#### Abstract

Fault plane solutions for earthquakes in the central Hellenic arc are analysed to determine the deformation and stress regimes in the Hellenic subduction zone in the vicinity of Crete. Fault mechanisms for earthquakes recorded by various networks or contained in global catalogues are collected. In addition, 34 fault plane solutions are determined for events recorded by our own local temporary network on central Crete in 2000-2001. The entire data set of 264 source mechanisms is examined for types of faulting and spatial clustering of mechanisms. Eight regions with significantly varying characteristic types of faulting are identified of which the upper (Aegean) plate includes four. Three regions contain interplate seismicity along the Hellenic arc from west to east and all events below are identified to occur within the subducting African lithosphere. We perform stress tensor inversion to each of the subsets in order to determine the stress field. Results indicate a uniform N-NNE direction of relative plate motion between the Ionian Sea and Rhodes resulting in orthogonal convergence in the western forearc and oblique ( $40-50^{\circ}$ ) subduction in the eastern forearc. There, the plate boundary migrates towards the SE resulting in left-lateral strike-slip faulting that extends to onshore Eastern Crete. $\mathrm{N} 110^{\circ} \mathrm{E}$ trending normal faulting in the Aegean plate at this part is in accordance with this model. Along-arc extension is observed on Western Crete. Fault plane solutions for earthquakes within the dipping African lithosphere indicate that slab pull is the dominant force within the subduction process and interpreted to be responsible for the roll-back of the Hellenic subduction zone.

Keywords: Crete, Hellenic subduction zone, fault plane solutions, seismotectonics, deformation regime, stress tensor inversion

## 1. Introduction

The Hellenic subduction zone is the seismically most active region in Europe. There, the convergent plate boundary between the African lithosphere and the Aegean plate as part of Eurasia is located south of Crete in the Libyan Sea. It approaches the passive continental margin of northern Africa due to roll back of the Hellenic subduction zone and the convergence between Africa and Eurasia (e.g. McKenzie, 1970; LePichon and Angelier, 1979; Jackson and McKenzie, 1988; LePichon et al., 1995). The overall rate of convergence is $3-4 \mathrm{~cm} / \mathrm{year}$ (e.g. McClusky et al., 2000). A well-developed Benioff zone was identified by seismicity to a depth of $150-180 \mathrm{~km}$ below the central Aegean (e.g. Papazachos, 1973; Makropoulos and Burton, 1981; Papadopoulos et al., 1986; Knapmeyer, 1999; Papazachos et al., 2000) and the subducting lithosphere can be followed down to about 1200 km by seismic tomography (e.g. Spakman et al., 1988; Bijwaard and Spakman, 1998). A tectonic reorganization in the entire south Aegean region at 3.4 Ma may mark the onset of continent-continent collision between the Aegean plate and the continental African plate (Lyon-Caen et al., 1988; LePichon et al., 1995: Mascle et al., 1999) at the western Hellenic arc. This resulted in a complex tectonic frame with a number of details such as the rapid uplift of western Crete (e.g. Lambeck, 1995) that are not yet fully understood. At the central and eastern part of the forearc indications for remnants of oceanic crust were identified (Bohnhoff et al., 2001; Brönner, 2003; Meier et al., 2004a).

Figure 1 gives an overview on the tectonic setting of the Aegean-Anatolian region with the Hellenic subduction zone. The island of Crete forms the central part of the Hellenic arc. Below the Libyan Sea an accretionary wedge with a sedimentary cover of up to 15 km is located between the active and passive continental margins. Recent microseismicity and surface wave studies (Meier et al., 2004b) as well as active seismic lines (Truffert et al., 1993; Bohnhoff et al., 2001; Brönner, 2003) allowed to refine the structural model along the Hellenic subduction zone (see inset in Figure 1) exemplifying the complex geometry along a strongly curved plate boundary.
The overall seismic activity of the Hellenic subduction zone is small compared to other subduction zones as can be observed from global earthquake catalogues. The distribution of hypocenters in the south Aegean region dominantly follows the Hellenic arc with stronger seismic activity observed in the eastern part. The hypocenters form an amphitheatrically shape of the Benioff zone in first order approximation (see e.g. Bath, 1983; Engdahl et al., 1998; Knapmeyer, 1999; Papazachos et al., 2000) and thus the trend of the steepest descent of the dipping slab significantly varies along the Hellenic arc. In contrast, the GPS horizontal velocities in this region as determined by McClusky et al. (2000) show only minor variation in trend (up to $18^{\circ}$ ) and magnitude (in the order of $\mathrm{mm} / \mathrm{a}$ ).
Several authors have analysed the stress field at the Hellenic subduction zone mainly based on fault trends and outcropping faults (e.g. Angelier et al., 1982; Meulenkamp et al., 1988; Ten Veen and Kleinspehn, 2003) or analysis of large earthquakes (Taymaz et al., 1990; Papazachos et al., 2000). In this study, we analyse fault mechanisms for earthquakes covering a broad magnitude range along the Hellenic arc in the vicinity of Crete. The area of investigation is indicated by the rectangle in Figure 1. We attempt to determine the deformation and stress regimes based on fault plane solutions that were collected from various local and regional studies as well as global catalogues. Furthermore, we newly determined fault plane solutions for smaller events recorded by our own local network in the Messara plain (Central Crete).

## 2. Data base and procedure applied

To compile a complete data base of fault mechanisms available we collected data from various published studies as well as from global catalogues available through the World Wide Web. We restricted the data base to events within $22.5-27.5^{\circ} \mathrm{E}$ and $33.5-36.5^{\circ} \mathrm{N}$ with no depth limitation. This resulted in a total of 352 events (including multiple occurrences) that cover a magnitude range between 0 and 6.5. Table 1 gives an overview on all events with occurrence time, hypocentral coordinates, magnitude, fault mechanisms and information on the relevant source. The sources that contributed to the data base and number of fault plane solutions taken are: Becker, 2000 [ 37 fault plane solutions]; Benetatos et al., 2004 [11], DeChabalier et al., 1992 [16]; Delibasis et al., 1999 [29]; Hatzfeld et al., 1993a and 1993b [37]; Jost et al., 2002 [12]; Kiratzi and Louvari, 2003 [8]; McKenzie, 1972 and 1978 [7]; Papadimitriou, 1993 [3]; Papadopoulos et al., 1986 [21]; Papazachos, 1973, Papazachos and Papazachou, 1997, Papazachos et al., 1991 and 2000 [24]; Taymaz et al., 1990 [14]; Harvard CMT, http://www.seismology.harvard.edu/CMTsearch.html, 1977-2004 [42]; MEDNET INGV, http://mednet.ingv.it/events/QRCMT/Welcome.html, 2001-2004 [10]; SED ETH Zürich, http://www.seismo.ethz.ch/mt, 2000-2004 [43]; USGS (except CMT solutions), http://neic.usgs.gov/neis/sopar, 1982-2002 [4]. Clearly, this catalogue is heterogeneous as it contains recordings from local, regional and global networks covering different time intervals as well as some relocations and redeterminations. Furthermore, non-uniform methods were used to determine the fault plane solutions (for description of methods used to determine the fault plane solutions in the individual studies we refer to the relevant article or webpage). Only some authors (Taymaz et al., 1990; Benetatos et al., 2004) give information on the accuracy of their fault mechanisms which was considered when skipping multiple-occurring events (see below). However, we assume having good control on the error bounds as we can compare the solutions from different sources for the same event in a number of cases. We thus estimate the overall errors for strike, dip and rake to be $15^{\circ}$. This value needs to be considered when discussing the significance of our results later in the text.
Some earthquakes occur plurally in Table 1 as they are listed in more than one study or catalogue and in some cases non-uniform fault mechanisms were given to the same event. We therefore carefully studied the entire catalogue and skipped multiple occurrences of individual earthquakes by eliminating all but the most reliable solution. We define the most reliable solution as the one determined with the best station configuration and most advanced method (which was usually that based on regional waveform modelling). This procedure reduced the catalogue to 232 fault mechanisms.

In addition to the collected fault plane solutions we determined source mechanisms for selected mircoearthquakes that were recorded by our own local network in southern central Crete in 2000/2001 (see Meier et al., 2004b). The network consisted of eight stations surrounding the Messara plain (see Figure 2, lower left). All stations were equipped with MARK 3C-L4 seismometers and operated at a 50 Hz sampling rate. Recordings from nearby permanent stations of the GEOFON network (Hanka and Kind, 1994) were added to improve the focal coverage for local events. To determine the source mechanisms we applied the FOCMEC program (Snoke et al., 1984; Snoke, 2003) that performs a gridsearch assuming a pure double-couple mechanism. P wave polarities as well as $\mathrm{SH} / \mathrm{P}$ amplitude ratios served as input data. To allow confident fault plane solutions we selected only events that occurred within or near the network and skipped those with errors $>15^{\circ}$. This resulted in a total of 34 fault plane solutions covering a magnitude range from 0.3-3.5. Three examples of fault plane solutions and the station distribution of the seismic network in central Crete are shown in Figure 2.
Finally, the entire data set of fault mechanisms for earthquakes along the central Hellenic arc consists of 264 fault plane solutions that form the base for further analysis. Figure 3a shows the entire catalogue of fault plane solutions in a map view of the lower hemispheres. To further analyse the data base we focus on the orientations of maximum compression ( P ) and tension ( T ) in the following. In Figure 3b we plotted the P and T axes of the entire catalogue in an equal-area projection of the lower hemisphere and scaled the size and shading of circles with magnitude and hypocentral depth, respectively. The distribution of P and T axes indicates that the stronger and deeper events show preferred orientations whereas the smaller and shallower events indicate a comparatively high diversity of mechanisms. The magnitude frequency of all earthquakes is shown in Figure 4. The catalogue is complete for magnitudes $\geq 5$. The large number of smaller ( $\mathrm{M}<3$ ) events documents the contributions from local networks on Crete that were operated for several (3-18) months. A remarkable decrease of number of events is observed within the range $3<\mathrm{M}<5$. We explain this by the fact that such events are not recorded by the permanent global network (which allows completeness of $\mathrm{M}=4$ only since the middle 1990s) due to their size nor by local networks due to their short recording period.
To analyze the data set for spatial clustering of faulting mechanisms we proceeded as follows: As a first step we defined a northward dipping layer of $\sim 25 \mathrm{~km}$ thickness representing the contact zone between upper Aegean and lower African plate. In fact this zone is supposed to be thinner. However, we have to take into consideration the location error of the globally recorded events for the hypocentral depth which is supposed to be in the order of $\pm 10 \mathrm{~km}$. Furthermore, the complex geometry of the Hellenic subduction zone requires some simplification when trying to analyse the seismic activity at the plate contact zone as a whole. We refer to all events located within this layer as interplate earthquakes in the following.
In a second step, this layer was subdivided into three segments along the Hellenic arc from West to East. The dip of each segment was adjusted following structural models of the forearc region that were derived from wide angle seismics (Bohnhoff et al., 2001; Brönner, 2003), surface wave and receiver function analysis (Li et al., 2003; Meier et al., 2004a; Endrun et al., 2004) and moving source profiles (Truffert et al., 1993). Furthermore, we implement data from a Moho map of the Eastern Mediterranean (Marone et al., 2003). We defined all events above the contact zone as brittle failure within the upper Aegean plate and all events below as earthquakes within the dipping African lithosphere.
In a third step we scanned all events within the Aegean plate for spatial clustering of P and T axes. We identified four distinct subvolumes with significantly varying clustering of fault mechanisms. This resulted in a total of eight subvolumes (1-4 within the Aegean plate, 5-7 interplate seismicity, 8 within the dipping African lithosphere) that are described in the following.

## 3. Results:

3.1 Fault mechanisms within the Aegean plate:

Most of the fault mechanisms within the Aegean plate group into four subvolumes with significantly different types of characteristic faulting and level of clustering. Figure 5 combines these four subvolumes in a map view of their fault plane solutions and distributions of P and T axes within each subvolume. The westernmost region combines 28 events on and offshore western Crete at a maximum hypocentral depth of 17 km (subvolume 1). The events cover a magnitude range between 0.0 and 4.5 . The majority of T axes trends EW at shallow plunge whereas the P axes have a dominant steep plunge and some being shallow with an average NS trend. This reflects a normal faulting regime for western Crete that is currently in the state of EW extension. In contrast, no preferred orientation of the P and T axes was identified in central Crete (subvolume 2). A total of 43 events are contained in this subvolume
most of which occurred below the Messara plain in southern central Crete down to 20 km depth. Magnitudes do not exceed $\mathrm{M}=4.4$. Whereas most P axes exhibit dominant trends at $\mathrm{N} 20^{\circ}-70^{\circ} \mathrm{E}$ and $\mathrm{N} 240^{\circ}-280^{\circ} \mathrm{E}$ at varying plunge, the T axes do not exhibit any preferred orientation at all. Forming subsets based on hypocentral distribution following the main tectonic features of the Messara plain does not result in a more uniform distribution of P and T axes. The distribution of P and T axes can thus not be the result of a locally varying deformation regime, at least not at the scale resolved by the detection threshold of the local networks operated in this region. One possible explanation for such a heterogeneous distribution could be a non-uniform stress field within this subvolume. We refer to this point later in the text.
Further to the East a total of 28 events were investigated that all occurred at depth levels between 10 and 25 km below Eastern Crete (subvolume 3). The depth distribution is different to Western and Central Crete where most events occur at shallower depth. The distribution of P and T axes indicates a predominant strike-slip mechanism with components of mainly reverse but also normal faulting. Interestingly, the P axes tend to the N as well as to the S at a plunge of $20-45^{\circ}$. In contrast, the T axes are concentrated to $\mathrm{N} 270^{\circ}-320^{\circ} \mathrm{E}$ with a similar plunge. Thus, the fault planes are left lateral, SW/NE oriented and steeply dipping to the SE or right lateral, NW/SE oriented and steeply dipping the NE.
The easternmost subvolume 4 covers the area around the island of Karpathos and contains 13 events. These occurred at depths between 5 and 20 km and are -on average- of greater magnitude compared to the three subvolumes to the West. Although they are distributed over a much wider area than the subsets on Crete, their faulting mechanisms show a stronger clustering of P and T axes indicating an $\sim \mathrm{EW}$ extensional deformation within the Aegean plate between Crete and Rhodos. Comparing the four subvolumes within the upper crust with respect to their magnitude contents suggests that stronger shallow events occur more frequently in the east than in the west. This correlates with the observation that the eastern part of the Hellenic subduction zone has higher seismic activity in general (see e.g. ISC catalogue by Engdahl et al., 1998). Shallow seismic events are leaking in the Karpathos region as no local network was operated there.
3.2 Fault mechanisms of interplate seismicity:

A total of 30 events were classified as interplate earthquakes as they occurred within the three northward dipping layers of $\sim 25 \mathrm{~km}$ thickness as described above. In Figure 6 the three subvolumes are plotted in a map view as well as in a depth section where upper and lower boundaries of the contact zone are indicated. The three subvolumes contain 15 , seven and eight events for the western, central and eastern part, respectively, and cover a magnitude range from 4.0-6.5 (smaller magnitudes were excluded as they may have larger location errors due to insufficient station coverage for regional networks on Greek territory). The P and T axes of interplate events in all three subvolumes have a preferred orientation of their deformation axes indicating shallowly N-NNE dipping thrust faulting. From the overall tectonic setting we can conclude that the steep plane does not represent the fault plane. Thus, the interplate events indicate a N-NNE trending direction of relative plate motion between the Aegean and African plates. This direction corresponds with measurements of the recent surface deformation in the south Aegean region (McClusky et al., 2000; see also black arrows in Figure 1). From west (subvolume 5) to east (subvolume 7) we observe a decreasing level of clustering of P and T axes in combination with small number of events contained in the subvolumes.
Furthermore, two of the subvolumes ( 5 and 7) contain a smaller number of strike-slip events that are among the best-constrained ones. The latest of these occurred in March 2004 south of Western Crete near the island of Gavdos (see Figure 6). Such events might reflect brittle failure along pre-existing faults within the upper crust although their hypocentral depth was uniformly set to 33 km as standard depth in the global catalogues. However, the overall set of interplate events indicates a N-NNE trending direction of relative motion between the Aegean and African plates that is uniform along the Hellenic arc.

### 3.3 Fault mechanisms of seismicity within the African lithosphere:

All hypocenters below the contact zone were identified as seismicity within the subducting African lithosphere (subvolume 8, 28 events). In Figure 7 the fault plane solutions of these events are plotted in a map view and as NS-depth section, respectively. The distribution of P and T axes differs from all other subvolumes. Whereas the compressional axes cover a wide azimuthally range ( $\mathrm{N} 110-270^{\circ} \mathrm{E}$ ) at shallow plunge, the tensional axes cluster at azimuths between $\mathrm{N} 300^{\circ} \mathrm{E}$ and $\mathrm{N} 30^{\circ} \mathrm{E}$ at an average plunge of $45^{\circ}$. Thus, a relevant part of the fault mechanisms within the subducting lithosphere is similar to those
observed for the interplate seismicity (shallow thrust faulting; see Figure 6) whereas the majority of fault mechanisms have T axes parallel to the dipping direction of the slab and shallow P axes with considerable scatter of their azimuth. We interpret this distribution to reflect two different types of faulting: A group of about five events reflects a nearly identical deformation mechanism as the interplate seismicity. We classify these events as interplate events which did not match the (simplified) geometry of the contact zone assumed here due to 1 . Their error in hypocenter location and 2. Local uncertainties in the existing structural models of the south Aegean region (that do not contain all local structural variations along the strike of the Hellenic arc). Thus, it is a difficult task to relate every single event to a certain type of seismicity (interplate versus in slab). Eliminating these five interplate events result in a sharper image of slab-related faulting mechanisms. The majority of events within the African lithosphere reflect slab-pull as dominant deformation mechanisms with both P and T axes being in plane with the dipping slab. The T axes point towards the dipping direction ( $\mathrm{N}-\mathrm{NNE}$ ) whereas the P axes are dominantly trending EW.

## 4. Stress tensor inversion

A stress tensor inversion using the technique of Michael $(1984,1987)$ was applied to the catalogue as a whole as well as individually to the eight subvolumes. The algorithm uses the statistical method of bootstrap resampling and allows determining the orientation of the three principal stresses ( $\sigma_{1}=$ maximum, $\sigma_{2}=$ intermediate and $\sigma_{3}=$ minimum $)$ as well as a relative stress magnitude $R=\left(\sigma_{1}-\sigma_{2}\right) /\left(\sigma_{1}-\sigma_{3}\right)$, $0<\mathrm{R}<1$. These parameters are determined by finding the best fitting stress tensor to the observed focal mechanisms. Assumptions that need to be fulfilled by the input data are: (1) stress is uniform in the area of investigation during the observed time interval, (2) the earthquakes are shear-dislocations on preexisting faults, and (3) slip occurs in the direction of the resolved shear stress on the fault plane.
The reliability of the deduced stress field orientation (given as the so-called misfit) reflects the level of stress field heterogeneity. We do not discuss the stress tensor inversion techniques here in detail but refer to the relevant articles where the methods themselves and their applications are entirely discussed (e.g. Gephart and Forsyth, 1984; Gephart, 1990; Michael, 1987; Michael, 1991; Hardebeck and Hauksson, 2001; Bohnhoff et al., 2004).
The inversion result for the entire catalogue reveals a well-constrained NS orientation for the maximum principal stress ( $\sigma_{1}$ ) at shallow dipping angle. In contrast, no clear separation between the intermediate $\left(\sigma_{2}\right)$ and smallest $\left(\sigma_{3}\right)$ principal stresses could be identified when considering the $95 \%$ ( $2 \sigma$ ) confidence intervals (Figure 8). This, however, is not surprising considering the varying deformation regimes within the eight subvolumes as discussed in the previous section that are all compatible with $\sim \mathrm{NS}$ trending shallow orientation of $\sigma_{1}$ but indicating different directions for $\sigma_{2}$ and $\sigma_{3}$.
Inversion results for the individual subvolumes reveal the following principal results (see Figure 9 for polar projection of the principal stress axes within each subset and Table 2 for exact values of trend and plunge of $\sigma_{1-3}$, misfit and R). Western Crete has a well-defined horizontal EW-trending direction of $\sigma_{3}$ whereas $\sigma_{1}$ and $\sigma_{2}$ overlap in their confidence intervals. For Central Crete no preferred orientation of the stress tensor was found which was expected due to the highly heterogeneous deformation axes contained in this subvolume. Eastern Crete reveals a well-defined orientation for $\sigma_{3}$ that trends EW (which is similar to Western Crete) but at $50^{\circ}$ dipping angle. This is compatible with a left-lateral strike-slip regime with components of reverse faulting. $\sigma_{1}$ and $\sigma_{2}$ are not clearly separated in their $95 \%$ confidence intervals. However, their $68 \%$ confidence intervals do not overlap indicating a $\mathrm{N} 30^{\circ} \mathrm{E}$ trending subhorizontal orientation for $\sigma_{1}$. The stress field around Karpathos is very similar to that on Western Crete but rotated clockwise by $\sim 20^{\circ}$.
Inversion results for interplate seismicity should be interpreted carefully due to the comparatively small number of fault mechanisms contained in the subvolumes 5-7 (15, eight and seven events, see discussion in Bohnhoff et al., 2004). The best solutions for $\sigma_{1-3}$ are not as well constraint as for the subvolumes 1-4 discussed above. We therefore combined all fault mechanisms contained in the subvolumes 5-7 (i.e. all interplate events) to one subset. The inversion result gives clear indication for a uniform stress field along the entire part of the Hellenic arc observed here indicating a thrust faulting regime with a subhorizontal and N-NNE trending direction of $\sigma_{1} . \sigma_{3}$ dips at $\sim 70^{\circ}$ with a trend of about $\mathrm{N} 50^{\circ} \mathrm{E}$ and $\sigma_{2}$ is almost horizontal trending EW.
The stress field within the African lithosphere exhibits a well defined direction for $\sigma_{3}$ that is trending NS at $\sim 50^{\circ}$ plunge. Different than for the interplate seismicity, $\sigma_{1}$ and $\sigma_{2}$ are not clearly separated but isolated at $68 \%$ confidence intervals which is well explained by the five interplate events contained in
this subvolume as discussed above. The stress field is compatible with slab pull as dominant force within the dipping slab.

## 5. Discussion

Western Crete reflects a clear normal faulting regime with dominant extension towards EW. Similar results were found earlier for this region based on fault plane data (Lyon-Caen, 1988; Hatzfeld et al., 1993a and 1993b; Jost et al., 2002; their data are contained in the here compiled catalogue) and from major fault trends, aerial photographs and outcropping faults (Angelier et al., 1982). Doutsos and Kokkalas (2001) identified normal faulting on Western Crete but with no preferred orientation for $\sigma_{3}$. Their data, however, cover also earlier stress regimes of different orientation, whereas the data base analysed in this study reflects the present (last $\sim 50$ years) tectonic setting. We interpret the present regime on Western Crete to reflect arc-parallel extension. The Karpathos area reflects a similar regime but rotated clockwise by $\sim 20^{\circ}$. The orientation of the smallest principal stress is thus significantly oblique with respect to the strike of the Hellenic arc at this part (see Figure 1). This is incompatible with the interpretation given by Benetatos et al. (2004) who analysed focal mechanisms of the Aegean region. They found EW-extension for the eastern Hellenic arc and interpret this as along-arc extension (their Figures 5+6).
Obviously, the extensional domains on Western Crete and around Karpathos are decoupled from the sinistral transtensional fault zone that is located south of Central and Eastern Crete. This fault zone consists of three branches misleadingly called Ptolemeus, Pliny and Strabo 'trenches' (indicated by dotted arrows in Figure 10). The term 'trench' is misleading as these structures do not represent subduction trenches as observed at various forearcs of subduction zones worldwide but, in contrast were identified as deep-sea depressions with wedge-shaped sedimentary basins of up to 4 km thickness (Bohnhoff et al., 2001). Furthermore, these branches have a dominant sinistral strike-slip faulting (LePichon and Angelier, 1979; Huchon et al., 1982; Huguen et al., 2001). Fault mechanisms for Eastern Crete reflect a subhorizontal NE trending direction for $\sigma_{1}$ and a $40-50^{\circ}$ dipping EW-trending direction for $\sigma_{3}$. This correlates with the main fault trend of the three deep-sea depressions which is NE to ENE (Angelier et al., 1982). Surprisingly, the fault mechanisms indicate sinistral transpression rather than transtension. The Eastern part of Crete might thus reflect a continuation of the Ptolemeus branch at slightly modified trend (ENE versus NE). This and the fact that Eastern Crete underwent significantly less stretching compared to the crust below the Libyan Sea (see Bohnhoff et al., 2001) might be responsible for the change from transtension to transpression. Furthermore this might be related to the laterally varying vertical deformation on Crete that is higher on Western and Eastern Crete compared to the central part of the island (Lambeck, 1995; their figure 14). This might also be a possible explanation of the heterogeneous stress field in Central Crete as observed here and for the high scatter of fault trends along this part of Hellenic arc in general (Angelier et al., 1982). Note, that this is different to western Crete where incipient collision is responsible for a blocked state which is probably one reason for the rapid uplift of this part of the island. The uplift seems to occur along steep normal faults as suggested by a number events contained in subvolume 1 (see Figure 5). Ten Veen and Kleinspehn (2003) report on $\mathrm{N} 70^{\circ} \mathrm{E}$ sinistral faults on southern central Crete to play a major role within the tectonic reorganisation of the Hellenic subduction zone at about 3.4 Ma . These faults are also included in our data and could be interpreted as presently reactivated remnants of the Plio-Pleistocene deformation.

Fault mechanisms of interplate seismicity indicate a uniform N-NNE trending direction of relative plate motion between the Aegean and African plates along the Hellenic arc between the Ionian Sea and Rhodes. This confirms earlier results that partly focussed on smaller portions of the Hellenic subduction zone. McKenzie (1978) proposed $\mathrm{N} 31^{\circ} \mathrm{E}$ and LePichon and Angelier (1979) argued for $\mathrm{N} 45^{\circ} \mathrm{E}$ as main trend for the relative motion between Africa and Crete. Taymaz et al. (1990) analysed events at $\sim 40 \mathrm{~km}$ depth and found slip vectors trending $\mathrm{N} 25^{\circ} \mathrm{E}$. Our data base covers the entire Hellenic arc between the Ionian Sea and Rhodes and shows that $\mathrm{N} 12^{\circ} \mathrm{E}$ is the representative orientation of relative plate motion for this part of the Hellenic subduction zone with an accuracy of $\pm 15^{\circ}$ (see Figures 6 and 9). This result correlates with the GPS horizontal velocities in a Eurasia fixed reference frame (McClusky et al., 2000; see Figure 1) within the accuracy resolved here. The amphitheatrically shape of the Benioff zone as derived from the spatial distribution of hypocenters (e.g. Knapmeyer, 1999), however, is not easily explained by a uniform direction of convergence. We interpret the shape of the Benioff zone to reflect the mechanical response of the subducting plate to the curved geometry of the plate boundary. Slab pull
results in rollback and forces Crete to become the leading edge of the plate boundary. This rollback and the curved earth's surface force the plate boundary to become concave with the consequence that the slab cannot descend in a simple planar shape.
A second major consequence of the uniform direction of relative plate motion along the Hellenic arc is the significantly varying angle of its trend to the strike of the plate boundary along the arc (see Figure 10). Both directions are approximately orthogonal in the western Hellenic arc. There, an incipient collision is likely to occur at present as was also proposed by Mascle et al. (1999) and TenVeen and Kleinspehn (2003). This might also be one principal reason for the rapid uplift of this part of the island. At Central Crete both directions form an angle of $60-70^{\circ}$ indicating a state of oblique subduction. The obliqueness increases further to the East towards Karpathos/Rhodos where it reaches a deviating angle of $40-50^{\circ}$.

At the central and eastern forearc, indications for remnants of oceanic lithosphere were identified by wide aperture seismic profiles (Bohnhoff et al., 2001; Brönner, 2003) that do not exceed 50 km in NSdirection as observed from surface wave studies (Meier et al., 2004a). A combined interpretation of the deformation and stress regimes within the upper plate and at the contact zone incorporating structural information suggests that the south-easternmost part of the Aegean plate advances towards the SE. This is also indicated by the GPS horizontal velocities in this region that show a small but systematically varying trend and increasing magnitudes while proceeding from west to east (Figure 11). We explain this velocity field to be initiated by the overall compressional regime due to the convergence between Aegean-Anatolia and Africa in combination with remnants of oceanic lithosphere below the eastern Libyan Sea. These remnants form the required space for plate boundary retreat and result in a counter clockwise rotation of the Eastern Hellenic arc towards the SE (see Figure 11) as indicated by the surface-velocity field and by the present deformation at depth. This regime also explains the development of the sinistral transtensional regime consisting of the Ptolemeus, Pliny and Strabo deepsea depressions SE of Crete. Furthermore, our model requires an ESE-trending normal faulting regime between Crete and Rhodes perpendicular to the direction of present velocity field at the surface which is exactly what we observe around Karpathos. This ESE-trending extension is thus not along-arc but in direction of the retreat of the plate boundary.
Doutsos and Kokkalas (2001) argue that the transtensional regime in the eastern forearc has been established since Late Miocene then comprising NNE- to NNW-tension associated to arc-normal pull of the Aegean plate. In a second state this system then changed to ENE- and N-trending strike slip faulting as well as to NNE-trending oblique-normal faulting representing the result of strain partitioning during oblique convergence. Thus, the setup of the counter clockwise rotation of the eastern Hellenic arc might correlate with the commencing collision in the western Hellenic arc at 3.4 Ma and even expanded towards SE Turkey in the following (TenVeen, 2004).

Inversion of fault mechanisms for earthquakes within the dipping African lithosphere reveals a downdip orientation for $\sigma_{3}$ at a plunge of $48^{\circ}$ trending to the North. $\sigma_{1}$ was found to be oriented dominantly orthogonal to the strike of the plate boundary and vary with strike of the Hellenic arc at a plunge of $39^{\circ}$. This indicates that slab pull is the dominant force within the dipping African lithosphere causing gravitational instability at the southern edge of the Aegean domain and resulting in rollback of the slab especially in the East (see also LePichon and Angelier, 1979; Jackson and McKenzie, 1988). Hatzfeld et al. (1993b, based on data from a regional network) and Taymaz et al. (1990, from teleseismic recordings) observed a similar deformation regime within the slab dipping below the South Aegean. Meijer and Wortel (1996) performed forward modeling to derive the stress field in the Aegean region. They conclude that the westward Anatolian push contributes to the stress field while the existence of tension appears to be due to subduction-related forces. Both observations are in agreement with our results. Analysis of stress fields in subduction zones worldwide and its tectonic implications was pioneered by Isacks and Molnar (1971). Since then a number of paper focused on subduction-related stress fields. McGinty et al. (2000) studied the Hikurangi subduction zone (New Zealand) by inversion of focal mechanisms and identified the least compressive stress to be closely aligned with the dip of the subducting plate. Similar results were obtained for the Copiapo (northern Chile) part of the Andean subduction zone (Comte et al., 2002) and for the Alaska subduction zone by Lu et al. (1997) who also found $\sigma_{1}$ to be parallel along strike of the plate boundary. Christova et al. (2004) observed a down dip direction for $\sigma_{3}$ in the Vanuatu (New Hebrides) Wadati-Benioff zone but limited to the upper 60 km . With two exceptions our set of in-slab fault plane solutions covers the upper 100 km . As a consequence
we can not argue on the stress regime at greater depth levels but find that the stress field in the subducting lithosphere of the Hellenic subduction zone as observed for the upper 100 km is compatible with other subduction zones. However, this might be not the case for all subduction zones worldwide.

For the upper plate of the Alaska subduction zone, Lu et al. (1997) observe a non-uniform stress field reflecting strike-slip and thrusting regimes. They observe a direct relation between the size of earthquakes inverted $(\mathrm{M}>3)$ and homogeneity of the stress field determined. This phenomenon was also observed for fluid-injection induced seismicity at lower $(-2<\mathrm{M}<1)$ magnitude range (Bohnhoff et al., 2004). However, the data base of fault mechanisms from the Hellenic subduction zone give no indication for a similar relation which might be due to the smaller number of intermediate-sized ( $\mathrm{M} \sim 3$ ) events which is explained by low seismic activity compared to other subduction zones. To perform such an investigation a long-term monitoring for the entire forearc at low threshold is required.

## Conclusions

We compiled a data base of focal mechanisms for the Hellenic subduction zone in the vicinity of Crete consisting of 264 fault plane solutions that cover a magnitude range between 0 and 6.5 .
Eight regions (subvolumes) were identified based on 1. Faulting regimes (upper plate, interplate, in-slab) and 2. Spatial clustering of deformation axes. Where as EW-extensional normal faulting on Western Crete was interpreted as along-arc extension, the $\mathrm{N} 110^{\circ} \mathrm{E}$ striking direction of $\sigma_{3}$ in the eastern Hellenic arc reflects the SE-directed retreat of the plate boundary at this part resulting in sinistral deformation of the outer forearc. This regime extends to onshore Eastern Crete. Interplate seismicity indicates a uniform N-NNE trending direction of relative plate motion along the Hellenic arc between the Ionian Sea and Rhodes. This corresponds with the GPS-derived horizontal velocity field for this region. Rollback of the subduction zone induced by slab pull as driving mechanism forces the Benioff towards an amphitheatrically shape as observed form the distribution of hypocenters.

## Acknowledgements

We acknowledge the comments by two anonymous reviewers that helped to improve an earlier version of the manuscript and discussion with J. Jackson. A. Kiratzi is thanked for helpful comments and making available her manuscript prior to publication. Furthermore, we acknowledge the focalmechanism catalogue for eastern Crete as courtesy of J. Makris and D. Becker and contributions by O. Knabenbauer and M. Messar. We are grateful to the Deutsche Forschungsgemeinschaft (DFG) for partly funding within the Collaborative Research Centre 526 'Rheology of the Earth'.

## FIGURES AND CAPTIONS:

Figure 1:

Figure 1: Location map of the Aegean-Anatolian region and its main tectonic elements. The Hellenic Arc is part of the forearc and consists of a number of islands of which Crete is the largest. Stars indicate active volcanic centers along the Hellenic volcanic arc $\sim 150 \mathrm{~km}$ north of the Hellenic Arc. Bold arrows indicate surface displacement rates with respect to stable Eurasia that are representative for each region (simplified after McClusky et al., 2000). The transect A-B is parallel to the dipping direction of the African lithosphere and shown as a depth section in the lower right. It combines results from microseismicity and surface wave studies in the Hellenic subduction zone (after Meier et al., 2004b). The rectangle marks the area investigated in this study.

Figure 2:

Figure 2: Selected fault plane solutions for earthquakes recorded by the temporal network on southern central Crete. Projection is lower hemisphere. Circles and diamonds represent compressional and dilatational first motions of the P wave, respectively. Crosses indicate stations for which $\mathrm{SH} / \mathrm{P}$ amplitude ration were determined. In the lower left the station distribution of our seismic network and two permanent station of the GEOFON network are shown.

MAGNITUDE

Figure 3: a) Data set analysed in this study. Shown is the lower hemisphere projection of all 264 fault plane solutions that were collected or determined, respectively (see text for details). The size of the beachballs is scaled to event magnitude. The polygons show the surface boundaries of the subvolumes 1-8 that were identified based on types of faulting (seismicity within the Aegean plate, interplate seismicity and seismicity within the dipping African lithosphere) and spatial clustering of faulting mechanisms (for seismicity within the Aegean plate): 1=Aegean plate, Western Crete; $2=$ Aegean plate, Central Crete; 3= Aegean plate, Eastern Crete; 4= Aegean plate, Karpathos area; 5= interplate seismicity, Western Hellenic arc; $6=$ interplate seismicity, Central Hellenic arc; 7=interplate seismicity, Eastern Hellenic arc; $8=$ seismicity within the dipping African lithosphere.
b) Distribution of P (left) and T (right) axes for all 264 fault plane solutions in equal area lower hemisphere projection. Size of circles is scaled with magnitude and shading indicates hypocentral depth.

Figure 4:

Figure 4: Magnitude frequency for the entire set of fault mechanisms investigated in this study. The catalogue covers the time interval 1959-2004 and is complete for $\mathrm{M} \geq 5$. A large number of events with small magnitudes where recorded by local networks in distinct regions during several months. Therefore this catalogue is somewhat heterogeneous (see text).

Figure 5: a) Map view of all fault plane solutions for earthquakes within the Aegean plate that are contained in subvolumes 1-4 (see Figure 3a).
b) Distributions of P (top) and T (bottom) axes for each of the four subvolumes. Size of circles scales with magnitude and is enlarged by a factor of two compared to Figure 3b.

Figure 6 :

Figure 6: a) Map view of all fault plane solutions for earthquakes within the contact zone between upper (Aegean) and lower (African) plate subdivided into three segments along the Hellenic Arc from West to East (subvolumes 5-7, see Figure 3a).
b) Depth sections for the three subvolumes shown in 6a). Upper and lower boundaries for the contact zone were fixed based on existing structural models of the Hellenic subduction zone taking into consideration the depth error for events located with global networks ( $\sim 10 \mathrm{~km}$ ). Note that the beachballs are rotated according to the viewers' perspective, i.e. lower hemisphere projection, seen from the East.
c) Distributions of P (top) and T (bottom) axes for each of the three subvolumes. Size of circles scales with magnitude and is enlarged by a factor of two compared to Figure 3b.

Figure 7 :

Figure 7: a) Map view and depth section of all fault plane solutions for earthquakes within the subducting African lithosphere (subvolume 8, see Figure 3a). In the depth section the beachballs are rotated according to the viewers direction, i.e. lower hemisphere projection seen from the East.
b) Distribution of P (left) and T (right) axes within subvolume 8 . Size of circles scales with magnitude and is enlarged by a factor of two compared to Figure 3b.

## Figure 8 :

Figure 8 : Result of stress tensor inversion for the entire catalogue containing 264 fault plane solutions (see Figure 3a). Bold black dots represent the best fitting orientations for the three principal stresses ( $1=$ maximum, $2=$ intermediate ; $3=$ minimum ). Small black dots and large gray dots represent the $1 \sigma$ ( $68 \%$ ) and $2 \sigma(95 \%)$ confidence intervals.

## Figure 9:

Figure 9 : Results of stress tensor inversion for the eight subvolumes and for the entire set of interplate events as combination of subvolumes 5-7. For explanation of symbols see Figure 8.

Figure 10 :

Figure 10: Angle between the direction of relative plate motion (that was identified to be uniform along the Hellenic arc) and the strike of the plate boundary for the Western, Central and Eastern Hellenic arc. Arrows indicate the deformation regime within the upper Aegean plate along the Hellenic arc as determined in this study. Dotted arrows mark the sinistral transtensional fault zone at the Ptolemeus, Pliny and Strabo deep sea depressions. Black lines indicate the active and passive continental margin, respectively.

Figure 11:

Figure 11: Summary of results focussing on the eastern Hellenic arc. Dotted arrows indicate strike (direction) and magnitude of the GPS-derived velocity field at the surface (after McClusky et al., 2000) that shows second order variations in the south-east Aegean region. Convergent black arrows indicate the direction of relative plate motion (uniform along the Hellenic arc) and divergent black arrows indicate the trend of extension on Western Crete and in the Karpathos area. Remnants of oceanic crust southeast of the Hellenic arc (indicated by the gray ellipse) form space for retreatment of the plate boundary at this part of the Hellenic as which correlates with the counterclock wise rotation of GPSderived trend of surface deformation while proceeding from West to East.

Table 1: Overview on the entire set of fault plane solutions analysed in this study. For each event the relevant source study is given: $\mathrm{BEC}=$ Becker, 2000 ; $\mathrm{BEN}=$ Benetatos et al., 2004 ; DEC=DeChabalier et al., 1992; DEL=Delibasis et al., 1999; HAT=Hatzfeld et al., 1993a and 1993b; JOS=Jost et al., 2002; KIR=Kiratzi and Louvari, 2003; MCK=McKenzie, 1972 and 1978; PDI=Papadimitriou et al., 1993; PDO=Papadopoulos et al., 1986; PPA=Papazachos, 1973, Papazachos and Papazachou, 1997, Papazachos et al., 1991 and 2000; TAY=Taymaz et al., 1990; CMT=Harvard Centroid Moment Tensors (1977-2004); MED=INGV MEDNET (2001-2004); SED=Schweizer Erdbeben Dienst, ETH Zürich (2000-2004); USG=US Geological Survey (except CMT solutions, 1982-2002).
In case of multiple occurrences of events we selected the most reliable fault plane solution (see text) ; in the table '*' indicates the most reliable fault mechanism for the relevant event, '(*)' indicates 'similar to most reliable solution but not considered' and '-‘ indicates rejected fault plane solutions (those that highly deviate from the most reliable solution). No symbol is given for events that occur only once.
Note 1: In the paper by DeChaballier et al. (1992) no information is given on the event magnitude. All events from this study are shallow and were recorded by a local network on western Crete. Futhermore, none of these events was recorded by a regional network. We thus set the magnitude of these events (99 in the table) to $\mathrm{M}=2$.
Note 2: The list in the paper by Papadopoulos et al. (1986) contains no information on the hypocentral depth ; instead a subdivision into shallower ( $\mathrm{z}<60 \mathrm{~km}$ ) and deeper ( $\mathrm{z}>60 \mathrm{~km}$ ) is given. We have set the depth of the shallower category to $\mathrm{z}=33 \mathrm{~km}$ similar to the procedure applied for the global catalogues. This was also done for two events from Papazachos et al. (1991).

## Table 2 :

| SUBVOL. | NO. FPS | $\mathrm{o}_{1}(\mathrm{tr})$ | $\sigma_{1}(\mathrm{p} 1)$ | $\mathrm{O}_{2}(\mathrm{tr})$ | $\mathrm{o}_{2}(\mathrm{pl} 1)$ | $\mathrm{O}_{3}(\mathrm{tr})$ | $\mathrm{\sigma}_{3}(\mathrm{pl})$ | MiSFIT | R |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Table 2: Results of stress tensor inversion for the entire data base as a whole (termed subvolume 0), for the eight subvolumes (termed subvolume 1-8) and for the sum of interplate events (termed subvolume 567). Results contain number of fault plane solutions within the relevant subvolume, directions for the three principal stresses $\left(\sigma_{1-3}\right)$ in terms of trend and plunge, misfit and relative stress magnitude $(R)$.
