond was observed due to high water levels caused by large amounts of
35 precipitation. The inflow into the pond reached significantly higher values and
36 showed higher temporal dynamics compared to the outflow measurements. The

1 pond storage attenuated these high dynamics, which produced a smoother curve of
2 pond discharge.
3

4 **3.3 Chemical development** 5 6

7 Chemical composition of surface runoff, pond water and soil solutions in the
8 catchment changed dynamically over time (Fig. 6). With time, concentrations and
9 EC values of the soil solution corresponded well to the chemistry of runoff waters
10 with similar temporal trends. The highest EC values and highest element
11 concentrations were found in the surface runoff sampled in the central erosion
12 gully.
13
14
15
16
17

18 Due to the carbonate content of the substrates, mean pH values varied between 7.0
19 and 8.4 in all water and soil solution samples. The parallel decreases of SO_4 as
20 well as of Ca and Mg (both not shown here) are clearly reflected in the electrical
21 conductivity (EC). Traces of gypsum in the substrates may be a source for both
22 Ca and SO_4 in the initial phase of leaching. Since the gypsum contents were very
23 low, decreasing sulfate concentrations in both soil water and pond water indicated
24 that gypsum was dissolved and mobilized within a few years. The occurrence of
25 gypsum in the Pleistocene substrates can be attributed to very high atmospheric
26 deposition of both sulfur and alkaline ashes from unfiltered lignite-fired power
27 plants in the former German Democratic Republic (GDR) together with low
28 precipitation and leaching (Dultz and Kühn 2005). With increasing vegetation
29 cover and litter input to the soil, carbonate weathering increased as indicated by
30 increasing inorganic carbon (TIC) concentrations and was the main control for
31 calcium concentrations in soil solution. With regard to water chemistry of the
32 upper weir and flume samples, concentrations decreased significantly, mainly for
33 calcium, magnesium and sulfate, whereas bicarbonate increased. The overall
34 concentrations at the flume and the upper weir were much higher compared to soil
35 solutions and pond water at the lower weir.

47
48
49
50

51 The element budgets were strongly influenced by both changes in water chemistry
52 and in discharge rates mentioned above. Whereas the concentrations found in bulk
53 deposition (values for “precipitation” in Fig. 6) were low and did not vary much
54 over the years, output rates increased over the observation period mainly as a
55 consequence of the strong increases in discharge, especially in the very wet year
56 2010. In all years, the catchment was a strong source for calcium, magnesium,
57
58
59
60
61
62
63
64
65

1 sulfur and inorganic carbon. In contrast, the catchment acted as a strong sink for
2 nitrogen as was expected for strongly nitrogen limited systems.
3

4 **3.4 Biotic development**

5
6
7 The initial spatial differentiation of substrate characteristics led to an early
8 patterning of species composition particularly with regard to spatial differences in
9 vegetation cover. For instance, the first dominating plant species *Conyza*
10 *canadensis* colonized the whole catchment but differences in cover reflected the
11 subareas of the catchment (Zaplata et al. 2011). During the first years a first
12 differentiation in species composition occurred, mainly reflecting the parts of the
13 catchment area consisting of slightly different substrates. Furthermore, some plant
14 species are mainly restricted to the area close to the pond, where an increasingly
15 broader reed belt (*Phragmites australis*) has its origin.
16

17
18 Total plant cover increased substantially and reached a preliminary maximum in
19 2009 (Fig. 7). Parallel to this trend, groundwater reached its maximum level
20 facilitating water supply also for shallower rooting plants. A general decline in
21 vegetation cover was then observed in 2010, mainly caused by a decreasing cover
22 of the dominant species *Trifolium arvense*. Possible reasons for this decline are
23 unfavorable weather conditions with a harsh winter season 2009/2010,
24 characterized by a long-lasting frost season and large amounts of snow, and
25 extremely high rainfall amounts during summer 2010. Further, this phenomenon
26 illustrates the large dynamics of plant populations (Zaplata et al. 2013) and the
27 low overall resilience in this developmental state. In 2011 the total cover again
28 reached almost the level of 2009. At the same time, the importance of woody
29 plants is increasing. Most important is the leguminous tree species *Robinia*
30 *pseudoacacia* which rapidly colonizes the catchment area. Generally, nitrogen-
31 fixing plant species became a major component of the establishing vegetation.
32 The importance of this plant functional type for early ecosystem developmental
33 states is clearly reflected by their comparatively high cover, especially from 2009
34 on. Parallel to the increase of vascular plants the cover of mosses has been rapidly
35 growing since 2009/2010, most probably favored by the wet weather conditions in
36 2010.
37

38
39 The total number of vascular plant species increased quite continuously (Fig. 7).
40 This increase was particularly rapid from 2005 (about two months after final
41
42

62
63
64
65

1 surface flattening) to 2006. Despite the still ongoing immigration, the increase of
2 total species numbers has slowed down. For instance, between 2010 and 2011 the
3 total number of vascular plants only grew by one additional species. However,
4 species turnover is not shown here, as presented numbers account for the net
5 balance and hence the sum of immigration and extinction.
6

7
8
9 The floristic colonization of the Chicken Creek pond was investigated by
10 Lessmann and Nixdorf (2011). They found a high species richness of
11 phytoplankton within a few years. Submerged macrophyte biomass, however,
12 soon exceeded phytoplankton biomass. According to their results phytoplankton
13 was characterized by a low number of steady taxa indicating a generally low
14 stability of the community. In addition, a sharp increase in phytoplankton biomass
15 occurred in 2010, one year after the increase of terrestrial vegetation cover.
16

17
18
19 One month after construction in autumn 2005, the initial substrates were already
20 inhabited by first representatives of the soil food web (Fig. 7). Specimens of those
21 first and later colonizing species found favorable conditions and nutrient resources
22 sufficiently available to survive in the newly formed substrate, and from there
23 some pioneer species spread almost immediately into individual-rich populations
24 (Russell et al. 2010). Still numbers of overall soil animals were low during the
25 first two years of succession. As of 2007, densities steadily increased and slowly
26 reached numbers determined for mature soils. Overall species numbers, on the
27 other hand, were still relatively low in the sixth year of catchment development
28 and many more species are expected to arrive and settle in the future. None of the
29 soil faunal groups under investigation have yet reached their usual species
30 numbers, except for tardigrades, which already passed their peak in 2009.
31

32
33
34 The basal status of the Chicken Creek communities is mirrored by the faunal
35 profile presented in Fig. 8. It suggests that the flow of resources into the food web
36 system as well as the prevalence and abundance of higher trophic level organisms
37 was dramatically low in 2005. By 2007, the number of trophic links within the
38 soil food web increased substantially and in October 2009 and October 2010
39 reached structure indices determined from mature, undisturbed soil food webs
40 (Fig. 8, dark green dots, quadrat C). This concurs with the vegetation becoming
41 more diverse and the plant cover rising, thus providing an increasing supply of
42 nutrient resources and niches. In accordance with the distinct increase of plant
43 cover in 2009, plant associated biota (e.g., root-feeding nematodes) are positively

1 correlated with the above-ground succession. Hence, the soil food web clearly
2 developed in association with the plant community, which is typical for the initial
3 stage of succession (Bardgett and Wardle 2010). Densities and species richness of
4 soil-inhabiting carnivores, on the other hand, remained rather low throughout the
5 first six years of ecosystem development and established populations were not
6 found until 2009.
7
8
9

10 **4. Phases of ecosystem development**

11 Ecosystem development comprises a series of transitions and changes in
12 environmental conditions, which again affect biological colonization. These
13 changes may be caused by varying external factors and/or may be controlled by
14 internal processes (Begon et al. 2005). During the first six years considerable
15 changes were observed within the Chicken Creek catchment. Both internal and
16 external factors could be identified as driving forces of new structures and
17 patterns. **It is hypothesized** that the very first phase of ecosystem development is
18 characterized by a still more or less abiotic system developing under the influence
19 of existing structures and external drivers (Schaaf et al. 2011). This is in good
20 accordance with the observed course of ecosystem development in the artificial
21 catchment Chicken Creek.
22
23
24
25

26 Most of the time series of ecological parameters registered at the Chicken Creek
27 catchment indicate distinct temporal trends. Some of them reveal that processes
28 have already reached their maximum whereas others are still at their beginning.
29 Different phases in the initial ecosystem development at Chicken Creek catchment
30 can be distinguished and defined preliminary as follows and summarized in Fig. 9.
31 Phase I was characterized by a very rapid alteration of surface structures by
32 geomorphic processes, particularly erosion and sedimentation. Simultaneously,
33 pioneering biota invaded the site forming early, irregular patterns of scattered
34 populations. **Since the catchment is situated within a large post-mining area,**
35 **surrounding sites are characterized by different types of ruderal vegetation, but**
36 **also initially restored agricultural (e.g., lucerne) or afforested sites (e.g., black**
37 **locust, pine, oak) that may have served as sources for the starting colonization**
38 **process.** Internal structures generated by the construction process and initial
39 substrate characteristics were decisive for distribution and flow of precipitation
40 water as well as for biotic succession. External factors such as episodic

1 thunderstorm events triggered erosion and dissection of the surface during this
2 first phase, promoted by the low vegetation cover and the unconsolidated
3 character of the sandy substrate. Thus, the covering sandy material with very low
4 organic matter content and a loose structure had to be classified as highly
5 erodible. As a consequence, water and sediment were transported and
6 redistributed within the catchment and new structural elements evolved.

7
8
9
10 Immigration of flora and fauna from nearby source habitats was another external
11 process leading to colonization patterns. As a result, an overall differentiation of
12 the catchment area was observed into subareas underlying abrasion or
13 accumulation processes on the one hand and subareas with stable surfaces on the
14 other hand (Schneider et al. 2011). This first phase was short in time and highly
15 dependent on initial structures such as substrate, texture and source habitats of
16 immigrating biota. For the Chicken Creek catchment this phase predominantly in
17 2007 when the extent of erosion clearly decreased, groundwater tables had
18 reached their preliminary maximum, and the steepest increase of both floristic and
19 faunistic species numbers was already completed. This phase was defined as
20 “geo-phase” as the system was still mainly dominated by substrate characteristics
21 and geomorphic processes (Schaaf et al. 2011). Processes of the second phase
22 were already active here such as dissolution processes triggered by infiltrating
23 water.

Phase II is defined by a growing importance of hydrologic processes, especially
the initial groundwater recharge leading to the establishment of a groundwater
body in the aquifer. This process depended on infiltration and seepage of
precipitation. In addition, seepage through the almost unweathered sediments was
further accompanied by the transport of ions from easily soluble salts like gypsum
into the groundwater body. The continued colonization by biological soil crusts
and vascular plants caused a significant decline of geomorphic processes as the
surface became progressively stabilized by these biota. Vegetation established
preferentially along the linear structures of former erosion channels, which was
probably due to the better growing conditions with respect to water availability of
the sediments found here. Also nutrient availability may be improved in these
stream beds due to matter relocation and concentration processes. With regard to
flora and fauna, species increasingly established in the course of Phase II and the
respective populations started to spread within the catchment. Nevertheless, this

1 phase is consistent with the “geo-hydro-phase” of Schaaf et al. (2011): Biota were
2 colonizing but not yet dominating ecosystem performance.

3 The dissection and stability of surfaces, however, was an important factor not only
4 for the formation of vegetation patterns but also for biological soil crusts. Initially
5 established structures such as soil crusts obviously influenced vegetation patterns
6 by altering soil surface properties and stability as well as by promoting surface
7 runoff and erosion. In the course of Phase II these initial physical and early
8 biological soil crusts were more and more replaced by moss crusts with
9 completely different ecological properties. Mosses are known as an important
10 player in the initial colonization of bare soil surfaces by biological soil crusts and
11 represent late-successional stages of these crusts (Belnap et al. 2001, Spröte et al.
12 2010). The impact of different types of biological crusts including moss crusts on
13 soil hydraulic properties particularly under temperate humid climate conditions is
14 still unclear and subject to further investigations (Belnap et al. 2001). However, it
15 is assumed that moss crusts have a positive impact on water infiltration and by
16 this may reduce surface runoff. Generally, biological soil crusts influence and
17 induce soil forming processes. Their effect at the micro-scale was described by
18 Fischer et al. (2010, 2012). Later in this phase decalcification as one of the first
19 pedogenic processes became evident as indicated by increasing concentration of
20 inorganic carbon in soil solution and runoff waters.

21 Finally, Phase III was marked by the gradually growing importance of these soil
22 forming processes as well as of biotic interactions and groundwater discharge.
23 Total cover of vascular plants was growing further and replacing the actual moss
24 crusts step by step. Soil fauna is drastically increasing both in number of species
25 and individuals as well as in the complexity of the soil food web. Hence, both the
26 interactions between flora and fauna as well as the impacts on their abiotic
27 environment will probably gain larger influence. For instance, Boldt et al. (2012)
28 demonstrated the importance of organic carbon and nitrogen inputs into the soil
29 via roots of the legume *Lotus corniculatus*. Particularly, feedbacks between the
30 further development of vegetation and hydrologic properties are expected as a
31 consequence of changing evapotranspiration conditions of the site. By now these
32 interactions between vegetation and hydrology are still less pronounced.
33 Nevertheless, with rising groundwater levels, the main erosion gullies developed
34 to (at least locally) perennial streams and spreading of specific plants such as reed

(*Phragmites australis*) was observed particularly along these erosion rills and at other restricted areas with higher soil moisture. Further, the importance of evapotranspiration as one key factor for lowering the groundwater table in summer when seasonal fluctuations of the groundwater levels were observed is rapidly growing.

Odum (1969) proposed trends of ecological processes to be expected in the development of ecosystems. These trends can be applied to the model of ecosystem development suggested by Fath et al. (2004): The distinct increase in the amount, number, and size of biota in the catchment corresponds to “structural growth”; this holds true for all presented groups, and especially since 2009. Moreover, the increasing complexity of food webs, and the rising importance of higher plants (i.e., macrophytes, trees) reflect slight network and information growth according to Fath et al. (2004), indicating a trend of increasing system organization and efficiency. The transformation of the initial geo-system into areas with evolving terrestrial or aquatic ecosystem characteristics and from a very episodic to a more permanent stream network and discharge, together with the observed biotic dynamics increased site diversity and heterogeneity with respect to water and nutrient availability and transformation processes.

5. Conclusions

Six years of monitoring in the artificial catchment Chicken Creek revealed a highly dynamic development of the initial ecosystem. On the basis of the recorded time series of environmental parameters, three phases of ecosystem development can be distinguished. According to this preliminary classification the system will be governed by biota in the short run.

However, indications of low resilience and stability in different compartments of the system, of below-ground species diversity being still low, and of feedback mechanisms playing a minor role clearly support the assessment that the Chicken Creek catchment is still in a very early, initial state. For the future, it is expected that (i) ecosystem biomass will increase quantitatively in the short term, capturing more of the incoming solar energy, (ii) connectivity both between and within the compartments will further grow, raising the internal organization in the mid-term, and (iii) a delayed qualitative growth to more conservative, energetically efficient patterns will occur. Finally, it is supposed that feedback mechanisms (e.g.,

1 primary producers and groundwater development) will intensify with the
2 increasing number of effective structures within the system in the near future.
3 Therefore, investigations of these interactions between different compartments of
4 the Chicken Creek catchment need to be intensified and adapted to the system
5 transitions.
6

7
8 With regard to interdisciplinary ecological research activities this site offers
9 unique opportunities. The multi-temporal observation approach refers to a
10 hierarchy of time scales, ranging from event based, continuous, to periodic
11 measurements, using ground-based (geomorphology, pedology, hydrology,
12 biology, limnology), meteorological and remote sensing techniques. In particular,
13 the gradual growth of heterogeneity and complexity of the ecosystem allows for
14 studies of initial ecosystem development processes and steps. The understanding
15 of this first stage of establishing natural systems based on high resolution time
16 series (Bakker et al. 1996) seems to be crucial for a better understanding of
17 reactions and resilience of ecosystems and feedback mechanisms between
18 different compartments. Furthermore, the highly dynamic development allows for
19 a monitoring of a fast sequence of successional stages and phases within a short
20 period of time. Thus, monitoring techniques designed for the observation of
21 global change reactions on different time scales and on the ecosystem level can be
22 tested, calibrated and validated at sites such as the Chicken Creek catchment with
23 well-known inner structures and previously determined boundary conditions.
24 Therefore, the artificial catchment Chicken Creek initiative contributes very well
25 to other recently established critical zone observation sites amongst Germany and
26 Central Europe.

¹⁾no data available: measurement started in May 2008

²⁾no data available: measurement started in July 2009

Fig. 6: Chemical development of the Chicken Creek catchment since autumn 2005: pH values and electrical conductivity in soil solution, runoff and bulk precipitation; sulfate and total inorganic carbon (TIC) concentrations in soil solution, different runoff components and bulk precipitation. Weather data (daily temperature and precipitation values) are given for comparison.

¹⁾no data available: measurements started in July 2006 (weir 1 and 2), May 2008 (flume), and November 2007 (soil solution), respectively

Fig. 7: Biological development of the Chicken Creek catchment since autumn 2005: Cover degree for plants and mosses and plant species number (both from geobotanic monitoring at permanent monitoring plots). Abundance and species number of soil fauna (both from repeated samplings in spring and autumn). Weather data (daily temperature and precipitation values) are given for comparison.

1) data from only 360 1 m² plots excluding the pond area

2) conservative estimations on the basis of preliminary determinations

3) no data available: samples not yet determined

Fig. 8: Faunal profiles representing the food-web condition in relation to its structure (SI) and enrichment (EI) as indicated by the “weighted faunal analysis” (mean ± 1 SE, n = 27); Quadrat A: poorly developed or highly disturbed food web condition, N-enriched, bacterial decomposition channel, low C/N ratio, Quadrat B: maturing food web condition, disturbance low to moderate, N-enriched, balanced decomposition channel, low C/N ratio, Quadrat C: undisturbed, structured food web and relatively low primary production, fungal decomposition channel, moderate to high C/N ratio, Quadrat D: basal or degraded food web condition, depleted, fungal decomposition channel, high C/N ratio.

Fig. 9: Schematic overview of intensity (from low to dominating with regard to the qualitative and/or quantitative importance of the respective process at a specific moment) of selected geomorphic, hydrologic, pedogenic and biologic processes and their temporal development during the initial ecosystem stage observed at the Chicken Creek catchment. The indicated phases are characterized in the text.

Tables

Tab. 1: Annual precipitation and average temperature measured at the Chicken Creek catchment compared to long term climate data (normal period 1961-1990, DWD weather station Cottbus, data provided by Deutscher Wetterdienst)

	2006	2007	2008	2009	2010	2011	1961-1990
	Chicken Creek catchment						weather station Cottbus
Temperature [°C]	10.9	11.3	10.9	10.3	9.0	10.9	8.9
Precipitation [mm]	403.4	667.2	659.9	664.9	793.6	639.1	563
