Abstract. In analogy to the study of critical phase transitions in statistical physics, it has been argued recently that the fracture of heterogeneous materials could be viewed as a critical phenomenon, either at laboratory or at geophysical scales. If the picture of the development of the fracture is correct one may guess that the precursors may reveal the critical approach of the main-shock. When a heterogeneous material is stretched, its evolution towards breaking is characterized by the appearance of microcracks before the final break-up. Microcracks produce both acoustic and electromagnetic (EM) emission in the frequency range from VLF to VHF. The microcracks and the associated acoustic and EM activities constitute the so-called precursors of general fracture. These precursors are detectable not only at laboratory but also at geophysical scales. VLF and VHF acoustic and EM emissions have been reported resulting from volcanic and seismic activities in various geologically distinct regions of the world. In the present work we attempt to establish the hypothesis that the evolution of the Earth's crust towards the critical point takes place not only in a mechanical but also in an electromagnetic sense. In other words, we focus on the possible electromagnetic criticality, which is reached while the catastrophic rupture in the Earth's crust approaches. Our main tool is the monitoring of micro-fractures that occur before the final breakup, by recording their radio-electromagnetic emissions. We show that the spectral power law analysis of the electromagnetic precursors reveals distinguishing signatures of underlying critical dynamics, such as: (i) the emergence of memory effects; (ii) the decrease with time of the anti-persistence behaviour; (iii) the presence of persistence properties in the tail of the sequence of the precursors; and (iv) the acceleration of the precursory electromagnetic energy release. Moreover, the statistical analysis of the amplitudes of the electromagnetic fluctuations reveals the breaking of the symmetry as the theory predicts. Finally, we try to answer the question: how universal the observed

electromagnetic critical behaviour of the failing system is?

1 Introduction

Fracture in heterogeneous systems has been an area of active study in recent years due to its relevance with practical engineering materials such as poly-crystals and fiber composites, biological materials such as bone, and possibly geological systems such as Earthquake faults. Despite great experimental and numerical efforts, many aspects still remain unclear. In the case of Earthquake the problem becomes more complex, because the source volume inside the Earth is inaccessible to direct observation and therefore the most important parameter, the stress level, cannot be measured.

In analogy to the study of critical phase transitions in statistical physics, it has been recently argued that the fracture of heterogeneous materials could be viewed as a critical phenomenon (Herrmann and Roux, 1990; Vanneste and Sornette, 1992; Laignere et al., 1996; Andersen et al., 1997; Sornette, 2000), either at laboratory scale (Petri et al., 1994; Guarino et al., 1998, 2002) or at geophysical scales (Chelidze, 1982; Allegre et al., 1982; Sornette and Sornette, 1990; Diodati et al., 1991; Sornette and Sammis, 1995; Saleur et al., 1996a,b; Main, 1996; Bowman et al., 1998; Kossobokov et al., 1999). This result comes from different observations including power law scaling in space (fractals), time and energy, long-range correlations, or the divergence of the rate of energy dissipation near the critical point. Fractals are critical features in the sense that they are not associated to any characteristic scale (Schmittbuhl et al., 1995; Lesne, 1996). Therefore, the numerous evidence from fractal geometry in the fracturing and fragmentation of rocks suggest an interpretation of these processes as critical phenomena.

If the critical picture of the development of a large Earthquake is correct, then one may guess that its precursors may indicate the critical approach of the main-shock. When a het-

erogeneous material is stretched its evolution towards breaking is characterized by the appearance of microcracks before the final break-up. Microcracks produce both an acoustic and an electromagnetic (EM) emission in the frequency range from VLF to VHF (Gross et al., 1993; Carrilo et al., 1998; Mavromatou and Hadjicontis, 2001). The microcracks and the associated acoustic and EM activities constitute the so-called precursors of general fracture. These precursors are detectable not only at laboratory but also at geophysical scales. VLF and VHF acoustic and EM emissions have been reported resulting from volcanic and seismic activities in various geologically distinct regions of the world (Diodati et al., 1991; Fujinawa and Takahashi, 1994; Fujinawa et al., 1997; Eftaxias et al., 2001a, 2002a).

In the present work we focus on the possible electromagnetic criticality, which is reached as the catastrophic rupture in the Earth's crust approaches. Our main tool is the monitoring of micro-fractures that occurs before the final breakup, by recording their radio-electromagnetic emissions during the last tens of hours prior to the main shock (Nomikos and Vallianatos, 1998; Vallianatos and Nomikos, 1998; Eftaxias et al., 2000, 2001a, 2002a). The observed precursory EM fluctuations might represent EM signatures of the energy rearrangements that occur as the external field drives the heterogeneous system of the pre-focal area from one meta-stable local free-energy minimum to another.

For the above mentioned purpose, we focus on ULF, VLF, and VHF EM activities observed before the 13 May 1995 Kozani-Grevena (K-G) Earthquake in northwestern Greece (40.2° N–21.7° E) with $M_s(\text{ATH}) = 6.6$, at Zante station (37.76° N–20.76° E) in western Greece. The basic arguments for this choice are: (i) This is probably the first time that precursors covering ULF, VLF and VHF bands were detected all together, for the same Earthquake at only one observation site and within the time-window of the last tens of hours prior to the main event. This experimental evidence helps to specify not only whether or not a single ULF, VLF or VHF electromagnetic disturbance is pre-seismic by itself, but also whether a combination of such disturbances at different frequency bands, could be characterized as pre-failure. Hence, in previous papers, we have shown that the evolutions of the sequence of the observed radio-emissions reveals similarities to that observed in laboratory acoustic and electromagnetic emissions during the last stages of failure preparation process in rocks (Eftaxias et al., 2002a). (ii) We have also shown that features of these precursors are possibly correlated with the corresponding fault model and with the degree of heterogeneity within the focal area (Eftaxias et al., 2000, 2001a). (iii) The VHF emission has a rather long duration, i.e. approximately a few tens of hours (the data were sampled at 1 Hz), thus, it provides sufficient data for statistical analysis. (iv) The scale of the fracture zone during the preparation stage of a significant EQ may be extended up to several kilometers. In the case of a significant surface Earthquake, such as the K-G Earthquake, the hypothesis that the associated fracture zone is extended up to the ground surface can be accepted. Notice that an outstanding feature of the

K-G surface Earthquake was the clearly observed fault traces of 8–12 km length (Meyer et al., 1998). This surface rupture is the confirmation that the highly stressed region reached the ground surface. This fact could support the consideration that the detected VLF and VHF signals may have emitted from fracto-electromagnetic emitters activated in the ground surface layer of the K-G Earthquake preparation zone.

More precisely, electromagnetic fluctuations before the K-G Earthquake at Zante station were observed as follows: (i) a few tens of hours prior to the Kozani-Grevena Earthquake at 41 MHz and 54 MHz respectively, with increasing electromagnetic emission rate (Fig. 1a). These bursts ceased approximately one hour before the Earthquake occurrence; (ii) very strong multi-peaked electromagnetic signals with sharp onsets and ends at 3 kHz and 10 kHz, lasting about half hour, emerged approximately one and half hour before the Earthquake (Fig. 1b) (Eftaxias et al., 2000); (iii) if someone follows the diurnal background pattern of the DC-ULF recordings finds the existence of a minimum around mid-day (Fig. 1c). However, as the Earthquake approaches this behaviour seems to change and a maximum instead of a minimum now is seen one day before the EQ. The curve attains its normal shape a few days after the event.

2 An approach based on the criticality concepts

In this section we attempt to establish the hypothesis that the evolution of the Earth's crust towards critical state takes place not only in a seismological but also in a VLF-VHF electromagnetic sense.

We focus on the study of the time-series of the amplitude $A(t_i)$ of the recorded VHF pre-failure electromagnetic fluctuations. One distinguishing feature of the dynamics of a heterogeneous medium close to a critical point lies in the emergence of memory effects. The power spectrum density (PSD) $S(f)$ is probably the most commonly used technique to provide useful information about the inherent memory of the system. Although the power spectrum is only the lowest order statistical measure of the deviations of the random density field from homogeneity, it directly reflects the physical scales of the processes that affect structure formation. If the recorded time-series $A(t_i)$ is a temporal fractal then a power law spectrum is expected:

$$S(f) = \alpha \cdot f^{-\beta} \quad (1)$$

where f is the frequency of the transform. In a $\log S(f) - \log f$ representation the power spectrum is a straight line, with linear spectral slope β . The spectral amplification α quantifies the power of the spectral components following the power spectral density law.

Applying the least square method, we calculated the spectral slope β , the spectral amplification α , and the linear correlation coefficient r of the power law fit. The “global wavelet spectrum” is used in order to provide an unbiased and consistent estimation of the true power spectrum of the time-series

Fig. 1. Electromagnetic fluctuations detected at Zante station before the $M_s = 6.6$ Kozani-Grevena Earthquake which occurred on 13 May 1995, 08:57 UT: (a) at 41 MHz and 54 MHz by electric dipoles antennas; (b) at 3 kHz and 10 kHz by magnetic loop antennas; and (c) at DC-ULF frequency range by Short Thin Wire Antennas (STWA).

Fig. 2. The power spectral density versus frequency plotted in a log-log diagram obtained from a raw data sample of the 41 MHz pre-seismic time-series.

(Percival, 1995; Torrence and Compo, 1998). The calculation is made by the Continuous Wavelet Transform based on the Morlet wavelet.

However, a system can exhibit a power law behaviour although not near to the critical transition (Perkovic et al., 1999). Thus, we calculated the parameters $\{\alpha, \beta, r\}$ upon dividing the signal into successive segments of 1024 samples each, in order to study not only the presence of a power law but mainly the time evolution of the associated parameters

$\{\alpha, \beta, r\}$. The results of this approach suggest that the under study electromagnetic phenomenon is governed by scaling laws.

In Fig. 2 we show an example of the fitting of Eq. (1). (Note that the power spectral density versus frequency is plotted in log-log scale.) It should be noticed that the data fit the power law quite well.

2.1 The evolution of linear coefficient r with time

The linear correlation coefficient r is a measure of the goodness of fitting of the power law (Eq. 1). In Fig. 3 we illustrate the histograms of the distribution of the coefficient r for the three time windows that presented in Fig. 1a. It is clear that as the time of the Earthquake occurrence approaches r is shifted close to 1. Notice that at the tail of the pre-seismic time-series the fitting to the power law is continuously excellent ($r > 0.98$). It is remarkable that this behaviour breaks down just after the cessation of the signal.

2.2 The evolution of dynamical parameter β with time

The dynamical parameter β indicates the strength of the signal's irregularity, i.e. as the value of β increases the spatial correlation also increases and the profile is smoothened (Turcotte, 1992). In Fig. 3 we demonstrate the histograms of the distribution of the spectral exponent β for the three time windows that presented in Fig. 1a. We recognize a systematic increase of the exponent β as the EQ approaches; the β -values are maxima at the tail of the pre-seismic time-series. In parallel, we recognize a progressive increase of the time intervals with $\beta = 1.5 \pm 0.2$ as the Earthquake approaches. This behaviour also fails just after the cessation of the signal, almost 1 hour prior to the Earthquake; the spectral slope β exhibits random fluctuations out of the range $\beta = 1.5 \pm 0.2$, just after the cessation of the signal.

The analysis of the time variation both of the spectral exponent β and the linear correlation coefficient r has revealed a fluctuating behaviour, with a variance changing with time. An important observation is that the variance attains its minimum at the tail of the precursory time-series, i.e. the fitting to the power law was continuously excellent ($r > 0.98$) while the values of the scaling parameter β oscillate around 1.5. This finding meets corresponding experience based on ULF precursors reported by Balasco et al. (2002).

The combined temporal evolution of β and r is reasonable if we accept that stress and strain become nonlinear at the end of the loading cycle, producing rapidly accelerating effects.

The finding of $1/f^\beta$ behaviour may reflect the fact that the final output of fracture is affected by many processes that act on different time scales. The power law form also indicates that we are dealing with long memory process. This implies that during the EM fluctuations each value co-varies not only with its most recent value but also with its long-term history in a scale invariance, fractal manner; the system refers to its history in order to define its future (non-Markovian behaviour).

Fig. 3. The probability distributions of the linear coefficient r for three different periods are presented on the top row of the figure. The intervals that mark these three periods of the VHF time-series are indicated in Fig. 1a. Top windows show the percentage of segments (duration is 1024 s) with $r > 0.94$. As the EQ approaches the distribution of r is shifted closer to 1. The probability distribution of the critical exponent β , for the same time intervals as before, are shown in the bottom row of the figure. We recognize a systematic increase of β as the EQ approaches.

However, there is something more: the tantalizing relationship between fractal structure (and fractal function) and non linear dynamics in order to explore the “raison d’ être” of many complex natural patterns being structurally fractal (Nicolis, 1991). What is the functional advantage of a geological pattern “playing $1/f^\beta$ music”?

2.3 The persistence properties of the VHF fluctuations

The spectral exponent β is related to another exponent, the Hurst exponent H , by the formula (Turcotte, 1992) $\beta = 2H + 1$. H lies anywhere in the range of $0 < H < 1$ and characterises the persistence properties of the recorded electromagnetic fluctuations according to the following scheme: (i) for $H = 0.5$ (i.e. $\beta = 2$) there is no correlation between the process increments and we are in a standard diffusing regime. As it is well-known, in the random walk which models classical Brownian diffusion the walker follows a random path driven by non-memory dynamics; (ii) the range $0.5 < H < 1$ (or $2 < \beta < 3$) suggests persistence of the signal (super-diffusion), i.e. if the amplitude of electromagnetic

fluctuations increase in one time interval, it is likely to continue increasing in the period immediately following. The accumulation of fluctuations is faster than in classical Brownian motion; (iii) the range $0 < H < 0.5$ (or $1 < \beta < 2$), on the contrary, suggests anti-persistence or clustering (sub-diffusion), i.e. if the fluctuations increase in one period, it is likely to continue decreasing in the period immediately following, and vice versa; (iv) at the limit $H = 0$ (or $\beta = 1$) it does not grow at all and the signal is stationary. Concerning our data, the β (or H) values gradually increase (see Fig. 3) as the EQ approaches. This indicates that the EM fluctuations become less anti-correlated (the exponents H are closer to 0.5) as the main event approaches.

The observed temporal evolution of the dynamical parameter H is compatible with the dynamics of the last phase of the EQ generation.

2.4 Indications of a universal behaviour

Recently, the fractal analysis has been performed for the ULF emission (Hayakawa et al., 1999, 2000a; Balasco et al.,

Fig. 4. The amplitude distributions of the 41 MHz time-series for three successive time periods. Middle diagram (b) covers a duration of ~ 6.5 h (see shaded region of Fig. 1a) and represents the “critical window” (WS). Diagrams (a) and (c) refer to 3 h interval before and after the WS respectively. The plateau’s breaking indicates the “symmetry” breaking.

2002; Smirnova et al., 2001; Hayakawa et al., 2000b; Gotoh et al., 2003). This study reinforces our hypothesis that the behaviour of parameter β (or H) seems to be a candidate precursor of failure. Indeed, an important question is as follows: how universal this signature of the failing system can be? Does it depend upon the frequency range of the precursors or the geographical position of the collated plates? Is it magnitude dependent?

The above mentioned literature indicates the existence of a possible universal behaviour in the temporal evolution of the critical exponents as the failure approaches. For example: (i) a similar increase with the time of the Hurst exponent from $H \approx 0.1$ to $H \approx 0.5$ was also observed in the VLF pre-seismic time-series associated with the Athens EQ (Kapiris et al., 2002; Eftaxias et al., 2002b); (ii) an increase of the exponents β and H (approximately from 0.1 to 0.25) has been observed in the tail of the electromagnetic ULF time-series associated with the Biak Earthquake ($M_w = 8.2$), on 17 February 1996 (see Fig. 4 in Hayakawa et al., 2000a) and the Guam Earthquake ($M_s = 8.0$) on 8 August 1993 (see Fig. 2 in Hayakawa et al., 1999). Also, encouraging are the relevant findings (associated with ULF EM precursors) described in Telesca and Lapenna (2001) and Balasco et al. (2002).

2.5 Broken symmetry indication

Recently, Contoyiannis and Diakonou (2000) and Contoyiannis et al. (2002b) have presented a new method for the study of the critical fluctuations. Their analysis is based on the observation that the fluctuation pattern in the order parameter space has intermittent origin. This suggests the introduction of a new critical exponent related to these intermittent dynamics. A necessary condition for their method to be applicable is the existence of a stationarity window (WS) in the corresponding time-series. This method has been applied to the under study VHF electromagnetic fluctuations

(Contoyiannis et al., 2002a). The authors observed a time-window (WS), approximately from 18 to 12 h before the EQ (shaded window in Fig. 1a) that appears to be stationary (Contoyiannis et al., 2002b). The behaviour of EM fluctuations within this window is a fingerprint of a continuous phase transition. The associated characteristics (e.g. the critical exponent) classify this transition to the 3-D-Ising universality class. It is worth mentioning that before and after WS we find amplitude distributions of the EM fluctuations that demonstrate the expected, from the critical theory, symmetry breaking (see Fig. 2 in Contoyiannis et al., 2002b). Indeed, in Fig. 4 we show the amplitude distribution within the “critical” window WS. In Fig. 4a and c we illustrate the amplitude distributions at the “symmetry” phase (phase I) and at the broken phase (phase II) respectively. A relevant paper is under preparation.

2.6 The VLF EM fluctuations as a temporal fractal

Now we focus on the detected impulsive VLF signal just before the Earthquake occurrence. The spectrum of the recorded activity displays a decreasing power law behaviour $S(f) \sim f^{-\beta}$, typical of critical dynamics, with the following characteristic: the analysis reveals two different power laws, one for the low frequencies: $r = 0.92$, $\beta = 1.04 \pm 0.03$ and another for the high frequencies: $r = 0.99$, $\beta = 2.91 \pm 0.03$ (Fig. 5). The high frequency power law may reflect the dynamics within the bursts while the low frequency one may indicate the correlation between the bursts.

We pay attention to the fact that the critical exponent $\beta = 2.91$ (or $H = 0.95$) of the high frequency power law indicates strong persistent behaviour of the electromagnetic fluctuations within the avalanches. The detected VLF fluctuations that exhibit critical behaviour, at the tail of the VHF precursory anomaly and just before the Earthquake, should be attributed to a new, rather final, stage of the Earthquake preparation process. Notice that, if we consider that the same

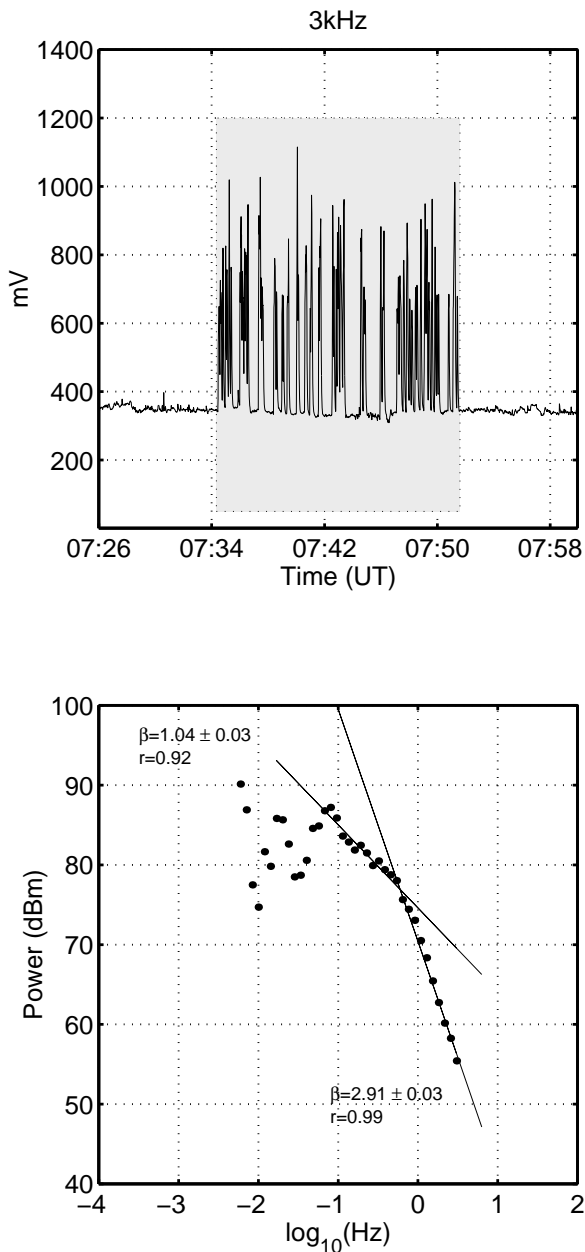

Fig. 5. The power spectral density versus frequency of the 3 kHz (NS) EM activity plotted in a log-log diagram.

dynamics governs the large-scale Earthquake and the laboratory scale sample rheological structure, then, the fundamental experiments performed by Ohnaka and Mogi (1982) lead to the suggestion that the recorded VLF bursts might reflect the last (nucleation) phase of the Earthquake (Eftaxias et al., 2002a). The following experimental finding also encourages the hypothesis of the association of the precursory VLF signals with the last phase of the generation of Earthquake. Two clear kHz EM signals were detected before the $M = 5.9$ Athens EQ (7 September 1999) Earthquake. The larger anomaly, the second one, contains approximately 80% of the total EM energy received. The fault modeling of the

Athens EQ, based on information obtained by radar interferometry (Kontoes et al., 2000) showed two faults. The main fault segment is responsible for the 80% of the total released seismic energy and the secondary fault segment for the remaining 20%. Notice that we found that the spectrum of this strong impulsive emission also displays decreasing power law behaviour, with the scaling exponent increasing during the process of the Earthquake preparation. At the tail of the activity the evolution of the VLF precursors also attains persistent behaviour (Kapiris et al., 2002; Eftaxias et al., 2002b).

3 Test of the acceleration of the precursory electromagnetic energy release

Theoretical studies suggest an acceleration of the energy release as the general fracture approaches. Using equations from crack propagation (Das and Scholz, 1981) and damage mechanics (Leckie and Hayhurst, 1977; Bufe and Varnes, 1993) a formula for the cumulative elastic energy release $\varepsilon(t)$ is derived:

$$\varepsilon(t) = A + B(t_f - t)^m. \quad (2)$$

Here, t_f is the failure time, the constant B is negative and m is a critical exponent. A is the value of $\varepsilon(t)$ when $t = t_f$, i.e. the final Benioff, strain up to and including the largest event. The cumulative Benioff strain at time t is defined as $\varepsilon(t) = \sum_{i=1}^{N(t)} E_i(t)^{\frac{1}{2}}$ where E_i is the energy of the i^{th} event and $N(t)$ is the number of events at time t .

Models also predict a power law time-to-failure function where the crust is in the state of “intermittent criticality” (e.g. Sammis and Smith, 1999; Bowman and King, 2001).

On the other hand laboratory results suggest an exponential acceleration of the energy release at the final stage of the macroscopic rupture: when the stress/time curve deviates from linearity, i.e. as the failure approaches, there is an acceleration in the acoustic/electromagnetic activity indicating the growth of new microcracks up to the point of failure (Mansurov, 1983; Yamada et al., 1989; Meredith et al., 1990; Reches and Lockner, 1994; Ohnaka, 2000; Mavromatou and Hadjicontis, 2001).

Now, we test the existence of the accelerating energy release in the under study EM activity. The wavelet power spectrum of the VHF time-series indicates an acceleration of the captured EM energy (Fig. 6). Indeed, an inspection of this figure reveals a progressive shift to higher levels in terms of frequency (emission rate) and amplitude.

Spectral analysis permits a quantitative test concerning the presence of an accelerating emission rate in the under study VHF time-series. The temporal evolution of the estimated spectral amplification α , corresponding to segments with $r > 0.98$, reveals a nearly exponential increase during the last few tens of hours prior to the K-G Earthquake (Fig. 7). Note that it is often difficult to distinguish in real data an exponential from a power law increase. A fundamental indication of criticality is the divergence of the rate of energy dissipation near the critical point. Hence, the observed

Fig. 6. The wavelet power spectrum of the readings recorded by the electric antennas tuned at 41 MHz. The intensity scale on the top of each diagram is brightness corresponding to the values of the square spectral amplitudes, in arbitrary units. There is a progressive increase in the emission rate as the K-G EQ approaches.

acceleration further strengthens the hypothesis that the system approaches the critical point.

4 The VLF precursor as the sub-product of the structural instability associated with the nucleation phase

Perhaps the most convincing evidence that there is a nucleation stage before major Earthquakes comes from observations of foreshocks (Dodge et al., 1995). The K-G Earthquake was preceded within 30 min of the main shock by five foreshocks with $M > 3.5$ clustered within 2 km of one another about 5 to 10 km from the main shock epicentre (Bernard et al., 1997). This size of foreshocks clustering fits well the correlation law with the main-shock magnitude obtained by Dodge et al. (1995) for Californian Earthquakes (Bernard et al., 1997). This unusual foreshock activity for the aseismic K-G region, which was completely quiet for a long period before the EQ, may be possibly regarded as a fingerprint of local dynamic rupture of asperities in the weak zone associated with the nucleation of the main rupture. It should be noticed that the series of the above-mentioned foreshocks was reported a few minutes after the cessation of the 3 and 10 kHz electromagnetic precursor. Thus, the 3 and 10 kHz impulsive electromagnetic emission could be considered as the electromagnetic signature of the underlying structural instability that belongs to the final (nucleation) stage of the EQ preparation process within the K-G pre-focal area.

5 The forming fault as a emitting EM fractal geo-antenna

Next, we propose a possible scenario concerning the mechanism of the generation of the detected pre-failure radio emissions. The K-G Earthquake created clear fault traces of NE-SW direction and of 8–12 km length. Such surface rupture is the signature of a highly stressed region that reached the surface. The principle feature of criticality is the fractal or-

ganization both in space and time: the spatial distribution of epicentres is fractal and Earthquakes occur on a fractal structure of faults (Bak et al., 2002). Moreover, there is additional evidence for the fractal character of fragments size distribution (e.g. Turcotte, 1992). Therefore, the hypothesis that an array of “fault elements” having a fractal distribution is formed as the Earthquake approaches can be accepted. However, it is well-known that fracturing in a solid body is associated with the emergence of a mosaic of charges at the edges of the moving cracks. This means that each “fault element-moving crack” can act as a “radiating element”. The notion is that as the Earthquake approaches a surface fractal antenna is formed (Kapiris et al., 2002).

Fractals are highly convoluted, irregular shapes. It is well-known that sharp edges, corners and discontinuities enhance radiation from electric systems. Thus, it seems logical to expect that curves and surfaces which have a characteristic highly irregular shape, which is fundamentally different from that of classical Euclidean shapes, should become efficient radiators. The radiation pattern of an antenna is specified by the characteristic length scale of the antenna, i.e. $kL \sim 1$, where k denotes the radiation’s wavenumber and L represents the scale length. Therefore, if there is no characteristic size, as in the case of a fractal structure, then the antenna will generate an effective radiation pattern for a whole range of frequencies controlled by the smaller and largest spatial scale. Notice that the EM precursors are observed in a wide frequency range. It is reasonable to assume that the order of the largest spatial scale of the geo-antenna is related either to the length of the observed fault traces, i.e. ~ 10 km, or to the critical region radius, i.e. ~ 100 km (Zoller et al., 2001). The fact that the 3 and 10 kHz pre-seismic electromagnetic anomalies were detected at the end of the 41 and 54 MHz pre-seismic emissions seems to confirm the under study scenario. The critical point hypothesis for large Earthquakes predicts two different precursory phenomena in space and time, an accelerating energy release (see Eq. 2) and growth of the spatial correlation length (Zoller and Hainzl, 2002).

Fig. 7. (a) The 41 MHz EM time-series recorded prior to the 13 May 1995 K-G EQ (the event is indicated by the vertical dashed line in all the diagrams). (b) The corresponding evolution of the linear coefficient r . Grey zones correspond to r greater than 0.98. (c) Time-dependence of the spectral amplification parameter α . Solid circles correspond to segments with r -values greater than 0.98. Grey zone indicates an exponential increase of α .

Part of mechanical energy released in the formation of cracks is transformed into electromagnetic energy by a variety of mechanism (Gershenzon and Bambakidis, 2000). Hence, the reported increasing EM activity as the EQ approaches further supports the concept of fractal geo-antenna formation.

Recently, particular interest attracts the research area known as “Fractal Electrodynamics”. The term “fractal electrodynamics” was first suggested by Jaggard (1990) to identify the newly emerging branch of research, which combines fractal geometry with Maxwell’s theory of electromagnetism. Particularly, the field radiated from a fractal channel has been studied and discussed in the time domain and the frequency domain (e.g. Werner, 1995; Puente et al., 1999). The authors found that the field radiated by a fractal channel appears to have fractal structure. We remind that the under study precursory EM time series appear fractal properties. Hence, “Fractal Electrodynamics” supports the hypothesis that the precursory EM signals have been emitted by an EM fractal-shaped geo-antenna.

The proposed scenario is simple, whereas the real situation is very complex. However, it seems to meet the physical aspects of the problem.

6 The DC-ULF critical indications

Although the DC-ULF recordings (Fig. 1c) is out of the frequency range we deal with in this paper, it is worth making some comments. The wavelet analysis revealed an accelerating ULF event-rate, associated with larger amplitudes (Fig. 8). This behaviour further supports the concept that the system is near the critical point.

The feature of this anomaly supports the hypothesis of its coupling with the phenomenon of the abnormal propagation in the Earth-ionosphere duct. Indeed, it is well-known that

the absorption in the D and E ionospheric layers decreases with the decrease in the density of electrons and ions at night. Hence, the nighttime radiation, due to a propagation mode formed between the ionosphere and Earth, is more intense than the daytime radiation. This arrangement rationalizes the normal diurnal undulation of the recordings of the STWA sensors. On the other hand, there is mounting number of indications on possible coupling between ionospheric anomalies and Earthquakes (Molchanov and Hayakawa, 1998; Liu et al., 2000; Pilipenco et al., 2001, and references therein). On physical grounds, we expect that the terminal nonlinear stage of the generation of a large shallow Earthquake of magnitude 6.6, with clear extensive surface fault traces, such as the K-G EQ, could be the required source for these ionospheric anomalies.

The reported surprising increase of the signal during the daytime on 12 May 1995 is explained in terms of the maximum height of the ionospheric layers and of maximum electron density. For example, Sorokin and Chmyrev (1999), based on satellite data (COSMOS-1809), found that the ionosphere had considerably changed one day before EQs, i.e. a significant increase of the maximum height of F-layer about 50% and a remarkable decrease of the maximum density of electrons. Parrot (1999) concludes that ionospheric perturbations produced by Earthquakes are revealed by an increase of the background noise level, a few hours before the shock.

7 Geomagnetic activity during precursory EM emissions

The most serious problem in the study of seismogenic emissions in any frequency range (i.e. ULF, VLF or VHF) is the distinction of the emissions possibly associated with Earthquakes from noise. There are different kinds of emissions in

Fig. 8. The wavelet power spectrum of the ULF signals (upper part) along with their corresponding signal (lower part) at: (a) EW STWA antenna; (b) NS STWA antenna. The intensity scale on the top of each diagram is the brightness corresponding to the values of the square spectral amplitudes, in arbitrary units. The spectrum reveals an accelerating ULF event-rate associated with larger amplitudes as the EQ approaches.

VLF frequency band originated in ionosphere and magnetosphere, which are found to be closely related to geomagnetic activity. We pay our attention to this point: geomagnetic activity as expressed by the planetary three-hour-range K_p index (<http://www.gfz-potsdam.de/pub/home/obs/kp-ap/>) is depicted in the visualization of the K_p values utilizing the Bartels musical diagram (Fig. 9). During the period 1995–1999 two additional destructive Earthquake occurred in continental Greece: on 15 June 1995 the Egio-Eratini ($M_s = 6.5$) and on 7 September 1999 Athens Earthquake ($M_s = 5.9$). These Earthquake were preceding by a sequence of EM anomalies (Eftaxias et al., 2000).

One can recognize that the recorded sequence of ULF, VLF and VHF electromagnetic emissions before the Kozani-Grevena Earthquake was observed during quiet magnetic conditions. Based on the classification of days (deduced from K_p indices) the 11 May 1995 is among the most quiet days (Q-days) of the month (Fig. 9).

The whole period of ULF, VLF and VHF electromagnetic activity prior to Egio-Eratini Earthquake also falls in the Q-

days time span of the month (see Fig. 9).

In the case of Athens Earthquake the K_p values (Fig. 9) are also low during the corresponding electromagnetic anomalies. Note that the 6 September 1999 is referred as one of the Q-days of the month.

All the above constitute an observational evidence that the precursory EM activities recorded before the Kozani-Grevena, Egion-Eratini and Athens Earthquakes have been detected during low geomagnetic activity. This evidence may support the hypothesis that the precursory electromagnetic phenomena could be related to the crustal activity during the Earthquake preparation stage.

8 Conclusions

The hypothesis that the evolution of the Earth's crust towards the Critical Point may take place not only in the seismological but also in the VLF-VHF electromagnetic sense is supported by the following experimental findings:

1. The Power Spectral Density of the VHF time-series, during the last few tens of hours before the K-G Earthquake, includes time intervals that exhibit a power law of a stable spectral exponent β and excellent linear correlation coefficient r . It is remarkable that the number of the time intervals meeting these two features increases progressively as the moment of the Earthquake approaches. This is a reasonable behaviour if we accept that stress and strain become nonlinear at the end of the loading cycle, producing rapidly accelerating effects. The spectral analysis of the precursory VHF time-series revealed an underlying criticality that can be described in terms of a 3-D-Ising model phase transition.
2. The power law form also indicates that we are dealing with a long memory process. This implies that during the EM fluctuations each value co-varies not only with its most recent value but also with its long-term history in a scale invariant, fractal manner; the system refers to its history in order to define its future (non-Markovian behaviour).
3. The observed decrease with the time of the anti-persistence behaviour as well as the emergence of persistence properties in the tail of the precursors are features consistent with the critical approach of the main shock.
4. The VHF activity during the last tens of hours before the K-G Earthquake exhibits a systematic accelerating energy release. Notice that a basic indication of criticality is the divergence of the dissipation near the critical point.

Thus, experimental evidence indicates that information on the preparation process of a significant surface Earthquake can be deduced from the high frequency part of the precursory EM emission. This statement is reinforced with the following arguments that we have published recently:

Fig. 9. The temporal evolution of the geomagnetic activity as expressed by the planetary three-hour-range K_p index (<http://www.gfz-potsdam.de/pub/home/obs/kp-ap/>). The shaded frames indicate the time windows of the precursory EM activities recorded before the Kozani-Grevena, Egion-Eratini and Athens Earthquakes. One can recognize that in all cases the precursory electromagnetic phenomena have been detected during low geomagnetic activity.

5. We have shown (Eftaxias et al., 2002a) that if the same dynamics govern the large-scale Earthquakes and the laboratory scale sample rheological structure, the recorded VLF EM fluctuations might reflect the nucleation phase of the Earthquake. The appearance of strong persistence properties in the VLF precursory time series further supports the former argument.
6. In terms of energy, features of VLF signals (see Sect. 2.6) are possibly correlated with the corresponding fault model (Eftaxias et al., 2001a). This experimental finding further encourages the hypothesis that the VLF part of the precursory emission might reflect the nucleation phase of fracture process.
7. We have shown that the distribution of the time intervals l between two successive VHF EM bursts exhibits a power-law behaviour $P(l) \sim l^{-1.20}$ (Kapiris et al., 2002). Diodati et al. (1991) have presented evidence of criticality in volcanic rock ruptures associated with the Stroboli activity, measured by acoustic emissions (AE). The distribution of the time intervals l between two successive AE bursts exhibits a power-law behaviour $P(l) \sim l^{-1.20}$. The perfect agreement between the two scaling exponents increases the confidence in the reliability of our conclusion that the detected sequence of electromagnetic burst is a sub-product of the fracture process in a fraction of the pre-focal area (Kapiris et al., 2002).
8. A key parameter is the degree of disorder (Sornette, 2000). The VLF-anomalies for the three EQs in Kozani-Grevena, Egion-Eratini and Athens differ in their lead-

time: as the structure in the pre-focal area becomes less heterogeneous, the lead-time becomes smaller (Eftaxias et al., 2000, 2001b). Gershenzon et al. (1989) have proposed a model for the micro-fracture of granular media consisting of rigid grains and interstices filled with a brittle elastic material. Strong grains can act as crack barriers, whereas the brittle elastic material may enhance crack growth. This elastic model predicts that the less the variance in the distribution of local threshold for breaking in the brittle material is the smaller the lead-time of the pre-failure signal is (Eftaxias et al., 2000, 2001b).

We have reasons to assert that the detected precursory VLF, VHF EM emissions include significant signatures of the last phases of the Earthquake generation. This argument implies that each of the detected VLF and VHF emission may have been emitted by corresponding VLF and VHF electromagnetic emitters that their number is efficient to represent the behaviour of the total number of the activated emitters during the evolution of complex seismicity patterns in nature. It is a reasonable hypothesis if we consider that the Kozani-Grevena, Egion-Eratini and Athens EQs occurred in the land of Greece, and all the three EQs were surface ones. An outstanding feature of the first two EQs was the clearly observed extended fault traces while in the case of the Athens EQ the energy centroid depth was 10.3 km for the main fault, and 5.4 km for the secondary one (Kontoes et al., 2000). Notice that typical values of skin depth (e.g. for Quartzite, Gabbro, and Soil of 6% humidity) is ~ 1 km for a few kHz and 100 m for a few MHz respectively (see Fig. IX.14, Gueguen and Palciauskas, 1994).

We must keep in mind that the Earth's crust in the pre-focal area is strongly heterogeneous, as far as the spatial distribution of the electrical parameters is concerned. The existence of waveguides between the vicinity of hypocenter and the ground surface cannot be excluded. Waveguiding of EM waves can take place in a complex medium by total internal reflection or through evanescent-field coupling (Yariv et al., 1999). Recently, in a number of papers the authors suggest that the evolution of the Earth's crust toward the critical point takes place not only in a seismological sense, as a formation of the block-spring fractal structure in the fault zone, but also in the electromagnetic sense as a possible formation of the fractal conductordielectric structure (Hayakawa et al., 1999, 2000a; Balasco et al., 2002). The propagation of EM waves in composite materials has been the object of considerable attention (Chew, 1995). Theoretical calculations have shown that the transmission and absorption of EM waves by conductive-dielectric non-periodic systems may be radically different from those of their homogeneous constituents (Modinos et al., 2001; Yannopapas et al., 2002). It is a tricky task to extrapolate results of theoretical study to the field, however, we cannot ignore the theoretical results. It is evident that much further investigation in order to get more convincing results is required.

Generally, heterogeneity constitutes a fundamental requirement for the transmission at a distance from source (more than 100 km) even for an ULF pre-seismic EM emission. The remarkable property of ULF Seismic Electric Signal (SES) is that it can be recorded at sensitive sites, which are hundred or more kilometers from the epicenter. Moreover, a sensitive site is sensitive only to SES from some specific focal area(s) (Varotsos et al., 1996). These basic properties cannot be explained by a homogeneous medium. To explain the experimental data, one needs to assume some highly conductive channel(s) between the source and the observation sites (Varotsos et al., 1998; Sarlis et al., 1999; Surkov et al., 2002). Recently, electrokinetic effects possibly associated with Earthquake preparation process have been theoretically investigated, with the assumption that the structure of pore space around hypocentral zone has fractal properties. To explain the observed amplitude of SESs signals, even in the frame of this approach, the electric source must be at a distance of about 10 km from the registration point for a homogeneous medium (Surkov et al., 2002).

An Earthquake is a long-term complex stress accumulation and release process occurring in the highly heterogeneous Earth's crust. The various stages of the EQ generation are accompanied by EM emissions at different frequency bands ranging from ULF, VLF to VHF. The time sequence deduced from these various observations seems to agree qualitatively with the idea that different frequency electromagnetic anomalies are not synchronous: signals of the ULF band tend to appear earlier (Uyeda, 1996). According to recent Greek experience ULF EM signals have a precursory time from a few weeks to several weeks (Varotsos et al., 2002) in contrast to much shorter lead-time (from a few hours to several tens of hours) for the VLF-VHF signals (Eftaxias

et al., 2000; Kapiris et al., 2002). These two groups of signals may arise from different mechanisms since they do not occur within the same time scales. It seems useful, as strongly recommended by Hayakawa et al. (1994), to combine ULF and VLF-VHF field measurements to enhance the understanding of the physics behind the various stages of the Earthquake preparation process. Of course as the depth of the hypocenter increases the VLF, VHF information fades faster than ULF one.

At any rate, the complexity of seismogenic systems is obvious, as also is the amount of research necessary before we begin to understand them.

Acknowledgements. The authors would like to thank Prof. S. Uyeda and Dr. H. Tanaka for their critical and constructive comments. We are pleased to acknowledge many stimulating discussions with Prof. T. Chelidze and Prof. J. Nicolis. We also acknowledge that the comments of the two referees Prof. M. Hayakawa and Dr. N. Gershenzon were helpful in improving the present work.
