General Circulation Model simulations of the current climate show large deficiencies in their radiative balance calculations in the midlatitude regions. Many GCMs allow excessive amounts of sunlight to reach the midlatitude surface, casting doubt on the atmospheric models' climate sensitivity and their ability to drive the ocean circulation when coupled to ocean models. One primary contributor to the midlatitude radiative balance is clouds formed by baroclinic storms. This study will examine the relationship between the structure and strength of the synoptic scale atmospheric patterns and the cloud fields. The 12-hourly NCEP sea level pressure data are used to define three dynamic regimes based on local sea-level pressure anomaly in the midlatitude regions, and the ISCCP dataset is used to accumulate the cloud type distributions in the three regimes. The same analysis method is subsequently applied to current-climate simulations of the GISS, ECHAM, and ECMWF GCMs, in order to try and identify the cloud structure deficiencies that may be responsible for the radiative imbalances in the models' midlatitudes. The ECMWF model will be used to investigate the role model resolution (horizontal and vertical), running mode (short-range forecasts vs. climate simulation), and the cloud parametrization play in the model's ability to represent midlatitude clouds in the different regimes.

MW02/W/10-B3 0950

SENSITIVITY STUDIES WITH A NUDGED VERSION OF ECHAM4 FOR THE PURPOSE OF CLOUD VALIDATION

Hans-Stefan BAUER and Lennart Bengtsson

Clouds are an important regulator of the Earth's radiation budget and present a major link between radiation and the hydrological cycle.
To improve the representation of clouds in our general circulation model ECHAM4 we first validated the model for specific synoptic situations. This was accomplished by using the so-called nudging technique, which enables the validation against observational data. In our simulations vorticity, divergence, temperature and surface pressure are nudged with ECMWF reanalysis fields.
We performed simulations with the resolutions T42 and T106 and diagnosed some systematic differences between the model and ISCCP DX satellite data.
From this basis we performed sensitivity studies with the lower resolution T42 of the nudged model in which we investigate the effects of small changes in the various parameterization schemes. They show the influences of different physical processes on the representation of clouds in distinct synoptic systems.

THE NORTHERN HEMISPHERE WINTERTIME STORM TRACKS IN HADAM3 AND THE ERA (ECMWF RE-ANALYSIS) DATASET

L. SHAFFREY AND P. Berrisford (CGAM, Department of Meteorology, University of Reading, reading, RG6 6BB, U.K., email: L.C.Shaffrey@reading.ac.uk) K. Hodges (ESSC, University of Reading, Reading, U. K., email: Kevin.Hodges@mail.nerc-essc.ac.uk)

The Northern Hemisphere wintertime atmospheric flow is characterised by two regions of synoptic-scale high-frequency eddies which are located over the North Atlantic and North Pacific Oceans, i.e. the Atlantic and Pacific storm tracks.
There are number of ways that the shape, location and strength of the storm tracks can be determined from observations or AGCMs (Atmospheric Global Circulation Models). One method is to use time-filtered variance and co-variance measures such as the high-pass eddy kinetic energy and the high-pass poleward temperature flux. Another method focuses on individual weather systems and involves using a feature tracking algorithm to determine the magnitudes, paths, propagation speeds and growth rates of extra-tropical cyclones as they move through the storm track. Both methods, though conceptually very different, provide complimentary information about the synoptic-scale variability of the mid-latitudes in both models and observations.
In this study the different measures of synoptic-scale variability are calculated from a ten member wintertime ensemble of the United Kingdom Meteorological Office's Atmospheric Climate Model, HadAM3, and are compared with the same measures from the ERA dataset. The prominent differences between the observed and modelled storm tracks are the slow propagation speeds of extra-tropical cyclones in HadAM3 as they move through the Atlantic storm track, and the shape of the Atlantic storm track which is more zonal in the model than in observations. Both these differences can be related to the structures of the time-mean jet streams and steering level flows in HadAM3 and the ERA dataset.

MW02/E/05-B3 1100

SENSITIVITY OF THE TROPICAL CLOUD RADIATIVE FORCING TO SEA SURFACE TEMPERATURE: TOWARD AN ASSESEMENT OF CLIMATE MODELS?

Sandrine BONY, Herve Le Treut (LMD/CNRS, Paris,France); Jean-Jacques Morcrette (ECMWF, Reading, UK); Catherine Senior, Mark Webb (Hadley Center, Bracknell, UK)

We investigate the sensitivity to sea surface temperature changes of the cloud amount, cloud optical properties and cloud radiative forcing derived from satellite observations and from climate model simulations. The following specific questions are addressed: how does the sensitivity vary among climate models, among coupled and uncoupled simulations, and between short-term climate variability and global warming experiments? Implications with regards to the validation of cloud feedbacks produced by climate models will be discussed.

MW02/W/02-B3 1120

THE USE OF SATELLITE BRIGHTNESS TEMPERATURE DATA FOR EVALUATING THE DIURNAL CYCLE IN TROPICAL CONVECTION AS SIMULATED BY THE UK METEOROLOGICAL OFFICE UNIFIED MODEL

Guiying Yang and Julia SLINGO (both at Centre for Global Atmospheric Modelling, Department of Meteorology, University of Reading, Earley Gate, Reading, RG6 6BB, UK.
Email: J.M.Slingo@reading.ac.uk)

A global archive of window brightness temperature with high spatial (0.5 degree longitude/latitude) and temporal (3 hourly) resolution has recently been constructed for the period 1983-1996 by the EU Project, 'Cloud archive User Service (CLAUS)'. This contiguous dataset has enabled a range of studies of the temporal and spatial characteristics of tropical convection. The high temporal sampling of the CLAUS dataset has been used to perform a detailed study of the diurnal cycle in tropical convection and clear sky land surface temperatures. The phase and amplitude of the diurnal cycle for different regimes (e.g. deep oceanic convection) have been computed. The results have confirmed the early morning maxiumu in convection over the tropical oceans, whereas continental convection tends to peak in the late afternoon and early evening.
This analysis has been used to evaluate the simulation of the tropical diurnal cycle by the latest version of the atmospheric component of the Hadley Centre climate model (HadAM3). The results have shown that the model has various systematic errors in its simulation which can be related to aspects of the physical parametrizations.

MW02/E/04-B3 1140

HOW WELL CAN CCM3 SIMULATE THE RESPONSE OF UPPER TROPOSPHERE AND LOWER STRATOSPHERE WATER VAPOR AND CIRRUS CLOUDS TO A PERTURBATION IN TROPICAL CONVECTION?

RONG FU, Mingxiang Chen and John McCormack (Department of Atmospheric Sciences, The University of Arizona, 1118 E. 4th. St., Rm. 576, P.O. Box 210081, Tucson, AZ 85721-0081, USA; 602-621-6955; e-mail: fu@atmo.arizona.edu)

Evaluating the responses of upper troposphere and lower stratosphere water vapor and cirrus clouds to a perturbation in tropical convection in climate models enables us to assess the adequacy of these models in simulating the physical and dynamic processes that determine water vapor and cloud feedbacks. We have used UARS MLS, SAGE II, ISCCP and TOVS data sets to examine both horizontal and vertical structures of water vapor and cirrus clouds in responding to changes in tropical convection. The results suggest that CCM3 appears to adequately capture the sensitivity of water vapor between 500 mb and 200 mb to perturbations in the tropical Pacific in the subtropical clear sky region, although the magnitude of water vapor anomalies disagrees with observation due to errors in convection. The sensitivity of water vapor above 200mb appears to be opposite in sign in large subtropical areas, as suggested by both UARS MLS and SAGE II data. Whether CCM3 can simulate this vertical dependence of water vapor sensitivity on convection and the underlying processes will be discussed. The responses of water vapor and cirrus clouds to changes in continental atmospheric deep convection, as in the Amazon basin, will also be evaluated.

MW02/W/03-B3 1200

CONSISTENCY BETWEEN TROPICAL DIVERGENT CIRCULATIONS FROM REANALYSIS DATA SETS AND SATELLITE-DERIVED PRECIPITATION, RADIATION, AND SURFACE FLUXES

1Franklin R. ROBERTSON, 2John Roads,3H.-I. Lu, 3Eugene W. McCaul, 1NASA / Marshall Space Flight Center, Global Hydrology and Climate Center, Huntsville, AL 35806, 2Scripps Institution of Oceanography, UCSD, 0224 , La Jolla, CA 92093-0224 , 3Universities Space Research Association, Global Hydrology and Climate Center, Huntsville, AL 35806

Large-scale divergent circulations are part of the atmospheric dynamic response to diabatic heating from condensation, radiative processes, and surface heat fluxes. Vertical motion and the associated divergent wind is thus intimately tied to the hydrologic cycle and the global heat balance. Vertical motions are recovered diagnostically from reanalyses and, as such, are subject to shortcommings in model physics, numerics, and data availability.We use several GEWEX EOS data sets derived from satellite data to assess interannual divergent flow anomalies in the NCEP, GSFC, and GSFC DAO analyses. Among the data sets are monthly, 2.5 degree gridded precipitation (MSU and SSM/I-based), TOA radiative fluxes from ERBS, surface radiative fluxes from the SRB project, and surface latent and sensible flux estimates from SSM/I. These data sets can be considered as independent of the reanalysis fields. We focus largely on the period 1987-1989 encompassing a strong El Nino / la Nina couplet. Consequently we emphasize interannual changes as well as climatological aspects of the reanalyses. In the processes of this study we use simple integral constraints enforced through the satellite-derived data sets to derive corrections to the divergent circulation produced from the reanalyses. We examine the implications of these corrections in describing how perturbations to the tropical heat balance evolve during a warm / cool couplet. In particular the perturbations to the planetary scale water vapor transport, and the resulting changes in TOA and surface radiative fluxes are considered.

MW02/L/01-B3 1220

MOISTURE TRANSPORT OVER THE AUSTRALIAN CONTINENTAL IN THE 1997/1998 ENSO EVENT: COMPARISON OF MODEL RESULTS WITH NCAR/NCEP REANALYSIS

HUQIANG ZHANG (Environment Division, Australian Nuclear Science and Technology Organisation, PMB 1, Menai, NSW 2234, Australia); Carsten Frederiksen (Bureau of Meteorology Research Centre, GPO BOX 1289K, VIC 3001, Australia); Ann Henderson-Sellers (Environment Division, Australian Nuclear Science and Technology Organisation, PMB 1, Menai, NSW 2234, Australia).

Every El Nino event has its own unique development. In addition, the regional and global impacts of the associated large tropical SST anomalies may vary between different events. For example, the 1997/1998 El Nino event did not produce as severe a drought over the Australian continent as was expected. Both statistical and numerical models showed limited skill in forecasting Australian rainfall anomalies. Improving our understanding of how large tropical SST anomalies affect Australian rainfall requires more diagnostic and modelling studies of the related physical and dynamical processes. In the current study, we focus our attention on the water vapour budget and horizontal moisture transport over the Australian continent. A climatology of regional moisture transport is established using the 40-year (1958-1997) NCAR/NCEP reanalysis data. From the analysis we note that there are some biases between the observed Australian rainfall climatology and that derived from the reanalysis data. We discuss how the biases affect our analysis and validation. Using monthly averaged reanalysis data, several past El Nino events covered by the reanalysis period are synthesized to give a general picture of how moisture transport changes during the El Nino events. We then study the changes of moisture transport and water vapour budget during the 1997/1998 El Nino event in more detail. Results from a set of AGCM experiments conducted in the 1997/1998 period by using persistent SST anomalies are compared with the results from the reanalysis data. The aim is to try to understand how the simulated changes of horizontal moisture transports affect the model rainfall forecasts and which factors contribute to those differences seen between the model and reanalysis results. The importance of soil moisture initialization and parameterization is also discussed.

MW02/W/09-B3 1400

GLOBAL SATELLITE CLOUD OBSERVATION DATA SETS

G. Garrett CAMPBELL (CIRA/CSU, Ft. Collins, CO 80523)

Two distinct satellite based cloud climatologies are available for comparisonto model simulation: ISCCP and the Pathfinder Atmospheric Cloud products. ISCCP assigns 100% cloudiness to pixels which are colder or brighter than a background radiance. Patmos constructs a similar background, but then assigns a cloud fraction using a radiation budget approach to account for partly cloudy pixels. These two data sets will be compared for the period 1983 to 1993. Generally Patmos measures less cloudiness than ISCCP. These measurements should bracket model simmulations of the Earth's climate. An NCAR Community Climate Model simmulation of the variation of cloudiness for this period will also be compared. This run used the monthly sea surface temperature observations to force the model, so the month to month cloud variations can be compared, not just the seasonal cycle. In most cases this model shows more cloudiness than either ISCCP or Patmos.
Better matches between the observations and the simmulations occur when the seasonal cycle is removed: anomally series. The most obvious feature is the El Nino events over the last 2 decades. In addition the model and observations match in the Atlantic area. The model and the real atmosphere are forced by the sea surface temperature in topical areas. Some results can be viewed at http://acamar.cira.colostate.edu/.

MW02/W/08-B3 1420

GLOBAL PRECIPITATION DATASETS OF GPCP: RESOLUTION, QUALITY-CONTROL AND ERROR ASSESSMENT

Bruno RUDOLF, Deutscher Wetterdienst, Offenbach/Germany

The objective is to provide the climate research community with gridded datasets of global precipitation derived from observational data. The continents are covered by more or less dense raingauge networks supplying in-situ observations, which are the most reliable data base, while satellite-based estimates are subject to larger biases and stochastic errors and need to be adjusted to conventionally measured data. The reference-status of in-situ data requires very careful handling and quality-control of the data, compensation of systematic errors and assessment of remaining stochastic errors. The Global Precipitation Climatology Centre (GPCC) disseminates gridded datasets of precipitation derived from 6,000 to 7,000 near-realtime data for the landsurface on a monthly routine basis. The gridded results are available on internet for the period beginning with January 1986 and are complemented regularly month by month under the name 'GPCC Monitoring Product' with a lag of two months after observation. Analyses including additional data from 40,000 stations supplied by the individual countries are in preparation.

MW02/E/07-B3 1440

ON THE TEMPORAL SAMPLING ERRORS IN GLOBAL DATASETS

ISAMU YAGAI, Takahiro Kayahara, and Kimpei Ichiyagagi National Research Institute for Earth Science and Disaster Prevention, Tsukuba Ibaraki 305, Japan

Recent development of orbital satellite such as TRMM (Tropical Rainfall Measuring Mission) makes very high spatial resolution observation of physical quantity but the sampling time is poor compared to the ordinary routine observation. Therefore, when they make monthly mean distributions of rainfall or other variables from TRMM observations, they have to experience sampling time error problems. Although the sampling problems in the observations are not new ones, we obtained interesting results by using the sophisticated climate model and REANALYSES data by ECMWF. The model used here has twenty-one layers in the vertical with the top level at 10 hPa, and a horizontal resolution of T42. The time integration starts at 31 December 1980; the initial condition of the model atmosphere adopted from the value in the long time integration. We used two kinds of data sampling interval. One is 6 hours which can analyze diurnal variations and the other 30 hours for climate analyses. When we compare the monthly mean values for each different sampling time case, relatively large temperature difference about 2_$B!k_(B K appeared at high latitudes in the troposphere in the northern hemisphere. There are also large values about 4_$B!k_(B K seen at high latitudes in the stratosphere due to stratospheric sudden warmings. For specific humidity the situation is quite different; large differences appeared near the boundary between land and sea at 925hPa. At 100hPa level large difference are seen near the equator since the moisture at this level is brought up by the cumulus convection and the convections have strong diurnal variations. Sampling time errors are seen in particular area in the globe, which are different in each physical quantities and associated phenomena.

MW02/W/07-B3 1500

PARAMETERIZING UNRESOLVED SCALE INTERACTIONS

E. KAAS, A. Guldberg, W. May, Danish Meteorological Institute, Denmark and M. Deque, Meteo-France, France.

A parameterisation of non-linear dynamical interactions with unresolved scales - usually referred to as horizontal diffusion - is needed in most atmospheric models to ensure realistic fluxes of energy and enstrophy near and at the truncation limit. In this paper a minimisation of tendency errors in low to medium resolution versions of the ARPEGE/IFS and the ECHAM4 general circulation models is sought in order to obtain spectral empirical interaction functions (EIFs) to be used in the formulation of horizontal diffusion. The tendency errors are calculated relative to reanalysis data and high resolution adiabatic versions of the models themselves. Different EIFs are obtained for vorticity, divergence and temperature. The most striking feature is that the vorticity and partly the temperature EIF has non-negligible negative values for low wave numbers in large parts of the troposphere. This implies that these waves are enhanced in amplitude due to non-linear scale interactions with unresolved scales. At low resolution the generation/dissipation of kinetic energy due to the interactions is not well parameterised by neither the standard horizontal diffusion nor when using the EIFs in this parameterisation. When the EIFs are used in the formulation of horizontal diffusion it is seen that the spectrum of kinetic energy is closer to observations than in the original model versions. Furthermore, the large scale systematic model errors are reduced in a medium resolution simulation, while less clear improvement is seen in a simulation at low resolution.

MW02/E/09-B3 1520

OBSERVATIONAL AND MODELED ESTIMATES OF TEMPERATURE CHANGE IN THE FREE ATMOSPHERE

JUSTIN J. HNILO, Benjamin D. Santer and James Boyle (all at Program for Climate Model Diagnosis and Intercomparison, Lawrence Livermore National Lab, Livermore, CA, USA, Email: hnilo@pcmdi.llnl.gov)

Observed Microwave Sounding Unit (MSU) brightness temperatures have been the focus of much spirited debate within the atmospheric science community given their lack of any significant lower tropospheric warming trend. This work uses observed and model data to compare different methods of producing simulated MSU temperatures. Data used herein are the ECMWF and NCEP reanalyses, the Comprehensive Aerological Reference Dataset (CARDS), the Hadley Centre radiosonde datasets (versions 1.1 and 1.2) and where possible, preliminary results from participant AMIP II models. Two methods of deriving a simulated MSU temperature will be employed. The first is a view angle resolving radiative transfer model which incorporates both skin and profiles of temperature as well as profiles of moisture and variations of surface emissivity. The second method is a simpler global weighting function applied directly to the profile of temperature. Global and hemispheric simulated values for these two methods are highly correlated and yield similar decadal trends and variability. At smaller scales,

however, the two moethods exhibit much larger differences, particularly in the troposphere. These regional differences are largely attributable to differences in the vertical coherence of temperature profiles and in the spatial variability of moisture changes. On regional scales, therefore, the use of two different methods to simulate a satellite signal from the same data can yield two different answers.

MW02/W/06-B3 1600

HEAT TRANSPORT IN THE ATMOSPHERE AND OCEAN

Paul BERRISFORD and Alan O'Neill (CGAM Department of Meteorology University of Reading Reading RG6 6BB U.K.).

Over long timescales the Earth absorbs more solar radiation in tropical regions than it does at higher latitudes. Similarly, more longwave radiation is emitted to space in the tropics than at high latitudes. However, the net effect of these two processes is that energy is absorbed at low latitudes and emitted to space at high latitudes.
Assuming that over long timescales the heat storage in the Earth's atmosphere and oceans does not change then the atmosphere and ocean must transport heat from the tropical regions to high latitudes. Heat transport in the atmosphere and ocean is investigated using the European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis (ERA) dataset covering the period January 1979 through to December 1993. The heat transports of the atmosphere, ocean and the combined system are computed separately for the fifteen year climatology and the individual annual means. These results can be compared with previous estimates of the heat transports. Given that the heat transports in the atmosphere and ocean add up to that required for the combined system, an intercomparison of the heat transports in the three systems allows an estimation of the internal consistency of the ERA data to be made. This gives an indication of how reliable the results are.
Heat transports are also calculated from the AMIPII dataset and these results are compared with the results from the ERA.

MW02/W/01-B3 1620

RELATIONSHIP OF OPTICAL DEPTH WITH EFFECTIVE RADIUS IN ECHAM AND OBSERVATIONS

Ulrike LOHMANN (Dept. of Physics, Dalhousie University, Halifax, NS, B3H 3J5, Canada, email: Ulrike.Lohmann@Dal.Ca)

ISCCP data were analyzed in terms of the relationship of cloud albedo and liquid water path with droplet size. It was found that only for optically thick clouds (with an optical depth > 15) and for clouds over land the cloud albedo increase with decreasing droplet size, which is the underlying assumption for the indirect aerosol effect. For optically thinner clouds (with an optical depth < 15) the time available for droplet growth leads to an increase in liquid water path and cloud albedo with increasing droplet size. For all warm clouds the liquid water path increases with increasing effective radius as to be expected in the droplet growth state where CDNC is almost constant. The ECHAM model was analyzed and the opposite behavior for optically thin and thick clouds over the oceans is captured. However, the land-sea contrast for optically thin clouds is not simulated. Here we want to investigate why optically thin and thick clouds behave so different with changing effective radius.

MW02/E/02-B3 1640

VALIDATION OF TOA RADIATION AND CLOUD SIMULATIONS BY DIFFERENT LMD GCM VERSIONS IN MIDDLE AND EQUATORIAL LATITUDES

Igor I. MOKHOV (A.M.Obukhov Institute of Atmospheric Physics RAS, 3 Pyzhevsky, Moscow 109017, Russia, e-mail: mokhov@omega.ifaran.ru) Marie Doutriaux-Boucher (Laboratoire d'Optique Atmospherique, Universite de Lille-I, e-mail: mdoutri@loa.univ-lille1.fr) Alexey V. Eliseev (A.M.Obukhov Institute of Atmospheric Physics RAS) Herve Le Treut (Laboratoire de Meteorologie Dynamique, Universite PetM Curie , e-mail: Herve.Letreut@lmd.jussieu.fr)

The ERBE data are used for validation of radiation fluxes at the top of the atmosphere (TOA) in the three LMD GCM versions with a quite different parameterizations of physical processes. The objective of this analysis is to show that a restricted number of key longitudinal profiles offers a good insight into the behaviour of different model versions. Detailed analysis is done for selected sections in middle and equatorial latitudes with a remarkable cloudiness due to intensive cyclonic or convective activity. The satellite ISCCP data together with ground-based data for clouds of different types have been used for the combined analysis of the causes of systematic model errors. Significant problem exhibit simulations of cloud radiative forcing (CRF) over oceans in the middle NH latitudes, especially in winter. It is related with simulation of clouds and CRF over storm tracks. Overestimation by models of the longwave CRF with not too strong negative shortwave CRF lead to the significant overestimation of the net CRF. It can result in the too strong positive cloud-related feedback with the increase of model sensitivity (at least at the regional scale) to different influences, particularly to the anthropogenic one. One of the importnant conlusions can be done for equatorial regions, in particular for Pacific regions with the realization of ENSO effects.

MW02/E/01-B3 1700

SURFACE CLEAR-SKY LONGWAVE IRRADIANCES IN CLIMATE MODELS

J.R.GARRATT (CSIRO Atmospheric Research, Aspendale, Vic.3195, Australia)

The clear-sky longwave irradiance at the surface (Clis) is an important property of climate and climate change and one of the principal drivers of the planet's greenhouse effect. We use mean monthly, grid-point results from three climate model simulations (NCAR, UKMO and CSIRO) and from the NCEP-NCAR re-analysis (based on the NCEP climate model) to investigate the seasonal and regional behaviour of Clis. In addition, we utilise global datasets of observed column water vapour (W) and screen-air or surface temperature (T) to validate indirectly the model simulations using the algorithm of Dilley and O'Brien (1998 - Quart.J.Roy.Meteorol.Soc., 124A, 1391-1401) for predicting Clis (to * 5W per square metre).
Over the oceans, annually-averaged Clis in the model simulations is a strong function of T, but less so over land. The main reason relates to the close link between W and sea-surface temperature. For monthly Clis (January and July) over the oceans, the dependence upon T forms two distinct branches according to hemisphere, with greatest January - July differences occurring in middle to high northern latitudes in both Atlantic and Pacific Oceans. This is closely linked to the analogous branching of the seasonal column water vapour variation with surface temperature, related to effects of large-scale dynamics on water vapour transport (Webb et al., 1993 - Clim.Dynamics, 9, 117-129). Regional January and July algorithm-determined fluxes (typical values of 250 to 350 W per square metre), using both observed and model-generated fields of W and T, are mostly within * 5 to15 W per square metre of model fluxes. The analysis provides further support for the Dilley-O'Brien algorithm in determining mean monthly values of Clis from W and T, particularly when more detailed radiative models are either unavailable or their use impractical.

MW02/E/06-B3 1720

A GLOBAL COMPARISON OF GPCP PRECIPITATION OBSERVATIONS WITH MODEL-GENERATED ESTIMATES

SCOTT CURTIS (JCET/UMBC NASA/GSFC, Code 912, Greenbelt, MD, 20771); Robert Adler (NASA/GSFC, Code 912, Greenbelt, MD, 20771); George Huffman (NASA/GSFC, Code 912, Greenbelt, MD, 20771).

The Global Precipitation Climatology Project (GPCP) community dataset blends satellite observations (SSM/I, IR, TOVS) and rain gauge data into a globally complete monthly product, available from January 1986 to present. This dataset is useful for monitoring climate variability on the synoptic scale. A primary objective is to validate model precipitation output with GPCP observations. Global satellite-derived precipitation estimates on smaller time and space scales will also be used for these purposes, including pentad averages of the SSM/I-based Goddard Profiling Algorithm (GPROF) and the new one degree daily (1DD) microwave-adjusted, IR-based estimates. In a recent study, Janowiak et al. (1998) quantified differences between GPCP observations and the NCEP reanalysis. In light of the fact that NCEP does not assimilate precipitation observations in their reanalysis product, substantial differences were found in the globally averaged precipitation rates, seasonal cycle, and interannual variability. NCEP is somewhat higher (3.0 mm day-1) than GPCP (2.8 mm day-1) in the global average which is mainly due to tropical rainfall. Our investigations into the 1997-98 ENSO revealed that NCEP tended to produce more positive than negative precipitation anomalies. For example, NCEP showed wet conditions over the Indian sub-continent, while GPCP observations did not. Also, NCEP did not have the extremes in rainfall observed in the tropical Pacific.
The precipitation estimates of other models will also be compared to satellite derived observations on a range of time and space scales. Finally, a component of this study will compare GPCP with model-produced circulation fields (divergence, vertical motion, precipitable water) to help us better represent and understand the global hydrologic cycle and elucidate improvements to the model's representation of atmospheric processes.
Janowiak, J. E., A. Gruber, C. R. Kondragunta, R. E. Livezey, G. J. Huffman, 1998: A comparison of the NCEP-NCAR reanalysis precipitation and the GPCP rain gauge-satellite combined dataset with observational error considerations. J. Climate, 11, 2960-2979.

MW03/E/06-B4 0935

THE IMPACT OF INCREASING HORIZONTAL RESOLUTION ON THE HADLEY CENTRE MODEL HADAM3

Rachel STRATTON (Hadley Centre for Climate Prediction and Research, Met Office, London Road, Bracknell, RG12 2SY, UK. Email: rastratton@meto.gov.uk)

HadAM3, the latest version of the atmospheric part of the Hadley Centre climate model, has been used for a series of AMIP II integrations to investigate the sensitivity of the model to horizontal resolution. The investigation has been done using a higher vertical resolution (roughly 50hPa in and around the troposphere) than previously used for most climate resolution studies. Three integrations have been performed, all with the same 30 vertical levels, as follows;

Name resolution	lat x long	timestep	physics	dynamics of run at midlatitudes	length resolution in km
SRES	2.5 x 3.75	15 min	15 min	17 years	300
MRES	1.25 x 1.875	15 min	15 min	17 years	150
HRES	0.888 x 1.25	10 min	5 min	10 years	100

where SRES is the horizontal resolution usually used for climate simulations. The HRES simulation is comparable in resolution to recent operational forecast models. For example it is comparable with that used for the ECMWF reanalysis project (ERA).
A comparison of the first 10 year means show that on increasing resolution the westerly jets move polewards in both hemispheres. The mean sea level pressure decreases over the poles and increases between 30 and 60 N/S. At mid -latitudes the troposphere warms, specific humidity decreases, the standard deviations of vertical velocity increases, eddy kinetic energy and eddy fluxes of heat momentum and moisture increase. On the whole the changes due to increased resolution improve agreement with ERA (ECMWF reanalyses for 1979-88). The most significant changes occur in going from SRES to MRES and are mainly due to a better resolution of synoptic scale disturbances.

MW03/E/02-B4 0950

THE IMPACT OF HORIZONTAL RESOLUTION ON THREE ATMOSPHERIC GCMS

DOBLAS-REYES, Francisco Javier and Michel Deque (CNRM, Meteo-France, 42, Av. G. Coriolis, 31057 Toulouse Cedex, France)

In the HIRETYCS project, a European research project funded by the Environment and Climate programme of the European Commission, the analysis of two AMIP I-type experiments has been undertaken. The experiments use a standard (T42 or equivalent) and a high (T106 or equivalent) horizontal resolutions. Three models have been run under these conditions to simulate the climate of 1979-88, namely the CNRM model, the Hadley Centre model, and the MPI model. The impact of the resolution increase is not systematically positive. The mean climate is in the best cases slighly improved and sometimes degraded. The most remarkable improvements are obtained on the climate variability, since this feature of the GCM is rarely tuned by a choice of empirical parameters which favours the version used in the tuning process, i.e. the standard resolution. Another interesting feature is the fact that the models are very different, and has thus very different systematic errors. But, in many instances, the impact of the resolution increase on this systematic error (which can be either positive or negative) is similar between the three models.

MW03/E/10-B4 1005

A STUDY ON THE INFLUENCE OF GLOBAL WARMING ON TYPHOON CLIMATOLOGY USING A HIGH RESOLUTION AGCM

MASATO SUGI, Jun Yoshimura and Akira Noda (Meteorological Research Institute, 1-1 Nagamine, Tsukuba, Ibaraki 305-0052, Japan, email: msugi@mri-jma.go.jp, jyoshimu@mri-jma.go.jp, noda@mri-jma.go.jp)

Influence of global warming on tropical cyclone climatology is studied using two ten-year integrations of the Japan Meteorological Agency (JMA) global model at T106 horizontal resolution. First integration (CNTL run), forced with observed sea surface temperature (SST) for the period 1979-1988, could simulate current tropical cyclone climatology reasonably well. The second integration (2xCO2 run) has been conducted with the SST increase corresponding to global warming and with doubled atmospheric CO2 concentration. The SST increase is estimated from the results of transient CO2 experiment with a low resolution coupled model, MRI-CGCM. Comparison of the two integrations has revealed significant reduction in the number of tropical cyclones due to global warming. The reduction in the tropical cyclone frequency seems to be associated with the weakening of the tropical circulation due to the increased atmospheric stability by global warming.
Several additional experiments have been conducted to see the sensitivity of the results to convection scheme and pattern of SST increase. The results of these experiments further confirmed the reduction in tropical cyclone frequencies due to global warming. However, it is strongly suggested that we need much higher

RESEARCH AND DEVELOPMENT FOR MEDIUM AND EXTENDED-RANGE FORECASTS: METHODS, RESULTS, AND PROSPECTS

A. HOLLINGSWORTH, M.Capaldo, A. Simmons (ECMWF, Shinfield Park Reading RG2 9AX, UK)

ECMWF's prime long-term goal is to deliver operational medium-range-weather forecasts of increasingly high quality, over the range from three to ten days and beyond. A complementary long-term goal is to establish and deliver a reliable operational seasonal forecasting capability. Overall success will depend crucially on new and improved satellite observations, on improvements in the data-assimilation system, and on improvements in the forecast models. Ensemble prediction will play a major role in attaining both goals.
Medium-range and seasonal-to-interannual weather forecasting have attained new levels of achievement and continue to offer exciting prospects for further development. A new generation of operational and research satellites is coming on stream; four-dimensional variational assimilation is established as a powerful and effective method to use all observations; numerical methods continue to provide improved accuracy and substantial economies; parametrization schemes are improving steadily through new approaches which jointly exploit field experiments, large-eddy simulations and operational data assimilation; ensemble prediction systems are providing a new dimension in probabilistic forecasting; the development of simplified Kalman filters, based on singular vectors, will benefit both the assimilation systems and the ensemble prediction systems; coupled atmosphere-chemistry models offer new ways to improve the initialisation of forecast models; coupled atmosphere-ocean models have delivered successful ensemble forecasts of the 1997-98 El Nino event; and computer vendors are confident they can meet the requirements for computational power in an affordable manner. These developments will undoubtedly lead to further gains in medium-range and seasonal-to-interannual forecast skill.
The new satellite data essential to achieve these goals over the next decade will be provided as a result of investments of 3B or more by Europe (EUM= ETSAT and ESA), 3B or more by Japan and 10B or more by the USA. By the end of 1999, in readiness to exploit the new satellite data, ECMWF will have implemented an advanced operational Earth-system model and data assimilation system. ECMWF's Earth-system model will comprise the following coupled modules:
• Atmosphere an atmospheric general circulation model
• Ocean circulation: an ocean general circulation model ocean ice processes
• Ocean surface waves ocean surface wave dynamics model
• Land land biosphere module land surface, soil, hydrological and snow model
• Ozone parametrized stratospheric ozone chemistry
Some modules of the model are already quite sophisticated, but others are at an early stage of development.
ECMWF's advanced four-dimensional

ASPECTS OF ATMOSPHERIC CIRCULATION SIMULATED IN A GLOBAL CLIMATE MODEL WITH 30 KM HORIZONTAL GRID SPACING

KEVIN HAMILTON and Richard Hemler (Geophysical Fluid Dynamics Lab/NOAA, P.O. Box 308, Princeton, New Jersey 08542, USA, Email: kph@princeton.edu); Frederic Vitart (European Centre for Medium Range Weather Forecasts, Reading, UK)

A version of the GFDL SKYHI global general circulation model with 30 km horizontal grid spacing and 40 vertical levels has been integrated for more than 8 months. This talk will examine aspects of the simulation including the large-scale wind and temperature structure in both the troposphere and the middle atmosphere. Also discussed will be the statistics of intense rainfall events including simulated tropical cyclones.

MW03/W/07-B4 1115

SIMULATION OF THE MESOSCALE SPECTRAL REGIME IN HIGH-RESOLUTION VERSIONS OF A GLOBAL CLIMATE MODEL

JOHN KOSHYK (Department of Physics, University of Toronto, Toronto, Ontario, Canada, Email: koshyk@mam.physics.utoronto.ca); Kevin Hamilton (Geophysical Fluid Dynamics Lab/NOAA, P.O. Box 308, Princeton, New Jersey,USA)

This paper will discuss the mesoscale variability found in the upper troposphere and lower stratosphere in simulations of the atmospheric circulation made with very high spatial resolution versions of the GFDL SKYHI GCM. Included will be one integration with horizontal grid-spacing of 30 km, and another with horizontal spacing of 100 km, but vertical level-spacing less than 400 m in the lower stratosphere. The horizontal spectra of winds in the simulations display two separate regimes: one at large scales (>1000 km) with steep power law behaviour and a shallower regime in the mesoscale. This is in general accord with the usual observational picture of tropospheric/lower stratospheric meteorology. In fact, the model-simulated kinetic energy spectrum near the tropopause compares quantitatively with the observations in the GASP archive of data taken during thousands of commercial aircraft flights. Detailed analysis of the spectral kinetic energy budget will be presented.

MW03/E/09-B4 1130

A LOOSE COUPLING OF GENERAL CIRCULATION MODEL WITH CHEMICAL TRANSPORT MODEL AND ITS APPLICATION TO OZONE DATA ASSIMILATION

Toshiki IWASAKI (Geophysical Institute, Graduate School of Science, Tohoku University, Aoba-ku, Sendai, 980-8578, JAPAN, Email: iwasaki@wind.geophys.tohoku.ac.jp); Hisashi. Kato, Atsuya Kinoshita and Toru Sasaki (Japan Meteorological Agency, Otemachi 1-3-4, Chiyodaku, 100-8122, JAPAN, email: tsasaki@naps.kishou.go.jp)

We are developing a high resolution General Circulation Model (GCM) coupled with a chemical transport model (CTM) to study interactions between the atmospheric circulations and the global distributions of minor constituents. CTMs have too many prognostic variables and vertical levels to increase horizontal resolutions under limited computational resources. GCMs, on the other hand, are expected to run high resolution simulations in the horizontal. To save computational resources, the time step length should be different between two models. Thus, we are concerned about a loose coupling technique of GCM and CTM which adopts different space and/or time resolutions between two models.
What is important for the loose coupling is to estimate vertical velocity used for advection of minor constituents in the CTM. Distributions of minor constituents of minor constituents, such as ozone, are very sensitive to vertical velocity because of large vertical gradients of its mixing ratio. When GCM-produced vertical velocities are used to advect minor constituents, the CTM may be subject to time truncation errors related to high frequency gravity modes. In the actual simulation, the predicted constituent distributions tend to have spurious spreading and bias. In order to get rid of time truncation errors, we estimate vertical velocities from the thermodynamic equation with diabatic terms.
A preliminary test is conducted focusing on data assimilation of ozone in comparison with satellite-derived total ozone amount. The T63 or T213 version of JMS's global NWP model is coupled with a CTM in 2.5 or 5 degree longitude-latitude co-ordinates. Prognostic variables are exchanged between GCMs and CTMs every 3 or 6 hours. The time step for CTM is set at 30 minutes, which is longer than that for GCM to save computational resources. Diabatically diagnosed vertical velocities allow us to successfully reproduce observed distributions of total ozone amounts. Further experiments are underway on impacts of vertical and horizontal resolutions of the CTM.

MW03/E/05-B4 1145

TOWARD THE REALIZATION OF CLOUD CLUSTER-RESOLVING GLOBAL ATMOSPHERE MODELS

Taroh MATSUNO (Institute of Global Change Research, Frontier System for Global Change, Seavans-N Bldg 7thF, Shibaura 1-2-1, Minatoku 105-6791, Japan, e-mail: taguchik@jamstec.go.jp)

Considering the recent development of computer technology it will become possible to use numerical J models of the global atmosphere having the horizontal grid-size of about 10km in the near future (probably within 3 years). For such high resolution models parameterization of convective clouds as usually used in current atmosphere models becomes inadequate because convection in the vast area of tropics takes place as meso-scale convective systems (cloud clusters) whose horizontal dimension is larger than 10km. Thus we are forced to jump to construct models to resolve cloud clusters. Judging from the observed structure of cloud clusters, the required horizontal grid-size may be around 5km at the greatest which could be attained not so far in the future. Development of such high resolution atmosphere models can be done basically by extending currently existing meso-scale cloud models to cover much larger areas, but we need to know much more about dynamics of meso-scale processes of J atmosphere such as generation of internal gravity waves, down-cascade of enstrophy, turbulent energy dissipation due to shear instability and so on. In current models, they are parameterized as double laplacian diffusion process or vertical eddy viscosity and their representation and the values of coefficients are determined more or less ambiguously and the physical reality of these processes have not been, discussed so far. Some elementary considerations on these problems will be made.

MW03/E/07-B4 1200

PROBLEMS IN NUMERICAL MODELING USING VERY HIGH RESOLUTION

Yoshio KURIHARA (Frontier Research System for Global Change, Sumitomo-Hamamatsucho Bldg. 4F, 1-18-16 Hamamatsucho, Minato-ku, Tokyo, 105-0013, Japan. email: ykuri@frontier.esto.or.jp)

A climate model with very high horizontal resolution of the order of 10km is expected to be capable of realistically describing climatic features peculiar to each of different regions or localities, as well as of simulating the structure and behavior of the mesoscale systems more accurately than models with coarse resolution. Construction of such models requires, on the one hand, rigorous evaluation of numerical schemes, which treat dynamical core of the model. These schemes are formulated once the grid configuration or the spectrum domain is determined. On the other hand, a guideline has to be developed for dealing with model physics in a very high-resolution model and performance of the numerical schemes representing it has to be tested. Among a number of problems concerning treatment of model physics, the most intriguing one is, perhaps, how to incorporate effects of convection and condensation processes into the model. One may consider usage of a cloud-resolving model despite a fact that the horizontal resolution of the order of 10 km may be too coarse and can cause bias of the model climate. Another approach is to rely on a scheme of parameterization. The basic environmental parameters controlling free convection are the atmospheric stability and the moisture content. If the size of cloud, i.e., a fundamental cloud property, is specified, one can derive a formula which defines the critical relative humidity for free convection with that cloud size to occur in the atmosphere of given static stability. A scheme of parameterization developed along this line has been used in the GFDL (Geophysical Fluid Dynamics Laboratory, NOAA) hurricane model. In the present paper, a method will be proposed to utilise the same formula in the estimate of cloud amount. The cloud amount is an important quantity, which substantially influences radiation budget. Also, in the evaluation of the radiation budget in high-resolution models, effects of detailed topography may have to be taken into consideration.

MW03/W/10-B4 1215

ON THE COMPUTATIONAL REQUIREMENTS OF HIGH-RESOLUTION CLIMATE MODELS

Carlos R. MECHOSO and Leroy A. Drummond (Department of Atmospheric Sciences, University of California, Los Angeles, CA 90024 USA, email: mechoso@atmos.ucla.edu)

Climate models are among the archetypical computer-demanding applications, a characteristic that is exacerbated by increases in resolution. This presentation discusses design and machine requirements of high-resolution climate models, viewed as a set of modules (e.g., atmospheric and oceanic codes) with different spatial/temporal resolutions and periodic/sporadic data exchanges.
First, there is the problem of load-balancing of individual codes. Methods are presented and

their impact on performance is discussed. Second, there is the load-balancing of different codes sharing computational resources. Since the scalability of a code decreases with increasing number of processors, it can be more efficient to simultaneously run several modules in sub-sets of processors than sequentially run individual modules in all available processors. Third, there is the problem of efficient data transfers between different modules running in parallel. A novel system for parallel data exchanges (Distributed Data Broker) is presented. Finally, there are aspects involving data mining and real-time visualization of very large model output.
These issues are discussed in the framework of the UCLA Earth System Model, which combines atmospheric and oceanic dynamics and chemistry codes. The models are both global and regional and have multiple resolutions. The potential for performances at the TFLOP level is examined.

A PLATFORM FOR THE STUDY OF GLOBAL CLIMATE MODEL STUDY WITH HIGH RESOLUTION

Takahiro INOUE, Yukio Tanaka, Yonejiro Yamagishi and Hisashi Nakamura (Research Organization for Information Science and Technology, 1-18-16, Hamamatsu-cho, Minato-ku, Tokyo 105-0013, Japan, email: don@tokyo.rist.or.jp)

A high-resolution, coupled atmosphere-ocean climate model, called 'NJR', has been developed. NJR is parallel software and designed as a platform for high-resolution climate model study. NJR consists of AGCM, OGCM and atmosphere-ocean coupler. As a total system, pre/post-processes of data are also well equipped. The AGCM has two alternative dynamics part as an option, one uses spectral method and the other uses finite difference method. They use common physics packages. The OGCM also has two alternative co-ordinate systems, one use sigma-co-ordinate and the other uses z-co-ordinate in vertical. Each component or sub-process is modularised and users can add or modify any sub-process model. NJR uses domain decomposition as the parallel algorithm and the MPI as the message passing library. Therefore, it runs on almost all parallel machines, such as SX-4, SR2201, or even on workstation clusters. NJR will be mainly optimised and used on the 'Earth Simulator', which is a very large-scale distributed and shared memory vector parallel machine currently under development. Through NJR with these high performance machines, such as the Earth Simulator, users will be provided a useful tool for high-resolution climate model studies. Although, there are still some questions such as: What would happen on 10km mesh climate model? Would it be valid on such a high-resolution model that physics sub-process models currently used? What would be needed to handle massive data from such a large-scale simulation? etc. Until 1998, basic part of NJR was completed and released as version 1.00 to users. Some validation studies of each component, in AGCM, OGCM, and coupled model, are proceeded in order to evaluate its performance in climatological and parallel aspects. In the presentation, we will show description of NJR and some results of our experiments.

THE CSIRO CONFORMAL-CUBIC GCM

John L. McGREGOR and Martin R. Dix (CSIRO Atmospheric Research, Melbourne, Australia)

A new global primitive equations model has been developed at CSIRO. It has the unique feature that it is based on the conformal-cubic grid (Rancic etal., QJRMS, 1996). The model utilises 2-time-level semi-Lagrangian advection (McGregor, 1996). A recent significant improvement is a modification to carry the velocities on a quasi-staggered grid which has superior dispersion properties for geostrophic adjustment, when compared to the A, B and C grids. This improvement is evident for standard test cases of the shallow water equations as well as for the 3D dynamic core test, compared to the previous C-grid scheme. The model employs a semi-implicit treatment for gravity waves; a simple tri-colour successive over-relaxation scheme has been developed to solve the associated Helmholtz equations. Major attractions of the model are its quasi-uniform resolution, and absence of the Gibbs' phenomena which occur for spectral models. The model is computationally efficient and its architecture should be suitable for massively parallel computers. The talk will describe selected aspects of the model formulation and implementation. A complete set of physical parameterizations has been incorporated. The parameterizations are essentially the same as those used by the CSIRO spectral GCM and by the regional climate model DARLAM. The computational efficiency of the model will be discussed, and results presented for present-day AMIP-style climate runs. Results will also be presented for a version where the Schmidt (1977) stretching transformation has been applied to the grid. McGregor, J. L., 1996: Semi-Lagrangian advection on conformal-cubic grids. Mon. Wea. Rev., 124, 1311-1322. Rancic, M., R. J. Purser and F. Mesinger, 1996: A global shallow-water model using an expanded spherical cube: Gnomonic versus conformal co-ordinates. Quart. J. Roy. Meteor. Soc., 122, 959-982. THE CUBED SPHERE: A NEW METHOD FOR THE HIGH RESOLUTION SIMULATION OF GLOBAL ATMOSPHERIC DYNAMICS

R. IACONO, P.M. Ruti and G. Pisacane (ENEA, Rome)

The Cubed Sphere (CS) [1] is a new gridding technique that has been successfully applied to the solution of the shallow water equations in spherical geometry. In fact, a detailed study of the performance of the method for the suite of test cases proposed by Williamson et al. has shown that CS can achieve accuracies comparable to those obtained by the spectral transform method, with substantial savings in computing time. Here we discuss the problems associated with the extension of CS to three-dimensional geometry and present the first results of a Navier-Stokes primitive equations solver based on this method. The performances of CS are compared to those of traditional methods in the test cases proposed by Held and Suarez for studying the behaviour of the dynamical core of GCMs in climatic integration.

MW03/W/12-B4 1430

AN EFFICIENT PREDICTION MODEL FOR ALL SCALES

Ferdinand BAER (Dept. of Meteorology, University of Maryland, College Park, MD 20742, USA, email: baer@atmos.umd.edu); Mark Taylor (LANL, X-HM Mail Stop D413, Los Alamos, NM 87545, USA, email: mt@lanl.gov)

A Spectral Element Atmospheric Model (SEAM) has been developed for prediction on all time scales and a variety of space scales over a spherical Earth. The computational domain is broken into rectangular regions called elements using spectral element discretization, and within each element all variables are approximated by polynomial expansions; herein those functions are Legendre polynomials. The vertical discretization selected is finite differencing and uses sigma co-ordinates following the NCAR/CCM3. The advantages of this model are numerous, but most dramatically it allows for arbitrary resolution in each element to provide regional predictions at any or all locations. The model is ideally suited to computation on parallel processors because it minimises communication requirements. It has been tested with the shallow water test suite and we will present results demonstrating its skill when compared with other models. The model's success in fully three- dimensional predictions using the Held-Suarez test conditions will also be demonstrated, indicating its feasibility as a GCM dynamical core. Additional applications with the model to be discussed include the incorporation of a state-of- the-art physics package, and three-dimensional small-scale (high-resolution) turbulence studies.

MW03/W/01-B4 1445

ON THE MODELLING OF THE SURFACE ENERGY EXCHANGE PROCESSES BY COMBINED "FUZZY SETS AND NEURAL NETWORKS" APPROACH

Oleg POKROVSKY (Main Geophysical Observatory, Karbyshev str.7, St.Petersburg, 194021, Russia, e-mail: pokrov@main.mgo.rssi.ru)

Climate numerical models depend on many surface energy variables . Principal variables are land/water and air temperatures and moisture, solar downward irradiance, albedo, reflected and emitted radiances, heat fluxes into ground and atmosphere, latent and eddy heat fluxes . Its values are mainly determined by individual optical, physical and chemical properties of a given homogeneous land/water pattern. The pattern scale, depending heavily on landscape pecularities,could variates from several meters to several kilometers (or even to tens or hundreds km in desert areas). However, there two weak sides of these data implementation in ecological model.s. First side is that all mentioned variables with the exception of air temperature and moisture are not synoptically observed and become available for users with one month delay at least. Second one is due to substantial departures between observed and modeled diurnal values of these variables. These differences are so grade that often exceed 100% level. New approach to surface variable diurnal cycle modelling was proposed in order to overcome this problem. The joint statistical distribution of principal meteorological variables is investigated. Ten-year length time series of one-hour temporal resolution for several meteorological sites of Russian North -West Region are used. The data set of simultaneous observations (for all variables and stations) allows to reveal main features of joint diurnal distributions by means of known "min-max" fuzzy set approach. Known and novel interrelationships between various meteorological and linked soil variables are reviewed. The revealed relationships between solar downward radiative fluxes and soil temperature diurnal patterns allow to simulate all principal elements of surface energy exchange : longwave outgoing radiative fluxes in the atmosphere, soil heat fluxes, available, turbulent and latent heat fluxes. It was found out that the most complicated links take place for fuzzy sets, corresponding to fractional cloudiness diurnal patterns. Proposed approach could be used as a part of downscaling procedure.

MW03/E/08-B4 1500

ROLE OF THE SHADE IN EXISTENCE OF THE MICROCLIMATE ZONES

Tarzadin ULAANBAATAR (Department of Earth Sciences, National University of Mongolia, email: numelect@magicnet.mn)

The shade influences powerfully and constantly on the microclimate zones and their extents in regional and local scale. But it does not calculated and drawn on any climate model and charts. Its precise calculation is one of the key factors for more realistic and detailed simulation of the climate zones, result of which will provide an opportunity for detailed comparisons of model results with recent weather and climate observations, as well for development of high resolution climate model, and more reliable predictions of global climate and climate change. The success of detailed simulation, precision and comparison of the coupled model depends on 1) how well are the high resolution airborne, space and geodesy images on which the shade is drawn by computer due to the model calculation, 2) how punctual does described the mathematical base of model.
In this paper methodology of a 3D mathematical model for representation of the shadow impact on the climate and geographical zones and method for computer drawing of shadow on the high resolution geographical and climate maps are described brand-newly. Resolution of this model is limited only by map resolution.

MW03/W/09-B4 1515

A REGIONAL MODELING APPROACH FOR STUDYING CLIMATE AND ENVIRONMENT OVER EAST ASIA

WEI-CHYUNG WANG and Wei Gong (Atmospheric Sciences Research Center, State University of New York at Albany)

In recent years, efforts to study regional climate change and the associated environmental impact have significantly increased, partly due to concerns over regional responses caused by the enhanced greenhouse effect, increased sulfates, and changes of atmospheric ozone. The climate over East Asia is the result of multi-scale interactions, including large-scale circulation (e.g., subtropical high and upper level jet) and regional-scale factors (e.g., topography, surface characteristics, and thermal and dynamic heating). Regional climate models, which incorporate in detail these regional factors with prescribed large-scale circulation as the boundary condition, is a useful tool for evaluating these scale interactions, and for studying the physical, chemical, and dynamical processes and their interactions. The continued development of the SUNYA regional model to study climate and environment over East Asia is presented. The initial focus is on the model's capability to simulate key climate characteristics, such as the summer monsoon. As a test case, we run the model with different objective analysis data (ECMWF-TOGA analysis, ECWMF-reanalysis and NCEP/NCAR-reanalysis) as the initial and lateral boundary conditions to simulate the 1991 severe flood over the Yangtze-Huai River Valley. The model is capable of reproducing the five-day mean features of monsoon circulation, anomalous rainfall in the Yangtze-Huai River Valley and the large- and regional-scale circulation statistics. The model is also used to simulate the interannual variability of the rainfall movement during the 1990s. Plans for using the regional model for climate change and environmental studies will be discussed. Further, the regional modeling approach will be addressed within the context of high-resolution global climate models.

MW03/W/05-B4 1530

DEVELOPMENT OF A REGIONAL CLIMATE MODEL FOR EAST ASIA BASED ON CSU-RAMS

Seita EMORI, Toru Nozawa (Atmospheric Environment Division, National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki, 305-0053 Japan, email: emori@nies.go.jp, nozawa@nies.go.jp); Atusi Numaguti (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro, Tokyo, 153-8904 Japan, email: numaguti@ccsr.u-tokyo.ac.jp); and Itsushi Uno (Research Institute for Applied Mechanics, Kyushu University, 6-1 Kasuga-Park, Kasuga, Fukuoka, 816-8580 Japan, email: iuno@riam.kyushu-u.ac.jp)

In order to evaluate the regional scale climate change over East Asia, a regional climate model is developed. The model is based on the Regional Atmospheric Modeling System developed at Colorado State University, which adopts compressible non-hydrostatic basic equations and a cloud microphysics parameterization. Several processes including radiation, cumulus convection and land surface are modified to make a long-term integration. A year-long integration targeting the regional climate of 1994 is conducted to evaluate the performance of the model. Twice-daily ECMWF analysis data are used for initial and boundary conditions. The horizontal grid resolution is set to 40km. The model simulated the spatial pattern of precipitation in wintertime over East Asia and the annual temporal variations of precipitation over various regions of Japan fairly well. It is suggested that the simulation of Baiu, the persistent precipitation band over Japan islands mainly in June, is strongly sensitive to cumulus parameterization. An Arakawa-Schubert type cumulus scheme tends to fail the simulation of Baiu, while the simulation is improved when the scheme is modified to consider the suppression of cumulus convection under a dry environment. The results of one-way nesting with a GCM, which adopts the same physical parameterizations as the regional climate model does, will be also presented.

MW03/E/04-B4 1610

NUMERICAL SIMULATIONS OF JAPANESE CLIMATE USING A HIGH-RESOLUTION NESTED REGIONAL SPECTRAL MODEL

Hideji KIDA (Department of Geophysics, Kyoto University, Kyoto 606-8502, Japan, Email: kida@kugi.kyoto-u.ac.jp) and Hidetaka Sasaki(Meteorological Institute, Tsukuba,Ibaraki 305-0052, Japan, Email: hsasaki@mri-jma.go.jp)

The necessity of higher resolution climate models increases in order to simulate the more realistic local climates and environments including the small-scale orography and patched distribution of vegitation systems. A way to such a high-resolution model is obtained by applying a limited-area model to climate simulations of the interested regions. This approach is not always completely in a mathematical view, but fully usable in a practical view to get quick results to so long-term integrations necessary for climate change simulations such as more than in the 1-10 thousand years scale, or very high-resolution climate simulations such as less than in 1-10 thousand meters.
The authors (1991) proposed a new method to nest a high-resolution model in a lower-resolution model such as GCMs. Here is presented some results from some experiments for winter climate simulations over the Japanese area to test its performance to local climates. The climatological contrast features of snow and temperature distributions both in Japan sea side and Pacific Ocean side of Japan islands are well simulated using 10-100 km resolution models. Furthermore, precipitation in the rainy season is fairly realistic over Japan as well. This suggests that the high-resolution nested model is usable for simulations of local climates provided that the large-scale simulation is well done.

MW03/E/03-B4 1625

A 2 X CO2 REGIONAL CLIMATE PREDICTION EXPERIMENT OVER JAPAN IN WINTER WITH AN MRI REGIONAL CLIMATE MODEL

Yasuo SATO, Hidetaka Sasaki, Kazuyo Adachi, Akira Noda & Seiji; Yukimoto (Meteorological Research Institute, 1-1 Nagamine, Tsukuba, Ibaraki 305-0052, Japan, email: ysato@mri-jma.go.jp)

A high resolution regional climate model is integrated using output of a transient CO2 experiment with the Meteorological Research Institute coupled atmosphere-ocean global climate model (MRI/CGCM) as initial and lateral boundary conditions. We use two-step nesting due to a coarser grid size of the CGCM, whose grid size in an atmospheric component is 5 degrees in longitude and 4 degrees in latitude and that of an oceanic component is two-times finer than that of the atmospheric component. Then, an East Asian model with horizontal grid size of 120km is nested in the CGCM. Further, a Japanese islands model with horizontal grid size of 40km is nested in the East Asian model. We have conducted several experiments under a January condition for two runs:one (referred to as CTRL hereafter) is a control experiment under the present-day CO2 concentration(1 x CO2) and the other (referred to as TRAN hereafter) a regional climate experiment under the doubled CO2 condition. Both experiments firstly do 10 runs each of which is 40 day prediction in each of 10 years predicted by either a constant CO2 concentration or a gradual increase (at a compound annual rate of 1%) in CO2 concentration experiment of CGCM for 71st through 80th year. Then the above 10 runs with the last 30-day results for both CTRL and TRAN are averaged as the predicted regional climate for January. Both runs can simulate detailed features over the land. Differences (warming signal) of the surface air temperature between two cases are about 2.5 degrees on the western part of Japan and about 3 degrees on the northern part of Japan, which are larger than biases (1 x CO2 - observed climate) over the land. As to precipitation, both cases show much precipitation belt along the north-western part of the main island facing the Japan Sea than the other side facing the Pacific. This feature in CTRL simulates well the present climate and much better than the simulation in a CGCM control experiment. Differences of TRAN from CTRL …

MW03/P/01-B4 1640

NUMERICAL SIMULATIONS ON IMPACTS OF THREE G GORGES RESERVOIR ON SUMMER MONSOON RAINFALL OVER EAST ASIA

Zongci ZHAO and Yong Luo (National Climate Centre, Baishiqiaolu, No.46, Beijing, 100081, P.R.China, email: zhaozc@sun.ihep.ac.cn)

Three Gorges reservoir along the Yangtze River Valley of China is going to be reconstructed. The numerical simulations of Three Gorges reservoir have been conducted by using a regional climate model (RegCM2/EA) which was based on the NCAR RegCM2. The model has a domain of about 100-150E and 10-45N with a horizontal resolution of 60kmX60km and a vertical resolution of 23 layers.
A sensitive experiment was designed a water body at around the Three Gorges region with 45 grid points and 50m or100m of water depth to replace the vegetation of the present time. To compare the simulations of Three Gorges' reservoir run with the control run, it is found that the summer rainfall over some regions where are near the Three Gorges reservoir such as Southwest China, Yangtze-Huaihe River Valley and Hetao might be increased clearly. Impacts of the Three Gorges reservoir on other variables have also been investigated in this research. The numerical experiments with the different areas and depths of this reservoir were also conducted.

MW03/E/01-B4 1655

ORIGIN AND MAINTENANCE OF THE TEXAS-OKLAHOMA DROUGHT OF 1998

Song-you Hong (1) and EUGENIA KALNAY (1), (2) (1) National Centers for Environmental Prediction(2) School of Meteorology, University of Oklahoma

The drought of the summer of 1998 was extremely strong and persistent. The Oklahoma mesonet showed that the soil moisture reached levels comparable or lower to those of the 1930's Dust Bowl (Ken Crawford, pers. comm., 1998). By May, a mid-summer circulation had been established, with high temperatures and low precipitation typical of July and August, and it persisted until early October throughout most of Oklahoma and Texas, except in some areas of southern Texas, were it rained in August and September (Figs. 1a-d from NCDC). Since 1997/1998 also underwent a very strong El Niño that produced many major changes in the global circulation, it is natural to assume that the Texas-Oklahoma (TXOK) drought could be "blamed on El Niño". However, the El Niño/Southern Oscillation (ENSO) episode faded in the beginning of the summer (Fig. 2, SOI), and the drought persisted until the fall, so that it is necessary to establish the processes that maintained it beyond the anomalous ENSO circulation.
In this study we make use of the NCEP/NCAR Reanalysis initial and boundary conditions to drive the NCEP Regional Spectral model (RSM). Comparisons of the soil moisture in the reanalysis indicate that the Reanalysis shows an anomalously low soil moisture level over most of central US on 14 April 1998, compared with 1993, a year with high precipitation. The RSM reproduces very well the precipitation for MJJ (Fig. 3) even though the only information it receives is through the boundary conditions (BC). Using 1993 initial soil moisture for 14 April 1998 does not increase the pp over TXOK (Fig. 4). This agrees well with the notion that El Niño anomalous circulation has forced the drought, since its influence is felt through the BC.
We will explore whether during July and August, after the end of the ENSO episode, low soil moisture and high albedo contributed to the maintenance of the drought through a local positive feedback (Atlas et al, 1990), or if it was still driven and maintained by the large scale circulation. The results will be presented at the conference.

MW03/W/02-B4 1710

APPLICATION OF THE CANADIAN REGIONAL CLIMATE MODEL OVER SWITZERLAND: ON THE SENSITIVITY OF MODEL'S RESOLUTION ON THE SIMULATED WIND AT THE SURFACE.

STEPHANE GOYETTE and Martin Beniston(Institute of Geography, University of Fribourg, Switzerland)

Switzerland is characterised by highly complex orography which has a determining influence on climate winds. In many instances, wind extremes impact more heavily upon the natural environment and human infrastructure than changes in mean wind conditions. We are interested in evaluating the manner in which the Canadian regional climate model (CRCM) is capable of reproducing extreme climatic events in the Swiss Alps using the multiple self-nesting technique. This is a very useful feature of the model when aiming to run at very F. More specifically, we are here looking on the sensitivity of the surface winds to model horizontal and vertical resolution, and on the way it impacts on simulated wind extremes. High spatial resolution in the horizontal is required for the orography and other surface characteristics to be resolved accurately. In the vertical, high resolution in the lower layers permits a better representation of the boundary layer and a better representation of the surface winds. This paper thus describe the results of the CRCM, applied to the European Alpine area using different resolutions to simulate extreme wind events during the February 1900 VIVIAN windstorm.

MW03/W/11-B4 1725

HIGH RESOLUTION SIMULATIONS OF EXTREME METEOROLOGICAL EVENTS OVER BELGIUM

BRASSEUR O. (Institut d'Astronomie et de Géophysique G. Lemaître, Université catholique de Louvain, Chemin du Cyclotron 2, B-1348 Louvain-la-Neuve, Belgium); Tricot C. (Climatology Department, Royal Meteorological Institute of Belgium, Avenue Circulaire 3, B-1180 Bruxelles, Belgium)

There are two ways of considering the improvement of an atmospheric model: refining the resolution, and improving the physics. Both these aspects are important and cannot be separately investigated because of the interactions between dynamics and physics. As the horizontal resolution is refined, some problems occur: phenomena considered at larger scales as subgrid processes can partly become explicitly represented by model. Such difficulties therefore imply a reconsideration of the physical parameterisations. An interesting test for current regional models is the simulation of extreme events that allow assessing of their limits. Moreover, these events are an important concern in the framework of operational weather forecast as well as climate change at the regional scale.
The MAR - Modèle Atmosphérique Régional - mesoscale model (developed at the University of Louvain-la-Neuve, Belgium) has been tested on several short-range (a few days) and medium-range (a few months) extreme situations characterised by extreme temperatures, storms originating from explosive cyclogenesis, and thunderstorms. The MAR includes sophisticated parameterisations of microphysics, turbulence, deep convection, and soil-vegetation-atmosphere interactions. The horizontal resolution generally ranges between 10 and 50 km. The simulation domain is centred on Belgium, and covers Western Europe or a sub-region of Europe depending on the resolution.
Simulated results have shown a very good accuracy for all these considered events. In particular, the MAR has underlined the relevant role of mesoscale circulations (gravity winds, breezes) in the prediction of extreme temperatures over Belgium. The deepening rate and the frontal structure of intense cyclones during the period from January to March 1990 are particularly well represented. Precipitation associated with fronts and represented by the convective parameterisation is in correct agreement with observations. We note also that the horizontal resolution of 20 or 25 km is probably the best compromise to represent all considered extreme events: the 50-km resolution is generally not accurate enough, while the 10-km resolution causes scale separation problem for the representation of deep convection.

LARGE-SCALE ATMOSPHERIC AND SEA SURFACE PROCESSES LEADING TO EXCESSIVE RAINFALL IN TUSCANY, ITALY

Francesco MENEGUZZO, Alfonso Crisci (Applied Meteorology Foundation (FMA), Via Einstein 35, I-50013 Campi Bisenzio, Firenze, Italy); Bernardo GOZZINI, Daniele Grifoni (Laboratory for Meteorology, Climatology and Environmental Modelling (LaMMA); Via Einstein 35, I-50013 Campi Bisenzio, Firenze, Italy); Stefano Pagliara (Dipartimento di Ingegneria Edile, Idraulica e del Territorio, University of Pisa, Via Gabba 22, I-56126 Pisa, Italy)

Monthly extreme rainfalls at several gauges and several durations (1, 3 and 5 days) in Tuscany, Italy, are compared with simultaneous and previous patterns of large-scale circulation, synthetized by the North Atlantic Oscillation (NAO) index, and patterns of sea surface temperature (SSTa) in central-western Mediterranean. Several statistical methods are employed, from simple contingency tables to frequency histogram. Scenarios of global change in terms of changes in Mediterranean SSTa anomalies are considered and the quantitative consequences in terms of extreme rainfalls are derived.

HS1/W/49-B4 0925

IMPACTS OF CLIMATE CHANGE ON MID-EUROPEAN RIVER BASIN HYDROLOGY

A. BÁRDOSSY, H. Giese, G. Hartmann (Institut für Wasserbau, Universität Stuttgart, Pfaffenwaldring 61, D-70550 Stuttgart, Germany); H. P. Nachtnebel, W. Diernhofer, K. Hebenstreit (IWHW, Universität für Bodenkultur, Nußdorfer Lände 11, A-1190 Wien, Austria)

The impact of climate change on the hydrologic regimes of medium-scale rivers in Europe is investigated in this work. The main aim is to predict hydrological changes at a medium time scale (referring to several decades) for medium-scale river catchments in Europe. A downscaling approach is used to apply GCM data for this: large-scale pressure distribution patterns were classified as a base for conditional statistics of rainfall and temperature data. These were utilized for the calibration of statistical models of local rainfall and temperature. Using appropriate interpolation methods, these data were then used as input for runoff models of medium-scale river catchments in Europe. This method was finally applied to GCM outputs representing a doubled CO2-scenario. Using the calibration for the historical data delivers a prediction about the impact of climate changes on the local weather parameters and changes in hydrological regimes. Application of the methodology and results are illustrated on the Neckar catchment (Germany) and the Enns catchment (Austria). In both catchments changes in temperature and runoff for the 2_CO2-scenario simulations are observed. However, due to the shortness of simulated time-series no detailed conclusions with respect to extreme events are possible.

HS1/W/29-B4 0945

INVESTIGATING THE INFLUENCE OF ATMOSPHERIC CIRCULATION PATTERNS ON REGIONAL STREAMFLOW DROUGHT IN SOUTHERN GERMANY

Kerstin STAHL and Siegfried Demuth (Institute of Hydrology, University of Freiburg, Fahnenbergplatz, D-79098 Freiburg, Germany, email: kstahl@uni-freiburg.de)

This study investigated the influence of synoptic meteorology on streamflow drought in a region with highly variable hydrological charac-teristics. First, groups of catchments with similar drought characteristics were identified by cluster analysis. A regional drought index (RDI) derived from aggregating the streamflow drought series of a cluster provided the basis for the link to the occurrence of atmospheric circulation patterns (CPs). Frequency crosstabulation revealed important information about the regionally different influence of CPs on drought events. Based on the results of the crosstabulation, the CPs were classified and reduced to eight groups. Finally, the possibility of simulating the regional drought index by CP-group occurrence was tested using a logistic regression model. The results show that high pressure over central Europe and the British Isles as well as anticyclonic CPs with easterly air flow were strongly associated with summer streamflow drought in all regions.

HS1/W/48-B4 1005

ATMOSPHERIC PROCESSES LEADING TO DROUGHTY PERIODS IN ROMANIA

Mary-Jeanne ADLER, Aristita Busuioc, Monica Ghioca (National Institute of Meteorology and Hydrology, Sos. Bucuresti-Ploiesti 97, 71552 Bucharest, Romania); Sabina Stefan (University of Bucharest, Faculty of Physics, Dept. of Atmospheric Physics, PO Box MG-11, Bucharest, Romania)

The study of climate variability is important for a better understanding of the hydrological and atmospheric processes that lead to droughty periods in Romania. The variability of the seasonal and annual precipitation at Romanian rain gauge stations are examined for characteristics of droughty periods in the atmospheric processes. The discharge series were statistical analyzed to complete the image of the water resources behavior in Romania. The changes identified in the time series of data by means of statistical methods, using Canonical Correlation Analysis, were shown to be correlated with the large atmospheric circulation.

HS1/W/36-B4 Poster 1025-01

EFFECTS OF QUASI-STATIONARY WAVE ANOMALIES ON THE REGIONAL HYDROLOGIC CYCLE IN THE CONTINENTAL UNITED STATES

Zaitao PAN, Moti Segal, Raymond W. Arritt, Tsing-Chang Chen and Shu-Ping Weng (Department of Agronomy, Iowa State University, Ames, Iowa 50011, USA, email: rwarritt@iastate.edu)

The interaction of large-scale quasi-stationary waves with regional forcing in the drought of 1988 and flood of 1993 in the north central United States was examined using a mesoscale numerical model. When the observed large-scale quasi-stationary wave anomalies in the dynamic and thermo-dynamic fields were filtered through adjustment of the observationally-based lateral boundary conditions, predicted rainfall and meteorological fields over the drought and flood regions tended toward those for normal years. This method for quantifying, isolating and filtering the relevant large-scale anomalies allows us to infer specific scale interaction mechanisms that produce regional hydrologic consequences of large-scale circulation patterns.

CLUSTER-BASED HYDROLOGICAL ANALYSIS AND PREDICTION OF LONG-TERM CLIMATE CHANGE AND DROUGHT DISCHARGE

Toshiharu KOJIRI (Water Resources Research Center, DPRI, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, email: tkojiri@wrcn2.dpri.kyoto-u.ac.jp)

Partly due to climate change, natural disasters such as flood inundation or drought have recently caused heavy damage inmany places in the world. Estimation and prediction of the present climate situation will provide significant information to reduce these damages. In this paper, pattern classification methodologies are introduced to analyse global warming effects and spatial relationships of considered meteorological events from a global viewpoint. Furthermore, the advanced AI technology of neural networks is applied to predict regional and local precipitation magnitudes and features.

HS1/W/21-B4 1120

CLIMATIC VARIABILITY AND ITS IMPACT ON RAINFALL EXTREMES AND URBAN RUNOFF DESIGN IN TUSCANY

Alfonso CRISCI, Bernardo Gozzini (Laboratory for Meteorology, Climatology and Environmental Modelling (LaMMA), Via Einstein 35, I-50013 Campi Bisenzio, Firenze, Italy); Daniele Grifoni, Francesco Meneguzzo, Gaetano Zipoli (Applied Meteorology Foundation (FMA), Via Einstein 35, I-50013 Campi Bisenzio, Firenze, Italy); Stefano Pagliara (Dipartimento di Ingegneria Edile, Idraulica e del Territorio, University of Pisa, Via Gabba 22, I-56100 Pisa, Italy)

The distinct role of errors in the extremal statistics used to infer design storms of any duration and any return period and trend in the extremal time series are analysed to derive uncertainties affecting the estimates of the design storms. Several extremal time series collected at gauges in Tuscany, Italy, are considered. The Generalized Extreme Value (GEV) distribution is employed to compute the design storms, and the uncertainties in the estimates are derived through the maximum likelihood method. Design storms are then computed for several consecutive 30-year moving time windows (step of one year) to evaluate intrinsic (climatological) uncertainties in the series. The climatological uncertainties in the evaluations are connected to trends and oscillations affecting general circulation features, tentatively expressed by the North Atlantic Oscillation (NAO) index. The hydrological consequences of climate variability are shown to have a major impact on the design of hydraulic works in an urban drainage network.

HS1/W/07-B4 1140

FORECASTING THE OCCURRENCE OF LOW PRECIPITATION THREE TO TWELVE MONTHS AHEAD

Ian CORDERY (School of Civil & Environmental Engineering, The University of New South Wales, Sydney, New South Wales 2052, Australia, email: ianc@civil.civeng.unsw.edu.au); Mark MCCall (Bureau of Meteorology, 300 Elizabeth Street, Sydney, New South Wales 2000, Australia); M. Jafar Nazemosadat (Agricultural Faculty, Shiraz University, Shiraz, Iran)

To be accepted and acted upon, forecasts of drought need to be seen to be reliable. A simple partitioning model is presented here in which occurrence of one variable (say geopotential height) within a specified range of values points to the existence of a strong relationship between another variable (say Southern Oscillation Index) in the same season and pre-cipitation one to four seasons later. Partition relations are demonstrated to explain more than 65% of the variance in the precipitation in the next season for areas of up to 500 000 km2 in Australia, and 50% of the variance in the precipitation four seasons (one year) ahead for similar sized areas.

STUDIES ON HYDROLOGICAL EXTREMES—ENSO SIGNAL

A. A. L. N. SARMA, B. Padma Kumari & S. Srinivas (Department of Meteorology & Oceanography, Andhra University, Visakhapatnam 530 003, Andhra Pradesh, India)

The Krishna River basin is one of the major river systems of south India. Its hydrological regime is studied using a season climate concept based on a water balance model. Proneness to humid and drought events along with frequency distributions of climate types for selected stations of the river basin are reported. The statistical correlation of the river discharge with the Southern Oscillation Index (SOI) and Sea Surface Temperature (SST) of the Nino3 region of the equatorial Pacific Ocean is also analysed.

DEPENDENCE OF THE FREQUENCY AND MAGNITUDE OF EXTREME FLOODS IN COSTA RICA ON THE SOUTHERN OSCILLATION INDEX

Irina KRASOVSKAIA (Department of Earth Sciences, University of Uppsala, Villavägen 16, S-75236 Uppsala, Sweden, email: irina.gottschalk@hoganas.mail.telia.com); Lars Gottschalk (Department of Geophysics, University of Oslo, Box 1022, N-0315 Oslo, Norway); Alexis Rodríguez and Sadí Laporte (Department of Basic Studies, Instituto Costarricense de Electricidad, Apartado 10032, 1000 San José, Costa Rica)

For the Caribbean and Central America, the positive values of the Southern Oscillation Index (SOI) are generally associated with drought and the negative ones with excess rainfall. For hydropower, as well as for many environmental problems, the existence of non-stationarity in the extreme events is of prime importance. The effect of the Southern Oscillation, described by SOI, on the frequency and magnitude of extreme floods in Costa Rica is investigated by applying a partial duration approach to the total of 91 mean daily runoff series. Statistical analyses of these data indicated that, in the majority of the cases, an assumption of randomness, widely used in operational extreme value analyses, is violated. The analysis of the extensive data sample indicates dependence between the frequency of extreme flood events and the SOI anomalies, while no clear connection can be noted for the magnitude of the extreme floods.

HS1/W/44-B4 1420

TRENDS AND VARIABILITY IN SWEDISH FLOODS

Göran LINDSTRÖM (Swedish Meteorological and Hydrological Institute, S-60176 Norrköping, Sweden, email: goran.lindstrom@smhi.se)

Trend analysis was carried out for time series of annual and seasonal extremes at 65 unregulated discharge stations in Sweden. The stations are clearly not independent, as shown by the occurrence of large floods in many basins at the same time. Neither the results from statistical trend tests nor visual inspection of the data suggest any change in flood frequency. Furthermore, the end period, 1995, was not chosen arbitrarily, since the reason for initiating this study was the many observed floods in recent years.

HS1/W/64-B4 1440

RECENT CHANGE AND PREDICTION OF GLACIER DAMMED LAKE OUTBURST FLOODS FROM KUNMALIK RIVER IN SOUTHERN TIEN SHAN, CHINA

LIU JINGSHI & Yoshihiro Fukushima (Institute for Atmospheric & Hydrospheric Sciences, Nagoya University, Nagoya 464-01, Japan, email: liu@hydro.nagaokaut.ac.jp)

Glacier Lake Outburst Flood (GLOF) from a glacier dammed lake in the Central Tien Shan has occurred during almost 100 years. Recent records of the GLOF events in the 1990's has indicated that the lake volume and peak discharge are becoming larger and larger corresponding to a warming and wetting of the inner Asian continent. Two extraordinary events of GLOF in summer 1994 and winter 1996 are investigated and described. There is evidence of a change in the magnitude and frequency of floods and in the extension of the glacier and the lake systems. A possible change of the GLOF for next 50 years is predicted by reviewing the history of GLOF events combined with water and heat indices of the current climate. The maximum peak discharge and the flood volume will be enlarged by 50% and 20% respectively, and the date of GLOF occurrence will be shifted to early summer and/or winter. The spring flow will be enlarged due to base flow originating from meltwater.

HS1/W/65-B4 1500

A STUDY OF EXTREME FLOODS IN CHINA FOR THE PAST 100 YEARS

Guowei LIU & Jingping Wang (Nanjing Institute of Hydrology and Water Resources, 1 Xikang Road, Nanjing 210024, China)

The peak flow and volume characteristics of the extreme floods of China are discussed, together with their seasonal and geographic distribution. Their secular variation is reviewed and a comparison made between extreme floods of the 20th century and the past 500 years, and with the world extreme flood records. Some characteristics of heavy and large area storms—the causes of extreme floods—are discussed. The conclusions contribute to a better understanding of characteristics of extreme floods of China.

HS1/W/74-B4 1600

EFFECT OF NOISE IN NONLINEAR HYDROLOGICAL TIME SERIES ANALYSIS AND PREDICTION

A. W. JAYAWARDENA & A. B. Gurung (Department of Civil Engineering, The University of Hong Kong, Hong Kong, China, email: hrecjaw@hkucc.hku.hk)

Hydrological time series are considered as the outcome of deterministic systems, which may become "chaotic" at times. Identification of such systems requires the data to be noise free. In this study three non-linear noise reduction techniques have been applied to two sets of hydrological data: daily river flow and sea surface temperature anomaly index (S-index). The correlation dimensions have been computed and predictions made before and after noise reduction. The results show that convergence in the correlation dimension as well as increase in the prediction accuracy can be achieved in the noise-reduced data.

HS1/W/42-B4 Poster 1625-02

VARIABILITY IN SPECTRAL CHARACTERISTICS OF HYDROLOGIC DATA

Khaled H. HAMED (Irrigation and Hydraulics Department, Faculty of Engineering, Cairo University, Giza, Egypt); A. R. RAO (School of Civil Engineering, Purdue University, West Lafayette, Indiana 47907, USA, email: rao@ecn.purdue.edu)

Conventionally, hydrologic time series have been studied in both the time and frequency domains. However, neither the time domain nor the frequency domain is adequate for revealing the underlying structure of such time series. Hydrologic time series can be shown to consist of a stochastic component with a continuous spectrum in addition to a number of added components with discrete spectra. These added components are often interpreted as the effect of a number of natural phenomena such as the sunspot activity, El-Niño Southern Oscillations (ENSO), Quasi-Biennial Oscillations (QBO) and others. However, these components are usually not well defined in hydrologic time series. This study investigates the variability in both the frequency and amplitude of the cyclic components in hydrologic time series. For this purpose, the Multi-Taper spectral analysis method (MTM) (Thomson, 1982) coupled with evolutionary spectral analysis (Priestley, 1965) are used to analyse a number of rainfall, flow, and temperature time series from the Midwest region of the United States. The results from evolutionary spectral analysis indicate variability in both the frequency and magnitude of the cyclic components in the studied time series. Furthermore, a statistical test of stationarity indicates that the continuous part of the spectrum varies significantly with time, indicating nonstationarity of the stochastic processes producing these hydrologic time series.

PREDICTION – DROUGHT

HS1/W/04-B4 1640

GLOBAL MODELLING OF RUNOFF AND IRRIGATION REQUIREMENTS IN TYPICAL DRY YEARS

Petra DÖLL, Frank Kaspar, Stefan Siebert and Joseph Alcamo (Center for Environmental Systems Research, University of Kassel, D-34109 Kassel, Germany, email: doell@usf.uni-kassel.de)

In order to assess the impact of global change on water scarcity, it is appropriate to look at the situation not only under average climatic conditions but also in dry years. With our global model of water availability and water use in drainage basins (WaterGAP) we calculated runoff and irrigation water use under average climatic conditions and in basin-specific typical dry years. On 33% of the global land area, runoff in the meteorological 1-in-10 dry year differs from runoff in the hydrological 1-in-10 dry year by more than 10%. Besides, years with high irrigation requirements do not necessarily coincide with either type of typical dry year. Therefore, it is necessary to analyse the water situation during three types of basin-specific 1-in-10 dry years that are defined based on (a) precipitation, (b) runoff and (c) irrigation requirements.

HS1/W/17-B4 1700

REGIONAL PARTIAL DURATION SERIES MODELLING OF HYDROLOGICAL DROUGHTS IN ZIMBABWEAN RIVERS USING A TWO-COMPONENT EXPONENTIAL DISTRIBUTION

Thomas R. KJELDSEN, Allan Lundorf and Dan Rosbjerg (Department of Hydrodynamics and Water Resources, Technical University of Denmark, Building 115, DK-2800 Lyngby, Denmark, email: trk@email.isva.dtu.dk)

A regional analysis of hydrological droughts is conducted using the partial duration series model with the two-component exponential (TCE) distribution as exceedance distribution. The index-flood method is applied in order to obtain more efficient estimates of the T-year events. Only one of the three parameters of the TCE distribution contributes significantly to the uncertainty of the T-year events and, therefore, only this parameter is regionalized. In total 25 gauging stations covering most of Zimbabwe were used to identify sufficiently homogeneous regions for use with the index-flood method. Separation of the stations according to mean annual precipitation indicated the existence of three or possibly more homogeneous regions, though the limited number of available stations did not allow for any rigorous conclusions.

HS1/W/45-B4 1720

MODÉLISATION DE L'OCCURRENCE DES ÉTIAGES À PARTIR DES DÉBITS MOYENS JOURNALIERS À L'AIDE DES PROCESSUS PONCTUELS

Assia CHEBCHOUB (Département de Mathématiques et Informatique, INSAT, BP 676, 1080 Tunis, Tunisie, email: assia.chebchoub@insat.rnu.tn); Zoubeida Bargaoui (Département de Génie Civil, ENIT, BP 37, 1002 Tunis, Tunisie); Irene Abi-Zeid (DRE-Valcartier, 2459 Pie-XI Boulevard North, Val-Bélair, Québec, Canada G3J 1X5); Bernard Bobée (INRS-Eau 2800, Rue Einstein, CP 7500, Sainte-Foy, Québec, Canada G1V 4C7)

La définition des événements de type étiages ou surplus à partir des débits moyens journaliers se fait généralement sur la base d'un débit seuil. Pour les étiages, ce débit représente par exemple le débit atteint ou dépassé 75% ou 90% des jours de l'année. L'application d'un tel critère est apparu inadéquate dans le cas d'un bassin versant tunisien de superficie 448 km_. Afin de prendre en compte le caractère fortement intermittent des écoulements, il est proposé de baser la sélection des événements sur un seuil plus élevé correspondant au débit caractéristique de crue (DCC), débit moyen journalier atteint ou dépassé 10 jours par an. L'examen du nombre et de la répartition des événements sur l'année a cependant montré la nécessité d'introduire un deuxième seuil permettant de réduire le nombre d'événements isolés (surplus et étiages). Il s'agit du DC1, débit moyen journalier atteint ou dépassé 30 jours par an. Ainsi, deux seuils de débit au lieu d'un seul sont proposés pour la définition des événements. En outre, un paramètre supplémentaire représentant une durée minimum d'étiage a été introduit. La modélisation de l'occurrence des étiages ainsi définis fait appel aux processus ponctuels alternés surplus/étiage. L'estimation des paramètres des fonctions d'intensités se fait par la méthode du maximum de vraisemblance. Ces estimateurs permettent de prédéterminer l'occurrence des étiages et la loi des durées d'étiages.

ON THE NECESSITY TO USE THREE-DIMENSIONAL GROUNDWATER MODELS FOR DESCRIBING IMPACT OF DROUGHT CONDITIONS ON STREAMFLOW REGIMES

Alain DASSARGUES, Jean-Christophe Marechal, Guy Carabin (Laboratoires de Géologie de l'Ingénieur, d'Hydrogéologie et de Prospection Géophysique (LGIH), University of Liège, Bat. B19, B-4000 Liège, Belgium, email: adassarg@lgih.ulg.ac.be); Olivier Sels (Hydrogeologie, Instituut voor Aardwetenschappen, Katholieke Universiteit Leuven, Redingenstraat 16, B-3000 Leuven, Belgium)

Integrated hydrological models are used to assess the impact of global climatic changes on the water cycle. Very often, they are supposed to represent with physical consistency the exchanged water flows between the different parts of the hydrological cycle. In drought conditions, it is particularly important to study with accuracy the baseflow groundwater component for a good assessment of the streamflow. However, in most of the integrated models, the contribution of groundwater in the total streamflow is calculated by use of an empirical or lumped coefficient (i.e. recession coefficient). Due to the lack of recharge during the long drought periods, a general piezometric drop is induced. In heterogeneous and especially in fissured aquifers, the baseflow is changed due essentially to desaturation of the upper zone. By this way, the geometry of the groundwater basin and the local values of hydraulic permeability and effective porosity are influencing the groundwater contribution. Conse-quently, three-dimensional groundwater models are strongly recommended in order to be able to describe locally different hydrodynamic characteristics in the aquifer. These models should be able to describe explicitly the river-aquifer exchanges with physical consistency, including space and time variations of the baseflow component.

INCIDENCES ÉVENTUELLES SUR LA RELATION PLUIE-DÉBIT D'UN CONTEXTE RÉGIONAL DE DIMINUTION DES RESSOURCES EN EAU EN AFRIQUE DE L'OUEST ET CENTRALE NON SAHÉLIENNE

M. OUÉDRAOGO, E. Servat, J. E. Paturel, B. Kouamé, M. Travaglio (06 BP 1203 Cidex 1, Abidjan 06, Côte d'Ivoire, email: eric.servat@mpl.ird.fr); H. Lubès-Niel (BP 5045, F-34032 Montpellier Cedex, France, email: helene.lubes-niel@mpl.ird.fr); J. M. Masson (Laboratoire Géofluides-Bassins-Eau, URA-CNRS 1767, Université Montpellier II, Place Eugène Bataillon, F-34095 Montpellier Cedex 5, France)

L'Afrique de l'Ouest et Centrale connaît, depuis 1970 environ, des conditions exceptionnelles, en intensité et en durée, de déficits pluviométrique et hydrométrique. Les pays de la zone non sahélienne (appelée zone "humide") ressentent également ces aléas climatiques et présentent des diminutions sensibles de la pluviométrie annuelle (20–25%) et des écoulements (modules en baisse de plus de 35–40% en général). Il apparaît, alors, légitime de s'interroger sur les liens éventuels entre un tel phénomène et la relation pluie–débit elle-même. Pour mener cette étude, on a eu recours à la modélisation de la relation pluie–débit. Le principe a consisté, essentiellement, à ajuster les mêmes modèles sur les deux périodes "humide" et "sèche", puis à tester si les paramètres obtenus sur les deux périodes variaient significativement.

HYDROLOGICAL MAXIMA IN PLAIN RIVERS OF RUSSIA

Elena ASABINA (Russian Research Institute of Water Resources Management, Mira Street 23, Ekaterinburg 620049, Russia)

Vast territory is characterized with great differences in both climatic factors and local conditions influencing upon origin and development of hydrological maxima. Particularity of hydrological regime is in different causes of maximum origin. The flood peaks may be formed both from snowmelt in spring (snow maxima) and from rain storms in summer and autumn (rain maxima). Usually the snow maxima exceed the rain maxima in plain rivers of Russia. Snow falls and covers territory during 2–6 months. Its melting takes several days or weeks and embraces whole watershed almost simultaneously. The conditions lead to flood with high and long period peak. Usually the maximum stays during some hours or days. Whole flood wave retains from 2 weeks to 2 months and takes place every year in all streams and rivers. The height and total duration of the flood waves change only from year to year depending on water storage in snow. The water storage in snow is the main estimating variable effecting upon all quantitative relations of hydrometeorological processes in snow and soil. In some years, it is possible for rain maxima to exceed snow ones. Rain floods have another time frames. Usually rain storms continue from several minutes to 2–4 h, but with high intensity. These floods have not high peaks and their peak duration continues from several minutes to one hour usually. Whole rain floods takes several days and weeks sometime. Location of them in a basin ties to places of rain storm event and does not embrace whole watershed. Rain floods may be unobserved during a year and may appear several times. Its height and duration change from year to year and from event to event in a year. The main estimating variable of rain floods is day maximum of precipitation and rainfall intensity. Probability of excess of rain maxima over snow maxima of low frequency (1 event per 100 years) is subject of special interest.

THE ROLE OF SPATIAL RAINFALL DISTRIBUTION IN FLOOD FORMATION: USING A DISTRIBUTED HYDROLOGICAL MODEL

Huaxia YAO and Michio Hashino (Department of Civil Engineering, The University of Tokushima, 2-1 Minami-Josanjima, Tokushima 770-8506, Tokushima, Japan, email: yao@ce.tokushima-u.ac.jp)

Hydrological events of flood, their magnitude and occurrence time, are determined by rainfall distribution in a basin and the basin's topography-soil-landuse conditions. The role of rainfall distribution could be interpreted and simulated by a distributed model taking consideration of spatial difference of these controlling factors. In this research a grid-cell-type distributed model is firstly constructed and calibrated for the upper and middle area of Fuji River in central Japan. Daily temperature at every grid-cell is derived from data of in-situ weather stations and GIS, using relationships of temperature and geographical variables such as altitude and latitude. Hourly rainfall at each grid is allocated from in-situ data or from radar rainfall data. Then evapotranspiration, soil water adjusting, and various outflows from soil and aquifer in each grid are estimated with the grid sub-model, and outflows at all grids are routed through a river network onto the outlet, using a river routing sub-model. And the parameters are spatially calibrated with discharge and GIS data. In order to check the validation of model, several rainfall events are selected and the estimated discharge hydrographs are compared with the observed ones. The model shows good reproduction of hydrograph at two gauges along the river. Then supposed rainfall scenarios are applied to explain the effects of distribution on flood formation. Three types of distribution: concentrated on the upper, on the lower parts and uniform on whole area, are considered. But they have same rainfall volume and same timely pattern. Model's outputs shows that these types of rainfall produce rather different flood responses. The rainfall concentrated on upper parts produces the most delayed and flattest flood shape, the rainfall concentrated on the lower parts produces the quickest and sharpest flood, and the uniform rainfall produces a mediating flood between the two cases. Furthermore, a rainfall moving in the basin is also considered. Two directions of movement are supposed. The partly-area-covering rainfall

PREDICTION OF VARIABILITY IN THE AMUDARYA RIVER FLOW ON THE BASIS OF HELIOGEOPHISICAL OBSERVATIONS

E. SHERMATOV, B. S. Nutaav (Central Asian Research Institute for Irrigation (SANIIRI), Karasu 4/11, Tashkent 700187, Uzbekistan)

There is no doubt that an interrelation exists between Amundarya River water supply and meteorological data (Tcinzerling, 1924) and identification of this relationship could clarify the possibility of river regime prediction. At present, the problem of climate or over long-term hydrometeorological prediction is not decided. We believe the above tasks can be solved using the accumulated database of many years observations. The current situation can be characterized as a conversion period from climatography (descriptional) to physical climatology. In order to understand climate change and development of hydrological events it is necessary to face the problem Sun–Earth. Heliogeophisical data can help in climatology in the theoretical identification of the climate cinematic components and elaborate theoretical basis of climate predictions. In accordance with current ideas, the effect of the sun on climate is about 60%, and of the moon 15%. The influence of the sun is already known – plot to ground water table fluctuation. In Uzbekistan eleven years regime cycle have been observed with one maximum and one minimum. Maximum concurs with minimum of Sun phase and minimum of the contrary. Generalized consideration of Sun activity fluctuations, temperatures of air, precipitation's and Amundarya River flow for a period of more than 100 years are demonstrated close interrelation. Hydrological events have been enforced by fluctuations (or avtooscilation) through Sun activity-climate relation. Annual water content of Amundarya River can be calculated as by Q = AeBT, where Q is water discharge, T is temperature (Kalvin) of North Hemisphere (latitudes 85–85), and A and B are statistical parameters. The correlation coefficient from 0.88 to 0.98 between temperature and Amundarya River flow, near Kerkey, for the period 1910–1952 before anthropogenic impact to river.

SHORT LEAD-TIME RIVER FLOW FORECASTING ON THE YANGHE RESERVOIR BASIN

Suxia LIU (Department of Hydrology, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, PR China)

With mighty advance of computers and automatic techniques being made and the need for reservoir operation and flood control, allowances have been made for considering river flow forecasting in which lead time is very short. Using a data set of precipitation, evaporation and discharge with 15-min time intervals collected in Yanghe Reservoir basin of north China, where the cocentration distance is short and the velocity of flow is high, some experiences are obtained by applying four UCG models. All the chosen 16 floods are considered as continuous time series data. For the Simple Linear model, the relationship between the memory length and the model efficiency is shown monotonous. The favorable memory length is 130 quaters. For simple linear-API model, there seems two optimal points when the memory length is equal to 70 and 140 quaters. Comparing with the shape of the unit hydrograpy, memory length being 140 quaters is more reasonable. The memory length for both UCGSMAR2 and UCGXIN2 is 75 quaters. The models were both designed for daily data, 75 is the upper limit of the memory length given. The unit hydrography shape of the four models are favourable agreeable with each other. It is promising to apply UCG models to short lead time river flow forecasting from flood event data. By comparing the discharge observed and estimated by the four UCG model, the model efficiency of UXGXIN2 model is a little higher than other three models. Based on fluid dunamics of porous media, an water transfer equation is build. By comparing analysis, it is found that when the unsaturated soil is considered as one layer and the river reach is not divided into subreaches, the simulation result of UCGXIN2 is in agreeement with that of the equation solution. We have reason to conclude that UCGXIN2 model is a better model to forecast short lead-time river flow.

USE OF WEATHER RADAR DATA FOR A FLOOD WARNING SYSTEM

H. BERGMANN & R. Schatzl (Institute of Hydraulics and Hydrology, Technical University, Graz, Austria)

Since 1979, the Institute of Hydraulics and Hydrology of the Technical University in Graz operates an experimental area on hydrological aspects in the Pöllau basin near Hartberg in the eastern Styria, in which step by step a measuring net with high density of gauges for scientific purposes was equipped. The area includes seven raingauges, four gauging stations as well as a meteorologiocal station in a catchment area of 58.3 km2. Extensive analysis is made as preliminary work for the development of a rainfall–runoff model based on weather radar data in the course of a flood warning system for flood endangered zones in western

H

Styria, in which the Institute for Hydraulics and Hydrology will also be engaged, whereas hydrological data from the Pöllau basin serve as basis, which are available in very detailed form because of the high density of the measuring net and the high discrimination of the measuring instruments. This concerns the precipitation, which is recorded on data loggers in time-variable form as well as the discharge. A comparative analysis of the weather radar data and the terrestrial precipitation measurement is the substance of the paper. Aim of the analysis is to make declarations about the origin of floods, whereas special attention is directed to the comparison of raingauge data with weather radar data. Radar data are intensity data (mm h-1), which are recorded in intervals of 10 min and for grids of 2 ¥ 2 km but which are in the form, which is at present available, affected with great unreliability's. To get a basis as well-founded as possible for the flood warning system it must be tried to put these unreliability's to a minimum. For this purpose, the radar data have to be compared with the precipitation data measured at the raingauges and furthermore they have to be calibrated, whereas the following proceeding is chosen: with the aid of a method, which was developed at the Institute for Hydraulics and Hydrology, it is possible to convert the precipitation data measured at the rain gauges into field precipitation data, which are orientated to the grid of the weather radar. Now it is possible to make correlations…

HALF-SELF ADAPTIVE UPDATING KALMAN FILTER MODEL OF CHANNEL FLOW ROUTING

LI ZHIJIA (Department of Water Resources and Hydrology, Hohai University, Nanjing 210024, China, email: lizhijia@public1.ptt.js.cn)

The half-self adaptive updating Kilman filter model of channel flow routing has been developed for real time application to flood forecasts. The model is based on the Kilman filter theory and Muskingum method. In the model, the measurement error covariance matrix can be estimated in real time through on the innovation sequence. A reasonable and simple model is used in the inflow errors. Examples are given of how the method works for the reaches of rivers. The results show the model are reasonable.

APPLICATION OF A PHYSICALLY-BASED DISTRIBUTED MODEL FOR RUNOFF ESTIMATION

U. C. KOTHYARI (Department of Civil Engineering, University of Roorkee, Roorkee, India)

The occurrence of hydrological extremes in a stream such as the floods or the droughts is greatly dependent upon the process of runoff generation in its catchment. The physically-based distributed modelling for stream runoff enables one to improve the understanding on the processes involved and to help solve the urgent environmental problems associated with man's impact on hydrological cycle e.g. soil erosion and water quality (Kothyari et al., 1997). In recent times a lot of work has been done on physically-based models for runoff generation and these are found to be reliable in estimation of runoff in a catchment. These models include TOP model (Beven, 1996), SHE model (Abbott et al., 1986), ARNO model (Todini, 1989) etc. Nevertheless, most of the existing physically-based models need for their use elaborate data on hydro-climatic, topographic, soil and land-use characteristics of the catchment and also the number of input parameters for most of these models is very large (Kothyari & Jain, 1997). Therefore, in the present study a simpler approach is adopted for runoff modelling which is mainly based on the concepts of Field (1982) and Field & Williams (1987). Rain falling into a catchment surface storage is considered to supply the flow to the main channel and also the ground water storage which then also feeds the main channel is routed by a kinematic wave model. Conventionally, in the kinematic wave model for flow in a channel, a unique relation is assumed between the storage and discharge (Singh, 1996). However, in practice such a relation is not unique and is found to form a loop. To account for this feature the following form of flux law (storage–discharge relation) is considered:
Ar = aQ1/m b(∂Q/∂x) where Q is channel discharge Ar is steam cross-sectional area, x is distance, m is channel conveyance exponent and a and b are coefficients. The main feature of present study is the use of above generalized flux law along with the conventional kinematic wave equations. The above generalized flow law is derived by combining the power and the gradient type flux laws and the same is also termed as the Burger's flux law. The model for runoff generation derived as above is applied to the daily rainfall-runoff data of river Narmada in India and is found to satisfactorily simulate the runoff values for the catchments studied.

INTEGRATED UNDERSTANDING AND MITIGATION OF FLOODS AND DROUGHTS IN NORTHERN INDIA

R. B. SINGH (Department of Geography, University of Delhi, Delhi 110007, India)

India is endowed with not only vast and varied geosystems and glaciers but also huge network of river basins. The changing ecohydrology of the catchment areas of the major rivers is also affected by the potential background of the snow cover melting and, consequently, increasing the water potentiality of these rivers. Geographical monitoring considers glaciers as a prime natural capital for development, utilization and conservation of water resources for human sustenance and sustainable mountain development. On the other hand, as increasing uncertainty with the water in streams and rivers, rainfall and snowfall, the natural disasters like floods and droughts are becoming frequent events. Conditions vary widely from region to region. Whereas, some are drought-affected, others are frequently flooded. Hydrological systems as a linking element between land and water are very sensitive to unsustainable and unadopted authropogenic activities in the highlands as well as in the lowlands. The occurrence of hydrological extreme events are becoming a common feature in Northern India. It is very difficult to say that the hazards are mainly produced by natural fragility of the region or the biotic degradation and land use practices more significant for the flood disaster processes. Flood region covers eight major river valleys spread over 40 million hectares of area in the entire country. This affects 260 million population of India. In recent years with increasing uncertainty in rainfall, drought occurred regularly in north India. Drought conditions are aggravated due to land degradation, loss of top soil and vegetative cover, unregulated surface run off and poor recharge of ground water aquifiers with limited landholdings and crop production dependent on erratic rainfall. The drought region covers 14 states and affects a population of 86 million. Drought mitigation is closely linked with groundwater management. An integrated understnding and mitigation strategy is needed to reduce the impact of both flood and drought disasters. A balanced and regular distribution of water harvesting ponds will store excess monsoon rainfall which may be used during the drought period. Flood control measures…

MODELISATION DE LA PROPOGATION DES ECOULEMENTS A SURFACE LIBRE PAR REGLES FLOUES

M. S. LALIAM and L. Duckstein (IATE Hydram, Departement de Genie Rural, EPFL, Suisse)

Le but du présent article est d'exposer d'une manière simplifiée, la faisabilité de modéliser les équations de St Venant grâce à logique floue. Les sources d'erreurs en modélisation hydrologique comprennent des facteurs hydrométrique, topographique et de représentativité comme lorsqu'une équation n'épouse pas fidèlement le phénomène réel. L'un des points forts de la logique floue est qu'elle offre la possibilité de manipuler à souhait des informations de nature incertaine, subjective ou imprécise telle que des informations linguistiques out des données entachées d'erreurs. Ici, l'application de la logique floue se fait grâce à des règles floues. Un modèle flou contient un ensemble de règles floues, chacune de ces règles est composée d'ensembles fous explicatifs et d'ensembles fous réponses. Dans le présent article, ce nouveau concept de modélisation sera décrit en exposant les points suivants: (a) établissement du modèle—les rgles foues s'ont obtenues après la génération des ensembles fous explicatifs selon l'avis du concepteur hydroaulicien et des ensembles fous réponses obtenues grace a l'application des équations classiques et reconnues des phénomènes considérés; et (b) la modélisation s'effectue par une pondération, mathématique, des règles floues. Cette manipulation s'opère par pondération puis combinaison des règles puis fuzzification et defuzzification successsives.

ON THE DISTRIBUTION FUNCTION OF EXTREME FLOOD DISCHARGE

Mikhail V. BOLGOV (Water Problems Institute, Russian Academy of Science, Gubkin Street 3, 117971 Moscow, Russia, email: bolgov@iwapr.msk.su); Vladilen F. Pisarenko (International Institute of Earthquake Theory and Prediction, Russian Academy of Science, Moscow, Russia); Marina I. Fortus (Institute of Atmospheric Physics, Russian Academy of Science, Moscow, Russia)

The examination of sample histograms of river runoff data for the Pacific coast of Russia revealed that it is reasonable to consider the hypothesis that the distribution density for annual maximum of runoff values must include a component with the so-called "fat tail". To describe the tails of maximum runoff histograms, we recommend using the distribution in the form of a mixture of two densities: the normal distribution for the main region and the Pareto distribution providing the slow decrease of the density in the tail region. To estimate the parameters of the mixture, the numerical method of solution of the maximum likelihood equations is proposed.

PRACTICAL APPLICATION OF HISTORICAL FLOOD INFORMATION TO FLOOD ESTIMATION

David ARCHER (Jeremy Benn Associates, The North Barn, Broughton Hall, Skipton, North Yorkshire BD23 3AE, UK, email: david.archer@jeremybenn.co.uk)

Recent UK legislation requires assessment of 100-year return period flood levels for flood plain planning control. Typical gauged data lengths give an unreliable estimate and the merits of regionalization and the use of historic data are discussed. Typically, existing methods of incorp-orating historic data require the assessment of event discharges when often all that can be assessed from available sources is the number of events in a specified period over a threshold. Whilst this may be considered statistically as a binomial censored sample, a graphical procedure based on the exceedence of the largest gauged discharge is demonstrated for two contrasting cases of the Rivers Wansbeck and Leam in England using data covering a period of over 200 years. These demonstrate both the limitations and the usefulness of incorporating historical flood data.

ANALYSE DES PLUIES EXTRÊMES ANNUELLES SUR LA RÉGION DE MINAS GERAIS (BRÉSIL): MODÈLE DE RÉGIONALISATION TCEV

Bruno Rabelo VERSIANI (Departamento de Engenharia Hidráulica e Recursos Hídricos, Escola de Engenharia da Universidade Federal de Minas Gerais, Av. do Contorno, 842, 30110-060, Belo Horizonte, Brésil, email: versiani@ehr.ufmg.br); Eber José de Andrade Pinto (CPRM, Serviço Geológico do Brasil, Av. Brasil, 1731, 30140-002, Belo Horizonte, Brésil); Philippe Bois (Laboratoire d'Etude des Transferts en Hydrologie et Environnement (LTHE), Domaine Universitaire, BP 53, F-38041 Grenoble Cedex, France)

Cet article présente la méthode de régionalisation des pluies maximales basée sur la fonction de distribution TCEV (Two Component Extreme Value), proposée par Rossi et al. (1984) et son application à des séries de pluies journalières maximales annuelles dans la région de Minas Gerais (Brésil). Ce modèle statistique est composé du produit de deux exponentielles, chacune représentant un processus de Poisson: le premier correspond aux pluies maximales générées plus fréquemment et l'autre aux pluies maximales plus rares, les horsains ("outliers"). Les aspects théoriques du modèle et de la méthode de régionalisation sont brièvement présentés. La région d'étude est un bassin de 50 000 km2 situé dans une zone répresentative du climat tropical de la région sudest du Brésil. La procédure utilisée permet de faire une analyse des horsains et d'identifier deux régions homogènes.

REASSESSMENT OF FLOOD RISK FOR SCOTTISH RIVERS USING SYNTHETIC RUNOFF DATA

Michael E. STEEL, Andrew R. Black, Alan Werritty (Department of Geography, University of Dundee, Dundee DD1 4HN, UK, email: m.steel@dundee.ac.uk); Ian G. Littlewood (Institute of Hydrology, Wallingford, Oxfordshire OX10 8BB, UK)

Increased hydroclimatic variability in recent years and the resultant flooding raise questions concerning flood risk estimation from short flow records in Scotland. Long peak flow series have been simulated using historical rainfall to reassess flood risk estimates for 11 selected rivers. Changes of >10% in the estimated value of the 100-year flood are reported for three rivers, as a result of the synthetic record extension achieved. Future changes in flood risk, as a result of possible changes in atmospheric circulation, are discussed briefly.

PREDICTING SHORT DURATION DESIGN STORMS IN SOUTH AFRICA USING INADEQUATE DATA

Jeffrey SMITHERS, Roland Schulze (Department of Agricultural Engineering, University of Natal, Pietermaritzburg, South Africa, email: smithers@agua.ccwr.ac.za); Geoffrey Pegram (Department of Civil Engineering, University of Natal, Durban, South Africa)

Relatively few recording raingauges with long, reliable records are available in South Africa for the estimation of short duration (£24 h) design rainfalls. Hence approaches to estimating short duration design rainfalls have been developed which are based on daily rainfall data measured by standard, non-recording raingauges at fixed 24 h periods ending at 08:00. These approaches include the use of regional frequency analyses, scaling the moments of the extreme events and stochastic modelling of the rainfall process. This paper presents results from estimating short duration design rainfalls at selected sites in South Africa, using synthetic rainfall series generated by a stochastic model with parameters derived from daily rainfall data.

SPATIAL–TEMPORAL STOCHASTIC RAINFALL MODELLING FOR HYDROLOGICAL DESIGN

Paul J. NORTHROP, Richard E. Chandler, Valerie S. Isham (Department of Statistical Science, University College London, Gower Street, London WC1E 6BT, UK); Christian Onof, Howard S. Wheater (Department of Civil and Environmental Engineering, Imperial College, Imperial College Road, London SW7 2BU, UK, email: c.onof@ic.ac.uk)

The concept of the design storm has its limitations because of its inability to take into account antecedent conditions and the consequent difference between the return periods of the storm and the flood it generates. Stochastic rainfall point models have been developed to model rainfall raingauge data at a single site and, through continuous simulation, provide a new design tool. In the case of many hydrological catchments however, the spatial variability of rainfall becomes crucial to the runoff generation. We present a model in which rain cell origins arrive according to a clustered point process in space and time. The model is fitted using a generalized method of moments. Results are presented for the simulation of individual storms over the Brue catchment in southwest England. These show that the spatial and temporal correlation structures are well reproduced. The model also provides a good fit to the observed marginal intensity and cumulative depth distributions.

ESTIMATING FLOODS IN PERMEABLE DRAINAGE BASINS

Duncan S. FAULKNER and Alice J. Robson (Institute of Hydrology, Wallingford, Oxfordshire OX10 8BB, UK, email: dsf@mail.nwl.ac.uk)

Basins with permeable soils and geology pose problems for flood frequency analysis. Several approaches to statistical flood estimation are reviewed which can account for the infrequency of flooding on rivers draining permeable basins. One method which makes efficient use of annual maximum flow data is based on conditional probability. This technique can be applied to single sites or to regional flood estimation, by allowing for the presence of years with no substantial flood. The approach is suited for use in cases where L-moments are used for flood frequency estimation. Examples illustrate that this can avoid underestimation of design floods. The method forms part of the new UK Flood Estimation Handbook procedures.

HS1/W/24-B5 **1420**

FACTORS AFFECTING THE RELATIONSHIP BETWEEN THE FREQUENCY OF A FLOOD AND ITS CAUSATIVE RAINFALL

Paul WEBSTER (School of Civil Engineering, The University of Birmingham, Edgbaston, Birmingham B15 2TT, UK, email: p.webster@bham.ac.uk)

The paper describes the use of a rainfall–runoff model for investigation of the relationship between the frequency of a flood and that of its causative rainfall. Previous investigation had shown that the annual maximum floods of a given return period were generally caused by storms of lesser return period than implied by the UK Flood Studies Report (FSR) design procedures. Further investigations were carried out to examine the effect of scale, soil type and climate change upon this relationship. It was found that the form of the relationship was applicable across a wide range of scales, and soil types. However, the relationship was characterized by considerable scatter for permeable catchments due to the influence of alternative modes of flood generation. The design event approach to flood estimation is not considered to be appropriate in such catchments. The relationship was little altered under elementary climate change scenarios.

INVESTIGATION ON THE PROBABILITY OF FLOOD EVENTS IN SMALL UNGAUGED AUSTRIAN CATCHMENT AREAS USING BASIN CHARACTERISTICS

Evelyn KRALL (Institute of Hydraulics and Hydrology, Technical University Graz, Mandellstrasse 9, A-8010 Graz, Austria, email: evi@hydro.tu-graz.ac.at)

For many projects concerning flood control it is necessary to base the flood design on parameters such as the flood peak discharge or the flood hydrograph of a certain probability of occurrence. Here an attempt is made to show the interaction between basin characteristics and those parameters, which are decisive for determining a design flood hydrograph. The knowledge of easily available basin characteristics makes it possible to estimate a design flood event of a certain probability for small ungauged catchment areas. The approach is examplified on data from the River Raab in eastern Styria.

REGIONAL ESTIMATION OF DESIGN SUMMER FLOOD DISCHARGES IN SMALL CATCHMENTS OF NORTHERN SLOVAKIA

Silvia KOHNOVÁ and Ján Szolgay (Department of Land and Water Resources Management, Faculty of Civil Engineering, Slovak Technical University, Radlinského 11, 813 68 Bratislava, Slovakia, email: kohnova@us.svf.stuba.sk)

Design floods in ungauged small and mid-sized basins in Slovakia are usually computed from simple regional flood formulae. In this paper other regional approaches have been tested in the flysh region in northern Slovakia. Sub-regions were constructed using hydrologic reasoning based on basin properties and K-means clustering of 17 physiographic basin characteristics and annual summer flood statistics from 43 basins. Regional formulae for the computation of the mean annual summer flood and its standard deviation were derived. Comparison of flood quantiles computed from data and from the formulae showed similar results for all tested methods. The practical applicability of the derived formulae is limited and possible reasons for this are discussed.

DESIGN DISCHARGE OF THE LARGE RIVERS IN THE NETHERLANDS - TOWARDS A NEW METHODOLOGY

Bart PARMET (Institute of Inland Water Management and Waste Water Treatment (RIZA), PO Box 9072, NL-6800 ED Arnhem, The Netherlands); T. Adri Buishand, Theo Brandsma (Royal Netherlands Meteorological Institute (KNMI), PO Box 201, NL-3730 AE De Bilt, The Netherlands); Rainer Mülders (Federal Institute of Hydrology (BfG), PO Box 309, D-56003 Koblenz, Germany)

The design discharge of the large rivers in the Netherlands has been derived from statistical analyses of time series of peak discharges. Because the available time series are relatively short compared to the required mean recurrence period of 1250 years, and may also be non-homogeneous, the estimated design discharge is subject to large uncertainties. In order to reduce these uncertainties, a new methodology is being developed, consisting of a stochastic multivariate weather generator and a hydrological/hydraulic model. Preliminary results are presented for the Rhine basin.

SEASONALITY OF FLOOD PROCESSES IN AUSTRIA

R. MERZ, U. Piock-Ellena, G. Blöschl & D. Gutknecht (Institut für Hydraulik, Gewässerkunde und Wasserwirtschaft, Technische Universität Wien, Karlsplatz 13/223, A-1040 Vienna, Austria)

Work towards an approach to flood regionalization is presented in which the seasonality of runoff and precipitation is used to infer the main flood producing processes which can in turn be used for delineating homogeneous regions. The rationale behind this study is that we believe that similarities in the seasonality of these hydrological variables are often a consequence of similarities in the underlying hydrological and meteorological processes. The analysis of the data shows, for example, that in all high Alpine catchments the mean date of occurrence of floods is in summer and the variability in the flood dates is low. Clearly, this similarity is due to glacier and snowmelt being the main flood producing processes. More detailed process interpretations are presented which are corroborated by examining the seasonality of mean monthly streamflow (i.e. runoff regime), the seasonality of mean monthly precipitation and the seasonality of annual maximum daily precipitation.

La sécheresse que connaît le Sahel se fait également ressentir dans les régions dites humides de l'Afrique de l'Ouest où la gestion des ressources naturelles est un élément important de la stratégie de développement. L'étude entreprise a pour objet d'étudier les conséquences de la sécheresse et de la pression anthropique sur l'utilisation des ressources en eaux dans le bassin du Bandama en Côte d'Ivoire. L'examen des séries de modules de quatre stations montre une diminution de près de 50% des apports annuels en phase avec les perturbations observées au Sahel. Fort de ce constat, le fonctionnement de deux schémas du système d'eau du Bandama a été simulé sur deux ans sous différents scénarios climatiques en termes de pénurie et de défaillance. Les résultats permettent de caractériser tant l'importance du phénomène de sécheresse sur la détérioration des performances du système que celle d'une pression anthropique sans cesse croissante dans un pays africain en voie de dévelopement.

EVALUATION OF SEASONAL FORECASTING METHODS FOR WATER RESOURCE MANAGEMENT IN THE BRAZILIAN NORTHEAST

Carlos Oliveira GALVÃO (Department of Civil Engineering, Federal University of Paraíba, Caixa Postal 505, Campina Grande, Paraíba 58100-970, Brazil, email: galvao@if.ufrgs.br); Robin T. Clarke (Institute of Hydraulic Research, Federal University of Rio Grande do Sul, Caixa Postal 15029, Porto Alegre, Rio Grande do Sul 91501-970, Brazil); Trevor D. Davies and Phil D. Jones (Climatic Research Unit, University of East Anglia, Norwich NR4 7TJ, UK)

Rain in the semiarid and drought-prone Northeast of Brazil is highly variable in space and time. Recently available forecasts of seasonal rainfall are at the regional or at the general circulation

model (GCM) grid-square scales, and their usefulness for water management will depend on how far they can be disaggregated to give forecasts at the drainage-basin scale. In this paper seasonal rainfall forecasts produced by two methods—a statistical–empirical and a GCM—are used to derive forecasts of flow volumes, using downscaling and resampling procedures. Performance measures show significant information loss where forecasts of seasonal rainfall are converted to runoff sequences intended for use in water resource management, although some gain is verified in a simulation of the operation of a reservoir using the forecasts.

OCCURRENCE, SEVERITY AND MAGNITUDE OF HYDROLOGICAL DROUGHT IN ZAMBIA: IMPACTS AND IMPLICATIONS

Henry M. SICHINGABULA (Department of Geography, University of Zambia, PO Box 32379, Lusaka, Zambia, email: hsichingabula@natsci.unza.zm); Happy Sikazwe (Department of Water Affairs, P. O. Box 50280, Lusaka, Zambia)

Persistent occurrence of drought under increasing water supply demands for municipalities and agriculture and under increased threat of global warming, requires increased understanding of drought characteristics and sustainable use of water resources. Using the theory of runs, several hydrological drought parameters of frequency of occurrence, run length, magnitude and run intensity, were investigated for the Kafue and Zambezi rivers. Objectives were to (a) determine magnitude-frequency characteristics of hydrological droughts; (b) determine some drought run parameters and frequency of their occurrence and (c) propose a new approach for increasing Zambia's utilization of its water resources without jeopardizing international relations with neighbouring countries. Better understanding of droughts and assessment of Zambia's present and future water requirements will enable planners and decision makers to bring increased economic benefits to citizens. Zambia's drought and water scarcity problems are outlined and linked to some proposed regional water projects designed to divert water from the Zambezi River system. One possible solution to problems of drought and dwindling water levels on Kafue River is proposed.

FLOODING IN MONSOON RIVERS: COMPLEX HYDROMETEOROLOGICAL RISK ANALYSIS

Boris GARTSMAN (Pacific Institute of Geography FEB RAS, Radio Street 7, Vladivostok 69041, Russia); Mark Karasyov (Far-Eastern Hydrometeorological Research Institute, Fontannaya Street 24, Vladivostok 690600, Russia)

Hydrometeorological risk is understood as the probability of the occurrence of hazardous events and is estimated from long series of observations. Here a complete analysis of risk related to flooding in monsoon rivers has been carried out. The analysis includes a study of destructive factors; a spatial analysis of flooding with the help of scenarios produced by a multi-site stochastic model; a regional risk classification of sections of river valleys, and a construction of risk maps in different scales for using in water and land-use management.

PERFORMANCE EVALUATION OF A STORAGE RESERVOIR: A CASE STUDY

Ivan MUZIK (Department of Civil Engineering, University of Calgary, Calgary, Alberta, Canada T2N 1N4)

The Dixon dam reservoir, located on the Red Deer River in central Alberta, Canada, was constructed in 1983. The drainage area of the reservoir is 5600 km2 and its purpose is mainly to augment the downstream flows for municipal and agricultural use. At the time of design of the reservoir, there were 61 years of historic mean monthly flows available some 60 river kilometers downstream of the dam site. Using regionalization techniques, 61 years of mean monthly flows were estimated at the dam site. The reservoir storage capacities required to meet certain water demands, and their associated probabilities of failure, were determined using: (a) the recorded historic sequence of streamflow, (b) a generated flow sequence of 9900 years by a stochastic model [ARMA (1,1)] and (c) synthetic mass curves of reservoir inflows obtained by statistical analysis of the historic flows. The three methods are briefly outlined and results of the design analysis presented. The paper objective is to take a first look at the reservoir performance using a thirteen year post-construction sequence of observed reservoir outflows and water levels. It is found that during this post-construction period the observed storages confirm design values obtained by the three methods of analysis.

SIMULATION OF THE NORTHERN HEMISPHERE SNOW COVER

Pierre ETCHEVERS, Hervé DOUVILLE, Eric MARTIN. (CNRM, Météo-France, avenue G.Coriolis, 31057 Toulouse Cedex, France.)

Within the framework of the GSW (Global Soil Wetness) Project, a comprehensive data set of meteorological and surface parameters is provided, enabling the simulation of the northern hemisphere snow cover for the years 1987 and 1988 . Two snow models are tested: ISBA (the operational land surface scheme of Météo-France) and Crocus, a multi-layer snow model used for avalanche risk forecasting. The results are compared with two observed data sets : the USAF snow depth climatology and the NESDIS weekly satellite measurement of snow cover. The comparison shows a reasonable agreement between simulations and observations on the global scale. The main discrepancy is the early apparition of snow in autumn and snowmelt in spring. Differences between models are mainly noticeable in mountainous and high latitude areas. They can be interpreted in the light of physical phenomena taken into account in Crocus and simplified in ISBA, such as the snow type dependence of albedo or liquid water retention in the snow pack.

THE INFLUENCE OF EURASIAN SNOW COVER ON NORTHERN HEMISPHERE CLIMATE VARIABILITY

Judah COHEN and Dara Entekhabi (Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.)

Numerical and observational evidence will be presented demonstrating dynamic interactions and feedback between the extent of multi-seasonal snow cover and the characteristics of wintertime circulation anomalies over mid-high latitudes. The cooling effect of Eurasian snow cover results in a strengthened and more expansive Siberian high with more frequent, topographically constrained intrusions of Arctic air west and north. Early-season snow cover variability results in altered general circulation patterns consistent with the dominant mode of winter variability observed in the Northern Hemisphere. The implications of the surface-atmosphere coupling for seasonal predictability will also be discussed.

HS2/W/03-B1 **0940**

TRENDS IN TURBULENT HEAT FLUXES OVER NORTHERN EURASIA

Pavel Ya. GROISMAN (National Climatic Data Center, 151 Patton Avenue, Asheville, North Carolina, 28801, USA), Eugene L. Genikhovich (Main Geophysical Observatory, Koroleva St. 7, St. Petersburg, 194021, Russia), Raymond S. Bradley AND Sun Bomin (Department of Geosciences, University of Massachusetts, Amherst, 01003, USA)

Recently we developed a method to obtain direct estimates of surface turbulent heat fluxes (latent heat fluxes are estimated only for saturated surfaces, wet and/or snow-covered) using routine meteorological observations. This was possible for the former USSR territory and some other countries, where the standard practice of hourly observations includes measurements of temperature at the atmosphere - land surface boundary and state of the ground. The method has been tested on several observational data sets and is now applied to Northern Eurasia. We use the 3- / 6-hourly station data for the past several decades to assess the trends of sensible heat fluxes and latent heat fluxes from well saturated surfaces, including snow cover, for the period 1960 to 1990. Large-scale changes in these fluxes, near-surface temperature inversions and wind speed have been revealed over all of Northern Eurasia during the cold season.

A MULTICHANNEL THRESHOLD TECHNIQUE FOR NOAA-AVHRR DATA TO MONITOR THE EXTENT OF SNOW COVER IN THE SWISS ALPS

Stefan Voigt, Michael Koch, Michael F. Baumgartner (Department of Geography, University of Bern, Hallerstrasse 12, 3012 Bern, Switzerland)

A muti-channel threshold technique is presented that allows monitoring of snow cover in mountainous terrain such as the Swiss Alps using NOAA-AVHRR data. The data preparation and calibration steps necessary to apply the method on time series are described. While some of the classification thresholds are stable with time others vary over the season. The classification skill proves to be better than that of supervised and unsupervised classification approaches. Comparison with ground measurements displays accordance between 60 % and 90 %. The method shows to be reliable and easy to apply and is therefore well suited for operational snow cover monitoring.

SNOWFALL RESPONSES OVER THE U.S.A. TO PHASE AND AMPLITUDE VARIATIONS IN THE TROPOSPHERIC WAVETRAIN

Martyn P. Clark and Mark C. Serreze (Cryospheric and Polar Processes Division, Co-operative Institute for Research in Environmental Sciences, Campus Box 449, University of Colorado, Boulder Colorado 80309-0449, USA.)

Variability in snowfall over the United States is examined with respect to changes in the phase and amplitude of the tropospheric wavetrain. Results are based on composites constructed for both high and low amplitude cases when the ridge axis of the wave train was located in each of six 10o longitude bands between 160oW and 100oW. The most striking signals occur over the central U.S. when the wavetrain is of high amplitude and just west of its mean position. Positive precipitation anomalies and negative temperature anomalies combine to provide positive snowfall signals. Over the western U.S.A., the strongest positive snowfall signals are found when the wave train is of low amplitude, and the ridge lies west of its preferred position. Temperature and precipitation anomalies again play reinforcing roles. Widespread decreases in snowfall occur when the wavetrain is amplified and lies on or east of its preferred location, reflecting high temperatures and low precipitation totals. Significant regional snowfall increases in some composites occur in the absence of positive precipitation anomalies, best expressed in the transient snow regions (e.g., the eastern U.S.) where precipitation phase is the limiting factor on snowfall.

INTERANNUAL VARIATIONS IN SNOW MELT ONSET AND LINKS TO 500 HPA ATMOSPHERIC ANOMALIES OVER THE ARCTIC

Sheldon DROBOT (Department of Geosciences, University of Nebraska, Lincoln, Nebraska, USA, 68588), Mark ANDERSON (Department of Geosciences, University of Nebraska, Lincoln, Nebraska, USA, 68588)

Interannual variations in the melt onset of snow provide a mechanism to observe climatic fluctuations. Timing of initial ablation is associated with certain poorly defined overlying atmospheric conditions. This paper investigates the spatial and temporal patterns in melt onset dates and associated 500 hPa height anomalies over the Arctic region from 1982 – 1992. Melt onset dates are derived from Scanning Multichannel Microwave Radiometer (SMMR) and Special Sensor Microwave Imager (SSM/I) data, while 500 hPa height anomalies are

computed from the National Centers for Environmental Protection (NCEP) reanalysis models. Results indicate significant interannual variations in the spatial pattern and timing of melt onset. With the assistance of principal component analysis (PCA) links between the melt onset dates and the 500 hPa height anomaly field are highlighted.

HS2/W/08-B1 1140

CLIMATE CHANGE AND SIERRA NEVADA SNOWPACK

Tammy JOHNSON (Department of Geography, University of California, Santa Barbara, 3611 Ellison Hall, Santa Barbara, California 93106-4060, USA); Jeff Dozier (Donald Bren School of Environmental Science and Management, University of California, Santa Barbara, 4670 Physical Sciences North, Santa Barbara, California 93106-5131, USA); Joel Michaelsen (Department of Geography, University of California, Santa Barbara, 3611 Ellison Hall, Santa Barbara, California 93106-4060, USA)

Most of California's water resources accumulate within the snowpack on mountains until it melts, which is usually in the spring. This study uses a statistical model which links snow water equivalent (SWE) measurements over a 60-year time-series to clarify the spatial characteristics of snow accumulation trends in the Sierra Nevada. To determine the effects of a monthly and irregular sampling schedule we analyzed daily snow sensor data spanning 28 years. Results are presented for monthly and seasonal maximum changes by range-wide elevation bins and by river basin groupings. We found a strong linear elevational component to monthly SWE accumulation trends. Below 2400 meters, less snow is accumulating and it is melting earlier. Higher elevations exhibit greater variability, with most stations accumulating more snow and melting earlier. This could be the result of warmer air masses having higher moisture contents.

HS2/W/09-B1 1200

MAPPING THE SENSITIVITY OF CANADIAN PERMAFROST TO CLIMATE WARMING

Sharon L. SMITH and Margo M. Burgess (Geological Survey of Canada, 601 Booth St. Ottawa, Canada, K1A 0E8)

A major concern in climate change impact studies in polar regions is the effect of warming on permafrost. Under climate warming scenarios, permafrost may ultimately disappear from about half of the present Canadian permafrost region. The Geological Survey of Canada, as part of a set of national syntheses of geological responses to climate change, is preparing maps to characterise the response of permafrost to climate warming. Digital data layers of factors that influence permafrost response have been combined to produce maps classifying permafrost within the zone where it may ultimately disappear according to i) the relative rate of response of its thermal regime to warming, and ii) the relative magnitude of the impact of permafrost thaw. A final map then combines these two components into one sensitivity index.

HS2/W/10-B1 1400

PRE-OPERATIONAL SNOWMELT FORECASTING BASED ON AN INTEGRATION OF GROUND MEASUREMENTS, METEOROLOGICAL FORECASTS AND SATELLITE DATA

Hannes Kleindienst, Markus Pfister, Michael F. Baumgartner (Department of Geography, University of Bern, Hallerstrasse 12, 3012 Bern, Switzerland)

A method for short term snowmelt runoff forecast based on a degree-day snowmelt model is discussed. Snow maps derived from NOAA-AVHRR satellite images, meteorological forecast data from a limited area model and data from several snow gauges are used to define daily input for the model. A test run for the main ablation period 1996 showed average errors of 12.6% and 16.6% for a one and two days forecast respectively. A modified forecast system based on the experiences presented here will be applied in real time for the ablation period 1999.

HS2/W/11-B1 1420

MODELLING SNOW-ATMOSPHERE INTERACTIONS IN COLD CONTINENTAL EVIRONMENT

J. W. Pomeroy (National Hydrology Research Centre, 11 Innovation Blvd., Saskatoon S7N 3H5 Canada), R. L. H. Essery, D. M. Gray, K. R. Shook, B. Toth (Division of Hydrology, University of Saskatchewan, Saskatoon S7N 0W0 Canada), P. Marsh (National Hydrology Research Centre, 11 Innovation Blvd., Saskatoon S7N 3H5 Canada)

Land surface process schemes are very sensitive to snow cover and snow processes. However many of these schemes are deficient in their representation of snow processes, as they are manifested in cold continental interior climates. The next generation of GCMs, meso-scale models and coupled hydrological models will require improved representations of snow surface processes. To this end, new algorithms have been developed and verified by field measurements to improve snow process representations for prairie and arctic environments. Based on the algorithm results, recommendations for advances in snow modelling are made regarding: redistribution of snow cover by blowing snow, sublimation loss during blowing snow, turbulent transfer during snowmelt and ground heat flux during percolation of snowmelt water through the snowpack and infiltration into frozen soil.

SHAPE CHARACTERISTICS OF FRESHLY FALLEN SNOWFLAKES AND THEIR SHORT-TERM CHANGES

S.R. FASSNACHT, E.D. Soulis & N. Kouwen (Department of Civil Engineering, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada)

The shape of newly formed snowflakes is an important qualitative parameter as input to the development of a snowpack, and for potential atmospheric scavenging, while changes in the shape of freshly fallen crystals influence the metamorphosis and transport of snow and contaminants. This paper uses known spatial properties to simulate the variety of crystal structures that can occur in the range of -4 to -6oC. Probability distribution functions (pdfs) are derived for the surface area to mass ratio, ranging from 0.10 to 0.20 m2.g-1. Observations of freshly fallen flakes are compared to predicted pdfs. The modification in the snow crystal shape, immediately after accumulation, is estimated from laboratory experiments that measured sublimation rates directly from the pack. For fresh flakes, there is a rapid decrease in the effective surface area up to 50% over only 2-3 days.

HS2/W/13-B1 1600

IMPACT OF CLIMATE VARIABILITY ON SNOW COVER REDISTRIBUTION AND SNOWMELT RUNOFF REGIMES IN MOUNTAINOUS REGION

Wang Jian and Li Wenjun (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, 730000 Lanzhou Gansu, P. R. China)

As a matter of fact, the annual average air temperature increases 1.4˚ C in test basin from 1956 to 1996. The results of analysis show that snow cover distribution and runoff regimes in western China has been obviously effected by globe warming and rising air temperature since 1960. Commonly, in the middle latitude mountainous region, the snow cover area reduces in the winter because of the accumulation period to be shortened while in the summer the snow cover extent increases for the adding of snowfall days. Snowmelt runoff will be increment in yearly round with higher melting rate, earlier melting starting data and longer melting interval. For vital reason is the permanent snowfield and glaciers would play two sensitive roles in melting period for flow supply by rising temperature. Based on the scenarios of 4˚ C rising in air temperature, the simulating discharges would be discussed in hydrological year of 1986.

REGIONAL CHARACTERISTICS OF GLACIER MASS BALANCE VARIATIONS IN HIGH ASIA

Liu Shiyin, Wang Ninglian, Ding Yongjian (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou 730000, PR. China), Xie Zichu (Department of Resources and Environment, Hunan Normal university, Changsha 410081, PR. China)

The High Asia, broad in area with numerous huge mountainous ranges, is one of regions with existing glaciers mostly concentrated. However glacier mass balance measurements can not be extended on much more glaciers covering most of the mountains because of the high altitudes and complex topography. Analyzing the temporal and spatial variations of mass balance sequences from presently observed High Asia glaciers is therefore of help to evaluate the regional regularities of balance variations and their response to the global warming. 17 sequences of mass balance obtained in various sources for glaciers in different mountains of Altay, Tianshan, Pamir-Alai Mountains and the Himalayas are selected for present analysis by means of frequency filtering, spectral analysis, principal component analysis (PCA) as well as Mann-Kendall non parameter rank statistic. Results indicate that mass balance series have a similar variation pattern when glaciers are within the vicinity of a short distance while regional inhomogeneity in balance variations appears when the spatial distance extends to a large range. This conclusion gives a fundamental base for establishing a plausible regional network of glacier mass balance monitoring. Furthermore, most of the balance sequences show a quasi- 2 years periodical fluctuations corresponding to that of the climatic parameters in the region. It is also found that there exists an abrupt change in the variations of mass balance of almost all glaciers. Based on the PCA method balance sequence from the area-weighted average of all observed mass balance can roughly represent the variations of different glaciers in the region.

HS2/W/17-B2 0940

IDENTIFYING LINKS BETWEEN LARGE-SCALE ATMOSPHERIC CIRCULATION AND LOCAL GLACIER ABLATION CLIMATES IN THE FRENCH PYRÉNÉES

David M. Hannah, Angela M. Gurnell & Glenn R. Mcgregor (School of Geography, University of Birmingham, Edgbaston. Birmingham. B15 2TT. UK.)

This paper adopts a synoptic climatological approach to elucidate associations between large-scale atmospheric circulation and local summer ablation climates for a small cirque glacier (Taillon Glacier, French Pyrénées), located at the climatically-sensitive southern limit of contemporary European glaciation. The air-mass categories identified possess differential influences on snow and ice melt dependent upon their thermodynamic properties. The observed climate-glacier links are employed to predict the impact of a shift in air-mass type frequency on Pyrénéan snowpacks and glaciers. Typically, cyclonic patterns are associated with low ablation whereas high melt is associated with anticyclonic systems. An extension of the North African-Mediterranean subtropical ridge with an associated polar shift in the westerlies, as proposed under global warming, would favour an increase in the prevalence of high-energy air-masses, thus enhancing Pyrénéan ablation climates. Further work is required to extend this air-mass identification scheme over a number of years and to

HS2/W/18-B2 1000

ENERGY BALANCE MEASUREMENTS ON A CANADIAN HIGH ARCTIC GLACIER AND THEIR IMPLICATIONS FOR MASS BALANCE MODELING

Anthony ARENDT and Martin Sharp (Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, T6G 2E3, Canada)

Meteorological measurements from 3 weather stations on John Evans Glacier were used to show that (a) lapse rates in air temperature were highly variable (values ranged between -0.02 and -0.63oC per 100 m), and generally lower than assumed in degree-day mass balance models; and (b) degree-day factors, calculated from energy balance measurements at the 3 stations, tended to increase throughout the melt season. Degree-day factors correlated well with measured surface albedo (r2 as high as 0.50), and relationships were consistent between years. A simple albedo algorithm implemented within a degree-day model for John Evans Glacier resulted in average melt predictions that were up to 0.13 m WE closer to observed values than those produced by simulations which relied upon constant degree-day factors used in previous studies.

VARIATIONS OF GLACIER MASS BALANCE AND THEIR CLIMATIC IMPLICATION OVER THE NORTHERN HEMISPHERE IN PAST FORTY YEARS

Ding YONGJIAN, Liu Shiyin, YE Baisheng And Zhou Wenjuan (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou 730000, P. R. CHINA)

Based on mass-balance data continuously measured at 40 glaciers from the last thirty to forty-years, some characteristics of mass balance variations of main glacial areas of the Northern Hemisphere have been analysed. The connection and difference of mass balance records and variations of mass balance and ELA have been discussed. Finally, relation between mass balance and climate in the hemispherical range is also analysed. Sensitivity of mass balance to climatic warming is approximately-800 mm/yr/0C according to recorded data.

HS2/W/20-B2 1040

ON THE CHARACTERISTICS OF GLACIER FLUCTUATIONS DURING THE LAST 30 YEARS IN THE URUMQI RIVER BASIN AND THE ESTIMATION OF TEMPERATURE RISE IN THE HIGH MOUNTAIN AREA

Liu Shiyin, Wang Ninglian, Ding Yongjian (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou 730000, PR. China), Xie Zichu (Department of Resource and Environment, Hunan Normal University, Changsha 410081, PR. China)

Based on field observations and repeated photo-grammetry, representative glacier and all the other glaciers in the Urumqi River basin have experienced definite shrinkage since the end of 1950s and the beginning of 1960s. It's found that the decreases in length, area and ice volume of glaciers show a close relationship with glacier dimensions, that is, the larger the glaciers, the bigger their retreats and vice versa. Analysis indicates that statistical relations can be established for the absolute and relative changes in length, area and volume of glaciers against with glacier lengths, which can be adapted to glaciers in other mountainous regions, if we conduct some supplementary measurements of glacier fluctuations. With this concept, an evaluation can be made for glacier fluctuations in a regional scale. Further calculation demonstrates that glacier shrinkage in the last 30 years corresponded to a warming of about 0.35?0.27? in the high mountain region of the Urumqi River.

HS2/W/21-B2 1120

HYDROLOGICAL RESONSE OF MELTWATER FROM GLACIER COVERED MOUNTAIN WATERSHEDS TO CLIMATE CHANGE IN THE NORTHWEST CHINA

Liu Jingshi Yoshihiro Fukushima Tetsuya Hiyama (Institute for Hydrospheric & Atmospheric Science, Nagoya University, Nagoya 464-01, Japan)

Most rivers in the Northwest China are recharged by snow and ice melt-water from the glacier covered area in the mountains. An obvious change in the regional climate with 0.5?h warming in annual air temperature and 10% - 20% increasing in the precipitation has occurred in the inner land Xinjiang of China since the late 1970s, relevant variation in the stream flow from grouped two typical glaciers covered watersheds in the North and the South Tien Shan Mts., the Pamirs, the Mts. Karakoram and the West Kunlun were analyzed based on hydro-meteorological records for 40 years. Results indicated that the stream meltwater didn't produce a response of increase to climatic fluctuation in the 1980s, the stream-flow in most rivers appeared a little decrease, and increase only in one basin with delayed about 5-6 years, summer discharge also performed the delaying and a little increase in the same period due to a little increase in summer precipitation and under a stable summer temperature. The most sensitive response with biggest variability of 15%-20% among the melt- water components to the climate fluctuation was from seasonal flow in May and the annual maximum flood in the smaller watershed with low glacier coverage. It is favourable to glacier development due to more snow accumulation and lower air temperature in summer in the high mountains under the current climate.

HS2/W/22-B2 1140

MASS BALANCE STUDY ON COLLINS ICE CAP, KING GEORGE ISLAND, ANTARCTICA: SPATIAL AND TEMPORAL VARIATION

Han Jiankang Xie Zichu (Hunan Normal University,Changsha,410006,P.R.China), Wen Jiahong Kang Jiancheng (Polar Research Institute of China,Shanghai,200129,P.R.China), Zhu Guocai Jin Xiaoping Gao Xinsheng (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou 730000, P.R. China)

The mass balance study carried out during Oct.1991 to Nov.1992 on Collins Ice Cap, King George Island, Antarctica suggested that the equilibrium line for 1991-1992 was at the elevation of 140m a.s.l., but the mean equilibrium line altitude for multiple years is at 160m a.s.l.. The net mass balance shows an increasing trend with altitudes, having a maximum up to 2480kg·m-2·a-1 in water equivalent on the summit. Using a relation between mean summer temperature and the total ablation, the variation of annual net mass balance during the period of 1971-1992 at the Low Dome was worked out. It showed that the mass balance of the ice cap was negative mostly in the years 1971/1972-1983/1984,while kept positive mainly from 1984/1985 to 1991/1992. The cumulative net balance during the 21 years was near zero.

A STUDY OF CLIMATE AND ENVIRONMENT DURING LAST MAXIMUM GLACIAL PERIOD IN WESTERN CHINA

Ye BAISHENG Ding Yongjian Shi Yafeng Zheng Benxing (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou 730000, China)

Since last maximum glacial period, mountain glacier in western China has been affected by global climatic warming and neotectonic uplift. To study climatic characteristics in last maximum glacial period, seven sites, source area of Urumqi River in Tianshan Mountains, east slope in A'Nyemaqen Mountains, Dongkemadi in Tanggula Mountains, Chongce in West Kunlun Mountains, Rongbu in Qomolangma Mount, Hailuogou in Gongga Mount and Yulungxueshan in Hengduan Mountains, were selected for comparing, where include almost all main mountains in western China. Based on sizes of glaciers in these sites during last maximum glacial period, the conditions of air temperature and precipitation are recovered using the method of glacier dynamics. The results show that precipitation in last maximum glacial period only is only 20-30% in comparison with that of present in central and eastern Qinghai-Xizang (Tibet) Plateau and Tianshan area. In the south part of the Plateau, Gongga and Yulungxueshan areas, precipitation is identical to or slightly over that of the present, but in the western side of the Plateau it is 60-70% of the today's. If effect of neotectonic uplift on climate is not considered, air temperature in summer in that time is 4.6-6.0˚ C lower than that of present in the eastern part and the southern part of Tibet Plateau and Tianshan area, and 2-3.5˚ C lower in the western side and the central part of the Plateau. Estimated air temperature in summer is relatively low in comparison with the results from other methods, because effect of neotectonic movement has been from the last glacial period to now. Differences of the temperature rising in varied regions of the Plateau reflect discrepancy of neotectonic lift. If air temperature in summer in last maximum glacial period is 6.0˚ C lower than today's, the amount of neotectonic lift can be roughly estimated by difference between supposed and estimated air temperatures. The central and the western parts of the Plateau have risen to a maximum of 400-600m since last maximum glacial period, and of which West Kunlun and Qomolangma areas raised about 650m. Relatively small rising of 100-200m occurred in the eastern and southern parts of Plateau and Tianshan area.

HS2/W/25-B2 1240

HIGH RESOLUTION CLIMATIC RECORD FROM THE TIBETAN ICE CORES

Yao Tandong (Lanzhou Institute of Glaciology and Geocryology, CAS, Lanzhou, China)

Based on ice core studies, climatic history since the Last Interglacial on the Tibetan Plateau has been reconstructed. Climate reconstructed from ice cores since the Little Ice Age indicated three cold sub-stages and three warm sub-stages. However, the date, duration and magnitude of each corresponding cold and warm sub-stage in the two records are different. The climatic changes in the past 2000 years were also carefully studied. In both precipitation and temperature records, there are gradual increasing trends from the past to present with many fluctuations. However, the magnitude and phase of each corresponding fluctuation is different in the two records. The most important progress in Tibetan ice core study is the climatic reconstruction since the Last Interglacial from the Guliya ice core. There are several features in this long record. Firstly, the major climatic events from deep-sea core were well recorded in the Guliya ice core. Secondly, the transition from warm to cold period was abrupt. Third, the temperature fluctuation indicated by the Guliya record is closely related to insolation. It is, therefore, speculated that insolation might be a major driving force of the major climatic events recorded in the guliya ice core.

THE TRANSMISSION OF SOIL GASES THROUGH SEASONAL SNOW COVER: AN EXPERIMENT TO DETERMINE THE DIFFUSIVITY OF N2O IN SNOW IN SITU

H.G. JONES (INRS-Eau, Ste-Foy, Quebec, Canada.), E. van Bochove and N. Bertrand (Agriculture and Agri-Food Canada, Ste-Foy, Quebec, Canada)

This study reports on an experiment to better estimate gas diffusion coefficients for N2O emitted from agricultural soils using a gas diffusion system composed of a mass flow controller, a diffusion enclosure and a diffusion chamber installed in situ. From the observed values of Ds and the known value of the diffusion co-effficient of N2O in air, the Aresistance factor@, Rs, of snow to gaseous diffusion was calculated. Rs is a parameter that integrates the different transport rates of the gas due to structural differences in the snow. A Rs value of 1 shows the snow to be an unimpeded diffusion matrix; a Rs of less than 1 shows that diffusion is restricted. The results demonstrated that Rs values (0.60 -$1.0) varied with time and could be related to the degree of heterogeneity of the snow cover as the winter season progressed.

COMPARATIVE FLUXES OF HCO3- AND SI FROM GLACIATED AND NON-GLACIATED TERRAIN DURING THE LAST DEGLACIATION

I. W. Jones, G. Munhoven & M. Tranter (Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, University Road, Bristol. BS8 1SS. U.K.)

There is current interest in the riverine fluxes of HCO3- and Si at the last glacial maximum (LGM), since modelling suggests that these were higher than today (Gibbs and Kump, 1994; Froelich et al., 1992). If this is the case, removal of atmospheric CO2 by silicate weathering is also likely to have been greater at the LGM (Munhoven and Francois, 1996), so contributing to the lower atmospheric CO2 recorded by ice cores (Barnola et al., 1987). To date, the magnitude of glacial chemical erosion on HCO3- and Si fluxes at the LGM is poorly quantified, and the locus of the inferred doubled terrestrial Si flux is unknown. This paper aims to provide first estimates of the relative fluxes of HCO3- and Si fluxes from ice-free and glaciated terrain for five time steps between the LGM (21ka), by extending the modelling approach of Gibbs and Kump (1994) and incorporating new data on glacial solute fluxes (Tranter et al., submitted).

CARBON DIOXIDE CONSUMPTION AND BICARBONATE PRODUCTION RATES BY CONTINENTAL WEATHERING AT THE LGM AND AT PRESENT-DAY—AN UPDATE

Guy Munhoven (Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, Bristol BS8 1SS, UK)

There is currently major debate on the variations of CO2 consumption and HCO3- production rates by continental weathering processes on glacial-interglacial time scales. In this study, we use two models of continental weathering to calculate the bicarbonate production rates from the distributions of drainage intensity and rock type exposure (lithology). A range of estimates for the distribution of runoff at the Last Glacial Maximum (LGM) is obtained by combining four different climatologies from General Circulation Models with two different runoff data sets for the present-day. Although there is some variability in the results derived from the different runoff estimates, both weathering models consistently indicate that the global production of HCO3- was about 30–40% higher at the LGM than at present-day. This increase is significantly larger than previous estimates of 20% based upon a similar approach. CO2 consumption was about 25–35% higher. The increase of the HCO3- production on the exposed continental margin counterbalances the reduction due to presence of ice sheets by a factor of about 3–4; for CO2 consumption, this factor is about 2.3–3.7. Areas exposed both at the LGM and at the present-day present only small variations, comparable to the range of uncertainty estimated for the global net change. Both models furthermore predict a higher consumption rate of CO2 at the LGM. For silicate weathering, results are contradictory, but indicate that variations were at least 2.5 times lower than those calculated by Munhoven and François (1996). Finally, sensitivity tests regarding the lithology of the exposed shelf were performed. These tests illustrate the wide range of variability that possibly affects our estimates of CO2 consumption rates by weathering in this environment at the LGM. They also emphasise the different sensitivities of both weathering models.

RIVER HABITATS, RIVER FLOWS AND RIVER MANAGEMENT

David HARPER (Dept of Zoology, Uni of Leicester, Leicester, UK, Email: dmh@le.ac.uk); Joanna Kemp and Benoît Demars

Habitats and habitat structure of river channels, play important roles in UK monitoring and management. Water quality, fisheries quality and wildlife quality assessments are all habitat-based. Biotic indices for water quality assessment which were initially derived from single-habitat sampling ('stony riffles') are now calculated from field collections made from all habitats in proportion to their abundance and one index, the 'Lincoln Index' takes 'habitat-poor' sites in account in its derivation. Assessment of fisheries used 'HABSCORE' - a means of evaluating the habitat features of importance to successful fish growth and recruitment in a reach. More recently, PHABSIM habitat modelling for individual species based upon MS methodology has been evaluated in several rivers. Assessment of conservation status, initially based on 'River Corridor Surveys' in the 1970s and 1980s, is now based on 'River Habitat Surveys' – both identifying habitat features and highlighting rare or unusual ones.
These uses of the concept of habitat are all based upon habitat structure. Additional uses, based upon the habitat-scale processes, are needed for future management applications and three under development are discussed. Firstly, biological species traits related to the 'habitat templet' concept already provide better perspectives than exiting systems for a bio-monitoring tool, such as relative independence of bio-geographical area and better sensitivity to a wide range of specific human impacts. Secondly, the idea of habitats as the basic unit for a river's metabolic processes provides a very clear link between habitat structure and water quality. Thirdly, the extent to which habitat structure changes in a predictable fashion with both discharge regime, extends the scale (beyond that of species) at which we can set ecological flow targets, as well as integrating the combined effects of channel morphology and flow regime.

VERTICAL INTEGRATION OF SPATIAL AND HYDRAULIC DATA FOR IMPROVED HABITAT MODELLING IN GIS

Thomas B. HARDY (Institute for Natural Systems Engineering, Utah State Univ, Logan, USA, Email: hardy@aaron.cee.usu.edu), Craig Addley

This paper highlights the application of several technologies for the spatial delineation and characterisation of river ecosystems for evaluating habitat quantity and quality. Spatial characterisation based on remotely sensed data using multi-spectral digital imagery and image classification is demonstrated to delineate aquatic habitat types and riparian vegetation community distributions. Derivation of high resolution digital terrain models for use in 1-, 2-, or 3-dimensional hydraulic modelling from the integrated application of low elevation aerial photogrammetry with precision real-time GPS hydro-acoustic mapping of channel topographies, substrates, and 3-dimensional velocity fields are demonstrated. The spatial characterisation of the river using remotely sensed data and hydraulic modelling results based on the digital terrain models are vertically integrated in a GIS to derive habitat based prediction in terms of quantity and quality. Vertical integration of these data in a GIS is also utilised to predict expected fish positions based on bio-energetics of feeding locations, which incorporate food availability and temperature. The use of a GIS for validation of modelling results is demonstrated for hydraulic model predictions and fish distributions relative to habitat quality and fish position choice based bio-energetic modelling predictions.

BROAD SCALE RIVER DRAINAGE DENSITY AND IN-STREAM ECOSYSTEM CHARACTERISTICS: SOME PRACTICAL ISSUES FOR HYDRAULIC WORK IMPACT ASSESSMENT

Pascal BREIL (Division Hydrologie-Hydraulique, Cemagref, Lyon, France,
Email: pascal.breil@cemagref.fr)

As written by a number of authors, the variability of flow conditions seems to be a major factor that influence running water ecosystem strategies. At a local scale, high flow variability is often linked to headwater system where observed fish species are known to have a wide range of capability to adapt to this high aquatic habitat temporal variability. At a broad scale of description, not limited to the upstream part of a basin, a high river drainage system density can be related to a high flow variability. This is a physical consequence of time efficiency to transfer flow variations in any part of the river network. Does it mean that such river basin characteristics could sustain specific and more flexible running water ecosystem strategies than in the case of more linear extended river networks? This question is of interest for hydraulic works impact in a all.
Hydraulic works have variable effects on flow regimes and by consequence variable impacts on freshwater ecosystems. A rough relationship exists between hydraulic work size and impacted length of river. However depending on the river network density we can make the hypothesis that physical effects can be rapidly diluted downstream hydraulic works. Same hypothesis concerns biological response which is determined both by an adaptation of the freshwater ecosystem to the overall unaffected flow regime and by refuges capacity that offers a high drainage density by the way of connected sub-streams. Validation of a such hypothesis is based, firstly, on a regional scale studies to verify existence of some range of regional flow characteristics, in accordance with major broad scale physical basin characteristics. Secondly, we try to verify biological hypothesis using a number of local scale studies based on fish surveys. Depending on regional community patterns distribution and case study located just downstream hydraulic works, we could verify if it exist a mitigation length of stream, depending on the river drainage density.
Practical applications of such regional coherence for eco-hydrological flow regimes concerns broad scale freshwater management objectives for society. As an example, in some areas, addition of hydraulic works could have a limited impact on the long term running fresh water ecosystem dynamics. As biological indicators are used as water health indicators, it means a reduced physical impact on the overall surface water resource in a region.

HW2/W/04-B1 1120

THE HYDRO-ECOLOGICAL FUNCTION OF LARGE WOODY DEBRIS IN BRITISH HEADWATER RIVERS

Conor LINSTEAD (Institute of Hydrology, Crowmarsh Gifford, Wallingford, Oxfordshire, UK, Email: clin@ioh.ac.uk)

The role of large woody debris (LWD) in the ecological functioning of streams has been the subject of much research in the US. The ecological importance of LWD in terms of habitat formation and maintenance, sediment storage and regulation and the retention of organic matter within the fluvial ecosystem has been clearly demonstrated by these studies. There have, however, been few published studies of LWD in the UK. Those studies that have been carried out in the UK demonstrate that, although the LWD in UK streams provides similar functions to that in the US, the morphology and dynamics are very different.
LWD is routinely removed from streams in the UK, principally due to the flood risk posed by excessive accumulations. However, the ecological benefits of LWD has been brought to the attention of some river managers and, recently, attempts have been made to incorporate LWD addition in stream restoration schemes. There is, therefore, clearly a need to understand both the processes surrounding LWD and the wider context of LWD in UK streams in order to provide scientifically based management recommendations for in-stream LWD.
In order to investigate the reach scale hydraulic effect of LWD accumulations, detailed studies were carried out in the New Forest and Forest of Dean (UK). The impacts of LWD on flow depth, velocity, channel roughness and the diversity of hydraulic conditions over a range of discharges and for a range of LWD accumulation morphologies were examined.
The Environment Agency's River Habitat Survey (RHS) database provides a unique opportunity to assess large scale patterns in LWD abundance in the UK and place the results of the reach scale hydraulic analysis of LWD into a larger spatial context. Analysis of the LWD data within the RHS database has supported and extended the results of previous studies into the catchment scale distribution of LWD, which found that abundance is strongly influenced by channel width and riparian landuse. The extent of the influence of channel clearance on the spatial distribution of LWD can also be estimated by comparing the data from the RHS database with detailed surveys of LWD density and distribution carried out in semi-natural catchments in the UK.

AN ASSESSMENT OF PHYSICAL HABITAT MODELLING IN A LOWLAND UK RIVER

ELLIOTT, C.R.N(CIRIA, 6 Storey's Gatte, Westminster, London, UK,
Email: craig.elliot@ciria.org.uk); Ibbotson, A., Gowing, I.M., Acreman, M.C., & Dunbar, M.J.

The application of the Physical Habitat Simulation (PHABSIM) system (a component part of the Instream Flow Incremental Methodology) forms a useful tool for the assessment of water resource issues in the UK and elsewhere. The operational application of the model in the UK has increased over the last 10 years and hydro-ecological modelling techniques such as the IFIM/PHABSIM are, and have been, the focus of a large amount of research and development work. Due to the multi-disciplinary nature of the IFIM/PHASBIM and other habitat models, there are still issues within the modelling procedure where further study is required.
This paper reports on some of the findings of a NERC funded study which has assessed the application of the IFIM/PHASBIM to Mill Stream, a side channel of the River Frome, Dorset. The study examines the links between habitat availability (predicted using PHABSIM) and fish populations (e.g. Dace (Leuciscus leuciscus)). It also assesses the effects of macrophyte growth on habitat prediction and examines other issues which may cause uncertainty interpreting model outputs.

GEOMORPHOLOGY: THE LINK BETWEEN THE HYDROLOGY AND ECOLOGY OF RIVER SYSTEMS

G.E. PETTS (Dept of Environmental Research and Mangement School of Geography, Uni of Birmingham, Edgbaston, UK, Email: g.e.petts@bham.ac.uk); and A.M. Gurnell

The ecology of river channels, exposed riverine sediments and vegetated riparian zones is heavily influenced by their geomorphology (i.e. their form and sedimentary structure) as well as by their hydrology. This paper presents a series of in-channel and riparian studies undertaken at spatial scales ranging from individual river bends to complete river corridors. It illustrates the complexities of hydrology-geomorphology-ecology interactions and the ways in which hydrological and geomorphological change impact upon plant and animal communities in British rivers.

GEOMORPHOLOGICAL AND VEGETATION COMMUNITY RESPONSES TO THE FLOW REGIME OF A SEMI ARID RIVER

M.W. ROUNTREE, G.L. Heritage(Dept of Geography, Peel Building, Uni of Salford, Manchester, UK, Email: g.l.heritage@geography.salford.ac.uk); and K.H. Rogers

Unlike many temperate river systems, semi arid river systems display highly variable flow regimes, with floods that can be two orders of magnitude greater than average daily flows. These infrequent flooding events have been shown to cause extensive stripping of vegetation and sedimentary features from the river channel. The prolonged 'recovery periods' following flooding events are influenced by the positive feedback mechanisms which exist between channel hydraulics, vegetation establishment and the geomorphological development of sedimentary bars. The nature and scale of these inter-relationships was investigated in the Olifants River, Kruger National Park, South Africa. Like most other rivers in the Kruger National Park, the Olifants River has extensive areas of considerable bedrock influence, creating a wide variety of channel types including anastomosing, pool-rapid, braided and single thread reaches. Five sets of aerial photographs (1944, 1965, 1974, 1986 and 1996) spanning a 50 year period were available to document the changes in vegetation and geomorphology which have occurred in response to progressive sedimentation and decreased flow. The 1996 aerial photographs recorded the effects of a high magnitude flood that resulted in catastrophic stripping of vegetation and sediment, exposing the underlying bedrock. This aerial photo set was used to infer the initial condition of the river prior to the decreased flow conditions and associated enhanced sedimentation observed in the other aerial photographs. At the broadest scale bedrock influenced channel types were observed to switch to more alluvial influenced channel types with increased sedimentation. This was reflected in an associated change in vegetation communities. Changes recorded for a particular channel type revealed distinct patterns of vegetation and geomorphological development and their interactions were found to be more complex in anastomosing reaches of the river, where the bedrock influence on the river is greatest, than in the more geomorphologically homogenous single thread reaches. In the single thread channel types vegetation distribution appears to be primarily a function of the geomorphic unit upon which it grows. Elevation above and distance...

HYDRO-ECOLOGICAL VARIABILITY WITHIN A GROUNDWATER-DOMINATED STREAM

Paul WOOD(Geographical and Environmental Sciences, Uni of Huddersfield, Queensgate, Huddersfield, UK, Email: p.j.wood@hud.ac.uk)

Excessive groundwater abstraction and drought has resulted in severe low-flows in many stream and rivers in the UK in the last decade. The response of in-stream ecology has been relatively hard to quantify in many cases due to the absence of long-term baseline data. Some of the most severe problems have been experienced in chalk streams where up to 80% of the discharge may be derived from groundwater sources. In some extreme cases previously perennial streams have become dry along some of their length. A long-term study of Little Stour River (Kent) commenced in 1992 following three winters of low rainfall. Drought and excessive groundwater abstraction resulted in severe low flow conditions and the desiccation of two sections of the stream. The recovery of the system was monitored until 1995 when a second drought commenced, leading to the de-watering of one section of the stream again. Fine sediment composition and low flow velocities resulted in deterioration of instream habitats, elimination of macrophytes and degradation of salmonid spawning habitats in the absence of flushing flows. The response of the macro-invertebrate community in the stream has been examined in detail throughout the period. Clear changes in the structure and composition of the macro-invertebrate community can be detected in response to hydrological variability. The relative abundance of macro-invertebrates was markedly lower during periods of hydrological stress. However, few taxa were eliminated and some were more common during drought periods. The paper highlights the threat posed by flow depletion to groundwater-dominated systems, and examines the need and value of long-term hydro-ecological studies.

SECONDARY PRODUCTION AND HABITAT FREQUENCIES IN EAFS DEFINITION IN AN ITALIAN ALPINE RIVER

Andrea BUFFAGNI (Water Research Institute-CNR, Via della Mornera, 25, 20047 Brugherio MI, Italy, Email: buffagni@server-mi.irsa.rm.cnr.it)

The identification or developing of simple, economically acceptable and ecologically sound methods are now required for Italy as new national rules regulating water abstractions are being set. In Italy, the definition of Ecologically Acceptable Flows has a short history, as laws and local rules on this topic started to be stated since a few years only. This led to a delay in application of existing methodologies and promotion of new methods suitable for the Italian geographical and socio-economical situation. Many commonly used hydrological methods to set standard flows can hardly be employed in Italian rivers for the lack of hydrological data and existing biological based methodologies to define optimum or minimum flows can find only local applications mainly because of uncertainties on ecological assumptions and target species selection. This paper presents the results of a study aimed at identifying optimum and minimum flow conditions for the benthic community in an Italian alpine river (R. Pioverna, Valsassina, LC). The field data collection was performed to link benthos secondary production and flows by means of the functional habitat concept. Production of benthic taxa is different among different in-stream habitats - four functional habitats were identified in the Pioverna river - and habitat frequencies vary with flow. Based on single habitat production and on habitat frequencies as a function of flow, the expected benthic production of the river can be estimated. The relationship between instream flow and total production is then established. The identification of inflection points on the curve, together with the selection of natural-like or desired habitat frequencies, is used to suggest optimum or minimum discharges to be set for the river. In its last step, the method is close to the approach adopted within PHABSIM, as it assumes that river secondary production (or biomass) can be related to flow and that notable discharge values, of ecological value, can be identified. To overcome the need of hydraulic simulation, flow is related to habitat occurrence and not directly to biota preferences for water depth and velocity. To use more information, attention is here given to the invertebrate community, on which fish species feed, and the most comprehensive representation of success for populations and assemblages …

ECO-ENVIRONMENT QUALITY ASSESSMENT: A CASE STUDY ON NING XIA, WEST-NORTHERN ARID AND SEMI-ARID REGION IN CHINA

Jun Xia (College of Water Resources and Hydropower, Wuhan University of Hydraulic and Electric Engineering, 430073, China Email: jxia@wuhee.deu.cn); Zhonggen WANG

As a developing country, China is facing increasing problems in managing its water resources. The new ethic of "sustainable development" not only reinforces but also extends the main principles of water resources management. In China, the emphasis has been and is currently on "elementary environmental care", i.e. oriented primarily to meeting basic water supply needs, for domestic use and wastewater disposal. The environmental management aspects of water engineering continue to be of major significance to the profession. one of the more important aspects of sustainable water management should be the inculcation of concern for ecosystem preservation and protection. Within China, this is especially important in the semi-arid and arid regions where the ecosystem significantly relies on water availability, which has been greatly reduced in the last several decades. The competition for limited freshwater resources between the economy and the ecosystem in these regions is extremely great. Rapid development of these regions has posed an increasingly greater pressure on water systems. The sharp competition for limited freshwater resources, coupled with irrational water utilization practices, induced a host of ecological problems. Desertification, soil salinization, vegetation degradation, the shrinking and disappearance of rivers and lakes are now commonly occurring in these regions. Ecological degradation has become a major threat to the sustainable development of related oases where social and economic activities of the local inhabitants are concentrated.
This paper focuses on ecological quality assessment that considered need to be integrated into the traditional development and economy oriented water resource management research areas of study. The studies on the index system applied to regional Eco-environmental quality assessment, Eco-environmental quality standards, Eco-environmental quality assessment methodology and applications on the West-Northern arid and semi-arid region in China were done. This systems involve… six folds, i.e., (1) the Forest Quality (e.g., arbors, bush, cover degree, underground water level , salinity content etc.); (2) Meadow Quality…

MODIFICATION OF NIGER DELTA PHYSICAL ECOLOGY: THE ROLE OF DAMS AND RESERVOIRS

Kingdon ABAM (Niger Delta Environmental Survey, NAL Tower, 8th Floor, 20 Marina, Lagos Island, POBox 56299, Falomo-Ikoyi, Lagos, Nigeria, Email: mosesb33@hotmail.com)

The Niger delta has a fragile ecology with a complex river network in which fresh and saline water and their underground extensions maintain a dynamic equilibrium. Large scale upstream impoundment in dams and reservoirs have drastically reduced flow and sediment delivery to the coast resulting in adjustments to ecological boundaries, coastline geometry, lowered flood water levels and upstream migration of tidal influences. Although the effects of dams and reservoirs are cumulative, the large capacity dams cause the most spontaneous impacts.

STREAMFLOW REGIME CHANGE AND ECOLOGICAL RESPONSE IN THE LAKE CHAD BASIN IN NIGERIA

Lekan OYEBANDE (Faculty of Environmental Science , Uni of Lagos, Nigeria,
Email: lekan@info.web.abs.net)

Lake Chad basin in Nigeria consists of five river systems, including the Komadugu-Yobe. The

Yobe River system, which empties into Lake Chad is the focus of the present study. It comprises three main rivers, the Hadejia, Jama are and the Misau with their tributaries. All the rivers derive their headwaters from wetter highland to the east and south of Lake Chad and most of them have high sediment carrying capacity. As they descend from the crystalline basement complex onto the ancient lacustrine basin of Lake Chad however, their gradient reduces abruptly, and they deposit their load of silt and fine sand to produce aggraded valley in which the channel becomes poorly defined and characterised by numerous small oxbow lakes.
Two major factors account for the streamflow regime change in the study area: the prolonged Sahelian drought since the mid-sixties and the management practices adopted by the operators of the water projects in the basin. For instance, two consecutive years of low runoff driven by drought were followed in 1974 by the closure of the overdesigned Tiga dam on the main tributary of the River Hadejia. Both events reduced the level of flood flows reaching the bifurcation of the river and River Burum Gana downstream. The reduction promoted rapid decline of R. Hadejia due to weed growth and silting. Test releases in 1996 from Tiga and Challawa Dams show that virtually no water from the Hadejia River system leaves the Hadejia-Nguru wetlands due to weed blockages (Typha reed beds), and siltation of the river bed in the zone of the wetlands.
During the pre-dam period, (1974), there was a very high concentration of the river flow during June-October, accounting for 98-99% of the annual flow. The post-dam period witnessed a reduction to 78-79% concentration. Correspondingly, the extent of wetlands fed by floods progressively decreased from 2,350 km2 in 1969 to 700 in 1987, 893 km2 in 1991, 387km2 in 1993, but was 1728 km2 and 967 km2 in 1994 and 1995 respectively. The effect of such decreased flooding on the ecology of traditional agricultural production and fisheries as well as groundwater recharge has been severe. Elsewhere however, the cultural landscape has been transformed in an otherwise semi arid environment by blossoms of agricultural crops made possible by water released from dam reservoirs. Also as the Lake Chad recedes, lake bed farming replaces water coverage with crop cover.

HW2/W/14-B2 0930

UPSTREAM INFLUENCE ON THE WETLANDS OF THE BAHR EL JEBEL

John SUTCLIFFE (Heathbarton, Manor Road, Goring-on-Thames, Oxfordshire, UK Tel: +44 1491 872268);& Yvonne Parks

Hydrological processes evidently control the ecology of riverine wetlands. Thus upstream influences, like land use change or reservoir control, on the nature of inundation of a downstream flood plain will change the local environment. However, prediction of the consequence of a hydrological change should depend on understanding of the chain of control. An example of a direct link between hydrological regime and wetland vegetation is given by the Bahr el Jebel floodplain in the southern Sudan.
Until the present the hydrological regime of the Bahr el Jebel has been natural, but there are sufficient differences between different locations and also time periods to deduce the means of control of vegetation by flooding. Analysis of flooding and vegetation distribution in two sample areas showed that the link was based on duration, maximum depth and range of inundation. These jointly determined the vegetation distribution by elevation and thus over the floodplain.
Between two surveys of the same area, in 1951 and 1982, the hydrological regime altered following the rise of Lake Victoria; this led to doubled river flows and greatly increased flooding from the Bahr el Jebel. Monitoring of changes in flooding regime and vegetation showed that the controls deduced were reasonable.
Because of the effect of evaporation within the wetlands, the outflow is about half the inflow. Various measures, like upstream storage operation and diversion of the natural river through the Jonglei Canal, have been proposed. Understanding of the mode of control makes it possible to make reasonable predictions of such operation on the vegetation, which is vital to the local economy. It also suggests ways in which the operation might be amended to minimise the adverse local effects.

HW2/W/15-B2 0950

THE FLOODPLAIN MODEL MOVER FOR PREDICTING ECOLOGICAL IMPACTS CAUSED BY ALTERATIONS IN MEAN RIVER STAGES

Dr. E. FUCHS (German Federal Institute of Hydrology, Kaiserin-Augusta-Anlagen 15-17, D-56068, Kobenz, Germany, Email: fuchs@bafg.de)

One aspect of changes in the hydrological regime of rivers is the long term lowering of mean river stages. This effect can be observed in some German rivers used as national waterways. Such changes of river water stages may have natural or anthropogenic causes. Well known are progressing river bed erosion or interference with water levels due to construction works. Logically the ecology of the floodplain will be affected by this shift in hydrological conditions. The riparian vegetation and fauna will react by changes in their communities.
Against this background and because of the growing importance of ecological aspects in river engineering the Waterways and Shipping Administration of the Federal Republic of Germany (WSV) decided to have the ecological impacts of long term river stage variations to be examined and to be evaluated. The German Federal Institute of Hydrology (BfG) was assigned to develop a respective methodology. In the meantime this project is installed as a basic research and development project within the framework of the main tasks of the BfG. The development of the methodology is carried out with a 15 km2 study area on the Lower Rhine. The results of comprehensive field studies covering abiotic and biotic parameters serve as the data basis for the model development.
In the first step the model focuses the riparian vegetation, because for the time being ecological impacts due to changes of mean water stages are defined as changes in vegetation units. Considerations on the conceptual idea of the model led to the fundamental thesis of the model: with view to ecosystem relations in floodplains and to the dependency of these relations on model scale the water regime is the most crucial site factor for determining riparian plant communities.
For the development of the ecological model the main regional dependent processes for the existence of riparian vegetation have to be enlightened and to be parameterised. This job was done by multivariate statistical analyses of the abiotic and biotic field data and moreover by intensive literature enquiries. The Model for Vegetation Response in floodplains MOVER is based on a combination of modelling the abiotic floodplain…

ECOLOGICAL FLOW SETTING USING MACRO-INVERTEBRATES

Chris EXTENCE (Environmental Agency, Kingfisher House, Orton Goldhay, Peterborough, UK, Tel: 44 1733 371811)

A method linking qualitative and semi-quantitative change in benthic macro-invertebrate communities, to prevailing flow regimes in lotic systems, is proposed. The Lotic-invertebrate Index for Flow Evaluation (LIFE) technique is based on data derived from established survey methods, which incorporate sampling strategies considered highly appropriate for assessing the impact of variable flows on benthic riverine populations.
Results from a number of contrasting rivers in England are presented and discussed, and LIFE scores are linked with flow regimes after determining specific relationships with an extended range of hydrological variables. This process identifies those features of flow which are of critical importance in influencing community structure at individual river sites. These distinct responses provide the opportunity to set highly relevant ecological flow objectives, and the Waithe Beck, a Lincolnshire chalk stream, is used as an example to show how this might be accomplished. Employing the LIFE methodology provides ample scope for analysing and elucidating hydroecological relationships in some detail, and a number of additional ancillary applications are outlined and discussed.
Key areas of further work are identified, including the need to provide rational and realistic procedures for setting ecological flow targets, and investigation of habitat quality and life score relationships, in both natural and degraded river reaches.

HW2/W/17-B2 1120

MODELLING ABIOTIC AND BIOTIC LINKS IN THE RIVERS OF THE KRUGER NATIONAL PARK, MPUMALANGA, SOUTH AFRICA: A KNOWLEDGE-BASED APPROACH

G.P.W. JEWITT, D.C. Weeks, G. Heritage, A.H.M Görgens (all at Dept of Agricultural Engineering, Uni of Natal, P BAG X01, Scottsville, 3209, Republic of South Afica, Email: jewitt@aqua.ccwr.ac.za)

The Kruger National Park (KNP) is South Africa's premiere national park and a major attraction to local and foreign tourists. The park is dependent upon several rivers for it's water supply, all of which rise outside of the Park's borders. These catchments are increasingly affected by agricultural, forestry and industrial development. A need to develop water supplies for a burgeoning human population has exacerbated the effects of this development on water quality and quantity in the KNP rivers and is placing its aquatic ecosystems under threat.
The Kruger National Park Rivers Research Programme (KNPRRP) is an interdisciplinary and co-operative endeavour aimed at contributing to the development of decision support tools for the conservation of the natural environment of rivers. These tools include models to predict responses of the aquatic biota to natural and anthropogenic influences. The development of such models is described in this paper and some important conceptual and scientific problems are discussed and analysed, including:
1. Abiotic-biotic linkages and difficulties for hydrologists and engineers (abiotic disciplines) in developing predictive tools in collaboration with ecological scientists (largely biotic disciplines) whose disciplinary fields have not traditionally focused on simulation.
2. Resolution of scale issues, emanating from linking information that is measured, developed and utilised by different biotic and abiotic disciplines acting at different spatial and temporal scales within a catchment.
3. inter-disciplinary research complexities.
Results from the construction and theoretical operation of qualitative rule-based models (RBMs) suggest that these may provide an effective means of integrating abiotic and biotic components of a catchment in a modelling system, and that this approach may assist in resolving the interdisciplinary and scale issues associated with such projects. Such RBMs are demonstrated through practical application of a spatial decision support system which includes an integrated suite of hydrology, geomorphology and fish models, developed to assess the impact of upstream development scenarios.
The development of knowledge-based…

A TECHNIQUE FOR PREDICTION OF HYDRO-ECOLOGICAL EFFECTS FOR THE ECOLOGICAL ASSESSMENT OF WATER PROJECTS

Elke FREISTÜHLER, Antje Giers, Hermann Josef Bauer, Gert A. Schultz (all at Institute of Hydrology, Water Resources Mangement and Environmental Techniques, Ruhr Uni OF Bochum, Germany, Email: elke.frestuehler@ruhr-uni-bochum.de)

In a current research project a computer-based hydro-ecological information and evaluation system is developed as a planning instrument in water resources management. The first step of the assessment method is a spatially detailed evaluation of the present ecological state of the area under consideration. Secondly, the expected degree of ecological damage caused by the planned construction is estimated and evaluated. Finally, the ordinal values resulting from the first two evaluation steps are aggregated to an ecological risk value for the affected area.
A fictitiously planned dam construction in a small river valley in the mountainous region of the "Hochsauerland" in western Germany serves as a case study.
Here a major task is to determine the degree of damage to the in-stream ecosystem. First of all this requires a detailed ecological effect analysis which allows to answer the following questions:
Which abiotic changes (emissions) are to be expected from the project?
Which organisms (receptors) could be affected by these emissions?
By combining each single emission with its specific receptors, so-called "pairs of effect" are formed (e.g. hyporheic interstitial filled with fine material – benthic invertebrates). This effect analysis is based on information gained from literature and studies of comparable projects. Next, we apply the results to the situation in the planning area by a specific effect prediction. To this end the intensity and the spatial extent of each single emission have to be assessed. Accordingly, the specific biotic response of the receptor (single effect) must be forecast. Subsequently, the degree of damage can be determined by aggregating these single effects. This procedure considers explicitly the cause-effect relationship between abiotic and biotic changes caused by the project.
There are, however, two basic problems when evaluating hydro-ecological effects in practice: In many cases the ecological knowledge is still too vague and incomplete for an exact forecast of biotic responses, a detailed modelling of abiotic processes might often be similarly complicated. Therefore…

FIELD OBSERVATIONS ON WOODY DEBRIS IN A WATERSHED DISTURBED BY A POWERFUL TYPHON, SOUTHWEST JAPAN

Y MIYABUCHI, A Shimizu, Y Ogawa and T Shimizu

A powerful typhoon in September 1991 severely damaged the northern part of Kyushu, Southwestern Japan, and produced large amounts of blown-down trees on hillslopes. Subsequent storm-triggered shallow slope failures deposited timber along streambeds. Distribution of woody debris and sediment and their characteristics were examined in a mountain stream three and half years after the typhoon. Log jams of various sizes occurred in the channel; the largest log jam as 100 m long, had a volume of 3,100 cubic meters, and was located along the middle reach of the research section. Principal component analysis of channel morphology and volume of woody debris and sediment suggests that sediment deposition is controlled by tractive force decrease owing to broad channel width and gentle gradient. The analysis demonstrates that there is no conspicuous relationship between volume of woody debris and geomorphic factors such as gradient and sinuosity. Field observations reveal that most log jams occur behind large boulders in the research section. Our results indicate that woody debris accumulation is influenced more by topographic barriers such as large boulders than by channel morphology. We believe that the supply of boulders from sideslopes greatly influences the storage of woody debris in the investigated stream.

DEPOSITION OF CARBON, SULPHUR AND PHOSPHORUS IN THE FLOODPLAIN SEDIMENTS OF THE YAMUNA RIVER BASIN INDIA IN THE RECENT PAST

D.P.SAXENA

Floodplains are in large measures produced by physical process of river deposition .Floodplain have a history of recording the environmental changes of recent past. It can be an important accumulation zones of pollutants that are dispersed by fluvial activity.
In the present study the floodplains of river Yamuna has been studied, which is the largest tributary of the river Gangs, guided by the Himalayas watershed. It originates from the Yamuntori Glacier, near Bunderpunch in the Mussorie range of the lower Himalayas at an elevation of about 6320 m above the mean sea level (MS).
The sediments core were collected from the floodplains of Yamuna river basin at five sampling stations : Saharanpur (next to Himalayas), Delhi , Jagmanpur, Hamirpur and Allahabad (river confluence with Ganga). The biogeochemical indicators Carbon, Sulphur, and Phosphorus were analysed in the core sediments .
Phosphorus concentrations ranges from 272 ug/g to 940ug/g, these values are comparable to the range of average content phosphorus in the sediments of Indian rivers, 11000 ug/g (Subramanian, 1989) Delhi core sediments has highest value (321 - 940 ug/g) in the present study.
Carbon and Sulphur values are higher in younger strata (upper) than older strata of floodplains .Land use is currently extremely rapid and its consequences are more evident in the tropical regions and is part because of the disproportionate share of human population growth that is taking place in the tropics land clearing and conversion causes substantial loss of Sulphur and Phosphorus from cleared site in most region climate change and increased nutrient deposition from the atmosphere, soils plants productivity and biogeochemical cycles The same pattern observed in the Yamuna river basin, Carbon, Phosphorus and Sulphur values are higher in Yamuna strata than the older strata as it reflect high use of fertilisers and detergents by human population. It signifies the change in nutrition of Yamuna river basin in recent past as a result of anthropogenic activities.

SOURCES, DISTRIBUTION AND FATE OF ARSENIC ALONG THE TOLIMAN RIVER, ZIMAPAN, MEXICO

M A ARMIENTA

The Tolimán river is located in the Zimapán basin, approximately 200 km north of México City. Arsenic pollution has been detected in the groundwaters of the Zimapán valley by previous studies. Sediments taken in 54 points along 35.8 km of the Tolimán river-bed were analyzed in order to quantify their total arsenic contents, and to identify the possible arsenic pollution sources. Besides, some samples were analyzed by a sequential extraction procedure to determine arsenic speciation. The fractions of arsenic bound to carbonates, to Fe and Mn oxides and oxihydroxides, to organic matter and amourphous sulfides, and residual, were determined. Arsenic was quantified by electrothermal atomic absorption spectrometry. The granulometry of the sediment samples was also obtained by standard procedures. Total arsenic concentrations ranged from 96 to 6575 mg/kg. The greatest arsenic contents were found in front of the tailing dumps settled on the river shore south of Zimapán town, and in the mineralized zones of E1 Carrizal and La Luz. The residual and the Fe and Mn Oxides and oxyhidroxides fractions were found to contain most of the arsenic. In addition to its mobility from arsenic sources, parameters like grain size and pH determined the high and low contents of arsenic in the sediments. Samples with middle grain-size of sine sand had greater contents of total arsenic, whereas samples with middle grain-size of coarse silt had a lower content. Lower total arsenic concentrations were found in the samples with high pH(>8), whereas samples with a pH between 7 and 7.5 had higher As concentration. Two main sources of arsenic were identified in the Tolimán river. The first one is a natural source due to the presence of the As-bearing minerals, and the second one is due to human activities related to minning operations. The speciation of arsenic showed that it will remain table in the sediments under oxidant and near-neutral pH condition. Changes of the pH to extreme values and more reducing conditions will allow As mobilization, increase its bio-availability as well as its environmental risk.

MULTIVARIATE ANALYSIS OF SLOVENIAN RIVER WATER CHEMICAL COMPOSITION

J UHAN M ZUPAN

Slovenia is a country with very different types of landscape, which is a consequence of heterogeneous climatic conditions (alpine, sub-mediterranean and continental) with 1570 mm annual average quantity of precipitation (from 800 to over 3000 mm) on the contact of three geotectonic units (Alps, Dinarides and Panonic basin). The same facts cause very different hydrological conditions, from step mountain streams to slow flowing rivers in flat land areas. Trough very dense stream net (1.32 km/km2) flows in average 590 m3/s of water from Slovenia territory to the Black See (catchement area 16.370 km2) and the rest to the Adriatic See (catchement area 3.860 km2).
The variability in chemical composition of water and the quantity of suspended solids and sediment is very high as well. Analysis of variance permitted to estimate the temporal and spatial variability of hydrochemical data. The variability in chemical composition of river water is influenced as by human impact as by climatic, hydrological and geological conditions in individual river basins. The selection of most important factors that caused variability in chemical composition of river water we estimated by multivariate statistical analysis (cluster analysis and principal component analysis). As groundwork we have chosen all available data from national water quality and quantity monitoring database for the 15-year period (1983-1997). To the national water quality monitoring program are included all rivers with mean annual flow higher than 4 m3/s (102 sampling points on 54 rivers). The result of three factors model was reduction of the data matrix and quantification of pollution, pedological and geochemical factor, as well as detection the distribution pattern of the most important factors in national scale.

CHANGES OF NITROGEN FLOWS FROM A RIVER BASIN IN A 100 YEARS PERSPECTIVE

L ANDERSSON

Sings of eutrophication in the Baltic sea were found already in the first half of this century, and questions have been raised about the causes of long term change in river loads of nitrogen. The aim of this project is to analyse how changes in land use, but also of the wetness of the landscape during the latest 100 years have affected flow of nitrogen to the Baltic.
Our hypothesis, which seems to be verified, is that a change in retention capacity, both in soil, watercourses and lakes, due to changed hydrology is a dominant factor for changes in nitrogen flow.
The nitrogen transport from the Svartå river basin (1 905 km2) was modelled with HBV-N, a conceptual hydrological model with nitrogen routines. The model considers soil leaching from fallow, ley and cereals, forest and non-classified land. In addition atmospheric deposition at water surfaces, discharge from water treatment plants and industries are considered. The model calculates, on a daily basis, retention for 26 subcatchments, and net transport from all sources to the outlet of the basin. The model is dynamic and considers that retention depends on loads, transit times and climate.
Much of the used statistics is based on data collected for the included parishes. GIS was used to determine the distribution in the sub-catchments and to determine other spatial parameters, such as distribution of soil-types and land-use.
As input to the HBV-N model, nitrogen concentrations in water leached from arable land, fallow and ley, on different soil types were calculated with the deterministic SOIL-N model for each decade from 1875-1995. Although there has been discussions about nitrogen saturation in the forests, still the N-exports from forests play a minor role, and they were therefore set to unchanged during the studied time period.
The HBV-N model was set up for each of the decades, using the calculated soil leaching from the SOIL-N model. Water was then transited… through groundwater, streams and lakes, until it reached the outlet of the catchment. The effect of an increasing amount of underdrained land was simulated, in addition to changes in lake percentages, and wetlands. To make it possible to compare the land-use and hydrology of the different time-steps…

TRANSPORT OF RADIUM ISOTOPE (RA-226) BY THE VISTULA RIVER DUE TO COAL MINE ACTIVITY IN THE SILESIA REGION.

J. Pociask-KARTECZKA, J. Jasinska, J.W. Mietelski, J. Krupa

One of a major source of radiation in the Silesia Region results from hard coal mining activity. The Silesia has been recognized as a natural radiohydroanomaly since the 70. this century. Coal, deep circulation waters and deposits contain significant quantities of Ra-226 (0-121 Bq/kg, 0,7-100 kBq/m3, 110-133200 Bq/kg respectvely). Radium is an extremely important member of the uranium decay series. The isotope Ra-226 is a particularly significant nuclide because of its relatively high radiotoxicity. The Silesian mines Ra-226 input to the environment reached about 306 MBq/d. in 1993, ie. two times less than in the beginning of the 1980s.
Present and former discharge of radium with mine waters caused enhanced natural radioactivity not only in the Salisia Region; also in the vicinity of it.
In our previous piloting work we have studied radium activity in Vistula river sediments. The aim of the presentation has been to find out the proportion between the radium content in soluble and not soluble form in river waters according to transport process. The second goal has been just to find the range of radium activity in waters (clay and colloids may carry a predominantly role in radium isotopes transport; so sorption process can have predominant role in Ra-226 transport for a long distance).
Samples were collected the Vistula River at 7 different locations. In the same time another water samples were collected one from each of the 6 tributaries of the Vistula River: the Chech_o, Przemsza, Bieruñ, Gostynia, Pszczynka and Dunajec. Each sample were of two litre volume, and were put into plastic vessel. Immediately after sample arriving to the laboratory they were acceded. Then they were filtrate on paper filter and then second time filtrate on a membrane filter (with pore diameter equal to 0.7 mm). Dried membrane filters were measured on gamma-rays spectrometer for Ra-226 and Ra-228 (Ac-228). The residues from paper filters were ashen in 600 C. Those ashes and a half of a litre of filtrate water from each sample were taken separately for radiochemical analyses. The Pb and Ba carriers were added along with radiochemical tracer (Ba-133, 55 Bq/sample). Ashes were wet mineralised using concentrate acid solutions (HF, HNO3, HCl) and then transferred to diluted HNO3 solution. Separation of radium for both kind of samples were done by co-precipitation with PbCrO4. Centrifuged residues were then dissolved with hot 0.1 M DTPA solution, and then second co-precipitation with ca 100 micrograms of barium sulphate were performed to obtain thin, alpha spectrometric source. Each source were measured on gamma-spectrometer for the determination of chemical yield (recovery of Ba-133 activity) and for the determination of Ra-228 content via Ac-228 measurement. Then samples were measured on alpha-spectrometer.

RIVER ICE TRENDS OF COASTAL RIVERS IN ATLANTIC CANADA

Bill BRIMLEY and Bridget Thomas (Atmospheric Environment Branch, Environment Canada, 16th Floor, 45 Alderney Dr., Dartmouth, NS, Canada, B2Y 2N6)

The presence of ice in streams and rivers is detected by observation and by the backwater effect that occurs due to the changing hydraulic characteristics of the streamflow. Ice data are recorded as part of the hydrometric record collected by Environment Canada. Preliminary analyses of data from long term hydrometric stations in the Reference Basin Hydrologic Network reveals a significant trend in the presence of ice in the river and the duration of the ice season in certain streams in Atlantic Canada. Data from hydrometric stations in Nova Scotia and Newfoundland show that the number of days with ice in the river has significantly increased since 1955 (when the ice data became part of the hydrometric record). Initial comparisons of ice data with winter season air temperatures showed that there was a cause and effect relationship between the temperature and ice. Links to the cold North Atlantic Current and the winter period of the North Atlantic Oscillation appear to support the winter cooling of this area. The downturn in the northern cod fishery has been linked to these colder waters however the potential impacts on the Atlantic Coast aqua-culture industry and the fresh water habitat are not fully understood.

HW3/W/03-B4 1005

LONG-TERM CHANGES AND ANNUAL VARIABILITY IN ICE COVER ACROSS THE NORTHERN HEMISPHERE OVER THE PAST 170 YEARS

D.M. ROBERTSON, US Geological Survey, WRD, USA (email: dzrobert@usgs.gov); J.J. Magnuson, Center For Limnology (University of Wisconsin-Madison, USA); and R.H. Wynne, Dept. of Forestry (Virginia Polytechnic Institute and State University, Blacksburg, VA, USA.)

Freeze and break-up dates from lakes and rivers across the Northern Hemisphere were assembled as part of a meeting of an ad hoc group of international scientists (Lake Ice Analysis Group, LIAG). Twenty-six of the sites had ice records over 100 years in length. These sites were used to quantify the long-term changes and interannual variability in ice cover and examine the causes of these changes and variability. Consistent long-term changes (later freeze dates and earlier break-up dates in recent years) were found throughout the Northern Hemisphere, indicative of late fall, winter, and spring warming. Most of the changes in these records occurred rather abruptly around the 1880's and 1970's rather than as long-term monotonic changes. The records were also examined to determine if consistent annual anomalies occurred during El Niño events. Freeze dates were consistently later during years of the mature phase of strong El Niños than in other years throughout the 1900's, indicative of warmer early winter air temperatures. Similarly, since 1940, years during the mature phase of strong El Niños were characterised by early break-up dates throughout North America, indicative of warmer spring temperatures; however, break-up dates in Europe and Asia were later than other years, indicative of cooler temperatures. From 1900 to 1940, this pattern in unusual break-up dates is reversed for North America and Asia; that is, break-up tended to be early in Asia and late in North America.

INCORPORATING ICE AND EFFECTS OF ICE INTO THE NORWEGIAN HABITAT ASSESSMENT STRATEGIES AND THE HABITAT PROGRAM SYSTEM

Knut ALFREDSEN and Einar Tesaker (SINTEF Civil & Environmental Engineering, Water Resources)

Habitat assessment through application of computer based simulation tools has been applied to several Norwegian rivers over the past decade. Over the last few years, the HABITAT program system has been upgraded to incorporate both more advanced hydraulic simulation tools and new strategies for habitat assessment. Current research involves the use of metrics to better classify spatial habitat arrangements, and research into habitat assessment through energetic modeling. Cold water conditions are incorporated into the habitat assessment process through cold water preferences for the target species, but direct and indirect impacts on available habitat by river ice are currently on the research and development stage. Ice poses several challenges to the traditional habitat modeling process, both regarding the biological responses in an ice covered environment and the hydraulic modeling of rivers influenced by ice. Typical problems may be 1) the study of under ice fish behaviour, both to create fish preference curves and to validate model predictions, 2) the effects of anchor ice on habitat selection and fish migration, 3) under ice hydraulics and 4) the dynamics of ice formation and breakup on the micro scale. Since habitat selection is a micro scale process, changes in habitat structure through ice induced erosion may also be an important topic. This paper outlines our ideas on how the effects of river ice could be incorporated into the habitat simulation system.

BIOLOGICAL AND PHYSIOLOGICAL RESPONSE OF TROUT TO WINTER HABITATS IN WYOMING, USA

Thomas C. ANNEAR (Wyoming Game and Fish Department, Cheyenne, WY) and Wayne Hubert (Co-operative Fishery and Wildlife Research Unit, University of Wyoming, Laramie, WY)

Fisheries managers of have long known that survival of trout during the winter is a major factor affecting population densities in many stream ecosystems in the Rocky Mountains. In Wyoming, trout population reductions in excess of 90% have been documented in some reservoir tailwaters. Though biologists have surmised that these reductions were the result of either mortality or emigration from some river sections, the specific mechanism was not defined and the factors leading to the trout loss were unknown. Between 1991 and 1998 the Wyoming Game and Fish Department funded four different studies in addition to conducting other work with department staff to better understand the extent of over winter losses, identify some of the mechanisms leading to those conditions and develop management strategies to help avoid those impacts. Winter studies were conducted on tailwater fisheries in the Green, North Platte, Bighorn and Shoshone Rivers to document trout population dynamics, assess physical habitat availability, evaluate trout movement and habitat selection, and understand the relationships between food availability and bioenergetic relationships. Preliminary results indicate that winter trout losses are extreme in some years, that trout movement and habitat selection is directly affected by super-cooled flows and that mortality is probably not directly due to reduced body condition (starvation). The combination of physiological impairment with frequently altered habitat availability probably leads to indirect mortality from predators and other factors.

STABLE ENVIRONMENTAL ISOTOPES IN LAKE AND RIVER ICE CORES

M.G. FERRICK, D.J. Calkins, N.M. Perron (U.S.A. Cold Regions Research and Engineering Laboratory, Hanover, NH) and C. Kendall (U.S. Geological Survey, Menlo Park, CA)

This study was initiated to assess the possibilities of using the stable isotopes of water from ice cores to capture the temporal isotopic signature of river water during the winter and as tracers of ice coming from different tributaries in a river system. A review of the literature revealed that ice growing at rates commonly measured in rivers and lakes experiences nonequilibrium fractionation of stable isotopes. Laboratory experiments conducted at small scales and sea ice data both show a strong correlation between ice growth velocity and the fractionation factor. Also, stirring of the water in laboratory experiments gave dramatically different results for similar ice growth rates, indicating the presence of a boundary layer in the water. Our objectives were to determine the isotopic composition and corresponding crystalline structure of river and lake ice cores, and to use these data to test the analytical diffusion model of Burton et al. (1953) that simulates the fractionation process. The field sites used for sampling were Post Pond, a small, deep lake with minimal inflow during winter, and Wilder Reservoir, an impoundment of the Connecticut River with minimal storage and significant through flow. Ice cores were collected weekly along with water and snow samples from each site. Ice thickness, snow depth and water velocity were routinely measured at the sites, and daily meteorological observations were made throughout the sampling period. The ice growth patterns at the sites were different, with later formation and lower growth rates at the river site, a result of heat conveyed to the ice by the flow. Flow velocities of up to 0.3 m/s just under the ice also caused greater mixing in the river compared to the pond. Application of the fractionation model revealed comparable boundary layer thickness at the two sites, an unexpected result. Apparently, most of the ice growth at the river site occurs during the night while the flow is minimal. We conducted large-scale laboratory experiments to verify this hypothesis and to more effectively test the diffusion model.

HW3/W/10-B4 1520

RECONSTRUCTING TEMPORAL ISOTOPIC VARIATIONS IN WINTER STREAM FLOW FROM RIVER-ICE ARCHIVES

J.J. GIBSON (Wetlands Research Centre, University of Waterloo, Waterloo, ON, N2L 3G1 Canada; email: jjgibson@fes.uwaterloo.ca) and T.D. Prowse (National Water Research Institute, 11 Innovation Blvd., Saskatoon SK, S7N 3H5 Canada)

Isotope stratigraphy of river-ice covers can be applied to reconstruct time-series of the stable isotopic composition of winter stream flow, although careful attention to ice type, morphology and location of sampling is required to obtain useful results. Ice surveys conducted in the Liard River Basin, north-western Canada during 1997 and 1998, suggest that the isotopic composition of winter stream flow is relatively invariant along the main river stem. Systematic isotopic shifts in winter stream flow are evident in ice-core records obtained from numerous tributaries. This effect is discussed and potential mechanisms are reviewed. Early analysis suggests that systematic isotopic shifts are tracing the winter base flow recession, and are

indicative of temporal shifts in the fraction of flow derived from groundwater vs. surface water sources. In combination with direct water sampling conducted during open-water periods, ice-core records are used to assemble near-continuous multi-year records of isotopic variations in stream flow in remote, low-accessibility areas.

PECULIARITIES OF THE DEVELOPMENT OF FILTRATION PROCESS IN THE RIGHT – BANK CONTIGUITY OF VILUI DAM

Svet MILANOVSKY (Institute of Physics of the Earth, Moscow, email: svet@uipe-ras.scgis.ru , Moscow); Toloshinov A.V. (Vilui Dam Cascade), Velikin S.A., Snegirev A.M., Kuchmin O.A. (Vilui Permafrost Research Station of Permafrost Institute RAS, Chernishevski)

The dam of Vilui hydro-engineering unit is the first one among big hydro-technical constructions raised in permafrost zone. Many parameters of this dam are unique therefor it's exploitation needs continual attention. Until the end of 70th - beginning of 80th the state of right-bank contiguity as well of the whole dam was considered acceptable. To obtain more electric power after proper preparation of the construction the water level was lifted above project level. Quick thawing of frozen ground in the basement of right-bank contiguity and appearance of filtration flow transferring heat has begun in 1995. We present results of complex experimental control observation of the development of filtration process. On the base of detailed surface and boreholes geophysical observations the numerical model of the part of right-bank contiguity was done. The model shows the behavior of filtration flow and thawing zone as a function of air and water temperature, water level in the headwater, lithology, thermal and other properties of the section. Forecasting possibilities of the model are shown as well as possibilities of model's improvement.

HW3/W/12-B4 1635

GEOPHYSICAL MONITORING OF HYDROTECHNICAL OBJECTS IN PERMAFROST ZONE

Svet MILANOVSKY (Institute of Physics of the Earth, Moscow, email: svet@uipe-ras.scgis.ru , Moscow); Velikin S.A., Snegirev A.M., Kuchmin O.A. (Vilui Permafrost Research Station of Permafrost Institute RAS, Chernishevski); Kalitin V.T., Sergievsky V.V.(both"Diamonds of Russia" Company, Mirni)

Hydroengineering unit is constructed in the middle reaches of Vilui River between the estuary of its tributary Malaya Botuobiya and the dam of the operating Vilui Hydropower Station - I and 2. This area is characterized by a complex geocryological situation. The edges of the valley at the gage site carry traces of their processing by landsliding. Nowadays the landslide activity is blocked by permafrost. The shore border massif of the reservoir are composed of terrigenic-carbonate rocks. The salinity (mostly of sulfate composition) of frozen grounds is up to 2%. The foot of the reservoir borders is occupied by grounds at the temperatures below zero but saturated with saline waters (cryopegs). The content of salts (mostly sodium chloride) in these waters is 40 g/l or more. After the reservoir filling, the increased water pressure may induce penetration of brines into the frozen massif through their weakened sites, melting of natural ground ice and initiate, respectively, the degradation of frozen grounds and activity of landslide processes. Due to a difficult and hardly predictable geocryological situation in this area, the geophysical methods were included into the system of local monitoring. We demonstrate several examples showing the possibilities of geophysical methods for monitoring of different types of instability in the system: frozen rocks-river (like landsliding, changing position of the boundaries of thawed and frozen grounds, development of filtration flows, etc.). Besides, it was taken into account that during a future exploitation of the reservoir the systematic geophysical observations would be highly useful for the inspection of the state of the shoreline at the upper water level which is also characterized as endangered because of the presence of ancient landslide systems in its structure.

RIVER ICE CHARACTERISTISC AND THE ASSOCIATED LOW-FLOWS OF SIBERIAN RIVERS

Daqing YANG (Inst. for Global Change Research, SEAVANS Building North, 7th floor, 1-2-1 Shibaura, Minato-ku, Tokyo 105-6791, Japan, email: dyang@frontier.esto.or.jp); Tetsuo Ohata (The Institute of Low Temperature Science, Hokkaido University, Kita-19, Nishi-8, Kita-ku Sapporo 060-0819, Japan, email: ohata@pop.lowtem.hokudai.ac.jp)

River ice is one of the important components of hydrological processes in cold regions. To accurately quantify hydrological cycle in cold regions, it is necessary to observe and study river ice. In Siberian regions, river ice thickness, date of river freeze-up, stream water temperature, and discharge have been measured since late 1940's for many large rivers (i.e. Lena, Yenisey and Obi rivers) and the observation records were archived by Russian Hydrological Services. These data are now available for the period of 1950 to 1988 to the GEWEX/GAME-Siberia project. These valuable data sets were analyzed in this study, with special emphases on: (1) temporal variation and spatial distribution of the river ice (thickness) and associated low-flows; (2) effect of river ice on low-flows for various basin scales; and, (3) relation of river freeze-up to air temperature and river discharge in different basins. The results indicate the significant influence of regional climate variation on river ice conditions (i.e. ice thickness and the timing of the river freeze-up) and also on the winter low-flows. Possible future changes of the river ice conditions and winter low-flows under a warmer climate scenario were predicted based on the identified dependence of river ice/low-flow on climate conditions. The results of this study will be useful for understanding the impact of climate variation on cold-region hydrological processes and for improving land-surface hydrological modeling particularly for large river basins in the high latitudes.

ASPECTS OF RIVER ICE HYDROLOGY IN JAPAN

Ken-ichi HIRAYAMA (Iwate University, Morioka, Japan); MakotoYamazaki (Hokkaido Electric Power Co., Inc., Ebetsu, Japan) and Hung Tao Shen (Clarkson University, Potsdam, NY, U.S.A.)

Rivers in Hokkaido and northern Honshu generally originated from mountains and discharge to the sea over relative short distances. The slopes are usually very steep, in the order of 1/100 to 1/300, especially in the upstream reaches. These rivers usually have very low discharges in the winter. In the steep upstream reaches, the ice covers are typically discontinuous and form step pools along the river. Considerable daily oscillations in water temperature and frazil ice production are observed in open water reaches due to the small discharges in these rivers. Daily oscillations in river discharge are also observed due to the formation and release of hanging dams and anchor ice. These processes will first be discussed in the paper. In addition, hydrological aspects of ice jam formation will also be discussed. Although geometric and hydraulic characteristics of Hokkaido rivers are ideal for ice jam formation, ice jam does not occur very often. This is due to the fact that Hokkaido winters do not have mid-winter thaw as often-observed in North America or other areas. River basins are covered by heavy snow accumulation that usually remains until the end of the winter and melt out slowly as the ice covers are also deteriorating due to the rising water temperature. Ice jam events occurred during the winter of 1995 will be used to demonstrate the hydrological process that caused the ice jam formation in Hokkaido rivers.

RIVERS OF THE ARCTIC BASIN, THEIR SEASON THERMOHALINE FLUX AT TIDERWATER AFFECTING THE HABITATS, ECOLOGY AND DISTRIBUTION OF FISHES

Richard Gordon MILLER (University of Arizona and Foresta Institute for ocean and Mountain Studies)

Boreal and Arctic north-flowing rivers of Eurasia and America have earliest spring thaws in their southern highlands, carrying freshet waters and ice downstream onto still frozen river channels. Ice dams build up at tidewater impounding the seasons runoff in broad lakes and ponds that last into summer when they are released by the break-up of the bay ice. This becomes a deluge of fresh water into the brackish and saline strata in the estuary and shore waters. The extremes of thermohaline flux thus imposed on the habitats of native fishes and other biota cause ecologic stress, not yet well studied. Fish populations, their feeding, nesting, reproduction and the dispersal of larvae and young are largely conjectural. Some inferences are gathered from nursery waters in the Antarctic. This project maps the known and conjectural distribution of four species of Arctic Sculpin (family Cottidae, Order Scorpaeniformes). It poses hypotheses on the origin, physiological and behavioral adaptations resulting from life in these troubled waters. The physical dynamics of these watersheds is a study that must be urged.

OBJECTIVE DISTRIBUTED-PARAMETER ESTIATION METHODS AND TOOLS IN THE USGS MODULAR MODELING SYSTEM (MMS)

GEORGE LEAVESLEY, Roland Viger, and Lauren Hay (all at U.S. Geological Survey, MS 412, Denver Federal Center, Denver, CO, 80225, USA, email: george@usgs.gov)

Objective parameter-estimation methods and tools are being developed and evaluated using the U.S. Geological Survey (USGS) Modular Modeling System (MMS). MMS is an integrated system of computer software developed to provide a framework for the development, integration, application, and analysis of hydrologic and ecosystem models. A geographic information system (GIS) interface permits application of a variety of GIS tools to delineate, characterize, and parameterize topographical, hydrological, and biological basin features for use in a variety of lumped- and distributed-parameter modeling approaches. Current methods are being developed using the USGS Precipitation-Runoff Modeling System (PRMS). Digital databases used for parameter estimation include USGS 3-arc second digital elevation models, State Soils Geographic (STATSGO) 1-km gridded soils data, and Forest Service 1-km gridded vegetation type and density data. Basin parameters estimated include slope, aspect, elevation, soil type, available water-holding capacity of the soil, vegetation type, vegetation cover density, solar radiation transmission coefficient, and interception-storage capacity. Precipitation- and temperature-distribution parameters are also estimated. Parameter-estimation methodologies, and evaluation of estimated parameters and their regionalization, are presented for selected basins within the MOPEX data sets and other USGS data sets for a variety of climatic and physiographic regions in the United States. While initial evaluation efforts are focused on PRMS applications, the tools are generic and applicable to a wide variety of models and geographic regions.

HW4/E/04-B2 1100

ASSESSING THE REGIONALISATION POTENTIAL OF HYDROLOGICAL MODELS

Matthew LEES, Thorsten Wagener, Howard Wheater (Department of Civil and Environmental Engineering, Imperial College of Science, Technology and Medicine, London, SW7 2BU, e-mail: m.lees@ic.ac.uk) Keith Beven (Institute of Environmental and Biological Sciences, Lancaster University, LA1 4YQ)

To date, only extremely simple event based models have been successfully regionalised. Developments in parsimonious continuous modelling, allied with progress in calibration techniques, promises a new generation of regionalised models for use in applications as diverse as global water cycling studies, water resources assessment and flood design. However, since models are commonly regionalised through a regression relationship between their parameters and catchment characteristics, parameter uncertainty is a crucial factor in model regionalisation. To improve the potential success of a multiple catchment exercise, it is proposed that a prior assessment of regionalisation potential should be made through an examination of the model's identifiability. Synthetic data sets, generated from parsimonious hybrid conceptual-metric rainfall-runoff models, incorporating realistic model structure errors, input and output data errors, will be used to investigate different methods of parameter estimation and associated parameter and output uncertainty. A number of commonly used calibration methods including: SCE-UA; system identification; and GLUE will be applied prior to an investigation of the relationship between model complexity and errors, and model parameter and output response uncertainty. Also the role of objective functions will be investigated with three major aims: (1) assess the suitability of different objective functions for identification of individual parameters; (2) investigate the use of multi-objective optimisation to both constrain behavioral parameter space, and estimate uncertainty; and, (3) investigate the use of different objective functions due to the purpose of the modelling effort.

EFFECT OF AREAL VERSUS POINT INFORMATION IN THE PARAMETER IDENTIFICATION OF LAND-SURFACE SCHEMES USING MULTI-CRITERIA METHODS

Luis BASTIDAS (Department of Hydrology and Water Resources, University of Arizona, Tucson, AZ 85721, USA, email: lucho@hwr.arizona.edu) Hoshin Gupta, Soroosh Sorooshian, and W. James Shuttleworth (Department of Hydrology and Water Resources, University of Arizona, Tucson, AZ 85721, USA, email: hoshin@hwr.arizona.edu)

Multi-criteria methods provide a useful framework for the calibration and regionalization of land surface parameterizations. This presentation describes and presents preliminary results of an on-going research project in which data collected at the ARM-CART site in Oklahoma/Kansas is being used to study how the information from different point locations, but with similar regional conditions, affects the parameter identification and the sensitivity of a land-surface model, the Biosphere-Atmosphere Transfer Scheme (BATS). Issues of areal averaging and/or aggregation are also addressed. Multi-criteria methods are used for carrying out the optimization procedures involved in both parameter identification and sensitivity analysis.

CASE STUDIES

HW4/E/08-B2 1400

PARAMETERIZATION OF A CONCEPTUAL CONTINUOUS RAINFALL RUNOFF MODEL BY MEANS OF CATCHMENT CHARACTERISTICS

Hubert HOLZMANN and Hans Peter Nachtnebel (both at Department of Water Management, Hydrology and Hydraulic Engineering, University of Natural Sciences BOKU, Muthgasse 18, A-1190 Vienna, Austria, email: holz@edv2.boku.ac.at)

At the IWHW a conceptual continuous rainfall runoff model was developed. Input and output data deal with daily time series. The model consists of a snowmelt module and a runoff formation module. The first is based on a simple day degree method, but uses detailed altitudinal discretization by means of a digital elevation model. Temperature profiles refer to observations or empirical gradients. Furthermore the areal precipitation is required.
The runoff formation module uses the concept of linear storages. The upper storage with two outlets represents the (near)surface flow and the interflow, the lower storage the base flow component. First estimates of the storage coefficients are made by analysis of the specific discharges at the catchment outlets. The depth of the interflow outlet can be interpreted as the mean plant available water content (field capacity minus welting point) multiplied with the root depth of the vegetation. The surplus of the upper outlet characterizes the retention capacity of the near surface layer which can be a function of soil permeability, texture and vegetation type. The model works in a broad range of areas (from about 10 km2 to 10000 km2). The experiences refer to catchments of the Austrian Danube. Test results of some MOPEX catchments with a priori etimates of model parameters will be presented.

HW4/W/05-B2 1420

SOIL HYDRAULIC PROPERTIES FROM RIVER FLOW

E.M.BLYTH

Data on soil hydraulic properties are sparse and often unreliable: based on small samples from a medium that is highly heterogeneous. On the other hand, data on large scale hydrological phenomena, such as river flow, are available world-wide. The seasonal pattern of river flow gives an indication of the porosity of the soil in the catchment: in porous soils, rainfall is transfered rapidly to the groundwater store. The river flow is therefore dominated by baseflow and is relatively uniform through the year. The opposite is true for non-porous soils. Using a simple layered soil model with a groundwater store, a method has been developed to calibrate soil parameters of an evaporation model for use in GCMs using monthly river flow.

A MULTIPLE PATCH SVAT MODEL CONDITIONED ON ESTIMATES OF LATENT HEAT FLUXES AS INFERRED FROM REMOTELY SENSED DATA

STEWART W. FRANKS (Department of Civil, Surveying and Environmental Engineering, University of Newcastle, Callaghan, New South Wales, 2308, Australia. email: ceswf@civeng.newcastle.edu.au); KEITH J. BEVEN (Institute of Environmental and Natural Sciences, Lancaster University, U.K.)

It has been shown that the calibration of SVAT models is inherently uncertain, even when data is available over a relatively limited homogeneous area. The representation of sub-grid scale variability of fluxes is not easily achieved due to the lack of information available about appropriate parameter distributions and their covariance. However, remote sensing of thermal surface responses offers the possibility of obtaining distributed estimates of surface fluxes. In this paper, multiple LANDSAT-TM images are used to derive uncertain estimates of the land surface - atmosphere sensible and latent fluxes over a period of time. Employing a novel 'function'-based framework, the parameter space representing all feasible 1-D parameterisations of a SVAT model are examined with respect to these image estimates. Areal weightings for a number of functional types of flux behaviour are then derived through which the temporal evolution of surface fluxes can be estimated.

REGIONALIZATION OF PARAMETERS FOR THE MODELLING OF AREAL EVAPOTRANSPIRATION

LUCAS MENZEL (Potsdam-Institute for Climate Impact Research, P.O. Box 601203, 14412 Potsdam, Germany, email: menzel@pik-potsdam.de)

In order to determine areal distribution patterns of evapotranspiration across the entire area of Switzerland a model to deliver evapotranspiration over complex terrain was developed. Intensive field studies at various sites of an alpine valley (Dischma, eastern swiss Alps) and a prealpine location (Rietholzbach experimental basin) served to study relationships between atmospheric conditions, soil moisture and transpiration/interception evaporation over various land cover types.
Different submodels were used, e.g. to describe transpiration (Penman-Monteith equation with variation of canopy resistances), or evaporation of water from bare or vegetated surfaces. A series of model parameters were determined through field measurements and related experience. These parameters mainly include a proper description of plant physiological conditions and land surface characteristics like vegetation cover, canopy height, LAI development, albedo, interception storage capacity etc.
To regionalize the evapotranspiration model with all its components simplifications and estimations of the model parameters had to be carried out. In order to apply the whole model for longer time periods further submodels, e.g. to describe snow accumulation, snow melt and snow albedo, had to be elaborated. In addition, interpolation of the meteorological input data over the complex terrain was a difficult task. It was solved through a combination of inverse distance weighting techniques and altitude regressions. Slope inclination, slope exposition and terrain shadowing were calculated using a digital terrain model.

HW4/E/05-B2 1645

THE EXPERIENCE OF APPLICATION OF DIFFERENT TECHNIQUES FOR REGIONALIZATION OF HEAT AND WATER EXCHANGE AT THE LAND SURFACE

Yeugeniy GUSEV and Olga Nasonova (both at the Institute of Water Problems, Russian Academy of Sciences, Gubkina St. 3, 117971 Moscow, Russia, email: sowa@ipcom.ru)

Results of application of three approaches to regionalization of heat and water exchange at the land surface are presented The first approach is to apply the existing point land surface schemes provided with so-called effective values for surface parameters instead of their point values. The second approach is explicit accounting for spatial heterogeneity when heterogeneous area is divided into a number of independent relatively homogeneous patches, or mosaic tiles, with different deterministic values of land surface parameters and with the same area-averaged atmospheric forcings. The components of heat and water budget are calculated separately for each mosaic tile and then averaged over the whole area. The third approach is statistical. In so doing, heterogeneous area is presented as statistical ensemble of patches for which the appropriate factors are treated to be random variables with known statistical parameters. In this case the problem consists in analytical or numerical solution of equations describing the dynamics of statistical moments of output variables or their distribution functions rather than the dynamics of outputs themselves. Application of the above mentioned approaches for regionalization of hydrological processes at different spatial scales is illustrated using the data for several catchments within the Arkansas-Red River basin (USA) as well as for the Kursk and Kiev regions (Russia). A set of various meso-scale models describing the processes of heat and water exchange at heterogeneous surfaces during both the warm and cold periods of a year is developed.
The magnitudes of spatial variability of the main influencing factors (precipitation, leaf area index, field capacity, and hydraulic conductivity at saturation) and statistical parameters of their distribution functions for the Kursk and Kiev regions are found.

GIS - BASED INTERPOLATION AND REGIONALIZATION OF MONTHLY LUMPED MODEL PARAMETERS

IONEL HAIDU (University "Babes-Bolyai", 1 Kogalniceanu Str., 3400 Cluj-Napoca, Romania, email: haidu@bioge.ubbcluj.ro) Calin Haidu (Hydropower Company "Somes", 2-4 Napoca Str., 3400 Cluj-Napoca, Romania, email: giss@codec.ro)

The main purpose of the paper is to check the ability of some GIS procedures in order to interpolate and regionalise hydrological model parameters. First step is to estimate model parameters at basin scale which is important to runoff response. A parsimonious model, having a little number of parameter and physical meaning is preferable because, in the next step, they will be regionalized. Therefore, a monthly rainfall - runoff model on basin scale (VUB model - Type 1) was applied to the available 40 basins of Arkansas - Red river basin. It results three filter parameters which stand for the evapotranspiration equations, slow flow equations and for the fast flow equations. In the second step we passed from the lumped representation of the space to the distributed representation. Starting from the 3 x 40 lumped parameters, now, the purpose is to derive significant parameter values for each grid point. The GIS procedures ofered by SPANS packages were used: TIN, Krigging, Density, Potential Mapping. The resulted layers (thematical maps) reveal some links with the basin characteristics. In the regionalization step we try to design hydrological homogeneous units (regions) using the classification facilities of the GIS. Some of the working steps are user depend and as consequences, the results have to be confronted with the reality of the terrain.

HW4/E/W/03-B2 1730

PARAMETERISATION OF DISTRIBUTED RUNOFF MODELS BY USE OF OBJECTIVE FUNCTIONS AND MULTIPLE STATE VARIABLES

Ing. T. RIENTJES1 , Prof.dr.ir. C. van den Akker 1 and Prof.dr.ir. P. van der Veer2 (1) Delft University of Technology, section Hydrology and Ecology, TUDelft Faculty of Civil Engineering, Stevinweg 1, 2628 CN Delft; (2) Delft University of Technology, Faculty of Civil Engineering, Stevinweg 1, 2628 CN Delft; section Civil Engineering Informatics

The rainfall response of a catchment is expressed by a runoff hydrograph at the catchment outlet where the hydrograph is interpreted as an integrated response function of the various (dominant) runoff processes. In runoff modelling it is common practice that only this hydrograph is used for model calibration. In distributed runoff models the calibration becomes unreliable by the large number of model parameters (e.g. Grayson et al., 1992a, b). Nowadays it is generally accepted that the model performance of distributed runoff models is doubtful by the over-parameterisation of these models. Models produce equally satisfactory model output (i.e. the catchment hydrograph) by use of different sets of parameter (values). Some ten years ago, groundwater modellers also were confronted with the phenomena of over-parameterisation in distributed groundwater models. In order to improve the reliability of distributed runoff models, the use of automated calibration procedures such as proposed by Carrera and Neuman [1986] is advocated in this article.
A catchment will be regarded as a set of interacting sub-systems where for each sub-system one or two model parameters and state variables must be defined. For model calibration, a maximum of four to five parameters must be selected for optimisation while the values of the other parameters must be fixed to a certain value. For the calibration of a model, automated calibration procedures must be employed where multiple state variables must be used for calibration. The use of automated calibration procedures in the field of physically based runoff modelling is advocated since a) multiple parameters can be optimised simultaneously with consideration of multiple state variables and b) parameter estimation is achieved for the model domain as a whole.
Variables to be used for calibration are the channel flow hydrograph, the ground-water table and the soil moisture content. By usage of an objective function in which the 'observation to measurement' discrepancies of state variables and parameters are minimised, it is believed that the model calibration procedure and so the model performance will improve.
For the modelling of catchment response in a distributed manner, the event based computer code 'Flowsim' has been developed within the Delft University of Technology. In this code a number of flow equations are used: overland flow and channel flow are described by 2-D and 1-D Strickler-Manning equations respectively; unsaturated sub-surface flow is described by Richards flow equation while groundwater flow is described by the Darcy flow equation. For model calibration the Gauss-Marquart-Levenburg algorithm will be applied. Model calibration and parameter estimation is achieved by usage of the Parameter ESTimation (PEST) programme (Watermark Computing, 1994).

THE CALCULATION OF EVAPORATION OVER LUOHE BASIN BY A SVAT MODEL AND USE OF IT TO CALCULATE THE RIVER FLOW

XINGUO MO (Environment and ecotechnology Station, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, P.R.China, email: moxg@dls.iog.ac.cn); Suxia Liu (Department of Hydrology, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, P.R.China, email: liusx@sun.ihep.ac.cn) Zhonghui Lin (the same as Xinguo Mo); Weimin Zhao (Hydrological Bureau, the Huanghe(Yellow River) Water resources Commission, Zhenzhou 450004, P.R.China, e-mail: wiminz@usanet.com)

Evaporation is usually calculated by experiential method in hydrological watershed model. When calculating annual river flow, evaporation is even more important. A Soil-Vegatation-Atmosphere water and energy Transfer model is established to calculate evaporation over Luohe basin, a typical catchment of Yellow river. Xinanjiang model with the improvement in evaporation by this SVAT model is used to calculate river flow for the basin. The results is useful for the solution to "yellow river without water now", one of the key water problems of China in 21 century.

COULD BE REGIONALIZED THE STOCHASTICAL MODEL PARAMETERS ?

Ionel HAIDU (University "Babes-Bolyai", 1 Kogalniceanu Str., 3400 Cluj-Napoca, Romania, email: haidu@bioge.ubbcluj.ro)

The regionalization procedures of any hydrological model parameter require an existing spatial relationship between the data point. But, the parameter values of a stochastical model beeing the result of a mathematical optimization procedure are considered to be independent of any physiographical basin characteristic. Also, because the possible climatic change and the stochasticity of the runoff process, the parameter values would be time dependent. The apparent conclusion is that no any reason to make regionalization of such parameters. However, one purpose of the paper is to check if exist physically and statistically significant relationships between some monthly stochastical models and physiographical basin characteristics. For a such analysis just the very small basins (area under 150 - 200 sq.km.) from a continous area are suitable, because the higher degree of intern homogeneity of basins characteristics. The monhly flow of 60 very small basins and their physiographical characteristics (like geology, slope, mean altitude, mean specific runoff etc.) from Northern Romania represent the data for this study. In order to have a limited number of parameter, two parsimonious stochastical models were derived: the Simplified Thomas - Fiering model (STF) which has 2 parameters (except for the monthly means) and an Extreme Parsimonious model (EP) which has only 1 parameter (except for the monthly indices of seasonality). The both models have been passed the specific tests on residuals and on simulation. Regional maps of these parameters were obtained using GIS procedure. The regional maps of stochastical parameters are used to test the procedures in order to compute runoff for ungaged catchements, but not all the cases are fulfiled. The conclusions is that the regionalization of stochastical parameters is model specific and limited to the considered area.

NUMERICAL EXPERIMENT OF CO2, LATENT/SENSIBLE HEAT EXCHANGE BETWEEN ATMOSPHERE AND DIFFERENT PLANT CANOPIES

Katsunori TANAKA (Frontier Research System for Global Change, Tokyo, Japan, email: ktanaka@frontier.est.or.jp) Masakazu Suzuki (Graduate School of Agricultural and Life Sciences, University of Tokyo, email: suzuki@fr.a.u-tokyo.ac.jp) and Nipon Tangtham (Faculty of Forestry, Kasetsart University email: ffornpt@ku.ac.th)

To clarify the mechanism of CO2, latent heat and sensible heat exchange between a plant community and the atmosphere, a multilayer model of these exchange has been developed. This model includes a feedback function and takes account of the canopy intercept of rainfall. It can calculate not only a profile of these fluxes within and above a canopy, but also the profile of meteorological elements within and above the canopy, such as solar radiation, long wave radiation, air/leaf temperature, specific humidity, wind velocity, and CO2 concentration. These profiles are calculated by using the information on the canopy structure, leaf characteristics, and the meteorological elements observed over the plant community. In order to validate the reproducibility of these fluxes over a tropical monsoon forest by this model, we observed CO2, latent heat and sensible heat flux over a canopy in Kog-Ma experimental basin in Thailand, which is one of target areas in GAME-Tropics, on several days in rainy season. As a result of the application of this model, we found that it could successfully reproduce CO2, latent heat and sensible heat flux over a canopy. Moreover, numerical experiments on CO2, latent heat and sensible heat flux were carried out using this model to investigate the influence of the characteristics of the canopy structure. I could consider about exchange of CO2, latent heat and sensible heat within and above a plant community, from the point of view of the canopy structure.

MODELLING SEDIMENT AND SOLUTE YIELDS OF THE RIVER WYE CATCHMENT, UK

DAVID J. MITCHELL (School of Applied Sciences, University of Wolverhampton, Wolverhampton West Midlands WV1 1SB UK. email: d.mitchell@wlv.ac.uk)

The sediment and solute yields of the River Wye Catchment (4010 sq.km) and nine sub-catchments were modelled using hydrometric and basin parameters. Although large data sets exist for the Wye Catchment, the following problemsarise in the application of data to statistical models:-
1.The historical format of data is usually perpetuated. 2.Data if often in the form of point values rather than areal values. 3.Temporal lag effects occur due to increasing catchment area. 4.Spatial patterns of basin characteristics are often complex.
In order to model sediment and solute yields traditional data sets were modified to overcome the above problems, using a mixture of standard manipulative proceedures and the introduction of surrogate parameters. Using national archives and large scale maps, 36 hydrometric variable, 3 seasonal factors and 29 catchment characteristics (geological, pedological, land use and morphometric) were deived on an extensive scale.

PALEOMAGNETIC EXCURSION AT 1.4 MA IN ASO VOLCANO, KYUSHU ISLAND, JAPAN

H. SHIBUYA, S. Honjo, K. Hirata and T. Yamasaki (Dep't Earth Sci., Kumamoto Univ., Kumamoto 860- 8555, Japan.)

A paleomagnetic excursion was found in Aso Volcano, Kyushu Island, Japan. Aso-2 pyroclastic flow was found to have a paleomagnetic direction of very steep inclination. The pyroclastic flow is one of the four major widely spread pyroclastic flows of Aso Volcano. Those have been very well studied because they are, as well as their tuffs are, used as good keybeds not only in Kyushu Island but all over the Japanese Islands. The age of the Aso-2 pyroclastic flow had been determined to be 0.141+-0.005Ma.To investigate that the anomalous direction was not by a rotation of a small block or by a local magnetic anomaly, we took the samples from multiple sites of the Aso-2 pyroclastic flow. As it spreads in an area of about 50km in diameter, it is easy to avoid a local disturbance of the paleomagnetic direction. The average direction of five sites distributed in the area was Dm=6.6, Im=78.9, a95=5.4 and k=198.2, and the corresponding VGP was at 54.2N and 135.1E. If the criterion of an excursion is set at 60 in VGP latitude, it is called an excursion, though the difference of the direction from the geocentric axial dipole field is only about 25. The good concentration of the magnetic directions of widely distributed sites indicates that the direction anomaly is not due to a crustal source. The k value was not much different from that of paleomagnetic directions of Aso-4 pyroclastic flow, which had typical normal direction (N=15, Dm=-3.8, Im=42.4, a95=2.6 and k=198.2). It may indicate that the paleointensity at the Aso-2 excursion was not significantly weak to be affected by the local magnetic anomaly. It was also confirmed by the preliminary paleointensity. Seven Thellier experiments of the strongly welded part gave 0.023mT to 0.048mT. They were as strong as or only slightly weaker than the present geomagnetic field.

GA1.03/W/13-B1 0920

FIELD BEHAVIOUR DURING A REVERSAL EVENT IN A LAVA SEQUENCE FROM WAI'ANAE VOLCANO, O'AHU, HAWAII

STEVE OPENSHAW, John Shaw (Geomagnetism Laboratory, Department of Earth Sciences, Oliver Lodge Laboratories, Peach Street, Liverpool, L69 7ZE. UK. Email: steveo@liv.ac.uk); Emilio Herrero-Bervera (Hawaii Institute of Geophysics and Planetology, University of Hawaii, 2525 Correa Rd., Honolulu, Hl 96822, USA Email: hererro@soest.hawaii.edu).

A suite of samples taken from lava flows on the Hawaiian Island of O'ahu are currently being investigated to illustrate field behaviour during a short period geomagnetic event. K-Ar dating has provided a date of 3.29 Ma at the base of the flow units. This corresponds to the onset of the Gauss Normal Epoch and includes the period of the Lower Mammoth polarity transition (3.06 - 2.94 Ma). Not only are we interested in the directional behaviour of the field during the transition but we are also attempting to produce a continuous palaeointensity record spanning the transition. Demagnetisation and palaeointensity studies are being performed on oriented 5mm diameter 1mm thick disk samples using an 8.2 GHz microwave demag / magnetisation SQUID system which avoids chemical alteration at temperature because the sample matrix is not directly heated. In addition to directional and palaeointensity determinations we present rock magnetic results obtained using a Variable Field Translation Balance (VFTB) which characterise the magnetic mineralogy throughout the flow.

GA1.03/L/01-B1 0940

PALEOMAGNETIC STUDY OF THE SOCIETY ISLANDS: ITS IMPLICATION FOR THE PAST 5MA PALEOSECULAR VARIATION

Hideo Tsunakawa, Koichiro SHIMURA, and Tetsu Kogiso (Department of Earth & Planetary Sciences, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo 152-8551, Japan,
email: kshimura@geo.titech.ac.jp, htsuna@geo.titech.ac.jp, kogiso@geo.titech.ac.jp); Hans G. Barsczus (GBE, Universite de Montpellier II, 34095 Montpellier, France, email: barsczus@dstu.univ-montp2.fr)

Reliable paleomagnetic data have recently accumulated but those from the southern hemisphere have not yet been enough. We have performed the paleomagnetic study of the Society Islands except for Tahiti, that is, Maupiti, Borabora, Tahaa, Raiatea, Huahine, and Moorea. The K-Ar ages of 1.5-4.8Ma were reported for the studied islands while Tahiti has younger ages (e.g. White and Duncan, 1996). Duncan (1975) reported the first systematic study of the paleosecular variation (PSV) in the Society Islands. Roperch and Duncan (1990) and Chauvin et al. (1990) carried out the detailed measurement of directions and paleointensities for the lava sequences in Huahine and Tahiti, respectively. The objective of this study is to obtain a number of reliable paleomagnetic direction and intensity data from the islands. We report the preliminary result of PSV from these six islands.
More than 5 cores were collected from 134 units of lavas and dikes by a portable gasoline engine drill and sun or magnetic compasses. Three specimens from each unit were subjected to stepwise thermal demagnetization. Most of the specimens show primary components while some units cannot. As a result, 68 normal, 39 reversed, and 10 intermediate directions were measured when a threshold VGP latitude of 45 deg is applied. The angular standard deviation (ASD) is calculated from these normal and reversed VGPs to be 14.8 deg. This value is similar to that of Tahiti (13.9 deg; Chauvin et al., 1990) and the global trend calculated from IGRF 1965 (McFadden et al., 1988) but larger than the Hawaiian PSV (11.2 deg; McWilliams et al., 1982).

GA1.03/W/01-B1 1000

PALEOMAGNETISM OF VOLCANIC ROCKS FROM KERGUELEN ARCHIPELAGO (24-30 MA): IMPLICATIONS FOR THE PALEOSECULAR VARIATION IN SOUTHERN INDIAN OCEAN

P. CAMPS (ISTEEM, University of Montpellier 2 case 060, France,
email: camps@dstu.univ-montp2.fr); B. Henry (IPGP, 75252 Paris, France,
email: henry@ipgp.jussieu.fr) and M. Prévot (ISTEEM, email: prevot@dstu.univ-montp2.fr).

We report a survey carried out on the flood basalts from Kerguelen Archipelago (indian ocean) for purposes of extending records of paleomagnetic directional fluctuations from a site in the southern hemisphere. We have sampled a hundred lava flows (667 oriented cores) from 5 stratigraphic sections from diverse regions of the archipelago. The 40Ar/39Ar estimated age of the sampled lava ranges from 24 to 30 Ma (Nicolaysen et al. 1999). The paleomagnetic treatment (stepwise thermal or alternating field demagnetization) is still in progress. Our preliminary results, obtained from 4 sections on the basis of NRM measurement for each core plus one pilot sample demagnetized per flow, revealed the presence of normally and reversely magnetized lavas but no transitional directions between the two polarities. For the 4 sections, we obtained a N-R-N, R-N-R, R-N and N-R stratigraphic sequences, respectively. Lavas seem not suitable for paleointensity determinations because we observe in most cases a contamination of the natural remanent magnetization by large viscous component. These results will be discussed by means of a paleomagnetic secular variation model describing the temporal changes in the geomagnetic field.

GA1.03/W/23-B1 1040

PALEOMAGNETISM AND K-AR AGES OF LAVAS FROM SUDURDALUR, EASTERN ICELAND

Saneyuki UDAGAWA (Earthquake Research Institute, University of Tokyo), Hajime Kitagawa (Patent Agency, MITI), Takehiro Koyaguchi (University of Tokyo), and Masaru Kono (Okayama University)

Two sequences of successive lava flows were sampled in Sudurdalur, Eastern Iceland. They are composed of 46 and 54 lava flows, respectively. These sampling sites are located in the valley adjacent to Nordurdalur studied by Liverpool group in 1970s. Paleomagnetic directions of all lava flows were determined after AF demagnetization to 50 mT. In most cases, secondary components could be removed by about 20 mT demagnetization.
K-Ar ages were obtained from about 30 lavas and they range between 3.0 and 6.0 Ma. The ages are generally consistent with the stratigraphy and shows that two sections overlap partially. Combinating our data with Watikns and Walker (1977) and McDougall et al. (1976), we obtain a composite of reversal history in this area, which may be reconciled with the geomagnetic polarity timescale of Gauss to Epoch 5, derived from marine magnetic anomalies.

GA1.03/P/01-B1 1100

LOW-LATITUDE VIRTUAL GEOMAGNETIC POLES IN NEOGENE ICELANDIC LAVA SEQUENCES

Leo KRISTJANSSON (Geophysics Division, Science Institute, University of Iceland, Hagi, Hofsvallagata 53, 107 Reykjavik, Iceland, email: leo@raunvis.hi.is)

Two paleomagnetic studies on altogether about 1400 lava flows from the subaerial Neogene basalt lava sequences of Iceland were published in 1977. In these collections, about 10% of the reliably determined remanence directions corresponded to virtual pole (VGP) positions below 40° latitude. This was a larger proportion than found in most other volcanic locations. To explain it, Harrison (1980) suggested that some 10% of the observed virtual geomagnetic poles from Iceland might be distributed at random over the globe. Such "random poles" can be envisaged as dating from periods when the geomagnetic field is weak and dominated by variable non-dipole terms. Remanence directions and intensities in additional collections of lava flows were analysed by Kristjansson & McDougall (1982); in these studies the within-flow directional uncertainties were generally smaller than in the work published in 1977. Not much change from the original results of Harrison (1980) was however observed in the overall distribution of poles. In collections completed after 1982, improved sampling and demagnetisation procedures are yielding further reductions in within-flow scatter (Kristjansson 1995, and work in progress). Poles below 40° latitude continue to amount to at least 10% of the total, and altogether 20% lie below 50° latitude. The poles have a fairly uniform distribution in longitude, and there is no significant difference between normal and reverse poles. The average strength of the virtual dipole falls by a factor of 3-4 between the geographic poles and Equator. Normalising of remanence intensity data by the use of anhysteretic remanence may improve the resolution of this type of analysis. There is some evidence for long-term variations in the amount of between-flow scatter of poles from Icelandic lava flows emplaced in the last 15 M.y.

GA1.03/E/07-B1 1120

MORE EVIDENCES FOR LARGE TERTIARY NON DIPOLE FIELD

Pierre ROCHETTE, Didier Vandamme and Y. Touchard (CEREGE, BP80 13545 Aix en Provence Cdx 4, France; email: rochette@cerege.fr)

A new well-documented pole for Africa at 30 Ma has been obtained in the Ethiopian traps (77N 208E, N=53 A95=3.7). This pole is far sided by 6 degree with respect to the synthetic pole from Besse and Courtillot but agree with other synchronous poles from African volcanic rocks, together with the pole derived by Schneider et al. (1990) from inclination data of ODP sites. We resampled two South Indian Ocean ODP sections at 30 Ma and found consistent inclinations with the Ethiopian data. The convergence of evidences from volcanic rocks and oceanic sediments widely distributed within the African plate clearly impose a large (>10% quadrupole and octupole) NDF at 30 Ma. This NDF is averaged out in the synthetic data because of longitude distribution of the sites in the global database but is visible when averaging on longitude sectors. It also accounts for the widespread paleolatitude problem encountered in the Eurasian data.
Another interesting feature of the Ethiopan traps data is that directions show clearly non-Fisherian distribution while VGPs do. Other equatorial data like from the Galapagos Islands (0-5 Ma) exhibit the reverse behavior (Fisherian directions, not VGPs). Does such a behavior relates to non-dipole field?

GA1.03/W/04-B1 1140

ANOMALOUSLY LOW ANGULAR DISPERSION DURING THE EARLY CRETACEOUS

Jonathan M.G. GLEN (Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709 USA; Earth Sciences Department, University of California, Santa Cruz, CA, 95064, USA; and Laboratoire de Paleomagnetisme, Institut de Physique du Globe 4 Place Jussieu, 75252 Paris Cedex 05, France); Paul R. Renne (Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709 USA); Robert S. Coe (Earth Sciences Department, University of California, Santa Cruz, CA, 95064, USA), and Simon C. Milner (Geological Survey of Namibia, PO Box 2168 Windhoek, Republic of Namibia)

we have sampled rocks from the parana-etendeka igneous province, one of the largest flood volcanic provinces in the world that formed 132 my ago, roughly coincident with the rifting of south america and africa in the south atlantic. paleomagnetic measurements yielded generally well defined characteristic components. mean paleomagnetic directions from normally and reversely magnetized units are indistinguishable at the 99% confidence level, confirming that primary directions of magnetization have been adequately isolated.geochemical and magnetostratigraphic correlations of sections reveal that the data span several polarity chrons

-- long enough to average out secular variation. however, the data surprisingly yield an anomalously low estimate of the angular standard deviation (asd), falling significantly below the expected value based on a compilation of data spanning 110 to 195 ma. most likely this indicates that the early cretaceous was a time of unusually low asd, as has been suggested for the immediately following cretaceous superchron because of its low reversal rate. if this observation holds up with additional data, it furnishes a critical test for models of the geodynamo.

PALEOMAGNETIC FIELD BEHAVIOUR 2

GA1.03/W/08-B1 1400

CRM EXPERIMENTS AND PALEOINTENSITY MEASUREMENTS ON VOLCANIC ROCKS WITH INITIALLY LOW CURIE TEMPERATURE

Ulrike DRAEGER (University of California Santa Cruz, Institute of Tectonics, Santa Cruz, CA 95064, USA, email: udraeger@earthsci.ucsc.edu); Michel Prévot and Thierry Poidras (Laboratoire de Géophysique et Tectonique, Université de Montpellier 2, 34095 Montpellier Cédex 05, France, email: prevot@dstu.univ-montp2.fr)

There is some evidence that the primary remanence of basaltic rocks which are oxidized at high temperatures can be a thermochemical magnetization (TCRM) rather than a TRM. This can cause errors in determination of the paleointensity of the Earth's magnetic field. In order to simulate two different kinds of oxidation processes we produced a CRM at a constant temperature of oxidation and a TCRM at a very slowly decreasing temperature. The original samples were carrying titanomagnetite with Curie temperatures far below the oxidation temperatures of the experiment. Subsequent Thellier experiments on the oxidized samples yielded different values for the intensity of the 'paleofield' (here: field which was applied during acquisition of CRM), depending on the oxidation experiment. While the apparent paleointensity estimated from a pure CRM is lower than the actual magnetizing field and is dependent on the oxidation temperature, the TCRM provides an almost correct apparent paleointensity. Performed rock magnetic experiments let us assume that we produce a CRM by crystal growth of a Ti-poor mineral like magnetite in the original titanomagnetite. Long-term heating experiments, paleointensity experiments and rockmagnetic studies are presented.

GA1.03/W/19-B1 1420

SHORT TERM VARIATIONS IN GEOMAGNETIC FIELD STRENGTH FROM MICROWAVE ANALYSIS OF PERUVIAN, CHINESE AND EGYPTIAN CERAMICS

JOHN SHAW and Shanlin Yang (Geomagnetism Laboratory, University of Liverpool, UK); Derek Walton (Department of Physics, McMaster university, Canada.); Hatem Odah (NRIAG, Cairo, Egypt.)

Microwave heating of the magnetic system within ceramic samples has allowed the determination of the ancient geomagnetic field strength without causing laboratory alteration. Application of the microwave palaeointensity method to ceramics from North West China, Peru and Northern Egypt has revealed smoothly varying changes in the strength of the geomagnetic field with time. The major source of change appears to be the movement of non-dipole anomalies. Further application of the new microwave archaeointensity method will allow us to construct a global map of dipole and non-dipole field strength changes over archaeological time.

GA1.03/W/24-B1 1440

ROCK-MAGNETIC CHARACTERISTICS AND PALAEOINTENSITY RESULTS: A STUDY ON HISTORICAL LAVES FROM MT. ETNA

Manuel CALVO (Dep. de Física, Universidad de Burgos, Spain. Email: mcalvo@ubu.es); Mireille Perrin and Michel Prévot (Lab. de Géophysique et Tectonique, UMR CNRS 5573, Univ. Montpellier II, France. Email: perrin@dstu.univ-montp2.fr and prevot@dstu.univ-montp2.fr)

In palaeointensity studies, a high percentage of samples do not yield reliable results and dispersion is often high.The aim of the present study is to obtain information about the effect on palaeointensity determinations of the presence of MD-grains and mineralogical, chemical and/or physical changes during heating in Thellier-type palaeointensity experiments. For this purpose, a refined palaeointensity experiment was devised, which could allow determination of CRM created during the experiment and recognition and quantification of the effect of MD-grains on palaeointensity. In addition, rock-magnetic experiments aimed to obtain information about carriers of remanence, their stability and the presence of MD-grains were carried out.
Different carriers of remanence and different behaviour during heating are reflected in the obtained k-T curves, although no direct correlation is observed between them and value and quality of palaeointensity determinations. The mean palaeointensity obtained in this study is in accordance with the expected one, although scatter of single values around the mean is considerable. If samples are analysed individually, four cases can be distinguished: apparently correct palaeointensity determinations are accompanied either by correct and incorrect "quality indicators", and the same holds for incorrect palaeointensity determinations.

GA1.03/W/07-B1 1500

MAGNETIC INVESTIGATION, PAYING PARTICULAR ATTENTION TO THE INTENSITY, OF A RECENT HAWAIIAN LAVA FLOW

Mimii J. HILL and John Shaw (The Geomagnetism Laboratory, The University of Liverpool, L69 7ZE, UK) and Emilio Herrero-Bervera (Hawaii Institute of Geophysics and Planetology, University of Hawaii, HI 96822, USA.)

Detailed investigation of historic lava flows where the field behaviour is well known permits a clearer understanding of the recording process that occurs in lava to be obtained. It has been shown (Rolph, 1997 and Böhnel et al, 1997) that there can be considerable variation in the magnetic properties within a single lava flow. Two vertical sections, approximately 16 m apart, of the 1960 lava flow in Puna were sampled. One section is 75 cm thick and the other 1 m thick. 2.5 cm diameter cores were taken at a vertical spacing of 5 cm.
We present rock magnetic, directional and palaeointensity results. Microwave demagnetisation / remagnetisation has been used for the intensity and directional analysis. The microwave method allows the magnetic minerals to be directly heated without heating the bulk sample (Walton et al, 1993) thus minimising the problems associated with alteration during experimentation. It is required for palaeointensity determinations that the NRM is a TRM and not a CRM. Many of the samples showed two distinct intensity components, a low microwave power / blocking temperature component and a high power / blocking temperature component with the low power intensity being considerably higher than expected. It is suggested that the higher intensity value could be due to a natural CRM. Using the high power component where two components were present, the evaluated intensity does show some variation though the flow but the average for the whole flow is within the limits of the expected value.

GA1.03/L/04-B1 1520

PALEOINTENSITY STUDIES OF A LAVA SUCCESSION FROM JILIN PROVINCE, NORTHEASTERN CHINA: AN EVIDENCE FOR THE BLAKE EVENT

Rixiang ZHU and Yongxi Pan (Institute of Geophysics, Chinese Academy of Sciences, Beijing 100101, email: rxzhu@mail.c-geos.ac.cn)

Geomagnetic reversals and short geomagnetic events are well-document modes of behavior of the Earth's magnetic field. One such convincingly demonstrated geomagnetic event is so-called Blake event, which was first reported by Smith & Foster (1969). This geomagnetic event has subsequently been reported in different lithologic and places and therefore appears to be a global event. Here we present a new study of absolute intensities for the period 210-88 kyr obtained from a sequence lava flows from the Tianchi lava flows (42.05˚N, 128.0˚E), Jilin Province, Northeastern China. The lava flows are formed entirely of alkali basalt located in the center of Changbaishan Mts lying to Sino-North Korean boundary. 5 lava flows can be recognized from the presence of stratigraphic discontinuities. The age of the lower flow named lava1is 210 kyr, which is overlain by other series lavas labeled as 2-5. 123±7 and 123±10 have been dated for the lava3 and lava4 respectively, and 88 kyr for the lava5. Total 275 oriented core samples were collected within these 5 lava flows. Rock magnetic analyses and reflected light microscopy indicate that the magnetic mineralogy of the lava flows is dominated by magnetite containing a significant fraction of single-domain grains. Stable characteristic remanence (ChRM) can be thermally isolated above 150-200˚C. Two intermediate directions held by the lavas with a age of ~123 kyr correspond to the Blake event, their virtual geomagnetic poles (VGPs) are located at the Eastern Asia and Australia. Over 121 samples are used to for paleointensity determinations carried out with Thellier method in an argon atmosphere. Of these, only 34 samples yield reliable results, with within-flow scatter lower than 15%. The results indicate that marked intensity low is coinciding with intermediate directions.

GA1.03/W/27-B1 1600

ABSOLUTE PALEOINTENSITY OF 0-1 MA OLD LAVA FLOWS FROM LA GUADELOUPE ISLAND: COMPARISON WITH SEDIMENTARY AND VOLCANIC DATASETS

J. CARLUT (email: carlut@ipgp.jussieu.fr, Lab. de Paleomagnetisme, IPGP, 4 Place Jussieu, 75252 Paris Cedex 05, FRANCE) and X. QUIDELLEUR (email: quidel@geol.u-psud.fr, Lab. de geochronologie UPS- IPGP, Bat.504, Univ. Paris Sud, 91405 Orsay, FRANCE)

Ten absolute paleointensity determinations covering the Brunhes chron have been obtained on andesitic lava flows from La Guadeloupe Island, French West Indies. The Thellier and Thellier method performed on 124 specimens under either ambient or argon atmosphere allows reliable determinations from high temperature steps. The average virtual axial dipole moment (VADM) for normal polarity flows from the Brunhes chron is compatible with the present day field. A paleointensity decrease of a factor of ten is observed for flows emitted during the Matuyama-Brunhes transition, as already observed in other records of this reversal. Each flow from this study is associated with a K/Ar age (Blanc, 1983; Carlut et al., 1999) obtained using the Cassignol technique (Gillot and Cornette, 1986). This allows us to compare the present dataset with other records from the Brunhes interval. The ten VADM values obtained show a relatively good agreement with the the global variations of the axial dipole strength, as displayed by the deep sea composite record (SINT800) of relative paleointensity, when rapid fluctuations of about 15% amplitude due to the non-dipole components are taken into account. We present a new global dataset including all recent studies with good age determinations. Within the most documented interval, a well defined 20 kyr long oscillation observed in the volcanic VADM values can be attributed to the long term evolution of the axial dipole part of the field. Because a large area of the Globe around the Caribbean Islands was previously devoid of data, the present dataset fills a gap towards construction of a global paleointensity database for the Brunhes chron.

PALEOMAGNETIC FIELD BEHAVIOR 3

GA1.03/E/06-B2 0900

REPEATED PATTERNS OF GEOMAGNETIC FIELD BEHAVIOUR ON THOUSAND YEAR TIME-SCALES IN THE LOWER CRETACEOUS

IORIO, M. (Geomare Sud, Via Vespucci 9, Napoli 80142, Italy Email: iorio@gms01.na.cnr.it); TARLING, D.H. (Geological Sciences, University, Plymouth PL4 8AA, UK Email: d.tarling@plymouth.ac.uk) and D'Argenio, B. (Scienze della Terra, Universita Frederico II di Napoli, Napoli 80138, Italy Email: ciclisiti@gms01.na.cnr.it)

Some twelve patterns in the directional behaviour of the palaeomagnetic signal have been recognised in shallow-water carbonate bore-core accumulated during some 3.2 Ma some 127 Ma ago. These patterns are each of several ka duration and follow consistent sequences during constant polarities and transitional polarities. The directional patterns do not appear to be related to changes in intensity or susceptibility. These sequential patterns appear to be attributable to the behaviour of the geomagnetic dipole as the individual measurements average out secular variations on time-scales of up to 2-5 ka.

GA1.03/E/08-B2 0920

THE GERMAN ARCHAEOMAGNETIC SECULAR VARIATION CURVE

Elisabeth SCHNEPP (Institut für Geophysik, Herzberger Landstr. 180, 37075 Göttingen, Germany, email: Grubenhagen@t-online.de); Rudolf Pucher (Geowissenschaftliche Gemeinschaftsaufgaben, Postfach 510153, 30631 Hannover, Germany, email: R.Pucher@bgr.de)

The archaeomagnetic secular variation (SV) curve for Germany is based on recent palaeomagnetic measurements carried out on 36 archaeological sites in Germany and on a collection of further 103 published or unpublished archaeodirections also from the neighbouring countries. All sites are lo-cated in an area ranging from 3 to 15°E in geographical longitude and 47 to 57°N in latitude. The German sites have been investigated by using standard palaeomagnetic and rock mag-netic methods. Samples come mainly from various kilns which were preserved from the epoch between the early middle age and the 18th century, mainly dated with the radiocarbon or thermoluminescence method. Although, geographical and age distribution of the data set is still uneven, for the time interval 900 to 1800 AD six to 26 data points per 50 year interval can be used to calculate an average SV curve. This curve clearly deviates from the neighboured French or British archaeomagnetic SV master curves. The German curve shows a delay in time of up to 75 years and around 1300 AD the inclination was about 5° higher than in France and Britain. It seems that the SV pattern changed consid-erably from mediaeval to modern times in Europe. This feature will be clarified with paleomagnetic measurements on further six mediaeval kilns under investigation situated in the eastern part of Germany. Furthermore the archaeomagnetic SV curves were compared with historical magnetic data. The correlation is for the overlapping time interval of about 200 years is not satisfying, presumably because geographic areas taken for the archaeomagnetic SV curves are too large.

GA1.03/W/06-B2 0940

RELIABILITY OF RELATIVE PALAEOINTENSITY OF SEDIMENTS WITH STRONG CLIMATICALLY AFFECTED MAGNETISATION CHANGES

Maja HAAG (Institut für Geophysik, ETH-Hönggerberg, CH-8093 Zürich, Switzerland
Email: maja@mag.ig.erdw.ethz.ch)

A late Pleistocene deep-sea core taken in the Central Atlantic along the coast of Mauritania (W-Africa) shows large variations of magnetic properties, such as natural and anhysteretic remanent magnetisation (NRM, ARM), low field susceptibility (k) as well as their ratios NRM/k and ARM/k. These rock magnetic parameters coincide with rapid changes of the stable oxygen isotope ratio which indicate climate changes, i.e. correspond to glacial stage or substage boundaries. Warm periods mainly correspond to high magnetisation intensity and cold periods to low intensity. Such intensity variations are due to changes in chemistry and concentration of ferromagnetic minerals and thus normally hinder the determination of reliable measurements of relative palaeointensity of the Earth's magnetic field. Previous investigations established the boundary conditions for the maximum variation of the ferromagnetic minerals and related magnetic properties necessary for reliable relative palaeointensity measurements. The mineralogical variations of the present study are much above these limits. However, the NRM/ARM ratio which is mostly used for relative palaeointensity determinations varies differently with depth than the other parameters and therefore reflects to a lesser degree such mineral changes. The most prominent lows of the NRM/ARM ratio are observed at ca. 17 kyr, 35-40 kyr, 60-65 kyr, 90-120 kyr, 128-132 kyr, 150-155 kyr and 180-195 kyr. The minimal relative palaeointensity is at 185 kyr. The most distinguished highs are visible at ca. 45-52 kyr, 125 kyr, 135-145 kyr and at 220 kyr. The maximal relative palaeointensities are at 52

GA1.03/W/03-B2 1000

RELATIVE PALEOINTENSITY OF THE GEOMAGNETIC FIELD DURING BRUNHES CHRON RECORDED IN NORTH PACIFIC DEEP-SEA SEDIMENT CORES: ORBITAL FORCING?

Toshitsugu YAMAZAKI (Geological Survey of Japan, Tsukuba 305-8567, Japan,
e-mail: yamazaki@gsj.go.jp)

Relative paleointensity records of the geomagnetic field during the Brunhes Chron were obtained from two sediment cores in the North Pacific near the Hess Rise. The cores, taken below the carbonate compensation depth (CCD), showed an oxidized environment, and accompany little paleoclimatically induced lithological changes. Utilization of such sediments has the advantage of avoiding paleoclimatic contamination to relative paleointensity through rock-magnetic changes, although relatively slow sedimentation limits resolution. Homogeneity of magnetic mineralogy and magnetic grain size, which is prerequisite for sedimentary paleointensity, was thoroughly examined using various technique including low-temperature magnetometry, room-temperature hysteresis parameters, and S ratio. The IRM was used as a normalizer of the natural remanent magnetization (NRM). The appropriateness of the normalization was checked by the absence of correlation between the normalized intensity (NRM/IRM) and the normalizer (IRM). The relative paleointensity records obtained are in general similar to the dataset from the east and central equatorial Pacific [1, 2]. The average geomagnetic field intensity during the Brunhes Chron is not lower than the present as suggested previously [3]. Spectral analysis of the relative paleointensity showed significant power at the orbital eccentricity (100 kyr) frequency. The eccentricity frequency is not dominant in bulk magnetic properties. This suggests orbital forcing of geomagnetic field intensity.

GA1.03/W/05-B2 1040

LATE MATUYAMA GEOMAGNETIC FIELD BEHAVIOR AS RECORDED AT HIGH SEDIMENTATION RATE SITE IN THE NORTHWEST ATLANTIC

BRAD CLEMENT and Zhong Yang (Dept of Geology, Florida International University, Miami, FL email: clementb@fiu.edu); Gary Acton (Ocean Drilling Program, Texas A&M University, College Station, TX); Steve Lund (Dept. of Geology, University of Southern California, Los Angeles, California); Trevor Williams (Borehole Research, Department of Geology, University of Leicester, Leicester United Kingdom)

Recent results of 40Ar/39Ar dating of basalts suggest a more complicated polarity reversal pattern during the late Matuyama than previously accepted. Dating of lavas on Maui and on Tahiti has produced dates of normal polarity flows that have been interpreted as being significantly different from ages consistent with the Brunhes, Jaramillo or Cobb Mountain polarity intervals. If correct, these results indicate the presence of additional excursions or short normal polarity subchrons during the late Matuyama. The fact that the proposed short polarity intervals have not been widely recognized in stratigraphic records of field behavior means that they must be very short intervals if they are truly present.
Ocean Drilling Program Leg 172 recovered very high sedimentation rate upper Matuyama sequences at Sites 1060, 1061, located on the Blake Outer Ridge, and Site 1063, located on the Bermuda Rise. Sedimentation rates in these sequences range up to 25-30 m/m.y. providing very high resolution of the geomagnetic field during this time. The paleomagnetism of these intervals was measured by collecting U channel samples from the cores and measuring the U-channels at 1 cm intervals on pass-though cryogenic magnetometer. The results exhibit a very high degree of coherence between the different sites even though they are separated by more than 1000 km. The high resolution nature of these records makes it possible to place upper limits on the duration of the proposed new short polarity intervals that are not observed, assuming that these intervals are in fact, global features of the earth's magnetic field.

GA1.03/E/09-B2 1100

RELATIVE GEOMAGNETIC FIELD INTENSITY ACROSS THE JARAMILLO SUBCHRON IN SEDIMENTS FROM THE CALIFORNIA MARGIN (ODP LEG 167)

Roman LEONHARDT (Department of Geophysics, University of Munich, Theresienstr. 41, 80333 München, Germany, email: leon@rockmag.geophysik.uni-muenchen.de); Franz HEIDER (GFZ Potsdam, Telegrafenberg Haus C, 14473 Potsdam, Germany, email: fheider@gfz-potsdam.de); Akira Hayashida (Science and Engineering Research Institute, Doshisha University, Kyoto 610-0321, Japan, email: ahay@doshisha.ac.jp)

A sedimentary relative paleointensity record of the Jaramillo subchron was obtained at Site 1010 during the Ocean Drilling Program Leg 167 on the California margin. The demagnetization of the natural remanent magnetization of discrete samples revealed a vertical drilling overprint. Reversal tests on the characteristic remanent magnetization of the discrete samples showed that the drilling overprint had been removed successfully by alternating field demagnetization at 20~mT. Rock magnetic criteria for determining relative paleointensities are fulfilled. Normalization with various magnetic parameters yielded similar results and contributions from viscous remanent magnetization could not be detected. Several intensity features are detectable in the record of Site 1010, displaying a maximum in intensity shortly above the lower Jaramillo transition, a prominent local minimum in the middle of the subchron and a gradual decrease toward the upper Jaramillo reversal. A comparison of the record from the California margin with several other records of relative paleointensity across the Jaramillo subchron with different sedimentation rates and sediment composition shows reasonable agreement between the paleointensity patterns but also differences in amplitudes. The amplitude differences suggests an influence of post depositional magnetization processes which were not removed during normalization.

GA1.03/W/31-B2 1120

MAGNETOSTRATIGRAPHY AND RELATIVE PALEOINTENSITY OF PELAGIC SEDIMENTS AT ODP LEG 167 SITE 1010 OFF BAJA CALIFORNIA

Akira HAYASHIDA (Doshisha University, Kyo-Tanabe, Kyoto 610-0321, Japan; e-mail: ahay@doshisha.ac.jp); Kenneth L. Verosub (University of California, Davis); Franz Heider and Roman Leonhardt (Ludwig-Maximilians- Universitaet, Muenchen)

Sediments recovered from the most seaward site of the Baja Transect of the California Margin (ODP Leg 167) yielded a high fidelity magnetostratigraphic record spanning the last 6 m.y. Using a long-core cryogenic magnetometer, we made NRM measurements of 59 u-channel samples, which cover the interval from 0 to 78.5 mcd (meters composite depth) of the spliced section of Holes 1010C and 1010E. Stepwise AF demagnetization between 20 and 60 mT showed that the remanence is essentially composed of a single stable component, which was not affected by a coring-induced magnetization. The investigated section can be divided into at least 25 polarity intervals, which are assigned to the chrons from C3A.n2 to the Brunhes (C1n). The sedimentation rate was nearly constant at about 13 m/m.y., except for a reduction to 9 m/m.y. between 4 and 5 Ma. ARM and IRM measurements of the u-channels revealed that the sediments below 23 mcd exhibit sharp drops in magnetic concentration at several horizons, but the upper part has relatively uniform magnetic concentration, containing magnetite of pseudo-single domain size. The upper interval yielded consistent relative intensity records when normalized with ARM, IRM and shipboard susceptibility data. Several peaks in the relative intensity variations correspond to the drops in the S-ratio or to anomalous peaks in the IRM and magnetic susceptibility profiles, suggesting that the normalized intensity record is partly influenced by episodic changes in the flux of magnetic grains. The normalized intensity for the intervals younger than 1.2 Ma shows similarities with published paleointensity records from the equatorial Pacific, including results from ODP Leg 138. In particular, intensity minima at 0.05, 0.11, 0.18 and 0.29 Ma and those associated with the onset and termination of the Jaramillo Subchron are well correlated.

GA1.03/W/28-B2 1140

DETAILED RECORD OF PALEOMAGNETIC FIELD CHANGE FROM SEARLES LAKE, CALIFORNIA (2) THE GAUSS/MATUYAMA POLARITY REVERSAL

Jonathan M.G. GLEN (Earth Sciences Department, University of California, Santa Cruz, CA 5064, and Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709, email: jglen@bgc.org), Robert R.S. Coe (Earth Sciences Department, University of California, Santa Cruz, CA 95064, email: rcoe@earthsci.ucsc.edu), and Joseph C. Liddicoat (Environmental Sciences, Barnard College, NY 10027, email: jliddicoat@barnard.columbia.edu)

This new study of the Gauss/Matuyama transition from Searles Lake, CA conjoined with other records from the western US, provides interesting insights into the structure of the reversing magnetic field. The present study employs improved measurement and data reduction techniques, multiple parallel strings of samples, and a finer sampling interval than was used in the original study by Liddicoat (1982). Particularly crucial to this investigation was the use of overprint directions to reconstruct declinations, required because the core was rotary drilled. The results of this technique were corroborated by employing an independent method that uses anisotropy of magnetic susceptibility to resolve a sediment fabric: the fabric facilitated the alignment of core segments. The new record reveals that the main swing of the transition occurs over a significantly shorter time span than was found in the original study. In addition, it brings out several small scale variations that were absent in the old record, some of which take the form of relatively rapid jumps in direction that punctuate more steadily varying changes. This alternating steady and rapid field change is similar to behaviour observed in volcanic records, which argues that such behaviour is not merely an artefact of episodic volcanism. The Searles Lake record is strongly non-zonal, and is defined in the northern hemisphere by a swath of virtual geomagnetic poles (VGPs) stretching from northern Eurasia to west Africa and to the northwest Pacific. Glen et al. (1994) showed that a collection (spanning >15 my) of western North American transition and excursion records displays this same pattern, indicating that the VGP swath is a persistent feature of the transitional field. In addition, the compilation reveals that the swath extends into the southern hemisphere, outlining a region marked by an absence of poles that is centred on the Indian Ocean. The fact that this pattern is offset from a similar one seen in global compilations suggests that the persistent fields have a significant nondipolar component. Six additional records are now available, making the w.NA dataset perhaps the finest regional set of high resolution records consisting of both igneous and sedimentary records. The new records, which provide an important test of the existence of the VGP pattern, strongly support the findings that reveal the presence of persistent, long-term (>15 my) nondipolar transitional fields.

PALEOMAGNETIC FIELD BEHAVIOR 4

GA1.03/W/11-B2 1400

A DETAILED RECORD OF THE BRUNHES-MATUYAMA TRANSITION FROM A MARINE CLAY OF A 1700-M CORE OF OSAKA BAY, SOUTHWESTERN JAPAN

Dipak Kumar BISWAS (Graduate School of Science and Technology, Kobe University, Kobe 657-8501, Japan, E-mail: dipak@kobe-u.ac.jp); Masayuki Hyodo (Research Center for Inland Seas, Kobe University, Kobe 657-8501, Japan, E-mail: mhyodo@kobe-u.ac.jp)

A detailed record of the Brunhes-Matuyama transition in a marine clay of a 1700-m core from Osaka Bay, south-western Japan revealed 5 conspicuous reversal episodes: three predating and two post-dating. Using a reasonable constant accumulation rate of 1.4 mm/yr, the mid-ages (duration) of the predating episodes are estimated to be about 3100(420), 800(143), 340(130) yr before the reversal and the mid-ages(duration) of the two post-dating reversal episodes are estimated to be about 370(90) and 1200(220) yr after the reversal. Decrease in field intensity during the transition process was apparently started about 4.6 kyr before the reversal. Highest intensity decay by about 15-20 % of the original value was observed about 2.1 kyr before the reversal. Reversal occurred during a period when intensity was gradually recovering and at the reversal boundary, intensity was about 17 % of its original value. By about 1.2 kyr after the reversal, intensity returned to its original value. The duration of decay and recovery of field strength is about 5.8 kyr

GA1.03/W/10-B2 1420

A LATE HOLOCENE GEOMAGNETIC SECULAR VARIATION RECORD FROM ERHAI LAKE, SOUTHWEST CHINA

Masayuki HYODO (Research Center for Inland Seas, Kobe University, Kobe 657-8501, Japan, Email: mhyodo@kobe-u.ac.jp); Arata Yoshihara (University of Tokyo); Kenji Kashiwaya (Kanazawa University); Takashi Okimura (Kobe University); Toshiyuki Masuzawa (Nagoya University); Ryotaro Nomura, Shingo Tanaka (Kobe University); Tang Bang Xing, Liu Su Qing, and Liu Shi Jian (Chinese Academy of Sciences, Chengdu, China)

A secular variation record of the geomagnetic field direction for the last 6.5 kyr has been obtained from the magnetization of sediment cores in Erhai Lake, Southwest China. In order to make a comparison with this record, secular variation in east central China was investigated by combining magnetic field data from historical records of observations and archeomagnetic measurements since about 350BC. The secular variation in Erhai Lake shows features consistent with the combined record, except for the oldest three observed declination swings in Sian from 720-900AD. Many features of declination and inclination in China also occur in Japan. From 500 to 1000AD, declination was westerly ranging from about -20 to -5 in Erhai Lake, east central China, and Japan. The three declination data observed in Sian from 720-900AD, which are easterly-ranging from +5 to +15, are probably erroneous.

GA1.03/W/25-B2 1440

A 4-32 KYR BP PSV RECORD FROM LAKE BIWA, JAPAN: IMPRINTS OF AN EXCURSION AT 23000 YR BP

MOHAMMAD ALI (Geoscience Laboratory, Geological Survey of Pakistan., Shahzad Town, National Park Road, Islamabad, Pakistan., email: ali@gsl.sdnpk.undp.org); Y. Kuniko, H. Kitagawa, K. Takemura, A. Hayashida and M. Torii (email: torii@big.ous.ac.jp)

A paleomagnetic record of the geomagnetic field secular variation for the period of 4 to 32 ky bp. has been obtained from a single core sediment recovered from Lake Biwa, central Japan. A total of 615 discrete samples from the core show strong and stable remanence, which is carried by magnetite. Time constraint is provided by the nine radiocarbon age determinations of leaves & total organic carbon (TOC) and five known tephras from the core. Comparison of the top ~5000 years record with the respective period of the Holocene master PSV record shows good agreement of morphology. However the amplitudes are subdued in the present record owing relatively low sedimentation rate of about 40 cm per ky. Our inclination record agrees well in morphology and time frame with the paleomagnetic secular variation (PSV) record from marine sediments off Shikoku Island. Thus for having high resolution and record for both declinations and inclinations the present record could be used for reconstructing chronology of sedimentary records in southwest Japan. We have found anomaly in the direction around 23 ky bp. that has close resemblance with fine details of PSV and virtual geomagnetic poles (VGPs) looping with that of the Mono Lake excursion. Furthermore, correlation with other reported similar excursions around mid-latitude in the northern hemisphere indicate a possible westward drift of non-dipole field at the rate of 2.18 degrees per century.

GA1.03/W/17-B2 1500

HOLOCENE PALEOMAGNETIC SECULAR VARIATION: A MASTER CURVE FOR JAPAN

MOHAMMAD ALI (Geoscience Laboratory, Geological Survey of Pakistan, Shahzad Town, National Park Road, Islamabad, Pakistan., email: ali@gsl.sdnpk.undp.org)H. Oda, H. Kitagawa, A. Hayashida, K. Takemura and M. Torii, (email: torii@big.ous.ac.jp)

Master paleomagnetic secular variation (PSV) curves for different regions are required to date local sedimentary sequences and to use them as source data in geomagnetic modelling. There have been many attempts to develop such curves for Holocene around the world including Japan. The PSV over Japan remains a matter of discussion because of the large discrepancies found in the proposed curves. Recently a development of a composite PSV record from a site in Lake Biwa, central Japan provided a master curve for the Holocene. The composite PSV record based on a total of 1430 samples from three cores, which shows strong and stable remanence carried by pseudo-single-domain magnetite. Paleomagnetic records from the individual cores show little scattering of directions, and excellent correlation among them. The age model is based on two wide-spread tephra layers and nine radiocarbon dates. Our result shows that the declinations and inclinations are strikingly similar to the archeomagnetic data from southwest Japan for last 2000 years. Furthermore, on the basis of this record we are able to resolve the apparent discrepancies observed in so far proposed PSV curves from the region. We can therefore, reliably use the master curve for age estimation of other sedimentary sequences. The record also shows positive correlation with those from the Britain and the western America, suggesting dominance of dipole nature of geomagnetic field for the last 10,000 years.

GA1.03/W/12-B2 1520

PALEOMAGNETIC AND PALEOENVIRONMENTAL HOLOCENE-PLEISTOCENE RECORDS FROM ESCONDIDO LAKE (41° S 71°30'O), PATAGONIA-ARGENTINA

Claudia S. G. GOGORZA (IFAS-UNCPBA, Pinto 399, 7000 Tandil, Argentina; email: cgogorza@ifas.exa.unicen.edu.ar); Ana M. Sinito (CONICET-IFAS-UNCPBA, Pinto 399, 7000 Tandil, Argentina; email: asinito@ifas.exa.unicen.edu.ar)'; Juan F. Vilas and María E. Rodriguez (CONICET-Lab. D. Valencio-UBA C. Universitaria, P.2, 1428 Bs. As., Argentina; email: vilas@.glg.fcen.uba.ar); Héctor Nuñez and Juan M. Lirio (IAA, Cerrito 1248, Bs. As., Argentina; e-mail: nunez@siscor.bibnal.edu.ar)

This work describes the preliminary results of an investigation on sediments from Escondido Lake in south western Argentina. Four cores up to 12 m long were taken with a push-corer. About 1300 subsamples for paleomagnetic studies were obtained.The intensity and directions of the natural remanent magnetisation were measured using a 2G magnetometer. Isothermal remanent magnetisation curves were obtained using a pulse magnetiser. The directions of the stable remanent magnetisation were compared with previous results obtained from shorter corers from the same lake, extracted by a Mackereth corer. This comparison allowed evaluating the reliability of the results obtained with the push-corer.The sedimentary sequence shows different lithologies related to different environments; they are varves, with isolated clusters, grey clays with thin tephra layers, light brown clays with thicker tephra layers and dark brown clayey mud with abundant organic material. These lithologies have unlike magnetic behaviour.

GA1.03/E/04-B2 1600

DETAILED RECORDS OF RELATIVE PALEOINTENSITY VARIATIONS ACROSS THE LASCHAMP AND MONO LAKE GEOMAGNETIC EVENTS - IMPLICATIONS FOR A STRONGLY DYNAMIC GEOMAGNETIC FIELD

Norbert R. NOWACZYK (GeoForschungsZentrum Potsdam, Haus C, Telegrafenberg, D-14473 Potsdam, Germany, email: nowa@gfz-potsdam.de)

The Laschamp geomagnetic event is one of the most prominent features in magnetostratigraphic records from northern high latitudes. It could be verified in a region from 69°N, 20°W to 82°N, 110°E. The generally high NRM intensity and a homogenous magneto-mineralogy of the mainly lithogenic sediments of the Norwegian-Greenland Sea and the Arctic Ocean, in combination with minimum or even absent bioturbation, and very low contents of organic matter, that could cause dissolution of magnetite, are ideal conditions for recording high-frequency geomagnetic directional as well as intensity variations. An increasing number of AMS14C ages and oxygen isotope stratigraphic records now provide a sufficient time frame especially for the younger sediments in order to analyse the documented geomagnetic variations with respect to time. Together with the Mono Lake excursion and other directional fluctuations older than 50 ka the obtained records revealed a strongly dynamic character of the earth's magnetic field with pronounced lows in intensity linked with directional variations, i.e. excursions and polarity events. Only longer events, such as the Laschamp event, are characterized by an increase of relative paleointensity during the reversed state of the geomagnetic field vector.

GA1.03/E/03-B2 1620

A LATE HOLOCENE RECORD OF GEOMAGNETIC SECULAR VARIATIONS FROM LAGO DI MEZZANO, CENTRAL ITALY

Ute BRANDT, Norbert R. Nowaczyk and Jörg F.W. Negendank (GeoForschungsZentrum Potsdam, Telegrafenberg, D-14474 Potsdam, Germany, email: brandt@gfz potsdam.de) Antje Ramrath (Dept. of Geography, University of Western Australia, Nedlands, WA6907, Australia)

A high resolution record of geomagnetic secular variation back to 8000 years has been obtained from four, 1.1 m to 26.7 m long, sediment cores from Lago di Mezzano. Dating of the sediments is based on varve counting, interpolated sedimentation rates and AMS-14C-dating on bulk sediment. Intra lake correlation was carried out using the data of continuous high resolution susceptibility measurements. Magnetite in the pseudo-single range was identified as the main carrier of the remanence. AF-demagnetization of the NRM intensity revealed a high stability of the magnetization directions after removing a viscous overprint at 15 mT. The ChRM directions were determined by vector analysis of the demagnetization results. Correlating the records for the single cores with the archaeomagnetic secular variation records from Eastern Europe and France and the records for historical lavas in Sicily, the lock-in time for the sediments investigated could be estimated to be about 300 years. This corresponds with a lock-in depth of 70 cm. The stacked inclination record from Lago di Mezzano generally agrees with those from other sites in Europe, especially with the British mastercurve, the records from the Eifel maars, Germany and from Lake Aslikul, Russia.

GA1.03/E/05-B2 1640

A LACUSTRINE RECORD OF RELATIVE PALAEOINTENSITY FROM LAGO DI MEZZANO, CENTRAL ITALY

Ute BRANDT, Norbert R. Nowaczyk and Jörg F.W. Negendank (GeoForschungsZentrum Potsdam, Telegrafenberg, D-14474 Potsdam, Germany, email: brandt@gfz potsdam.de)

Two 27 and 17 m long sediment cores from Lago di Mezzano (central Italy) were subjected to detailed palaeo- and rockmagnetic investigations in order to obtain a high resolution record of relative palaeointensity for the last 31 ka. The investigations comprise magnetic susceptibility (kLF), ARM and IRM aquisition, hysteresis loops and backfield as well as thermomagnetic measurements. Magnetite in the pseudosingle to multidomain range was identified as the main carrier of the remanence. The relative palaeointensities were estimated normalizing the NRM intensities after demagnetization at 20 mT by kLF, the ARM intensities at the same demagnetization level and the SIRM, yielding not only slightly differences between the curves obtained by different methods, but also between the results of both cores. Those differences could clearly be attributed to changes in the relative grain size of the magnetite as reflected by the ratio kARM/SIRM due to sedimentation and dissolution processes. A new method was developed to eliminate the influence of the grain size of the remanence carrier in order to stack the records of relative palaeointensity obtained for both cores. The reconstructed palaeointensity record for Lago di Mezzano generally agrees with those from other sites around the globe.

PALEOMAGNETIC FIELD BEHAVIOR 5

GA1.03/W/22-B3 0900

A RIGOROUS STATISTICAL APPROACH TO PALEOMAGNETIC FIELD MODELLING

A.KHOKHLOV (International Institute of Earthquake Prediction Theory and Mathematical Geophysics 79, b2, Warshavskoe shosse 113556 Moscow, Russia, email: khokhlov@mitp.ru); G. Hulot. J. Carlut, V. Courtillot (Institut de Physique du Globe de Paris, 4, Place Jussieu, 75252, Paris, France, email: gh@ipgp.jussieu.fr)

Modern studies of the paleomagnetic field behaviour in the recent past (0-5 M.y), all rely on statistical analysis of mainly directional data randomly distributed in both time and space. Such studies are not as straightforward as one would wish. The data is quite sparse and ill distributed. In addition, directional parameters are non-linear and correlated functions of the local field. Up to now these difficulties have usually been ignored or taken into account by relying on some simplification (linearization, neglecting of internal correlation, etc). Such approximations can be justified only if the field behaves in a simple way but not if the field contains some amount of complexity. Whether this is the case, is a matter of current debate and it would therefore be desirable to propose a rigorous statistical approach to the problem. The purpose of the present paper is precisely to present such an approach based on standard tools in Information Theory. It is designed to test any statistical model of the paleomagnetic field against any given dataset of directional data, when the field model is being defined in terms of the statistical behaviour of its Gauss coefficients (along the lines pioneered by Constable and Parker in 1988). This approach can equally be used to test the models on a site by site basis, or on regional and global scales. Examples of tests will be provided.

GA1.03/W/02-B3 0920

CORRELATION FUNCTIONS BETWEEN HOLOCENE PALEOMAGNETIC SECULAR VARIATIONS TO SYNTHETIC SECULAR VARIATION CAUSED BY A DRIFTING RADIAL DIPOLE

Chizu ITOTA (Department of Management Information, Osaka College, Mihara, Osaka 587-8555, Japan, email: citota@osaka-c.ac.jp)

Correlation functions between Holocene paleomagnetic secular variation records from Japan, Britain and North America and synthetic secular variations caused by a single drifting radial dipole of various drifting rates were calculated. The radial dipole of fixed intensity located at the core surface was drifted westward along the equator. The synthetic data were obtained by the geocentric axial dipole and the radial dipole drifting from +90o to -90o to the longitude of the observing site. Drifting rates were set to 0.36 - 0.09o/yr. In the results, good correlations are observed between the paleomagnetic records and the synthetic data of some rates for the three sites. In Japan, a synthetic variation, which a radial dipole was pointing upward and its drifting rate was 0.2o/yr, showed a good correlation to the paleomagnetic record at 3250yrBP. In Britain, the variation, which a radial dipole was pointing downward and the rate was 0.3o/yr, was correlated well at 2250yrBP. Furthermore, in North America, the synthetic variation caused by an upward-pointing radial dipole with drifting rates both at 0.15o/yr and 0.3o/yr were correlated at 8500 and 6100, and 1850yrBPs, respectively. These results may indicate that a maximum or minimum focus of non-dipole field passes through the sites' meridian at the time when the maximum correlations were obtained. Unfortunately, peaks of these correlation functions among sites considered them as introduced by the same radial dipole were not observed.

GA1.03/W/16-B3 0940

PLUNGE AND AZIMUTH - AN ALTERNATIVE WAY TO REPRESENT THE DIRECTION OF THE MAGNETIC FIELD

Masaru KONO (Institute for the Study of the Earth's Interior, Okayama University, Misasa, Tottori-ken 682-0193)

Paleomagnetic directions are almost always described by inclination and declination. With the addition of the intensity, they form the spherical co-ordinates,which can easily be converted to any other co-ordinates, such as cartesian elements. As representations by any co-ordinate system is equivalent, inclination-declination representation is satisfactory to represent the direction of the field as any other co-ordinates. This does not apply when we have statistically distributed data, which is usual in paleomagnetism. As is well known, the mean of inclinations are always biased, while declination loses much significance when we are dealing with high-latitude data. Kono (PEPI, 1997) proposed the use of two alternative angles plunge and azimuth. While inclination and declination are defined with the coordinate axis in the vertical direction, plunge and azimuth have the co-ordinate axis in horizontally east west. As the field is quite unlikely to be near this co-ordinate axis, plunge and azimuth co-ordinates are not plagued by the singularity associated with the axis. The use of these two angles is particularly useful in paleosecular variation studies.

GA1.03/W/21-B3 1000

STATISTICAL ANALYSIS OF CENOZOIC VGP AND MODELS OF GEOMAGNETIC FIELD DURING POLARITY INVERTIONS

Mabel MENA (CONICET- Fac. de Cs. Exactas y Naturales- UBA- Ciudad Universitaria - Pab.2, 1428 Ciudad de Buenos Aires, Argentina, email: mena@tango.gl.fcen.uba.ar); Ana M. SINITO (CONICET-IFAS - UNCPBA - Pinto 399, 7000 Tandil, Argentina, email: asinito@ifas.exa.unicen.edu.ar)

To study the behaviour of the geomagnetic field during polarity transitions, an statistical analysis of cenozoic VGP positions was carried out. Data from the Blake event and all transitions from the last 5MA, registered in the Global Paleomagnetic Database (McElhinny &Lock, 1996) were analysed. Those VGP were obtained from volcanic and sedimentary rocks as well as deep marine sediments from sites spanning the 360° of longitude. To perform this analysis the VGPs were classified in 12 latitude stripes of 15° each. A test for uniform distribution of longitudes was rejected in most cases for the stripes between latitudes of+60° and -60°. An analysis of the shape of longitude distribution using eigen values shows that the stripes ranging between latitudes of +-30° have the best defined bipolar distribution with maximal around 300° and 120° meridians. A simple morphological model of geomagnetic field, consisting of two centred oblique dipole with magnetic poles at about 60oN, 120oE and 60oN, 300oE, respectively, which change their intensities sinusoidally and have an additional small precession around the mean position is postulated. This model suggests the existence of two equally stable states when both dipoles have the same polarity, and unstable states when dipoles have opposite polarities. The main implications of this model are that VGPs recording excursions describe similar paths and that the patches suggested by Hoffman agree with the pole positions of both dipoles.

GA1.03/W/26-B3 1040

DIPOLE NATURE OF PALEOMAGNETIC FIELD OBSERVED IN THE SHAPE OF ANGULAR DISPERSION

Hidefumi TANAKA (Faculty of Education, Kochi University, Kochi 780-8520, Japan, email: hidefumi@cc.kochi-u.ac.jp)

Paleomagnetic secular variation (PSV) from lavas shows latitude dependent variation of angular standard deviation (ASD); the higher the latitude, the smaller in field directions and the larger in VGP positions. On the other hand, distribution is distorted when field is transferred to pole or vice versa, as mathematical formulation was give by Cox (1970). Only a few authors, however, payed attention to the shape of distribution of paleomagnetic field.
This study applies a Bingham statistics to paleomagnetic dataset from lavas for the last 5 my, and studies the shape of distribution in field and VGP. When data of distinct site is examined, dataset from Hawaii clearly shows an oval shaped distribution of field directions, elongated along a plane of the meridian, while distribution of VGP is almost circular. This indicates that most of PSV at Hawaii was caused from a dipole wobble. This tendency is also observed in the combined data along a latitudinal band of lower latitude. Although this elongated shape in field distribution is not clear for most of distinct site data, anisotropy analysis of the distribution depict this feature at almost all sites.

GA1.03/W/34-B3 1100

CORRELATION BETBEEN VARIATION OF GEOMAGNETIC FIELD PALAEOINTENSITY AND THE EARTH'S ROTATION RATE IN THE PHANEROZOIC

V. P. APARIN (Inst. of Physics SB RAS, Krasnoyarsk, Russia, 660036, email: dir@iph.krasnoyarsk.su); V. T. Sarychev (Tomsk State University, 634050, Russia); M. V. Kiselev, N.Y. Romanova, V. V. Vilisov (All of Krasnoyarsk State University, 660071, Russia)

Phanerozoic time series of geomagnetic field palaeointensity (Ha) and angular rate of the Earth's rotation (W) were approximated by cubic splines and are underwent to spectral analyses by new modification of maximum entropy method. Cycle about 250 Myr is revealed in Ha(t) and W(t) variations. Cycle about 700 Myr is shown in the Earth's rotation. Negative correlation between Ha(t) and acceleration of the Earth's rotation suppose the existence of whole regulation mechanism of these two processes. Probably main contribution belongs here to mantle convection, which by means of plate kinematics change the Earth's rotation and geomagnetic field generation.

GA1.03/E/01-B3 1120

AN APPROACH TO REGIONALLY MODELLING THE GEOMAGNETIC FIELD FOR EUROPE FROM DIRECTIONAL ARCHAEOMAGNETIC DATA

J. Miquel TORTA, Lluis Gaya-Pique (Observatori de l'Ebre, CSIC, 43520 Roquetes, Tarragona, Spain, email: ebre.jmtorta@readysoft.es); Juan I. Nunez, Maria L. Osete (Departamento de Fisica de la Tierra, Astronomia y Astrofisica, Universidad Complutense de Madrid, email: juanig@eucmos.sim.ucm.es); Angelo De Santis (Istituto Nazionale di Geofisica, email: desantisag@ing750.ingrm.it)

The recent compilations of declination and inclination data obtained from baked archaeological materials offer an unprecedented opportunity for advances in the analysis of the spatial-temporal behavior of the ancient magnetic field. However, the temporal and, especially, the spatial distributions of these data are far from being uniform and they only allow for very low degree spherical harmonic models to be determined. In Europe, the density of these records is greater than anywhere else in the world, so that smaller scale features can be represented by means of an appropriate regional modelling scheme. The results from the few previously determined low-degree global models are used to provide the necessary boundary conditions to fill-in an adequate spherical cap region, and a time-varying spherical cap harmonic analysis has been attempted, first for the centuries bracketing the Roman Epoch, and afterwards from that epoch to recent. Geographical and age distribution of the data set is still very uneven but our results suggest that, at least for Europe, some of the nondipole archaeomagnetic field can be discriminated.

GA1.03/E/02-B3 1140

ON APPLICATION OF WAVELET ANALYSIS TO GEOMAGNETIC POLARITY TIME SERIES

Maxim RESHETNYAK, Vladimir PAVLOV (United Institute of the Physics of the Earth, Moscow, Russia, 123810, email: pavlov@uipe-ras.scgis.ru and rm@uipe.srcc.msu.su)

Usually, the analysis of the geomagnetic time scale reduces to investigation of the reversals frequency (e.g., Mazaud et al., 1983), or to distribution of the lengths of magnetozones of constant polarity proposed by Gallet & Hulot (1997). Nevertheless, the signal of polarity itself contains much more information, which can be useful for understanding of the geodynamo process nature. The difficulty of direct application of the Fourie or MEM analysis is concerned with the fact that the signal of polarity P is a step function: P(t)=+/- 1, and the traditional approaches leads to existence of artificial noise in the spectra. On contrary, the wavelet approach looks to be a good candidate for this purpose. We present the wavelet analysis of the geomagnetic polarity signal over the last 165Ma. Using the additional information about paleointensity of the magnetic field (Perrin & Shcherbakov, 1997), we distinguish the four different regimes of geomagnetic field generation. The scenario of the geodynamo system evolution in terms of aw-model (Pechersky et al., 1998) is discussed.

PALEOMAGNETIC FIELD BEHAVIOR 6

GA1.03/W/30-B3 1400

ARCHAEOINTENSITY DATA CORRECTION FROM GREEK CERAMICS

V.SPATHARAS1 and N.Jordanova2 1-(Dept.Of Geophysics. Aristotle University of Thessaloniki) 2-(Geophysical Institute, Bas, Bulgaria)

It is known that in an isotropic medium the direction of a remanent magnetization vector coincides with the direction of the ancient magnetic field. But in the case of a significant anisotropy, it is necessary to involve a correction factor in order to obtain the true direction of the ancient field. The causes of magnetic anisotropy of rocks have been summarized by Hrouda (1982) and are related, among others, to shape, lattice or magnetic domain alignment. It has been shown (Aitken et al., 1981) that ancient ceramics exhibit significant magnetic anisotropy due to the way in which they have been manufactured and explained by the "easy

plane" of magnetization. The detection of this anisotropy and the calculation of an "anisotropy factor" are of crucial importance during Thellier experiments aiming to the determination of the ancient geomagnetic field. Pottery as well as bricks anisotropy affect the direction and the intensity of the NRM. After Thellier's experiment for the definition of archaeointensity into 12 samples for which we obtained good results, we made an attempt to study the effect of the texture's anisotropy as well as to calculate the coefficient for the correction of the archaeointensity. The calculation of the anisotropy parameters as well as that of the magnetic susceptibility is done by the device of the K-bridge according in the methodology suggested by Jelinek (1977). Stephenson et al (1986) show that IRM and TRM anisotropy ellipsoids are of identical shape. We used this result to apply the method for correcting archaeointensity, proposed by Veitch et al. (1984). The rates of the parameter P' are high, those rates become bigger after Thellier's experiment (during the whole experiment, we studied the change of the magnetic susceptibility). For the studied collection the correction factor (f) varies from 0.90 to 1.05 for bricks and from 0.93 to 1.27 for pottery. The internal agreement among the archaeointensity results improves after applying the correction for anisotropy.

GA1.03/W/20-B3 1420

PALAEOMAGNETIC RECORDS WITHIN ISOTOPE STAGE 9 TRAVERTINES FROM BAD CANSTATT, GERMANY.

STEVE OPENSHAW, John Shaw, David Heslop (Geomagnetism Laboratory, Department of Earth Sciences, Oliver Lodge Laboratories, Peach Street, Liverpool, L69 7ZE. UK, email: steveo@liv.ac.uk); and Ulrich Hambach (Universitat zu Koln, Zulpicher Str 49a, D-50674 Koln, Germany, email: Uli.Hambach@uni-koeln.de).

Travertine is a calcium carbonate deposit produced when CaCO3 saturated groundwaters reach the open environment and precipitate hard crystalline carbonate through CO2 degassing. In temperate regions travertine deposition is thought to coincide with the warmer and wetter phases of glacial / interglacial cycles and in addition lamination within travertine deposits may represent seasonal climatic variation. We have begun a study of several travertine deposits in Germany including massive sheet deposits and a 30-40cm thick annually laminated deposit in a Roman water pipe representing around 200 years of continuous precipitation. We aim to develop magnetic characterisation parameters for both the magnetic recording processes and to enable palaeo-environmental reconstruction.
We present here preliminary palaeomagnetic results from a 26m thick deposit of travertine found in a quarry on a river terrace of the River Neckar at Bad Cannstatt, Stuttgart. TIMS uranium-series dating suggests deposition over the period of MIS stage 9 (300 kyr). The lower travertine is broken by three thin (~1m) loess layers which represent shorter periods of cooling and termination of travertine deposition. Alternating Field (AF) demagnetisation yields stable, single component remanence vectors which are easily measurable on a LN2 SQUID magnetometer despite being magnetically very weak (6-30 x10-8 Am2 kg-1).

GA1.03/W/14-B3 1440

A GEOMAGNETIC EXCURSION OBSERVED IN A TRAVERTINE-COMPLEX FROM STUTTGART - UNTERTUERKHEIM (GERMANY)

Jan REINDERS and Ulrich Hambach (Department of Geology, University of Cologne, Zuelpicher Str. 49 a, 50674 Cologne, Germany, email: jan.reinders@newmail.net)

The Biedermann-travertine is situated on a river Neckar terrace. U-series dating of the complex suggests that it grew from 109 to 101 ka bp with a rate of 0.91 mm/year (Frank et al. subm. Quat. Res.). Oriented samples were taken from a 7.5 thick section, and three 1.0 m thick parallel sections (2.5 cm average spacing). Rock magnetic investigations indicate that the mineral magnetic assemblage consists of varying relative amounts of maghemite and hematite. Alternating field demagnetization reveals a stable, characteristic remanent magnetization (ChRM) after 27mT. The high fidelity of the paleomagnetic signal is corroborated by the good correlation of the ChRM amongst parallel sections, laterally (contemporary) differing paleo-environmental conditions. The Biedermann-paleofield record (BM-PFR) suggests that a reversed stationary flux patch north of the observation site predominates from 105.0 - 102.0 ka bp. It culminates in an excursion of the geomagnetic field between 103.0 and 102.6 ka bp. A geomagnetic field model derived from the BM-PFR and literature data favours a regionally restricted efficiency of the reversed flux and puts forward transitional field models inhibiting a temporary predomination of non-dipole components.

GA1.03/W/09-B3 1520

PALEOMAGNETIC REVERSALS IN AN ARCHEAN BANDED IRON FORMATION AND POSSIBILITIES OF THEIR ORIGIN

Tadahiro HATAKEYAMA, Ikuro Sumita and Yozo Hamano (Univ.of Tokyo, Japan)

For an Archean banded iron formation (BIF) outcropped in the Cleaverville region (ca. 3.3Ga) of the Pilbara craton, north Western Australia, we have made paleomagnetic and rockmagnetic measurements and have obtained following results: (1) the main ferromagnetic mineral and remanence carrying mineral is hematite, (2) most of the specimens have single components of the natural remanence and (3) many paleomagnetic reversals were discovered. The smallest scale of the one magnetic polarity is less than the size of specimen; about 1cm, which is larger than the thickness of the visible bands ("mesobands") which is generally several millimeters. However, the paleomagnetic results from two columns 2m apart from each other show that the distribution of the magnetic polarities from these columns do not coincide but seem shifted. From these results two or more possibilities of the origin of the characteristic remanent magnetization can be considered; one is depositional origin; DRM, PDRM or CRM in the process of the deposition-diagenesis in the Archean era, the other is due to weathering (lateritization) where secondary CRM was acquired after the upheaval and long after the deposition. From the measurements of paleomagnetism and rockmagnetism, we discuss how we can constrain the origin of the remanent magnetization.

GA1.03/W/15-B3 1540

PALEOSECULAR VARIATION DURING THE KIAMAN REVERSED SUPERCHRON

P.P. KRUIVER, C.G. Langereis, M. J. Dekkers (Paleomagnetic Laboratory Fort Hoofddijk, Utrecht University, Budapestlaan 17, 3584 CD Utrecht, The Netherlands, e-mail: kruiver@geo.uu.nl)

The Permian red beds of Dôme de Barrot (Southern France) were deposited during the Kiaman Reversed Superchron near the paleoequator. The natural remanent magnetisation (NRM) of these sediments resides in hematite. It is very resistent against both alternating field and thermal demagnetisation. Thin section studies suggest that the hematite is of primary origin. The patterns and amplitudes observed in declination and inclination resemble those of present-day secular variation. The high magnitude of paleosecular variation (PSV) during a Superchron contrasts with current dynamo theories which suggest that the magnitude of PSV is argued to be less in the stationary mode of the geomagnetic field.

To verify secular variation during a Superchron, an accurate time control is required. This is hampered by the absence of fossils and the single polarity. However, the cyclic sedimentation pattern of red and purple layers provides control on duration, if we assume that these cycles are caused by climate (Milankovitch) forcing. We argue the probability of Milankovitch cycles in the ed beds on the basis of (spectral analyses of) sedimentological, magnetic and other data.

GA1.03/W/18-B3 1600

SHORT GEOMAGNETIC EVENT RECORDED IN CHINESE LOESS-SOIL SEQUENCES

Guo BIN (Institute of Geophysics, Chinese Academy of Sciences, Beijing 100101, China, email: guobin@mail.c-geos.ac.cn.); Lin Mian (Institute of mechanics, Chinese Academy of Sciences, Beijing 100080, China)

The nature of geomagnetic field behavior during polarity transitions is one of the most highly debated issues in modern geophysics. The detailed study of geomagnetic reversals and excursions has provided some insights on fluid motion in the Earth's core. Since the short geomagnetic event within the Jaramillo normal subchron had been discovered in the Wanganu Basin, New Zealand, the similar phenomena had also been uncovered in the Weinan and Jiuzhoutai, China. Its global nature and even their existence, however, are still deputed. Recently, the detailed rock magnetic and paleomagnetic investigations had been carried out in Chinese loess-paleosol sequences at Jinbian (37.4˚N, 108.8˚E), China. It has been shown that both loess and paleosol in the northern margin of the Chinese loess plateau can capture geomagnetic variation during the polarity transition, also that a reversal bounding the onset of a reversed-polarity zone within the Jaramillo normal subchron was recorded. Rock magnetic and paleomagnetic studies demonstrate that this short-term feature is geomagnetic signals, rather than artefacts. The relative paleointensity records determined also confirm that the weakest geomagnetic field intensity correspond to the short-term feature. Therefore, we conclude that this short-term feature is an independent geomagnetic event. The statistical analysis reveal that the VGP paths of the short geomagnetic event are predominantly situated in the longitudinal sector over the America continent and its antipodal longitudes, while the VGP paths of upper Jaramillo recorded in the same loess-paleosol sequence exhibits a tight cluster located at western Australia. It suggests that the transitional field is very complex, VGP paths for

SEPARATION OF INTERNAL AND EXTERNAL FIELD VARIATIONS

GA1.07/W/03-B2 0900

A PROBLEM IN USING SPHERICAL CAP HARMONIC ANALYSIS TO SEPARATE INTERNAL AND EXTERNAL FIELDS

Frank LOWES (Physics Department, University of Newcastle, Newcastle Upon Tyne NE1 7RU, UK, e-mail: f.j.lowes@ncl.ac.uk)

Spherical Cap Harmonic Analysis (SCHA) is useful when analysing data available only over a limited area on the Earth's surface, but it does have limitations when used for separation of the observed surface field into its parts of internal and external origin. Such separation involves (in effect if not explicitly) comparing the results of separate analyses of the horizontal and vertical parts of the field vector. In this context, analysing the horizontal component is essentially the same as making a least squares' fit to the scalar potential, while analysing the vertical component involves a least squares' fit to the radial derivative of the potential. However, even if all the field were of, say, purely internal origin, SCHA will give different solutions for the potential for these two situations, so a separation analysis would wrongly indicate the presence of a significant contribution of external origin. So in a real situation significant errors could be expected.
A simulation was done using a model of the surface Sq over a 50 degree polar cap. Although the total (internal + external) field was fitted to 0.1%, the separated internal/external fields had errors ranging from 10 to 40%. It is therefore doubtful if the results of such an analysis are very useful. This problem is not unique to SCHA, but will occur in any method which uses observations over only a small part of the surface.

GA1.07/W/05-B2 0920

DIFFERENTIAL VECTOR MAGNETOMETRY (DVM) - A NEW METHOD FOR REMOTE DETERMINATION OF MAGNETIC PROPERTIES OF ANOMALY SOURCES AND IMPROVED DRILL TARGETTING

David A. CLARK (CSIRO Exploration and Mining, PO Box 136, North Ryde NSW 1670, Australia, email: d.clark@syd.dem.csiro.au); Phillip W. Schmidt, David A. Coward and Mark P. Huddleston (all at CSIRO Exploration and Mining, PO Box 136, North Ryde, NSW 1670, Australia)

The local perturbation of the geomagnetic variations arising from a subsurface magnetic body can be determined by simultaneous monitoring of geomagnetic variations at two sites: one within the static magnetic anomaly associated with the body and another at a remote base station. Monitoring of all three field components at the on-anomaly and base stations allows the components of the second order gradient tensor of the anomalous pseudogravitational potential to be determined. This tensor depends only on the source geometry and the measurement location and is independent of the nature (remanent or induced), magnitude or direction of the source magnetisation. Without making any assumptions about source geometry or location, the Koenigsberger ratio (Q), the direction of remanence and the direction of total magnetisation can be obtained from the components of this tensor. This information can constrain magnetic modelling prior to drilling and remove a major source of ambiguity in magnetic interpretation. The direction to the centre of a compact source can be determined directly from diagonalisation of the tensor. Values of Q constrain the magnetic mineralogy of the source and the remanence direction can discriminate sources of different ages or geological histories. Thus the method can also alleviate the geological ambiguity that afflicts magnetic interpretation. Field trials of differential vector magnetometry (DVM) at several sites, including the Tallawang magnetite deposit, New South Wales, have demonstrated the validity of the proposed in situ method. However, a number of technical difficulties must be resolved before this method can be used routinely.

GA1.07/W/01-B2 0940

SEPARATION OF THE MAGNETIC FIELD INTO EXTERNAL AND INTERNAL PARTS AT THE SURFACE OF PROLATE SPHEROID

ZVEREVA Tatjana I (Institute of Terrestrial Magnetizm, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, Russia, email: golovkov@izmiran.rssi.ru)

We solve the problem of separation of a magnetic field, measured at the surface of a body having the special form of a prolate spheroid, into two parts, one of which is external with respect to this body while the other is its own magnetic field. This problem is considered in the orthogonal co-ordinate system of a prolate spheroid where this body is one of co-ordinate surfaces. By presenting of the solution of the Laplace equation in this co-ordinate system in the form of an infinite series of expansion in terms of spheroidal functions, separation of the field into the external and internal parts is carried out formally, but mathematically correctly, without dwelling on its origin. The results may be used in magnetic cartography and magnetic navigation.

GA1.07/E/02-B2 1000

PRINCIPAL COMPONENTS ANALYSIS OF THE (INTERMITTENT) GLOBAL GEOMAGNETIC OBSERVATORY ARRAY

Gary D. EGBERT (College of Oceanic and Atmospheric Sciences, Oregon State University, 104 Ocean. Admin. Bldg, Corvallis, OR 97331, e-mail: egbert@oce.orst.edu)

Magnetometer arrays are inevitably sparse and/or of limited spatial extent. As a result, direct application of formulae from classical potential theory to separate the observed fields into internal and external components is generally problematic. We discuss a statistical approach to this problem based on generalised (multivariate) transfer function methods. In essence, the idea is to take advantage of the very different properties of internal and external sources. Internal sources are inhomogeneous, and are largely determined by conductivity variations of fixed geometry inside the earth. Geometries of external sources are generally more transient, and, in a time averaged sense, often exhibit some degree of statistical homogeneity. (E.g., the statistical properties of external parts of daily variations should be approximately independent of absolute longitude.) Without making any specific assumptions about internal and external sources, a principal components (or EOF) analysis can generally be used to project the observed data (internal+external) onto a small set "array modes". This initial step greatly facilitates separation, by reducing noise and allowing us to more reasonably impose a priori constraints on the external portion of the projected data. These constraints can be hard (assuming a simple form for external sources) or soft (assuming a semi-homogeneous statistical model for sources). We consider application of these ideas to the global array of geomagnetic observatories. To allow for the many data gaps in the observatory record we have developed specialised EOF methods. These allow us to provide a characterisation of statistically averaged global source geometries which makes use of a large part of the historical observatory data base. Application to geomagnetic induction studies of deep mantle conductivity will be considered.

GA1.07/E/01-B2 1020

ELECTROMAGNETIC RESPONSE AND SOURCE FIELD CHARACTERISITATION FROM MERIDIONAL CHAIN OF GEOMAGNETIC OBSERVATORIES

B.R. ARORA (Indian Institute of Geomagnetism, Colaba, Mumbai 400 005, India,
e-mail: bra@iig.iigm.res.in)

With a purpose to estimate electromagnetic (EM) response of the Earth at long periods, the space-time characteristics of natural EM sources are established by subjecting the geomagnetic field variations for a dense chain of geomagnetic observatories along the Indian-Russian sector to Singular Spectrum Analysis and Principal Component Analysis. The alignment of geomagnetic observatories along a single meridian, extending from equator to the pole, is used to test the assumption of zonal morphology for each principal component describing the spatial structure of the fields at a given period. Besides facilitating separation of long period geomagtnetic field into external and internal parts, the approach helps to isolate sources not compatible with zonal approximation. The possible contamination of the EM response function from sources other than zonal terms, is evidenced by the marked differences in the single-station response function using both the Z:Y and Z:H. The contamination resulting from the near-surface conductivity structures also hamper the reliable estimation of the EM response functions. The results show that effects of localised sources and contimination from lateral conductivity contrast, if not guarded for, lead to totally spurious model of electrical conductivity structure. The significance of establishing the source characteristics in deriving EM response free from the source field structure and lateral conductivity contimination is discussed.

GA1.07/W/04-B2 1100

USES OF SATELLITE DATA FOR SEPARATION OF INTERNAL AND EXTERNAL SOURCES IN GEOMAGNETIC FIELD MODELLING

Benoit LANGLAIS, Pascale Ultré-Guérard and Mioara Mandea Alexandrescu (Institut de Physique du Globe de Paris 4 Place Jussieu 75252 Paris Cedex 05 France
email: langlais, ultre, mioara@ipgp.jussieu.fr)

Satellite measurements are an important source of data for improving our knowledge of the Earth's magnetic field. OErsted has been launched in January 1999 and several others are planned in the next few years (e.g. SAC-C, CHAMP). There have been no reliable vector measurements by satellite since MAGSAT, which operated for six months in 1979/1980 with a tri-axial magnetometer. In this study we compute geomagnetic field models by using MAGSAT data together with hourly means values of observatories for the same epoch. In this kind of study, the crucial point is the separation of external sources, i.e. ionospheric and the magnetospheric fields from internal ones. Indeed, satellite measurements are made above ionospheric currents, which can then be described as internal sources. Furthermore, internal and external fields are not fixed by the same parameters: the internal part is fixed by geographic location, while the external part is fixed by both dipole and sun location. So we have to take into account the periodic variations of the external fields (from diurnal to yearly variations). A geomagnetic potential is used in the spherical harmonic expansion in order to separate the ionospheric contribution from the internal (core and crust) and the external (magnetosphere) sources. We discuss of quiet-time data selection, using geomagnetic activity indices, and especially those computed by sectors of longitude. Moreover, we show that the magnetospheric contribution and the corresponding induced effects can be estimated by using a linear relationship between the first degree Gauss coefficients of the external and internal field, and the Dst indices.

GA1.07/P/01-B2 1120

SOURCE CONSIDERATIONS FOR ELECTROMAGNETIC RESPONSE ESTIMATES WITH GEOMAGNETIC SURFACE DATA

Ulrich SCHMUCKER (Geophysikalisches Institut, Herzberger Landstr. 180, D-37075 Göttingen)

While in magnetotellurics source effects are of second order and thus are usually ignored, knowledge about the inducing source geometry may be essential for response estimates from geomagnetic observations alone. Three alternative methods exist for deriving such responses:
(i)The source geometry is given a single-term description, in spherical or Fourier spatial harmonics, and responses are derived from local Z:H or Z:D ratios.
(ii)A single or multiple-term description is used in conjunction with a separation of external and internal parts, yielding from their relationship global response estimates.
(iii) Ideally, source and response informations should be derived in a single computational process which on a regional scale can be achieved with the gradient method, based on relations between local Z and spatial derivatives of H and D. As a rule, in this third approach no attention is given to the implications of the inserted spatial derivatives with respect to meaningful source geometries.
Each of the three approaches has its own problems, In local responses the observed H:D relation may be in conflict with the single-term description, in global responses information about radially symmetric Earth models may be mixed with that of large-scale deviations from such symmetry and the same applies on a regional scale to results obtained with the gradient method. - An attempt is made to interconnect the approaches. Since separations into external parts are without any restrictive assumptions (except that the source is tangential-electric and quasi-stationary) and since the derivation of external parts is a fairly stable process, the external source geometry of various well defined types of variations are combined with first order layered Earth models to derive H:D relations and spatial gradients of H and D, which are consistent with such sources and of sufficient general validity to be utilised, when no global data are available for a separation analysis.

GA1.07/E/03-B2 1140

A ZONALLY DOMINANT STOCHASTIC PROCESS ON THE SPHERE FOR STATISTICAL MODELING OF LONG-PERIOD EXTERNAL SOURCE FIELDS

Gary D. EGBERT (College of Oceanic and Atmospheric Sciences, Oregon State University, 104 Ocean. Admin. Bldg, Corvallis, OR 97331, e-mail: egbert@oce.orst.edu)

Long period (T > 1 day) external magnetic source fields are dominantly (but not exactly) zonal, and fluctuate over time. I consider here stochastic processes on the sphere suitable for modelling the spatial behaviour of these fields. By constructing the process as a superposition of purely zonal random processes with randomly varying axes of symmetry, an inhomogeneous (but not-overly parameterised) random process on the sphere can be generated which has many properties in common with the external source variations observed on the real earth. The random process (which is motivated by the observation that there is no single, well-defined axis of symmetry for external source processes), is zonally dominant, but not exactly zonal; the most extreme departures from zonal dominance occur at high latitudes, around the mean symmetry axis. I will discuss procedures for fitting free model parameters, and the adequacy of the model in describing the spatial statistics of hourly mean observatory data. Application of the model as prior information to improve separation of internal and external field components will be discussed.

GA1.07/W/06-B2 1200

SQ STUDIES ON A GLOBAL SCALE - INDUCTION IN A 3D EARTH

GRAMMATIKA, Nafsika (UBO-IVEM, UMR Domaines Oceaniques, Place Nicolas Copernic, Plouzane Email: naphsica@sdt.univ-brest.fr)

The first global analysis of the solar magnetic tide was that of Schuster(1889) based on a spherical harmonic analysis of magnetic daily variations. This method assumes that the daily variation is dependent on local time alone, its relation to the universal time UT being identified to the dependence on longitude. With the aim of describing the Sq field globally as closely as possible, we discuss two different methods for the determination of the spherical harmonic coefficients. Observatory data acquired during the period of the Magsat mission is used. In one method, the spherical harmonic coefficients are estimated by a singular value decomposition method. In the second method, the spherical harmonic coefficients are estimated using a MCMC (Monte Carlo Markov Chain) method. In the latter, the result is described in terms of a posteriori probability density function of the coefficients which is the invariant probability of the Markov chain. It is estimated by means of the average of the transition probabilities of the Markov Chain. The internal field induced by the estimated Sq variation is calculated, at Magsat local times and for a selected range of Magsat altitudes, using a heterogeneous earth model, dominated by the electrical conductivity contrast between the oceans and the continents. The calculated total field is compared to Magsat observations.

GA1.07/W/07-B2 1220

SPHERICAL CAP HARMONICS ANALYSIS OF GEOMAGNETIC VARIATIONS OVER HIGH LATITUDES

Irina A. Burdelnaya, Vladimir GOLOVKOV and Tatjana I. Zvereva (all at Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, Russia, e-mail: golovkov@izmiran.rssi.ru); Vladimir O Papitashvili*, O Rasmussen, and P Stauning (all at Danish Meteorological Institute, Lyngbyvej 100, DK-2100, Copenhagen, Denmark,
e-mail: vp@dmi.dk; * also at SPRL, University of Michigan)

The complexity of ionospheric current systems and insufficient network of polar magnetic observatories makes difficult to model magnetic variations at high latitudes. Combining observatory data with the low-altitude satellite surveys, researchers are able, at least, to obtain realistic distributions of high latitude magnetic variations and then apply various techniques for their modelling. The proposed algorithm for that kind of modelling is a two-step approach. First, the 1-min data from magnetic observatories are utilised in the framework of the Natural Orthogonal Component (NOC) algebra. Then the obtained models of magnetic variations for each observatory are subjected to the Spherical Cap Harmonics Analysis (SCHA) together with existed magnetic satellite data. Presented examples of analysis of the polar cap observatory data and MAGSAT magnetic survey show high resolution of the proposed technique in describing high latitude magnetic variations produced by different current systems. Application of the technique to the analysis of Orsted magnetic satellite data are also discussed.

DECOMPOSITION OF MAGNETIC ANOMALIES ALONG SOUTH CHINA SEA GEOSCIENCE TRANSECT BY WAVELET TRANSFORM

Yang WANG (Lab. for Geothermics, Institute of Geology, Chinese Academy of Sciences, P.O.Box 9825, Beijing 100029, China, email: thalassa@263.net)

The regional magnetic anomalies provide information about magnetic properties of the crust. However, magnetic fields are superposition of some components which correspond to different scales, patterns, and buried depths of sources within the crust. It is necessary to decompose magnetic field into their components in order to identify magnetic features of crust on different scales. Numerical tests have shown that the wavelet transform is a powerful tool for decomposition of regional potential field. According to the principle of multi-scale analysis, a signal function can be decomposed as the sum of wavelet detail function (D1) and base function (A1); then we can decompose the base function A1 into second order detail function (D2) and second order base function (A2), and so on. Finally we can obtain the details of signal function in different scales. Using the technique of multi-scale analysis, we decompose the magnetic anomalies along South China Sea Geoscience Transect, which extends from Guangzhou to Palawan, into multi-scale components. The original data comes from the 500 km long oceanic crust segment of the Transect. The decomposition produces a series of magnetic anomalies profile related to different scales. Among them, the low order details of the wavelet transform (e.g. D1, D2 etc.) correspond to magnetic feature of small space scale, and the high order details (e.g. D5, D6 etc.) is related to the feature of large scale. We find that there is a ~100 km wavelength structure of the third order wavelet details, which correspond to shallow magnetic layer (oceanic layer 2A). The high order base function of wavelet transform (e.g. A6) reflects the regional trend of anomalies, which change from negative in north to positive in south. These negative anomalies in the north part is caused by deep magnetic source which is the relics of continental crust, and those positive anomalies in the middle and south part is originated by deep mafic magma chambers which were products of sea floor expanding. Furthermore, the relative high positive anomalies in south are possibly superposed by sea mounts located in there.

INTERNAL PART OF THE GEOMAGNETIC SQ FIELD

Masahiko TAKEDA (Data Analysis Center for Geomanetism and Space Magnetism, Graduate school of Science, Kyoto University Kyoto 606-8501, Japan, e-mail: takeda@kugi.kyoto-u.ac.jp)

Internal part of the geomagnetic Sq field has long been used to study the conductivity of the upper mantle. In the present study, spherical harmonics analysis was applied to the geomagnetic Sq field for the several years. The monthly averaged values of the internal and external parts are used to the estimation of the conductivity distribution and its stability of the result. Effect of the currents induced in the ocean will be also discussed.

AN ASTRONOMICAL POLARITY TIME SCALE FOR THE MIDDLE MIOCENE BASED ON A CONTINENTAL SUCCESSION (CALATAYUD BASIN, N.E. SPAIN)

H. Abdul Aziz, F.J. Hilgen, W. KRIJGSMAN, E. Sanz, J.P. Calvo, M. Hoyos (Faculty of Earth Sciences, Utrecht University, Utrecht, The Netherlands, Email: krijgsma@geo.uu.nl)

In the vicinity of Orera village (Calatayud Basin, NE Spain), an extraordinary cyclic succession of distal alluvial fan-floodplain, lacustrine and palustrine sediments of middle Miocene age is developed. The sections comprise grey, occasionally red, clays and dolomitic marls alternating with white palustrine carbonates. In the succession, sedimentary cycles can be recognised at four different scales varying from basic small-scale cycles up to large-scale cycle patterns. Cyclostratigraphy and magnetostratigraphy of several subsections were used to construct the composite record. The magnetostratigraphy was correlated to the Geomagnetic Polarity Time Scale (GPTS) of Cande & Kent (CK95), providing an age of 10.7 to 12.8 Ma for the entire succession.
Colour measurements of the sedimentary cycles proved an excellent tool for an objective recognition of these different scales of sedimentary cycles. Spectral analysis of the colour data set resulted in several peaks with frequencies similar to the periodicity of earth's orbital parameters. The average periodicity of the basic small-scale cycles arrives at about 23 kyr implying that these cycles are related to the earth's orbital cycle of precession. The large-scale cycles, characterised by the intervals of well developed small-scale cycles with distinct carbonate beds alternated with more clay-rich with less well defined small-scale cycles, are related to the 100 and 400 kyr eccentricity cycles. The sedimentary cycles were correlated to the eccentricity, precession and summer insolation curves of Laskar 93, thereby assuming that the carbonates represent higher lake levels and thus correspond to precession minima and eccentricity maxima. This correlation provides astronomical ages for the individual sedimentary cycles and for the polarity reversals whereby the latter results in an extension of the Astronomical Polarity Time Scale (APTS) into the middle Miocene.

GA1.15/W/01-B4 **1415**

THE TIMING OF REVERSALS IN VARIOUS MIOCENE RED BEDS

P.P. KRUIVER, W. Krijgsman, C.G. Langereis, M. J. Dekkers (Paleomagnetic Laboratory Fort Hoofddijk, Utrecht University, Budapestlaan 17, 3584 CD Utrecht, The Netherlands, e-mail: kruiver@geo.uu.nl)

In Spain extensive Miocene continental sections are present, of which an important part consists of red beds. The sedimentation patterns in these sections appear to be cyclic and are driven by Milankovitch forcing. Therefore, these sections are extremely suitable for comparison of Milankovitch cyclicity between the continental and the marine realm. Moreover, these sections provide excellent means for the extension of the Astronomical Polarity Time Scale (APTS). We have studied two continental sections from different sedimentary environments, with emphasis on the timing of the acquisition of the natural remanent magnetisation (NRM). The Librilla section (southern Spain) consists of an alternation of red (fan delta) and grey (lacustrine) sediments. The La Gloria section (central Spain) consists of red (flood plain) deposits with a regular alternation of clay and caliche rich beds. The interpretation of the magnetic signal is not always straightforward. In a large interval of Librilla the grey lithology has a reversed polarity whereas the red lithology displays normal polarity. We interpret the reversed polarity as a complete overprint related to the Messinian salinity crisis. The overprinting occurred long after deposition of the sediment. In the red bed section of La Gloria one polarity reversal (C5n to C4Ar) is investigated in detail. The polarity transition is recorded by different magnetic minerals at different depths. The NRM displays three components. At least one of these components is interpreted as a diagenetic overprint. The overprinting was effective on a much shorter time scale than in Librilla. In the light of magnetostratigraphy the error in dating is small for La Gloria. However, the error in timing of the reversals in Librilla would be severe and would seriously distort the calibration of the APTS.

STRATIGRAPHY AND PALAEOMAGNETISM OF A 2.8 KM LAVA SUCCESSION IN CENTRAL N ICELAND

Bjorn S. Hardarson and Malcolm S. PRINGLE (both at Scottish Universities Research and Reactor Centre, Scottish Enterprise Technology Park, East Kilbride, G75 0QF, UK, e-mail: bjorn@glg.ed.ac.uk, m.pringle@surrc.gla.ac.uk); Leo Kristjansson (Geophysics Division, Science Institute, University of Iceland, Hagi, Hofsvallagata 53, 107 Reykjavik, Iceland, e-mail: leo@raunvis.hi.is); Agust Gudmundsson (AGVST Geological Services, Armuli 4, 108 Reykjavik, Iceland); Haukur Johannesson (Icelandic Institute of Natural History, Hlemmur, 101 Reykjavik, Iceland, e-mail: haukur@nattfs.is)

We have carried out detailed geological and magnetic mapping of a lava pile in Eyjafjardardalur and OExnadalur in central N Iceland. The succession consists of 7 overlapping profiles comprising tholeiitic lava flows (olivine basalt through to rhyolite in composition) and interbedded sediments representing a continuous 2800 m (235 lava flows) geological record. The sediments generally indicate warm climate which became colder at the top of the succession. Preliminary radiometric data, using 40Ar-39Ar incremental heating analyses on whole-rock cores show that the lavas were erupted from about 8.9 to less than 4.8 m.y. ago which corresponds to an accumulation rate of about 700m/m.y. This is a significantly slower rate than the 4000m/m.y. observed in the upper part of a 5 km lava succession located immediately below the one reported here (Saemundsson et. al., J.Geophys. Res., 85, 3628-3646, 1980). Combined geomagnetic polarity measurements and radiometric data imply that the geological record in the study area embraces the polarity time scale between C4An and C3n,3n (Sidufjall) and our data indicate that at least 16 Normal Polarity Chrons, Subchrons (and possibly excursions) may have occurred during this period. This exceeds the number of reversals generally accepted. We hope to solve some of these discrepancies by detailed 40Ar-39Ar analysis of transitional lavas in the succession.

MESSINIAN ASTROCHRONOLOGY: THE SOLUTION TO AN OLD PROBLEM

W. KRIJGSMAN, F.J. Hilgen, I. Raffi, F.J. Sierro, D.S. Wilson (Faculty of Earth Sciences, Utrecht University, Utrecht, The Netherlands, Email: krijgsma@geo.uu.nl)

Recently, we established an astronomical polarity time scale (APTS) for the Late Miocene (6.7-9.7) based on cyclically bedded sequences in the Mediterranean. The astronomical ages of the Messinian polarity reversals are much older (up to 166 kyr) than expected from CK95. Because the previous APTS covered the last 5.3 m.y., we still have a "Messinian gap" from 5.3 to 6.7 Ma. This gap is caused by the notoriously complex history of the Mediterranean during the so-called "Messinian salinity crisis" and the deposition of less-favourable sediments (diatomites and evaporites) during this time interval.
However, most of these Messinian sediments display a very clear sedimentary cyclicity what makes them especially suitable for cyclostratigraphic calibration to the astronomical curves. Field observations indicate that the cyclicity in the Messinian diatomites and evaporites are related to precession/insolation with an average periodicity of 21 kyr. We will present the results of our detailed integrated stratigraphic studies on various sections located throughout the Mediterranean. This will close the "Messinian gap" and, for the first time, provide an accurate and reliable time frame for the Mediterranean Messinian in which several important palaeoceanographic and tectonic events are now accurately dated.

GA1.15/W/04-B4 **1500**

APPLICATION OF HIGH-RESOLUTION DATING OF DIFFERENT LACUSTRINE ENVIRONMENTS

Nicole VAN VUGT, Cor Langereis, Joris Steenbrink (Faculty of Earth Sciences, Utrecht University, Budapestlaan 4, 3584 CD Utrecht, the Netherlands, e-mail: vanvugt@geo.uu.nl)

Study of the timing of cyclic environmental changes or bed-to-bed comparison of different sedimentary settings over hundreds of kilometers has become possible using high-resolution dating based on combination of magneto- and cyclostratigraphy. We compare three coal-bearing lacustrine basin fills: the Lower Pliocene (Gilbert) lignite/carbonate system of Ptolemais (N. Greece); the time-equivalent lignite/detrital system of Lupoaia (Romania); and the Pleistocene (Brunhes) lignite/detrital system of Megalopolis (S. Greece). All these sequences have been dated using biostratigraphy, magnetostratigraphy, cyclostratigraphy and, in two cases, 40Ar/39Ar dating. The Megalopolis sequence is dominated by eccentricity, as are the marine Brunhes archives from both the Atlantic and the Pacific, where the ice ages were registered during eccentricity minima. The Pliocene lithological cycles of Ptolemais are forced by precession, but unlike the Mediterranean reference section of the same age (Rossello composite), influence of eccentricity is virtually absent. In the parallel Lupoaia section, however, eccentricity controls the occurrence of cyclic coal seams, with precession only playing a minor role. Strikingly, the Lupoaia and Megalopolis deposits were formed in similar environments. Certain lacustrine sedimentary environments are apparently more influenced by eccentricity, while others are more susceptible to precessional forcing. Similar as for different marine basins, e.g. the precession dominance in the Mediterranean at times when obliquity is the main driving force behind the Atlantic and Pacific cycles.

GA1.15/E/04-B4 1515

THE LOCATION OF THE KAEANA POLARITY CHRON

E. HERRERO-BERVERA (Hawaii Institute of Geophysics, University of Hawaii, Honolulu Hl 96822, USA. E-mail: herrero@soest.hawaii.edu); D.H. Tarling (Geological Sciences, University, Plymouth PL4 8AA, UK. E-mail: d.tarling@plymouth.ac.uk)

There is some confusion about where the Kaeana Reversed Polarity chron was originally identified on Oahu, Hawaii. Re-examination of the available records suggest that one of the key radiometrically dated sites may well have been in a different part of the Waianaea Series. However, the original quarry site cited in the original naming of the chron is now under-water and the surrounding rocks are of normal polarity, overlain by rocks of reversed polarity. On the basis of re-evaluation of the earlier sparse studies, a detailed sampling campaign of several sequences in the Waianaea Fromation suggests that the transition from normal to reversed polarity was rapid, relative to the eruption rate, usually comprising of less than two lavas. The results from these sequences are only now providing sufficient data for magnetostratigraphic zonation of this Formation.

GA1.15/P/01-B4 1630

AR40-AR39 DATING OF TRANSITIONAL LAVAS AT TWO POLARITY BOUNDARIES IN THE SKARDSHEIDI AND AKRAFJALL MOUNTAINS, SW-ICELAND

Leo KRISTJANSSON (Geophysics Division, Science Institute, University of Iceland, Hagi, Hofsvallagata 53, 107 Reykjavik, Iceland, email: leo@raunvis.hi.is); Malcolm S. Pringle and Björn S.Hardarson (both at Scottish Universities Research and Reactor Centre, Scottish Enterprise Technology Park, East Kilbride, G75 OQF, U.K., email: m.pringle@surrc.gla.ac.uk and bjorn@glg.ed.ac.uk); Agust Gudmundsson (AGVST Geological Services, Armuli 4, 108 Reykjavik, Iceland)

We have obtained radiometric dates on lava flows at two polarity zone boundaries in the lava pile of SW- Iceland, by using 4OAr-39Ar incremental heating analysis. One location is in the NE part of Mt. Skardsheidi where previous paleomagnetic laboratory measurements showed that ten transitional flows (units SH 9-18 in Kristjansson and Sigurgeirsson, J. Geomag. Geoel. 1993) occur at a R-N boundary. Duplicate age determinations on a sample from flow SH 12 yield a weighted mean of 3.613 +/- 0.058 M.y., and flow SH 19 similarly yields a mean age of 3.612 +/- 0.039 M.y. We have now sampled over 100 lavas in two profiles on the S side of Skardsheidi for paleomagnetic measurements; in these the number of transitional flows at the same R-N boundary is one and three respectively. Some other reversals and excursions are also recorded in Skardsheidi.
Our other location is in Mt. Akrafjall which lies about 20 km south-west of Skardsheidi and is at a similar stratigraphic level. In the profile FA (Kristjansson et al., J. Geophys. 1980) in Akrafjall intermediate directions are not found at a R-N polarity zone boundary which is correlated with the one in profile SH mentioned above, but four flows FA 45-48 with a cluster of low-latitude virtual poles are found at the overlying N-R zone boundary. The weighted mean age of the units FA 46 and 47 which were measured in duplicate, is 3.285 +/- 0.018 M.y. Our results agree well with other recent estimates of the ages of the Gilbert-Gauss and Lower Mammoth transitions.

GA1.15/E/06-B4 1645

40AR/39AR AGES AND PALAEOMAGNETIC DATA FROM CERRO FRAILE, ARGENTINA: FURTHER CONSTRAINTS ON TIMING OF REVERSALS DURING THE MATUYAMA CHRON

Bradley Singer (Department of Geology and Geophysics, University of Wisconsin, Madison, WI 53706, USA, e-mail: bsinger@geology.wisc.edu); Laurie BROWN (Department of Geosciences, University of Massachusetts, email: lbrown@geo.umass.edu); Hervi Guillou (Centre des Faibles Radioactivitis, CEA/CNRS); Jorge Rabassa (Universidad Nacional del Comahue); Lyn Gualtieri (Department of Geosciences, University of Massachusetts)

Cerro Fraile (50.5 S, 72.7W), located 40 km east of the crest of the Andean Cordillera in southwestern Patagonia, is a splendid exposure of meseta-capping Plio-Pleistocene basaltic lava flows interbedded with glacial tills. Classic K-Ar and paleomagnetic work by Fleck et al. (1972) provided the first age constraints on multiple early Pleistocene glaciations in the Southern Hemisphere. In addition, the confirmation of several polarity subchrons between 2.2 and 1.0 Ma contributed to early refinements of the GPTS. Revisions of the GPTS over the past several years reflecting problems with K-Ar dated samples prompted us to reassess the Cerro Fraile section using modern geochronologic and paleomagnetic methods. Oriented cores and geochronologic samples were collected in 1996 and 1998 from 10 lava flows interbedded among 7 glacial tills.
Detailed 40Ar/39Ar incremental-heating experiments on 9 of the 10 lavas found to comprise the 200 m thick section along the northwestern escarpment of Cerro Fraile, plus one unspiked K-Ar age from the ninth flow in the sequence, gave the following isochron ages* in ascending stratigraphic order: 2.16 +/- 0.06 Ma; 2.24 +/- 0.09 Ma; 2.07 +/- 0.04 Ma; 1.89 +/- 0.03 Ma; 1.95 +/- 0.01 Ma; 1.89 +/- 0.03 Ma; 1.83 +/- 0.03 Ma; 1.76 +/- 0.04 Ma; 1.43 +/- 0.02 Ma; 1.08 +/- 0.01 Ma. New paleomagnetic results on the same flows indicate strong, stable, uni-vectoral magnetizations for flows with normal or reversed polarities. Three flows have weaker magnetizations with greater directional variability during demagnetization and characteristic directions classified as transitional. Magneto-stratigraphy, corresponding to the above age determinations, is: R-T-N-R-R-T-N-R-R-T-N. All reversed flows correspond to the Matuyama chron, while the normally magnetized lavas record the Reunion event, the Olduvai event, and the Jaramillo subchron. The new age determinations lead us to suggest that the lower two transitional flows actually record the reversal process marking the onset of the Reunion and Olduvai events, whereas the uppermost transitional flow, K-Ar dated at 1.43 +/- 0.02 Ma, may correspond to one of several short events suggested in the mid Matuyama between the well-established Gilsa and Cobb Mountain events. The 1.08 +/- 0.01 Ma age for the uppermost normally magnetized lava coincides with the astronomically determined age of 1.07 Ma for the onset of the Jaramillo Normal Subchron, and together with recent results from a Tahitian lava sequence indicates, that the Jaramillo Normal Subchron lasted about 80 k.y. between 1.07 Ma and 0.99 Ma.
*All 40Ar/39Ar ages are relative to the Taylor Creek Rhyolite sanidine standard @ 27.92 Ma

GA1.15/W/02-B4 1700

SHORT GEOMAGNETIC EVENTS IN THE EARLY BRUNHES AND MIDDLE MATUYAMA CHRONS IN THE 1700-M BORING CORE FROM OSAKA BAY, SOUTHWEST JAPAN

Masayuki HYODO (Research Center for Inland Seas, Kobe University, Kobe 657-8501, Japan, E-mail: mhyodo@kobe-u.ac.jp); Dipak Kumar Biswas (Graduate school of Science and Technology, Kobe University, Kobe 657-8501, Japan, E-mail: dipak@kobe-u.ac.jp)

Paleomagnetic measurements of Plio-Pleistocene sediments were made in a 1700-m core from the Osaka Basin. Two short geomagnetic events of reverse polarity including excursional fields were found in a marine clay Ma5, over a section of 3.7 m thick around the lower boundary and over a thin section of 80 cm in the topmost part. The lower event was reproduced in another core at a site 14 km separated. The marine layer Ma5 deposited during a period of eustatic high sea level corresponding to the marine isotope stage 17. Assuming a constant accumulation rate of 0.50 mm/yr between the Brunhes/Matuyama boundary and the AT tuff dated as 24.5 ka, the short events are dated to be about 0.69 Ma. This estimate is consistent with the age of the marine isotope stage 17.3. The Delta event is correlated to them. A short geomagnetic normal polarity event was found in a zone from 910.9-921.7m and in between the Cobb Mountain and Olduvai subchrons. This event began with an excursional field of steep inclination, and became dominated by normal polarity fields in the latter half. The age range is estimated to be 1.60-1.62 Ma with a duration of about 18 kyr, assuming a constant accumulation rate of 0.61 mm/yr between the mid-point of the Cobb Mountain subchron and the Upper Olduvai boundary. A duration of about 8 kyr is estimated for a zone with only positive inclinations. This event is correlated to the Gilsa event, the Stage 54 event, and the event preceded the Sangiran Excursion.

GA 1.15/E/01-B4 1715

GEOMAGNETIC EVENTS AND RELATIVE PALEOINTENSITY VARIATIONS WITHIN THE BRUNHES CHRON AS INFERRED FROM MARINE NORTHERN HIGH LATITUDE SEDIMENTS

Norbert R. NOWACZYK (GeoForschungsZentrum Potsdam, Haus C, Telegrafenberg, D-14473 Potsdam, Germany, e-mail: nowa@gfz-potsdam.de)

Numerous magnetostratigraphic results especially from northern high latitudes revealed the existence of a whole series of short reversals of the earth's magnetic field during the last 300 ka of the Brunhes Chron (the last 780 ka). These short events with estimated durations from 1 to about 5 ka can be traced from the Iceland Sea across about 30 coring sites into the Arctic Ocean, covering a distance of more than 3000 km. At least the longer events have also been found at other locations over the globe. All geomagnetic events are linked with pronounced lows in the relative paleointensity variation record, as estimated by different techniques. Especially the polarity transitions are characterised by relative intensities of sometimes less than 5% of the preceding intensity maximum. The polarity transition is completed mostly within less than 1 ka whereas the intensity decay (and increase) takes about 10 ka. The overall pattern of relative paleointensity together with directional variations within the Brunhes Chron indicate a strongly dynamic character of the geodynamo as the source of the Earth's magnetic field.

GA1.15/W/05-B4 1730

GEOMAGNETIC EXCURSION DURING THE LAST INTERGLACIAL / GLACIAL RECORDED IN LACUSTRINE SEDIMENTS FROM SALAWUSU, INNER MONGOLIA, CHINA

Su PU. (Department of Geosciences,Taiyuan University of Technology,Taiyuan, Shanxi 030024, China. e-mail: supu@hotmail.com); Reidar Løvlie. (Institute of Solid Earth Physics , University of Bergen, Norway. e-mail: reidar.lovlie@ifjf.uib.no); Fan Xingzhao. (Department of Geosciences, Taiyuan University of Technology, Taiyuan, Shanxi 030024, China. e-mail: supu@public.ty.sx.cn).

The Salawusu section is located in Inner Mongolia (North China) and consists of a suite of aeolian-fluvial-lacustrine sediments with a total thickness of 70m. The lower 50m is composed of layers of fluvial–lacustrine sediments deposited between 124.9±15.8 and 70±1.2ka B.P (TL, ERS) corresponding to the last interglacial period. The overlying 20m consist of aeolian derived sand with ages ranging from 70.9±1.2 to 9.7±0.1ka B.P. (C14, TL, ERS) corresponding to the last glacial period. Paleomagnetic and rock magnetic investigation on some 390 samples collected along this section is reported. Susceptibility and NRM intensity reflect clear relationships to lithology; the sand at the top carry lower values compared to the fine-grained silt-clay intervals. Magnetic fabric, based on AMS measurements, reveals typically depositional features; oblate susceptibility ellipsoids associated with sub-horizontal kMAX axes. Remanent coercivity analysis indicates a uniform composition of magnetic minerals within the lower 50m that is dominated by magnetite with a small contribution of hematite. Alternating field demagnetisation reveals single component magnetisation defining a northerly distribution around the present geomagnetic fields with inclinations around 45°. Two or three short intervals at the bottom carry anomalous magnetisation with negative inclinations, possibly representing the Blake geomagnetic excursions (117ka).

GA1.15/W/10-B4 1745

ETRUSSIA EXCURSION IN HOLOCENE DEPOSITS OF THE WESTERN SIBERIA

Z.N. GNIBIDENKO, L.A. Orlova (United Institute of Geology, Geophysics and Mineralogy, SB RAS, Novosibirsk, Russia)

Complex palaeomagnetic, palinological and chronological investigations of Holocene deposits of high flood-lands of the Aley river in the south of the Western Siberia have been accomplished by us. From the investigated section (6 m in thickness), which is represented by loesslike loams, sandy loams and buried soils two dates 14C - 3185 year (SOAN-3146) and 3080 years (SOAN-3146) were obtained by humus, which make it possible to ascribe the deposits of high flood-lands to the subboreal period (SB-2, SB-3) of the Late Holocene. In the obtained palaeomagnetic recording of the rocks of this section, characterised by normal polarity (Brunhes chron), the horizon of rocks (0,4 m in thickness) with reverse magnetisation has been revealed. The composition of ferromagnetic minerals, behaviour of magnetic susceptibility and natural remanent magnetisation permit to judge about the geophysical nature of reverse magnetisation of this interval of rocks and to ascribe it to the excursions of the geomagnetic field. Obtained for this interval dates by 14C - 3185 years and 3080 years make it possible to identify this excursion with the Etrussia excursion. As palinological data showed, in the south of the Western Siberia this excursion coincides with the phase of rise in temperature at the end of subboreal period.

MAGNETOSTRATIGRAPHY AND MILANKOVITCH CYCLICITY IN SHALLOW WATER CARBONATES DURING THE LOWER CRETACEOUS

B. D'Argenio (Scienze della Terra, Universita Frederico II di Napoli, Napoli 80138, Italy E-mail: ciclisiti@gms01.na.cnr.it); Iorio, M. (Geomare Sud, Via Vespucci 9, Napoli 80142, Italy Email iorio@gms01.na.cnr.it); D.H. TARLING, (Geological Sciences, University, Plymouth PL4 8AA, UK E-mail: d.tarling@plymouth.ac.uk)

Cyclities in the sedimentological and textural features in a Lower Cretaceous 88 m carbonate

bore-core from southern Italy correspond with the predicted Milankovitch cyclicities for that time. Identical spectral peaks are observed in the palaeomagnetic properties - intensity, inclination and declination - although there are no linear correlations between the geological and palaeomagnetic parameters. The spectral similarities enable the thickness to be related to directly to the astronomical time-scale; an average thickness of 1 cm equating with an average time interval of 360 years. As a range of spectral peaks in uncorrelated parameters are involved, it is also possible to estimate the standard deviation on this time equivalent as some ±16 years. When smoothed, this directional polarity record can be compares with the sea-floor magnetic anomaly intensity record of the same time. Such comparison also shows some Milankovitch cyclicities are also present in the anomaly records. This enables the linkage of astronomical and magnetostratigraphic dating techniques for extremely high precision dating under suitable circumstances.

MAGNETOSTRATIGRAPHY ACROSS THE J/K BOUNDARY STRATA AT PUERTO ESCANO (S. SPAIN): CORRELATION WITH HIGH-RESOLUTION DATA AT BRODNO AND BOSSO VALLEY

Václav Hou_a, Miroslav KRS, Otakar Man, Petr Pruner, Daniela Venhodová (Institute of Geology, Academy of Sciences, Rozvojová 135, 165 02 Prague 6 – Lysolaje, Czech Republic, e-mail: housa@gli.cas.cz)José M. Tavera and Federico Oloriz (Departamento de Estratigrafía y Paleontología, Instituto Andaluz de Geologia Mediterranea, Universidad de Granada, 18071 Granada, Spain, e-mail: jtavera@goliat.ugr.es; foloriz@goliat.ugr.es)

This study presents first results of magnetostratigraphic investigations across Jurassic/Cretaceous (J/K) boundary limestones in Puerto Escano, Province of Córdoba, S. Spain. This locality was chosen because of the concomitant presence of calpionellids and ammonites. The aim is to prepare the background for the correlation of Late Tithonian and Early Berriasian biostratigraphic zonation with the geomagnetic events (manifested in detailed magnetostratigraphy), between the Tethyan realm and other regions on the Earth, particularly the Boreal and Pacific realms. Laboratory tests using the MAVACS apparatus showed extremely suitable physical properties of the studied limestones allowing a precise derivation of A-, B- and C-components of remanence. The C-component is clearly of pre-folding origin and indicates normally and reversely polarized magnetozones. Two reverse subzones were detected in the Puerto Esca(o section within the magnetozones M20n and M1 K-boundary in the Tethyan realm are already available, two of them (Brodno and Bosso Valley) being high-resolution profiles. Due to palaeontological significance of the Puerto Escano section, it will be subjected to next detailed magnetostratigraphic investigation.

GA1.15/W/11-B4 Poster **1530-03**

DIRECT INTERCALIBRATION OF ASTRONOMICAL AND RADIOISOTOPIC TIME IN THE MEDITERRANEAN NEOGENE

Klaudia KUIPER and Jan Wijbrans (both at Department of Isotope Geochemistry, Vrije Universiteit, De Boelelaan 1085, 1081 HV Amsterdam, The Netherlands, e-mail: kuik@geo.vu.nl, wijj@geo.vu.nl); Frits Hilgen, Wout Krijgsman and Joris Steenbrink (all at the Faculty of Earth Sciences, Utrecht University, Budapestlaan 4, 3584 CD Utrecht, The Netherlands, email: fhilgen@geo.uu.nl, krijgsma@geo.uu.nl, jsteen@geo.uu.nl)

Cyclically bedded sediments in the Mediterranean Neogene form a continuous record of dominantly precession controlled climatic oscillations during the Pliocene and Miocene. This signal can be identified in both marine and continental (lacustrine) records. Astronomical tuning of these sediments allows the calculation of discrete ages for individual beds of the sedimentary cycles. Thus astronomical ages can be assigned to volcanic ash beds intercalated in these successions. Sedimentary basins containing suitable tephras intercalated in astronomically dated cyclically bedded successions occur in southern Spain, Morocco, Italy, Greece and Turkey. Biotite and sanidine separates from the tephra layers in these successions have been dated by the 40Ar/39Ar laserprobe technique (both multiple single fusion and incremental heating techniques are used) and the 40Ar/39Ar ages are compared with astronomical ages for the same volcanic ash beds.
Research carried out on the Ptolemais section in northern Greece and the Faneromeni section on northeastern Crete indicate that 1) the cyclically bedded successions are of Pliocene age and follow the 21.7 kyr precession cycle, and 2) a discrepancy in absolute age of ca 200 kyr exists between the astronomical derived ages and the isotopic ages, where the 40Ar/39Ar ages are significantly younger. Only part of the problem might be explained by the use of erroneously young ages for the neutron fluence monitors, and/or incorrect values for the decay constants of 40K.

GA1.15/W/06-B4 Poster **1530-04**

MAGNETOSTRATIGRAPHY OF MIDDLE-LOWER JURASSIC SECTIONS FROM BETIC CORDILLERA (SOUTHERN SPAIN): BAJOCIAN-BATHONIAN AND TOARCIAN-AALENIAN BOUNDARIES

OSETE, C., Osete, M.L. (Departamento de Geofísica de la Facultad de Ciencias Físicas de la Universidad Complutense de Madrid. Spain, e-mail: crisol@eucmos.sim.ucm.es) Sandoval, J. (Departamento de Estratigrafía y Paleontología. Universidad de Granada. Spain, e-mail: sandoval@goliat.ugr.es)

A detailed palaeomagnetic study was carried out in two sections (Sierra Lugar and Cerro Méndez) in the Betic Cordillera (Southern Spain). Both sections contain a well-preserved and completed record of ammonite assemblages. The boundaries Bajocian-Bathonian and Toarcian-Aalenian in Sierra Lugar and Cerro Méndez respectively, are represented by a uniform sucession of marls, nodular marly-limestones and nodular limestones ("ammonitico rosso" facies) with abundant Positra filaments and Conoglobigerina. The initial NRM in the samples are between 2.7 10-3 and 4 10-4 A/m. In all the samples three magnetisation components could be identified by thermal cleaning. A low unblocking temperature component, close to the present field, was generally isolated between 80ºC and 200ºC. The second component has been observed in all samples as well and it is responsible for the major part of the non- viscous fraction of the NRM. It´s maximum unblocking temperature 450ºC and is always of normal polarity. The third component presents low intensity. It´s maximum unblocking temperature ranges are between 550-600ºC. This component exhibits both reversed and normal polarities and it is interpreted as the primary magnetisation.

GA1.15/W/07-B4 Poster **1530-05**

MAGNETOSTRATIGRAPHY OF THREE LOWER TOARCIAN SECTIONS FROM THE IBERIAN RANGES (CENTRAL SPAIN)

Paola Romana GIALANELLA (Dept. of Earth Science, Univ of Naples "FedericoII". Italy.), Maria Luisa Osete (Dept. Geofisica, F. CC Fisicas, Complutense University, Madrid 28040, Spain. E-mail: mlosete@eucmax.sim.ucm.es); Juan José Villalaín (Escuela Politecnica Superior. Burgos University. Spain); Friedrich Heller (Institut fur Geophysik, ETH, Zurich. Switzerland); Antonio Goy (Dept. Estratigrafia y Paleontologia. Complutense University. Madrid 28040, Spain)

Three well dated sections (Arino1, Arino2 and Sierra Palomera) covering the lower Toarcian (from Tenuicostatum to Variabilis subzones) have been palaeomagnetically investigated . The sections are located in the central part of the Iberian Ranges (Central Spain). The lower Toarcian are represented in the three investigated sections by an exceptionally thick and uniform succession of marls and marly limestones. The successions contain a well-preserved and complete record of ammonite assemblages. About 180 oriented samples were collected. Specimens are characterised by a multicomponent NRM. After initial removal of a viscous component, an intermediate component was isolated between 250ºC and 450ºC. This component has always normal polarity and it is interpreted on basis of previous palaeomagnetic studies in this region as a Cretaceous remagnetisation. The Characteristic component is isolated after 450ºC and presents a maximum unblocking temperature up to 575ºC and carries both normal and reversed polarities. The magnetostratigraphic columns obtained in the three sections can be easily correlated.

PALAEOMAGNETIC RESULTS OF THE MIDDLE-LATE TRIASSIC IN THE WESTERN IBERIAN RANGES

Vicente Carlos RUIZ-MARTÍNEZ and Maria Luisa Osete (both at the Dpto. de Geofísica, Facultad de CC. Físicas, Universidad Complutense de Madrid, 28040 Madrid, Spain, e-mail: vcarlos@eucmax.sim.ucm.es & mlosete@eucmax.sim.ucm.es);.Daniel Rey (Facultad de CC. del Mar, Universidad de Vigo, Apdo. 874. 36200 Vigo, Spain, email:); Juan Jose Villalaín (Dpto. Física Aplicada, E.U. Politécnica, Universidad de Burgos, 09006 Burgos, Spain, e-mail: villa@ubu.es); Paola Gialanella (Dip. Scienze della Terra, Universitá degli Studi di Napoli "Federico II", Lgo S. Marcellino 10, I-80138, Napoli, Italy); Alfonso Sopeña (Instituto de Geología Económica, Consejo Superior de Investigaciones Científicas, Universidad Complutense de Madrid, 28040 Madrid, Spain, e-mail: sopena@eucmax.sim.ucm.es)

Middle-Late Triassic strata of the Cuevas de Ayllón section and Late Triassic correlated strata of the Liceras section (westernmost margin of the Iberian Ranges, Spain) present predominantly reverse polarity characteristic magnetisations of high coercivity and distributed unblocking temperatures up to 700ºC. Samples of these formations (interbedded mudstones and sandstones dipping gently to the north) also contain normal polarity secondary remagnetisations, interpreted as result of the overlapping of the present field and an older overprint probably related with the extensional phases of the Iberian Basin in the Cretaceous. Primary remanence is better preserved in the finer-grained beds, with a lower overlapping degree with the high temperature overprint. The palaeomagnetic poles obtained in this study contribute to fit more accurately the apparent polar wander path of Stable Iberia for the Middle-Late Triassic time span.

GA1.15/C/U6/W/05-B4 Poster **1530-07**

MAGNETOSTRATIGRAPHY OF THE NUUANU AND WAILAU GIANT HAWAIIAN SUBMARINE LANDSLIDES

Gary McMURTRY and Emilio Herrero-Bervera (both at SOEST University of Hawaii, 1000 Pope Road, Honolulu, Hawaii, 96822, USA, email: garym@soest.hawaii.edu) Toshiya Kanamatsu (JAMSTEC, 2-15 Natsushima-Cho, Yokosuka 237, JAPAN, email: toshiyak@jamstec.go.jp)

A joint Japan-USA investigation on the origin of giant Hawaiian submarine landslides was launched in 1998 with the JAMSTEC R/V Kairei and ROV Kaiko. Four 7 meters long piston cores were recovered from the vicinity of the Nuuanu and Wailau giant submarine landslide, which dispersed onto the seafloor some 10s to 100s of km NE of Oahu and N of Molokai Islands, respectively. Three of the four 7 m long piston cores collected NE of Oahu contain distinct buried turbidites composed primarily of volcanic ash with some included forams, whereas the fourth core, located on a large detached slide block near Molokai displays a complex stratigraphy that contains numerous turbidites from that island. The three cores so far investigated contain reversals and excursions of the geomagnetic field, as revealed by marked changes in the inclination, declination and intensity profiles taken at 5-cm intervals. Preliminary ages (not yet constrained by radioisotope and/or paleontological dating) assigned to the polarity events yield sedimentation rates of 1-52 mm/k.y. for Kairei cores KR98-01,02 and 03. The changes in sedimentation from relatively fast rates to the Matuyama-Brunhes reversal to slower rates afterward are similar to a nearby core site (KK-78O30, 19 N, 160 W) but are generally lower in magnitude, perhaps reflecting increasing winnowing near the islands. A single distinct turbidite buried within the carbonate ooze atop Tuscaloosa Seamount (PC-01), a very large detached slide block of the Nuuanu landslide, and that within a pelagic red clay ~50 km in front of the seamount (PC-03) both date to approximately 1 Ma BP. The PC-03 turbidite ash suggest a mixed Koolau (Oahu) basalt composition (M. Garcia, pers. comm. 1998), whereas the turbidite atop Tuscaloosa likely deposited from the Wailau giant submarine landslide. If so, the maximum age of the Nuuanu landslide is presently best constrained by a lack of turbidite deposits in core PC-02, ~100Km in front of the slide, to >1.8 Ma BP, with the minimum age or last phase of the Nuuanu landslide deposition at approx. 1 Ma BP, followed closely in time by the Wailau event. It may be significant that this latter date was a time of eustatic sealevel rise. The Wailau and Nuuanu landslides apparently occurred near the apex of shield building for East Molokai volcano (from 1.75 to 0.75 Ma BP--Naughton et al., 1980; J. Moore, pers. comm., 1998) and perhaps also for Koolau volcano (from 2.6 to 1.8 Ma BP-- Doell and Dalrymple, 1973). Longer cores will likely reveal earlier landslide events in this area.

COORDINATED OBSERVATION OF THE FIELD-ALIGNED IRREGULARITIES IN MID-LATITUDE F-REGION IONOSPHERE WITH THE MU RADAR AND GPS

S. FUKAO, M. Yamamoto, M. Nishimura and Y. Otsuka (Radio Atmospheric Science Center, Kyoto University, Uji 611-0011, Japan, Email: fukao@kurasc.kyoto-u.ac.jp) A. Saito (Department of Geophysics, Kyoto University, Kyoto 606-8502, Japan, Email: saitoua@kugi.kyoto-u.ac.jp) S. Miyazaki (Geographical Survey Institute, Tsukuba 305-0811, Japan, Email: miyazaki@gsi- mc.go.jp) K. Shiokawa, M. Ejiri and T. Ogawa (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa 442- 8507, Japan, Email: shiokawa@stelab.nagoya-u.ac.jp) M. Kubota, M. Ishii and F. Isoda (Communication Research Laboratory, Koganei 184-8795, Japan, Email: mkubota@crl.go.jp) K. Nakajima and T. Sakanoi (Graduate School of Science, Tohoku University, Aoba-ku, Sendai 980-8578, Japan, Email: ken@pat.geophys.tohoku.ac.jp)

The mid-latitude F-region field- aligned irregularities (FAIs) observed with the MU radar show marked upwelling structures with large Doppler velocities up to 200 m/s. A coordinated observation, F- region Radio and Optical measurement of Nighttime TIDs (FRONT), was conducted with the MU radar, the GEONET GPS receiver array, and several optical instruments during May 16-24, 1998. While the MU radar detected intense F-region FAIs, horizontal distributions of the total electron content were measured by 900 GPS receivers. Also, five all-sky CCD Imagers observed emission of the air-glow in a wide ionospheric area over Japan and a Fabry-Perot interferometer observed thermospheric neutral wind velocities at two sites. Based on these variety of data, generation mechanisms of FAIs will be discussed.

GA2.02/W/10-B4 0920

FIRST 50 MHZ CONTINUOUS WAVE INTERFEROMETRY MEASUREMENTS OF LOCALIZED BACKSCATTER REGIONS IN THE MIDLATITUDE E-REGION IONOSPHERE

Christos HALDOUPIS and Anastasios Kamburelis (Physics Department, University of Crete, Iraklion, Crete, 710 03 Greece, Email: haldoupis@talos.cc.uch.gr) Kristian Schlegel (Max-Planck-Institut fuer Aeronomie, Katlenburg-Lindau, Germany, Email: schlegel@linmpi.mpg.de); Mirela Voiculescu (Physics Department, University of Galati, Galati, Romania, Email: mvoic@phys.ugal.ro)

The radar interferometer technique, which has been applied in the past years to studies of short wavelength plasma turbulence in the earth's ionosphere, can provide, in addition to the Doppler spectrum, estimates of mean size, mean angular position, and velocity transverse to the viewing direction. Here we describe the conversion of SESCAT (Sporadic E Scatter experiment, a bistatic 50 MHz continuous wave (CW) Doppler radar located in the island of Crete, Greece) to an interferometer that is capable to investigate short term dynamics of localized scattering regions in the midlatitude E region ionosphere with mean transverse sizes as small as a couple of kilometers. The first results show that SESCAT, which provides high quality spectra and excellent temporal resolution, has its measurement capabilities enhanced significantly when operated as interferometer. In this paper we will present and discuss results of azimuthal SESCAT interferometry for typical midlatitude echoes, that is, type II echoes characterized by small mean Doppler velocities. In addition we will present examples of uncommon echoes characterized by large line-of-sight velocities due to elevated electric fields. In the latter case, the cross-phase changes with time indicate rapid zonal movements of backscatter regions, presumably due to neutral winds, having at times velocities as high as at least 150 m/s, that is, well above typical neutral wind velocities at midlatitude. Finally, an effort is made to interperet the interferometry findings within the framework of our present theoretical understanding.

GA2.02/L/06-B4 0940

A PHYSICAL MODEL FOR 3.2-M AND 6.1-M BACKSCATTER FROM MIDLATITUDE E REGION

Ludmila M. Kagan (Radiophysical Research Institute, B.Pecherskaya st.25, Nizhny Novgorod 603600, Russia, e-mail: kagmil@nirfi.sci-nnov.ru)Tadahiko Ogawa (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Aichi 3-13, Japan, e-mail: ogawa@stnet1.nagoya-u.ac.jp)Mamoru Yamamoto and Shoichiro Fukao (both at Radio Atmospheric Science Center, Kyoto University, Uji, Kyoto 611-0011, Japan, e-mail: fukao@kurasc.kyoto-u.ac.jp, yamamoto@kurasc.kyoto-u.ac.jp)

We propose that backscatter from 3.2-m and 6.1-m field-aligned irregularities observed by MU and FAR radars over Japan within a 90-150 km altitude range is caused by a presence of the same source, neutral motions, which due to different values of ionospheric parameters result in different dominating processes (and so different backscatter echo types) at different altitudes. Such an approach allows to explain the QP-echoes by the gradient drift processes [1] and the continuous, thick continuous and high-altitude echo types by the thermal processes [2].

GA2.02/L/01-B4 1000

ROCKET/RADAR SPORADIC-E EXPERIMENT CONDUCTED DURING THE EL COQUI II CAMPAIGN

R.F. Pfaff, M. Acuña, S. Bounds, H. Freudenreich (NASA Goddard Space Flight Center, Greenbelt, MD), J. Clemmons (Aerospace Corporation, El Segundo, CA), G. Earle, R. Heelis (Univ. of Texas at Dallas, Richardson, TX), E. Kudeki, S. Franke (Univ. of Illinois, Urbana-Champaign, IL), M. Larsen (Clemson University, Clemson, SC), S. Gonazales, C. Tepley (Arecibo Observatory, Puerto Rico), C. Hanuise (LSEET, Toulon, France), A. Bourdillon (Univ. of Rennes, Rennes, France), W. Swartz (Cornell University, Ithaca, NY)

In order to investigate the complex electrodynamics and neutral-plasma coupling inherent to sporadic-E layers in the earth's mid-latitude ionosphere, a series of rocket/radar experiments were planned as part of the NASA El Coqui II Campaign from Tortuguero Launch Range, Puerto Rico, in March-April, 1998. The rocket experiments consisted of two pairs of "mother-daughter" payloads with limited apogees so that the payloads "hovered" in the sporadic-E region (95-125 km). Each payload pair included vector DC and AC electric field detectors, a highly accurate flux-gate DC magnetometer, an ion mass spectrometer, an ionization gauge, and spaced-electric field receivers to measure the wavelength and phase velocity of the unstable plasma waves. Separate rockets were included to simultaneously carry aloft TMA trails to measure the neutral wind and its velocity shear, believed responsible for the sporadic-E layer formation. In addition to the rocket experiments, incoherent scatter radar measurements of plasma density and drift velocity were gathered almost every night during the 3 week campaign. Continuous VHF backscatter radar operations were carried out from a site near Salinas, Puerto Rico, where 3-m backscatter echoes were observed associated with sporadic-E and other types of low altitude ionospheric layers. Other radars that operated during the campaign included an HF backscatter system near Ponce, Puerto Rico, and a second VHF backscatter radar set up near Aguadilla, Puerto Rico. On 24 March 1998, one of the instrumented rockets was launched, attaining an apogee of 129 km. The payloads successfully pierced an intense sporadic-E layer observed by both the Arecibo radar and the in-situ density and ion mass spectrometer probes. In-situ DC electric fields revealed very low (~1-2 mV/m) ambient fields with small amplitude structures of the same order. No high frequency (short scale) waves were observed, consistent with the VHF backscatter observations at the time of the launch. An overview of the observations will be presented

GA2.02/E/13-B4 1100

INTENSE 630NM AIRGLOW OBSERVED IN JAPAN DURING A STORM-TIME SUBSTORM ON AUGUST 26, 1998

Kazuo SHIOKAWA and Tadahiko Ogawa (Solar-Terrestrial Environment Laboratory, Nagoya University, 3-13, Honohara, Toyokawa, Aichi 442-8507, Japan, Email: shiokawa@stelab.nagoya-u.ac.jp) Akinori Saito (Department of Geophysics, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan, Email: saitoua@kugi.kyoto-u.ac.jp) Shinichi Miyazaki (Geographical Survey Institute, Kitagou, Tsukuba 305-0811, Japan, Email: miyazaki@gsi-mc.go.jp) Kiyoshi Igarashi (Communication Research Laboratory, 4-2-1, Nukuikita, Koganei 184-8795, Japan, Email: igarashi@crl.go.jp) Frederick J. Rich (USAF Research Laboratory, 29 Randolph Road, Hanscom Air Force Base, MA 01731, USA, Email: rich@plh.af.mil) Kiyohumi Yumoto (Department of Earth and Planetary Sciences, Kyushu University, 6-10-1, Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan, Email: yumoto@geo.kyushu-u.ac.jp)

We show an enhancement of OI 630nm airglow emission observed at Shigaraki (34.8N, 136.1E) for 15:10-16:10UT (00:10-0110LT) on August 26, 1998 using data from a north-south meridian scanning photometer and an all-sky cooled-CCD camera. The maximum zenith emission rate reached up to 250 R. The enhancement was mainly seen in the southern sky of Shigaraki. Ground magnetometer data indicate that a substorm occurred coincide with the airglow enhancement during the initial phase of a magnetic storm. Total electron content (TEC) data obtained by more than 900 GPS receiver network in Japan show similar enhancement in the southern part of Japan associated with the substorm. Intense subauroral ion drift (SAID - westward ion flow) was observed at 15:19UT in the evening sector (20MLT, 55-60MLAT) by the DMSP-F12 satellite at an altitude of 800 km, suggesting a penetration of magnetospheric electric field to subauroral latitudes. The F-region virtual height obtained at four stations of the Communication Research Laboratory in Japan show upward (at higher latitudes) and downward (at lower latitudes) motions of the ionosphere associated with the substorm. Based on these data, we discuss possible mechanisms that caused observed airglow and TEC enhancements during the storm-time substorm.

GA2.02/W/06-B4 1120

EVIDENCE FOR PLANETARY WAVE EFFECTS ON MIDLATITUDE BACKSCATTER AND SPORADIC E LAYER OCCURRENCE

Mirela VOICULESCU (Department of Physics, Faculty of Sciences, University "Dunarea de Jos" of Galati, Str. Domneasca nr. 111, Galati 6200, Romania, Email: mvoic@phys.ugal.ro); Christos Haldoupis (Physics Department, University of Crete, Iraklion, 710 03, Crete, Greece, Email: haldoupis@talos.cc.uch.gr); Kristian Schlegel (Max-Planck Institute fur Aeronomie, D-37191, Katlenburg-Lindau, Germany, Email: schlegel@linmpi.mpg.de)

A large database of midlatitude E region coherent backscatter, obtained with a 50 MHz Doppler system, is used in this paper to investigate the long-term variability in echo occurrence. The backscatter is found to be dominated by pronounced quasi-periodic variations with periods in the range from 2 to 9 days that persist for time intervals from about 10 to more than 20 days and have no relation to geomagnetic activity. The most commonly observed periods appear in two preferential bands, that is 2-3 day and 4-6 day band. Using concurrent ionosonde data we find the variations in backscatter to be exactly in phase with similar eriodicities in the occurrence of relatively strong sporadic E layers. The present findings support the possibility that planetary waves are responsible for the observed long-term periodicities which also indicates a close relation between planetary waves and the well-known, but not well understood, seasonal sporadic E layer dependence. We suggest that the planetary wave option constitutes a new component into the research of midlatitude sporadic E layer formation and occurrence that needs to be considered and closely investigated.

SIMULATION OF THE IONOSPHERIC AND THERMOSPHERIC IRREGULARITIES DURING MAGNETIC DISTURBANCES

N.A.KILIFARSKA, Geophysical Institute, Bulgarian Academy of Sciences, Sofia 1113, BULGARIA

A theoretical ionospheric model (TiM), combined with a special procedure for updating the input parameters of the model, is applied to model the spatial/temporal irregularities in mid-latitude ionosphere during the storm-time period 9-11 October 1988. The moment distributions of thermospheric dynamic and composition (particularly, the ratio O/N2), determined from real measurements of foF2 and hmF2 in a meridional chain of VI stations are also presented. It was found that the main contribution to the ionospheric plasma depletion are the changes in O/N2 ratio, reaching 50-70% deflection from its median values, while electron density is decreased more than 70%. The variations of the vertical plasma drift (W), induced by electric fields and thermospheric winds, are much smaller. The maximum deflections of W from its median state are ±30%, detected in 04:00 and 16:00 UT respectively. The accuracy of TiM model in foF2 simulation is presented by spatial relative errors e(lat, long) between measured and calculated values. The most typical values of e are ±10% during the most hours of the disturbed period. The real measurements of foF2 in all available mid-latitude stations in the Northern hemisphere have been used as criteria for the models accuracy.

COMPARISONS BETWEEN RADAR SIGNATURES OF THE FARLEY-BUNEMAN AND THE ELECTRON PEDERSEN CONDUCTIVITY INSTABILITIES

Ranvir Singh Dhillon, University of Leicester, UK, email: rsd6@ion.le.ac.uk

Recent theoretical and experimental work directed towards the D-region and lower E-region, at altitudes of around 80-95km, has indicated the existence of a new type of plasma instability. This instability, the Electron Pedersen Conductivity Instability (EPCI), excites waves that propagate preferentially along a direction parallel to the bisector between the electric field and ExB directions. The differences between radar backscatter signatures for the EPCI and the more widely known E-region Farley-Buneman Instability (FBI) are discussed and characterised. The data were collected using CUTLASS, a bistatic component of the HF SuperDARN array with sites in Iceland and Finland, and STARE, a bistatic coherent scatter radar with sites in Finland and Norway. A summary of previous experimental studies, providing possible confirmation of the EPCI, is also presented.

GA2.02/E/06-B4 1420

BACKSCATTER FROM THE AURORAL E-REGION AT ASPECT ANGLES CLOSE TO 90 DEGREES

R.RUESTER and K.Schlegel Max-Planck-Institut fuer Aeronomie, 37191 Katlenburg-Lindau, Germany

Backscatter from E-region irregularities at aspect angles close to 90 degrees (i.e. almost parallel to the direction of the magnetic field) was observed at 53 MHz using the ALOMAR SOUSY Radar at Andoya/Norway. Strong electric fields and increased E-region electron temperatures simultaneously measured with the incoherent scatter facility EISCAT, indicate that the Farley-Buneman plasma instability was excited. In addition strong particle precipitation as inferred from EISCAT electron densities shows that the gradient drift instability may have been active, too.
Auroral backscatter at such large aspect angles was not expected and has not been observed before. The characteristics of the backscatter are in many aspects completely different from usual auroral radar observations : the velocities are only of the order of 10 m/s, the half-width of the spectra is about 5 m/s and the echoes occur at altitudes well below 100 km. It is concluded, therefore, that the observed strong radar echoes are not directly caused by the above mentioned instabilities and that other mechanisms have to be considered to explain these observations.

GA2.02/L/8-B4 1440

CAN FIELD ALIGNED CURRENTS GENERATE RADAR BACKSCATTER AT VERY LARGE ASPECT ANGLES?

T R Robinson (Department of Physics, University of Leicester, Leicester LE1 7RH, UK, email: txr@ion.le.ac.uk); K Schlegel (Max-Planck-Institut fur Aeronomie, Katlenburg-Lindau, Germany)

Recent ALOMAR SOUSY radar observations indicate that radar backscatter at 50MHz can arise in the lower E-region of the auroral ionosphere when the radar beam is pointing in a direction close to that of the geomagnetic field. If this scatter is due to 3 m plasma density irregularities then these would have to be propagating in a direction almost parallel to the geomagnetic field. There is strong evidence to suggest that field aligned currents are usually present during these large aspect angle backscatter events. This paper explores the theoretical possibility of a causal connection between the large field aligned currents and the backsctter. In particular the role of electron intertia is examined, together with thermal effects which accompany frictional heating by rapidly moving field parallel electron streams. The effects of ionisation of neutrals by fast electron impact on the stability of small scale plasma irregularities is also considered. Attention is also given to particle beam effects as well as bulk electron motion.

GA2.02/W/01-B4 1500

OBSERVATIONS OF E REGION DENSITY CAVITIES

HANS NILSSON (Swedish Institute of Space Physics, Box 812, 981 28 Kiruna, Sweden, email: hans.nilsson@irf.se)

Incoherent scatter radar observations of deep E region density cavities are reported. The observed cavities occur at the altitude of peak Pedersen conductivity and are thus likely related to downward field-aligned currents (electrons going out of the ionosphere). The cavities have electron density decreases of 30 - 50 % as compared to the background (solar EUV produced) plasma and were observed during midday in the cusp region. It appears that the seeding of the cavity may be from conductivity structures caused by cusp (proton) precipitation, causing the initial field-aligned current.

GA2.02/W/33-B4 1520

A REVIEW OF THE PERKINS INSTABILITY

Abdelhaq M. Hamza, University. of New Brunswick, Canada, email: ahamza@unb.ca

A thorough review of the Perkins instability is presented in this paper. We introduce two new elements to the earlier model presented by {\it Perkins} [1973], namely the neutral wind velocity and gradients in the background field line-integrated density and Pedersen conductivity respectively. We derive the eigenfrequency and growth rate for the new instability, and recover the limiting cases discussed by {\it Perkins} [1973], and {\it Miller} [1997].

GA2.02/W/19-B4 1600

FLOW ANGLE DISTRIBUTION OF THE ION AND ELECTRON TEMPERATURES ACROSS THE STATIONARY CONE OF THE PRIMARY MODIFIED FARLEY-BUNEMAN WAVES

E E TIMOFEEV (Polar Geophysical Institute of the Russian Academy, Murmansk, Russia); M K Vallinkoski, J Kangas, P Pollari (Department of Physics, University of Oulu, Finland); T Virdi, P J Williams (Department of Physics, University of Aberystwyth, Wales, U.K.); E Nielsen (Max-Planck-Institute fuer Aeronomie, Katlenburg-Lindau, Germany)

As it has been shown in the accompanying our IAGA paper devoted to the experimental study of the thermal effects in the excitation of the Farley-Buneman (FB) waves, the primary cone of the modified FB waves with about 45 degree half-width exists permanently within the Finnish STARE radar echo layer (108_6 km altitudes) for small (near-threshold radar echo) level of the DC ionospheric electric fields. The present paper deals with analysis of the flow angle properties of the electron (Te) and ion (Ti) temperatures as averaged within the echo layer and over 30 degree flow angle bins. It is found that: 1) both temperatures are minimal in the center of the cone while their local maxima are at the edges of the cone; the temperatures decrease beyond the cone limits; 2) both temperatures are essentially flow angle asymmetric. Ti (Te) has its absolute maximum at -45 (+45)degree flow angle bin. As a result, such a puzzling phenomenon as cooling of electrons relatively to ions stationary exists near the negative flow angle edge of the cone. The difference of temperatures (Ti-Te) is of about 50 K degrees; 3) standard deviation of the Ti (Te) sharply (2-5 times) increases near the negative (positive) flow angle edge of the cone, respectively.

GA2.02/W/32-B4 1620

INTEGRAL CONDUCTIVITY OF THE TURBULENT IONOSPHERE

Leonid ALPEROVICH (Department of Geophysics and Planetary Sciences, Tel Aviv University, 69978 Israel. Email: leonid@jupiter1.tau.ac.il)

The influence of local and random inclusions on the ionospheric conductivity has been analyzed. The calculations have demonstrated strong influence of small perturbations of the electron concentrations on the effective Pedersen conductivity in the D- and E-layers even during weak ionospheric turbulization. This is connected with the anisotropy in a strong magnetic field where the electron Pedersen conductivity which is small usually in the homogeneous ionosphere increases drastically due do an engagement with the electron Hall conductivity because of the polarization fields of ionospheric irregularities. It is found a general expression for the effective conductivity valid for both high- and low-latitude ionosphere. One can be hold for example that the effective integral conductivity of the equatorial electrojet region is almost nonsensitive to sporadic electron irregularities. Conversely, the integral conductivity of the middle latitude ionosphere and the ionosphere of the outlying regions of the polar electrojet and the polar cap can be changed drastically even during small perturbations of the electron density.

GA2.02/E/12-B4 1640

STATISTICAL RELATIONSHIP AMONG ECHO POWER, DOPPLER VELOCITY AND SPECTRAL WIDTH OF HF RADAR ECHOES FROM THE HIGH-LATITUDE F REGION

Masaaki Fukumoto, Nozomu Nishitani and Tadahiko OGAWA (Solar-Terrestrial Environment Laboratory, Nagoya University, 3-13 Honohara, Toyokawa, Aichi 442-8507, Japan, email: ogawa@stelab.nagoya-u.ac.jp) Natsuo Sato, H. Yamagishi and A. S. Yukimatu (National Institute of Polar Research, 1-9-10 Kaga, Itabashi, Tokyo 173-8515, Japan)

Three parameters (echo power, Doppler velocity and spectral width) derived from ionospheric HF and VHF radar echoes have been very useful to study the characteristics of equatorial and high-latitude E region irregularities, their generation mechanisms and nonlinear plasma state. The generation mechanisms of F region irregularities at high-latitude seem to be more complicated than those at the equator and mid-latitude because, in addition to electric fields, particle precipitation (field-aligned current) from the magnetosphere may play a part in producing the high-latitude F region irregularities. In this paper, we present some statistical relationships among the three parameters in the auroral and polar cap F regions obtained from the Syowa Station HF radar in Antarctica. Although data points are largely scattered, there exists an indication of positive correlation between the Doppler velocity and echo power and also between the Doppler velocity and spectral width (and therefore, between the echo power and spectral width). Based on these results, we discuss possible generation mechanism(s) of the F region irregularities responsible for the HF radar backscatter.

GA2.02/W/04-B4 1700

COHERENT HF RADAR BACKSCATTER CHARACTERISTICS ASSOCIATED WITH AURORAL FORMS IDENTIFIED BY INCOHERENT RADAR TECHNIQUES: CUTLASS AND EISCAT

S E MILAN, J A Davies, M Lester (All at Department of Physics and Astronomy, Leicester University, Leicester LE1 7RH, UK. Email: Steve.Milan@ion.le.ac.uk)

CUTLASS Finland HF coherent radar backscatter from decametre-wavelength field-aligned F region irregularities is compared with common-volume plasma parameters and the electric field deduced by the EISCAT UHF incoherent radar system, for a 12 hour period from the 18 and 19 June 1996. During this interval we find an excellent agreement between irregularity Doppler velocity and bulk ion drift resolved along the CUTLASS beam. Furthermore, backscatter is found to exist only in regions of non-zero electric field, as the ExB instability growth rate is dependent on E. Also, no backscatter is observed in regions where the E region Pedersen conductivity is greatly enhanced, as the perturbation electric field associated with the F region irregularities is shorted-out and the instability growth is quenched. The presence of auroral arcs within the scatter volume increases both the intensity and spectral width of backscatter returns. We show how this allows the location of precipitation features within the field-

GA2.02/W/22-B4 1720

ORIENTATION OF SMALL-SCALE ELECTRON DENSITY FLUCTUATIONS AND THE DIRECTION OF PLASMA FLOW IN THE IONOSPHERIC F LAYER

T Nygren (Department of Physical Sciences, University of Oulu, FIN-90570 Oulu, Finland, email: tuomo.nygren@oulu.fi), E.D. Tereshchenko, B.Z. Khudukon and M.O. Kozlova (Polar Geophysical Institute, 183010, Murmansk, Russia)

A new method of determining the anisotropy parameters of ionospheric field-aligned electron density fluctuations is presented. The method makes use of amplitude scintillation of a signal from a satellite to a ground-based receiver. In simple terms, the method is based on the fact that sheetlike irregularities cause maximal scintillation when the ray from the radio source to the receiver lies in the plane of the irregularity sheets. Hence, due to a straightforward geometric effect, a maximum scintillation level should be met in some specific ray direction during the satellite passage. Using the known geomagnetic field and a reasonable assumption of the height range of the irregularities, the variation of the scintillation level around this direction allows the determination of both the field-aligned and field-perpendicular anisotropy as well as the orientation of the field-perpendicular anisotropy of the spatial spectrum of the density fluctuations. Results are shown from an experimental campaign where satellite scintillation was observed at three sites at high latitudes and, simultaneously, the F region plasma flow was measured by the near-by EISCAT incoherent scatter radar. The orientation of the anisotropy determined from the scintillation observations is compared with the direction of F region plasma flow. The results indicate that, in cases where the observed irregularities lie close to the threestatic radar volume and the experimental errors of the radar velocity measurement are not great, a good agreement between the two directions is obtained.

DYNAMICS OF THE POLAR CAP IONOSPHERE: A STUDY OF POLAR PATCHES ABOVE CASEY, ANTARCTICA.

A.M. Breed(1), T.M. Maddern(1), P.L. Dyson(2), R.J. MORRIS(1) (1) Australian Antarctic Division, Channel Highway, Kingston, Tas. 7050, Australia. (2) School of Physics, La Trobe University, Bundoora, Vic. 3083, Australia.

A Lowell Digital Ionosonde (DPS-4) has operated at the Australian Antarctic polar cap station Casey (-80.6o CGM latitude), since early 1993, primarily to study the dynamics of the southern

polar cap ionosphere. To gain a better understanding of the ionospheric motions involved, animated data displays have been developed using ionospheric drift and ionogram data combined together with other geophysical data sets to help identify dynamical features. These displays generally show ionospheric skymaps (echo locations), drift velocities and Doppler ionograms (vertical profiles), produced with a resolution of up to a frame every 2 minutes. Ionospheric changes can then be viewed frame by frame using commercial animation software. This provides a simple means of viewing large amounts of data and identifying, for example, drifting polar patches, or the response of ionospheric drift to changes in the IMF. Since the ionosonde takes measurements throughout the bottomside ionosphere, different height regions (eg. E and F) can be examined independently or compared directly. Doppler and directional information featured in the animations provide a powerful technique for studying the evolution of ionospheric phenomena, such as polar patches.
This paper will demonstrate the applications of the 'ionomovie' animations, and then present results of a study of polar patches.

ELECTRODYNAMIC PROCESSES – LOW-LATITUDE IRREGULARITIES

GA2.02/W/05-B5 0900

ZONAL WIND VARIATIONS FROM HF/VHF RADAR OBSERVATIONS OF THE EQUATORIAL ELECTROJET REGION

C.V. DEVASIA, Sudha Ravindran, K.S. Viswanathan and K.S.V. Subbarao (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum - 695022, India, email: spl_vssc@vssc.org)

The electric fields generated by local east-west wind structures in the electrojet region are very important as they are involved in many other ionospheric processes in addition to the generation of currents which modulate the normal electrojet current. Depending on the height structure of the wind, the wind generated polarization field can have a much greater fine structure in height compared to the smooth altitude structure of the normal vertical polarization electric field due to the heightinvariant global east-west electric field present in the electrojet region. The height structure of the wind generated electric field can have a large variability on different time scales due to the large variability of the causative wind structure.
These characteristics of the wind generated polarization field are manifested in the height structure of the type II plasma phase velocities as observed by the HF and VHF backscatter radars at Trivandrum (Dip 0.5 deg. N) as the radar measured phase velocities are proportional to the polarization field in the electrojet region. The inverse problem of deducing the zonal wind velocities at the electrojet altitudes from the radar measurements thus provide a simple method for studying the wind variations in the electrojet region. The characteristics of zonal winds deduced from the radar measurements are discussed in detail in terms of their spatial and temporal variations.

GA2.02/W/08-B5 0920

FIRST RESULTS OF EQUATORIAL ELECTROJET OBSERVATIONS USING INPE'S 50 MHZ COHERENT BACK-SCATTER RADAR

M. A. Abdu, J. H. A. Sobral, Clezio M. Dinardini, I. S. Batista, P. Muralikrishna, E. R. de Paula (Instituto Nacional de Pesquisas Espaciais- INPE, 12201-970 Sao Jose dos Campos, Brazil.)

A VHF coherent back-scatter radar developed at INPE is now partially operational at the magnetic equatorial site, Sao Luis (2.33(S, 44.2(W dip angle: -.5() in Brazil. The radar operating at 50 MHz is projected for a nominal transmiting peak pulse power of 120 kW although only a partial capability of ~40kW was used in its first measurements of the electrojet irregularity dynamics carried out in a one-week campaign conducted in August 1998. The radar employs a coaxial-colinear type antenna system arranged in a phased array of 16 pararallel antennas (each having 48 half wave dipoles) arranged in 8 pairs each fed by one of the 8 units of its modular transmittor system. Backscattered echos are received by the same antenna through the use of T/R switches. Doppler velocity spectra of the 3-m irregularities of the electrojet were recorded at 2.6 km height resolution between 90 and 120 kms. The measurements to be reported here were made in a time sharing mode between the antenna beam oriented vertically and at 30(tilted eastward. The few days of observation covered a disturbance interval associated with the major magnetic storm of 26 August 1998. The velocity spectrum and intensity distribution of electrojet irregularities showed large fluctuations in response to prompt penetration of magnetospheric electric field to equatorial latitudes as indicated by the simultaneous fluctuations observed in the auroral activity indices and in local magnetogram. Instances of total inhibition of the plasma instability process was also observed possibly caused by disturbance dynamo electric field associated with the storm. Results of a detailed analysis of the data set will be presented in this paper.

GA2.02/E/09-B5 0940

IONOSPHERIC E REGION IRREGULARITIES DURING COUNTER ELECTROJET

R.G.RASTOGI, Department of Physics, Gujarat University, and Physical Research Laboratory, Ahmedabad 380 009, India e-mail: parvs@prl.ernet.in V.V.Somayajulu, Space Physics Laboratory, Vikram Sarabhai Space Centre, Thiruvananthapuram 695 022, India

The paper describes the ionospheric observations at Thumba during intense midday equatorial counter electrojet events, which occur on a series of days of December solsticial months. It is shown that Es-q type of plasma irregularities or blanketing type of sporadic E layer are often generated during westward electric field. On certain events the occurrence of these irregularities are preceded by the down drifting of intermediate E2 layer from 150 km to below 100 km level. Possible suggestions for such events are made.

GA2.02/W/28-B5 1000

VHF RADAR OBSERVATIONS OF E REGION IRREGULARITIES OFF THE MAGNETIC EQUATOR OVER GADANKI

K.S. VISWANATHAN (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum 695 022, India, email: spl_vssc@vssc.org) A.K. Patra (Department of Physics, K.O. College, Gumla 835 207, India) K.S. Raina and P.B.Rao (both at National MST Radar Facility, P.O. Box 123, Tirupati 517 502, India, email: nmrf@isro.ernet.in)

The MST radar,located at Gadanki (13.5 deg.N, 79.2 deg.E; dip 12.5 deg.N), has been operated in ionospheric coherent backscatter mode for mapping the structure and dynamics of E region field aligned irregularities on several days during summer and equinoctial months since 1994. The observations are presented in the form of Doppler power spectra, height-time-intensity (HTI) maps and height-time variations of Doppler velocity and velocity spectral width. The spectra are found to be quasi-Gaussian, showing variations in both height and time that are more intense during nighttime compared to daytime. During daytime, the E region is found to be unstable in two distinct height ranges, nominally 85-95 km and 100-115 km and they merge during nighttime. The signals are found to drop out, in general, for 3 to 4 hr. around noontime at Gadanki, in contrast to that observed over the equator. The signal intensity often undergoes quasi-periodic variations with periods of few tens of min which seem to be a manifestation of medium-scale gravity waves. The Doppler velocities in the higher height range are mostly upward during daytime and downward during nighttime with values generally not exceeding 40 m/s and are clearly of electrodynamic origin. In the lower height range, however, the drift velocities are downward during daytime and upward during nighttime with values less than about 30 m/s and seem to be due mainly to the meridional component of the neutral wind. The velocity spectral width, representing turbulence, often exceeds 100 m/s and is thus greater to the mean Doppler velocity.

GA2.02/E/14-B5 1040

STUDY OF ELECTROJET ASSOCIATED IONOSPHERIC IRREGULARITIES THROUGH VHF SCINTILLATION

B.M.PATHAN,D.R.K.Rao and S.Banola(all at Indian Institute of Geomagnetism Colaba, Mumbai 400 005 India, email: bmpathan@iig.iigm.res.in)

Daytime scintillations observed at the equatorial region are attributed to the instabilities in the electrojet currents flowing in the E-region of the equatorial ionosphere. These scintillations are rather weak and hence have a narrow latitudinal coverage. The occurrence of Esq associated weak scintillations is maximum (~ 90%) near the dip equator while on few occassions strong scintillations associated with blanketing type of Es are seen near the edge of the electrojet.
Strong scintillations (S4~0.8) with moderate fade rate (~ 13 fades per min) on 250 MHz signal were recorded at Pondicherry (4.4 deg. dip lat.) on 05 May 1998 (Ap=42) during 16-17 hr IST. Ionosonde operated at a nearby station Kodaikanal indicated the presence of multi layer blanketing Es at about 100 km altitude. The high frequency asymptotes of power spectra have yielded two dimensional irregularity power spectrum index of about 3 over wave lengths of 100-700 m which are close to the theoretical prediction of 8/3 for type I and type II irregularities. The transverse drift speed of the irregularity as determined from the Fresnel frequency is about 70 m/s. The results are discussed in terms of variation in electrojet characteristics.

GA2.02/E/08-B5 1100

SHAPE AND SPATIAL DISTRIBUTION OF F-REGION ELECTRON DENSITY IRREGULARITIES AS OBSERVED BY THREE DIFFERENT PLASMA PROBES DURING THE GUARA CAMPAIGN

P. MURALIKRISHNA, M.A. Abdu, M.G.S. Aquino (all at Instituto Nacional de Pesquisas Espaciais - INPE/MCT, C.P. 515, 12201-970, Sco Josi dos Campos - SP, Brazil, email: murali@dae.inpe.br), J LaBelle (Department of Physics and Astronomy, Dartmouth College, Hanover, NH 03755, USA, email: jlabelle@einstein.dartmouth.edu)

Nighttime F-region electron density height profile and the amplitude of the electron density fluctuations were measured simultaneously by three different plasma density probes during the Guara campaign, conducted from Alcantara in Brazil in the year 1994. During this campaign a Black Brant X sounding rocket was launched on 14-th October 1994 at 1955hrs (LT) to investigate into the phenomenon of high-altitude equatorial spread-F events. The rocket, as expected passed through an active topside spread-F event, monitored simultaneously by several ground-based instruments. A High Frequency Capacitance (HFC) probe, a conventional Langmuir Probe (LP) and a Plasma Frequency Probe (PFP) were used to measure the electron density and the spatial fluctuations in it. While the PFP and HFC measurements (except for an estimated plasma sheath factor for the HFC probe) provide the absolute electron density, the LP gives the relative variation in the electron density. The spatial resolutions that can be obtained from the three probes are also different. While the HFC probe has the lowest spatial resolution and thus can be used to study the shape of large scale irregularities, the PFP has the highest spatial resolution and thus can be used to study the shape of small scale irregularities. The LP has an intermediate spatial resolution. Thus, the three probes provided data, which could be used not only to obtain reliable electron density data, but also to study the shape and spatial distribution of the electron density irregularities over a wide range of scale sizes. The shape of the irregularities is seen to change not only with the range of their scale size but also from one height region to another. These spatial characteristics of the irregularities are presented and discussed here in the light of the plasma instability mechanisms responsible for their generation.

GA2.02/E/05-B5 1120

FIRST SIMULTANEOUS MEASUREMENT OF ELECTRON DENSITY AND ELECTRIC FIELD FLUCTUATIONS FROM THE INDIAN ZONE

H.S.S. SINHA, Shikha Raizada and R.N. Misra, Physical Research Laboratory, Navrangpura, Ahmedabad -380 009, INDIA

Simultaneous measurements of electron density and electric field were made from SHAR (13?N, 80?E) using a Langmuir probe and two pairs of double probes respectively onboard a RH-560 rocket. This constituted the first simultaneous in-situ measurement of electric field and electron density from the Indian zone. The aim of the experiment was to study the nature of irregularities during a fully developed phase of ESF. It was observed that the electric field and electron density fluctuations were co-located in the altitude regions between 165-175 km, 210-260 km, and 295-330 km.
The electron density profile exhibited new type of irregularities in 165-175 km altitude region. Structures with vertical scale sizes with wavelengths of about 40 km, were seen in this region. Presence of fluctuations with such scale sizes suggests that gravity waves might be playing a dominant role in producing irregularities in this region. Smaller scale perturbations with scale sizes less than 6 km superimposed on large perturbations were prominent in this altitude region. Power spectral analysis of the irregularities showed the presence of perturbations with scale sizes from 15 m to 1 km in 165 - 175 km region. These irregularities display very steep spectral indices which were not seen in earlier experiments and cannot be explained by Generalized Rayleigh Taylor Instability (GRTI), Gradient Drift Instability (GDI) or image striation theory. We conjecture that these perturbations might be due to the cascade of larger scale structures as in the case of neutral turbulence in the lower atmosphere.

GA2.02/W/27-B5 1140

INTRINSIC LOCALIZED MODES AND ONSET OF THE EQUATORIAL SPREAD F

BAMANDAS BASU (Air Force Research Laboratory, Hanscom Air Force Base, MA, 01731, USA, Email: basub@plh.af.mil); Bruno Coppi (Department of Physics, Massachusetts Institute of Technology, Cambridge, MA, 02139, USA, Email: coppi@pfc.mit.edu)

A theoretical model for the onset of the Equatorial Spread F (ESF) is introduced considering all the effects of the electric fields that are present together with those of the neutral wind velocity, of gravity, and of the density gradient. These impose well-defined topological constraints on the modes that can be excited. The horizontal (east-west) ion velocity is shown to be one of the key factors for the intrinsic vertical localization of modes that are driven unstable by the effective vertical gravity (including the E-field contribution). The width of the layer of localization is related to the vertical gradient of the ion horizontal velocity, of the neutral wind velocity, and of the ion-neutral collision frequency. The "horizontal gravity" resulting from the difference between the horizontal ion and neutral velocities is shown not to be a driving factor for the instability, when the eastward electric field is included in the analysis, but to have an important influence on the mode topology (vertical profile). An explicit analytical solution is found for the relevant dispersion equation that includes the contribution of a vertical ion velocity. The mode vertical profile under realistic conditions is found. It is suggested that the onset of the ESF is determined by the necessary conditions for the intrinsic localization of the modes, and that this fact may explain why the onset is not observed to correlate only with the formation of steep density gradients. The mode ballooning structure, along the magnetic field, including the effect of the plasma finite resistivity is also described.

ELECTRODYNAMIC PROCESSES – LOW-LATITUDE IRREGULARITIES – PART 2

GA2.02/E/01-B5 1400

INTERACTION OF TWO LONG WAVELENGTH MODES IN THE NONLINEAR EVOLUTION OF EQUATORIAL SPREAD-F

R. SEKAR and E. A. Kherani (Physical Research Laboratory, Navrangpura, Ahmedabad, India, email: rsekar@prl.ernet.in); P. B. Rao and A. K. Patra (National MST Radar Facility, Gadanki, India).

Plasma irregularities during nighttime in the equatorial F-region (ESF) manifest themselves in many different forms on VHF radars, ranging from spectacular rising plumes and multiplumes to modest bottomside spread-F events. The plumes which extend from bottomside to the topside of the ionosphere were identified earlier as the manifestation of large scale plasma bubbles generated by the action of generalized Rayleigh-Taylor instability. For seeding the above instability, gravity waves in the neutral atmosphere is thought to be a potential source. As the spectra associated with the gravity waves are diverse, it becomes important to investigate the development of ESF with different modes simultaneously. As a first step, an investigation is made with two long wavelength modes as initial perturbation in the nonlinear simulation model of ESF. It is demonstrated that the longer wavelength mode developed into a bottomside structure, while the second mode developed into multiple plumes. Further, the interaction between the modes has been shown to modify the electric field structures. The results obtained from this investigation explain some of the unique patterns of plumes and their Doppler velocities observed by the Indian MST Radar in ionospheric mode.

GA2.02/W/34-B5 1420

ROCSAT-1 OBSERVATIONS OF LOW LATITUDE: IONOSPHERIC IRREGULARITIES

Y. C. Yeh, J. M. Wu, S. Y. Su,and H. C. Yeh(all at Institude of Space Science, National central University, Ching-Li, 320, Taiwan, email: ycyeh@csrsddc.csrsr.ncu.edu.tw); R. A. Heelis(University of Texas at Dallas, email: heelis@utdallis.edu)

The ion density observation from Ion Trap(IT) of IPEI payload onboard the ROCSAT-1 at 600 km altitude is capable of sampling at 1024 Hz to obtain the high spatial resolution of density variations in the ionospheric bubble event. The fast variations in densities developed on the steep walls of convection bubble will be presented. The general morphology of the bubbles will also be presented.

GA2.02/W/18-B5 1440

ROCSAT-1 OBSERVATIONS OF LOW LATITUDE IONOSPHERIC IRREGULARITIES - PLASMA FLOW OBSERVATIONS

J.M Wu, Y.C. Yeh, S.Y. Su, H.C. Yeh (Institute of Space Science, National Central University, Chung_Li 320, Taiwan, ROC. email: jmwu@csrsddc.csrsr.ncu.edu.tw) R.A. Heelis (University of Texas at Dallas, email: heelis@utdallas.edu)

The ion drift meter (IDM) of the IPEI payload on board ROCSAT-1 is designed to take in-situ measurement of ion drift velocity over a large dynamic range with high accuracy. The IPEI ion drift data observed at the high sampling rate (32 Hz in Normal mode, and 1024 Hz in Fast Mode) will provide ion flow structures in the ionosphere at middle and low latitudes at 600 km altitude. In this report, horizontal and vertical ion drift data from the ROCSAT1 will be used to determined the average zonal and vertical plasma flow characteristics during a disturbed ionospheric condition when mid-latitude irregularities and/or low-latitude spread-F have occurred. Detail comparison of the flow patterns for these two difference ionospheric phenomena will be presented. of AMS particularly for sediments.

GA2.02/W/24-B5 1500

CONTRIBUTION OF MULTI-LATITUDINAL MEASUREMENTES OF TEC ON THE UNDERSTANDING OF THE DEVELOPMENT OF LOW-LATITUDE SCINTILLATIONS

C.E. Valladares, R. Sheehan (Institute for Scientific Research, Boston College, Chestnut Hill, MA 02167; 781-863-5928; email: cesar@dl5000.bc.edu) A. Mazzella (Northwest Research Associates, Bellevue, WA) J. W. Meriwether (Department of Physics and Astronomy, Clemson University, Clemson, SC 29634; 864-656-0915; email: john.meriwether@ces.clemson.edu)

Measurements of the total electron content (TEC) using four stations (Bogota, Ancon, Arequipa, and Santiago) located near the west coast of South America were used to obtain long-term statistics of the preferred conditions of the low-latitude ionospheric plasma during the occurrence of scintillations at the magnetic equator. The scintillation activity is quantified using the S4 index gathered both in the UHF- and L-bands at two stations (Ancon and Antofagasta). The first site is placed near the magnetic equator and the second station is situated close to the equatorial anomaly. The multiple site measurements allow us to infer the altitude extension of the layers containing irregularities and the distribution of TEC along the magnetic field lines. We have also used measurements of the zonal and meridional winds at the Arequipa station, first to understand the latitudinal distribution of TEC and secondly to observe the dominant conditions of the electrodynamics driving zonal winds during the onset of irregularities. We present here measurements of the degree of symmetry/asymmetry that can exist between the southern and northward anomalies during times of the development of the equatorial irregularities and values of the neutral wind during these times.

GA2.02/P/01-B5 1520

ON THE 01 630.0 NM, 557.7 NM AND 777.4 NM NLGHTGLOW MEASUREMENTS OF EQUATORIAL PLASMA DEPLETIONS DURING SPREAD-F-EVENTS

G.K. Mukherjee, L. Carlo and S.H. Mahajan, Indian Institute of Geomagnetism Colaba, Mumbai 400 005, India e-mail: gkm@ iig.iigm.res.in

During the period January-April 1998, a good series of measurements of the 01 630.0 nm, 557.7 nm and 777.4 nm nightglow emissions of equatorial plasma depletion have been obtained during spread-F condition of the ionosphere using an All-Sky Camera at Kolhapur (16.8 deg N, 74.2 deg E; dip]at. 10.6 deg N). The All-Sky Camera offers broad and instantaneous coverage of the movement of large scale size irregularities (depletions or bubbles) over a region of horizontal diameter of 1800 km at about 300 km. The location of the station is important as a single image at a given instant maps the irregularities over a large area starting from the geomagnetic equator to the anomaly region. The images also show altitude-latitude extent of the plasma depleted fluxtubes and it is observed that most of the bubbles rise to an altitude of I 000 km over the magnetic equator, only few of them could exceed the height of 1500 km which corresponds to the northern edge of the image. The characteristics of bubbles at this longitude zone have been brought out. The maximum number of depletions occur during the equinoctial months, March. Simultaneously the data from other complementary experiments such as VHF scintillation, ionosonde and photometers are presented to study the characteristics of small and large scale size irregularities. Using the field aligned movement of the bubbles, the bubble rise velocities at the equator have been estimated and compared with other experimental results.

GA2.02/E/11-B5 1600

FURTHER RESULTS REFERRING TO THE NEUTRAL DENSITY DEPLETIONS ATTRIBUTED TO PLASMA BUBBLES

Pal BENCZE (Geodetic and Geophysical Research Institute, Hungarian Academy of Sciences, H-9401 Sopron, P.O.B. 5, Hungary, email: bencze@ggki.hu) Ivan Almar and Erzsebet Illes-Almar (both at Konkoly Observatory, H-1525 Budapest, P.O.B. 67, Hungary, email: almar@ogyalla,konkoly.hu) Csilla Nemeth (H-1112 Budapest, Koerberki u. 37. Hungary)

Our former investigations have indicated that short period depletions of the total neutral density - found in the data of the high temporal resolution accelerometer measurements of the San Marco V satellite - might be attributed to plasma bubbles in the vicinity of the equator. As it is known, plasma bubbles are generated by the Rayleigh-Taylor instability, the growth rate of which depends on the vertical gradient of the electron density. This gradient is greatest by night and in the winter months. Furthermore, the occurrence of plasma bubbles depends on geomagnetic activity as indicated by the occurrence frequency of spread F. Therefore the temporal variation of the occurrence frequency of the total neutral density depletions was investigated to confirm the assumption that these depletions in the vicinity of the equator are due to plasma bubbles.

GA2.02/W/07-B5 1620

THERMOSPHERIC MERIDIONAL WINDS AND ITS RELATION TO SPREAD-F

N. JYOTI and C.V. Devasia (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum-695 022, India, email: spl_vssc@vssc.org)

One of the important characteristics of the night time equatorial F-region is the occurrence of F-region plasma density irregularities known as equatorial spread-F(ESF). Experimental evidences have shown that a rapid vertical plasma drift due to enhanced zonal electric fields of F-region dynamo action which becomes prominent over the E-region dynamo action in the post sunset period leads to an elevated F-region ,thus providing the prerequisite for the onset of ESF. The above physical condition is conductive for a fast growth of Rayleigh-Taylor (R-T) plasma instability processes which account for ESF generation .Still there remains some observational aspects of ESF which are not clearly explained. Using the ionograms recorded during March-April, 1998, under I-STEP campaign, we attempt to ascertain the ambient ionosphere-thermosphere conditions especially the role of meridional winds in the occurrence of ESF at Trivandrum,an electrojet station and SHAR, a non-electrojet station both over India.A large wind velocity significantly reduces the instability ,even if a large upward ExB drift velocity is applied and the wind effect is more prominent when the reversal time of the ExB drift is late. We also attempt to assess whether the favourable or unfavourable conditions found are related to geomagnetic activity or merely extreme forms of the day to day variability.

GA2.02/W/23-B5 1640

MODELLING SECTIONS OF THE EQUATORIAL F-REGION DURING SUNRISE AND SOLAR ECLIPCE

O.P.KOLOMIITSEV (1), I.B.Egorov (1), B.M.Reddy (2), V.A.Surotkin (1) (1) IZMIRAN, Troitsk 142092 Moscow Region, Russia (2) National Physical Laboratory, New Delhi 110012, India

The description of numerical-analytical method of construction of vertical structure ionospheric plasma is caused. The method permits to reproduce two-dimensional the sections of F-region - isolines of plasma frequency in coordinates height-time (height-distance) under various solar-geophysical conditions: the initial conditions, solar activity, season, photochemistry, geomagnetic disturbance, diffusion, and vertical drift of the ionospheric plasma. The method was used for construction of the ionospheric sections to sunrise and eclipse periods. For example, the results of accounts to equator present, where in the ionospheric F-layer near sunrise or at eclipce for certain conditions a hole of lower electron density can arise, which is situated between the F-layersurviving after the night and the new morning F-layer. It is shown that near to total phase of eclipse below of maximum Ne the decrease Ne is observed. This spot of perturbation of eclipce Ne with increase of height is run and displaces aside of midday. On vertical it covers the region of heights 150-270 km, till time of ~30 min with maxima shifted to midday concerning to total phase eclipse on 10-15 min. Solar eclipce renders also the influence and on rate run of night F-layer, and layer actually disappears by 07.40 LT, i.e. the hole lifetime increases, and without eclipce it already disappears by 07.05 LT. The total lifetime of the hole (the sunrise and solar eclipce effects) is equal ~120 min.

MEASUREMENT OF EXPLOSION-INDUCED GEOMAGNETIC DISTURBANCES*

D. LYNN SHAEFFER, Donald R. Rock, J. Patrick Lewis, and Stephen I. Warshaw (all at Lawrence Livermore National Laboratory, P.O. Box 808, L-183, Livermore, California, U.S.A. 94550, email: shaeffer1@llnl.gov

The Black Thunder Coal Mine (BTCM) near Gillette, Wyoming was used as a test bed to determine the feasibility of detecting explosion-induced geomagnetic disturbances with ground-based induction magnetometers. Two magnetic observatories were fielded at distances of 50 km and 64 km geomagnetically north from BTCM. Each observatory consisted of three mutually orthogonal magnetometers, Global Positioning System (GPS) timing, battery and solar power, a data acquisition and storage system, and a three-axis seismometer. Explosions with yields of 1 to 3 kT of TNT quivalent occur approximately every three weeks at BTCM. Explosion-induced acoustic waves propagate upward and interact collisionally with the ionosphere to produce ionospheric electron density perturbations that act as sources for geomagnetic disturbances. These disturbances propagate through an ionospheric Alfvén waveguide that we postulate to be leaky. Consequently, wave energy may be observed on the ground. We observed Q-bursts that appear to be excited in the earth-ionosphere cavity by Alfvén solitons that may have been generated by the explosion-induced acoustic waves reaching the ionospheric E and F regions and that subsequently propagate down through the ionosphere to the atmosphere. In addition, we observed late time (> 800 s) ultra low frequency (ULF) geomagnetic perturbations that appear to originate in the upper F region (~ 300 km) and appear to be caused by the explosion-induced acoustic wave. We suggest that explosion-induced Q-bursts may be discriminated from naturally occurring Q-bursts by association of the former with the late time explosion-induced ULF perturbations. Experimental results, analyses, and conclusions will be presented. (… This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48.)

SPATIAL DISTRIBUTION OF E-REGION DECAMETRE WAVELENGTH IRREGULARITIES OBSERVED BY THE HIGH FREQUENCY VALENSOLE RADAR

Glenn Hussey (Institute of Space and Atmospheric Studies, University of Saskatchewan, Saskatoon, Canada); Christos HALDOUPIS (Physics Department, University of Crete, Iraklion, Crete, 710 03 Greece, Email: haldoupis@talos.cc.uch.gr) ; Alain Bourdillon (Laboratoire Radiocommunications, URA CNRS 834, Universitede Rennes 1, Rennes, France); Jean Delloue (Laboratoire de Physique de l'Exosphere, Universite Pierre et Marie Curie, Paris, France); Dieter Andre (Institute of Space and Atmospheric Studies, University of Saskatchewan, Saskatoon, Canada)

We use data from a high frequency (HF) Doppler radar experiment at midlatitudes to perform a statistical analysis of the spatial occurrence of E region decametre backscatter. The radar, which is located near Valensole in Southern France made multifrequency measurements of high resolution spectra simultaneously at four frequencies, namely, 9.23, 11.03, 12.71 and 16.09 MHz, which correspond to backscatter from field-aligned, E region irregularities with wavelengths of 16.3, 13.6, 11.8 and 9.3 m, respectively. Based on the premise that E region scattering is fully magnetic aspect sensitive, the spatial occurrence statistics show that the aspect sensitive region moves towards the radar (southward) with respect to line-of-sight propagation calculations with the lower frequency echoes being closer towards the radar than the higher frequency ones, in agreement with refraction theory predictions. Ray-tracing calculations inside nighttime midlatitude electron density profiles augmented with dense sporadic Es layers was used to calculate the expected echoing region and, indeed, good agreement with the observed region was found. Another finding is the angular distribution of backscatter inside the wide azimuthal sector covered by the radar scan. The spatial distribution of echo occurrence has its maximum at small azimuths at and about the geomagnetic north, suggesting that statistically the meridional direction is strongly preferred for backscatter. Under the postulation that these are secondary decametre waves, we conclude that the observed angular anisotropy in spatial occurrence is at odds with the concept of strong isotropic plasma turbulence (i.e., see Sudan, JGR, 88, 4853, 1983), but in general agreement with he two step instability theory of secondary wave generation proposed earlier (i.e., see Sudan et al., JGR, 78, 240, 1973).

LARGE POLARIZATION ELECTRIC FIELDS ASSOCIATED WITH MIDLATITUDE SPORADIC E

Sergei Shalimov (Institute of Physics of the Earth, Moscow, Russia, Email: shalimov@uipe-ras.scgis.ru)Christos HALDOUPIS (Physics Department, University of Crete, Iraklion, Crete, 710 03 Greece, Email: haldoupis@talos.cc.uch.gr)Kristian Schlegel (Max-Planck-Institut fuer Aeronomie, Katlenburg-Lindau, Germany, Email: schlegel@linmpi.mpg.de)

Recent 50 MHz E region coherent backscatter observations and in siturocket measurements established the existence of enhanced electric fields in the midlatitude ionosphere that can become at times sufficiently large to excite the Farley-Buneman instability. To understand the origin of these fields, we present a simple quantitative model that relates to a local polarization process acting inside spatially confined, nighttime sporadic E layers of dense ionization.
By including the effects of field-aligned currents in the current continuity equation we estimate the necessary conditions on the relative horizontal E layer extent and the ratio of integrated Pedersen conductivities above andinside the layer for the generation of both zonal and meridional polarization fields. We show that the polarization process can account for the elevated electric fields of several millivolts per meter, which are implied often from backscatter Doppler measurements during unstable E region conditions at midlatitude.
The polarization process can become much more effective for dense and strongly elongated Es layers under the action of an enhanced ambient electric field. In this case, large polarization fields that may be capable of exciting Farley-Buneman plasma waves can be sustained. The stringent requirements for strongly elongated sporadic E layers with sharp boundaries, low ionospheric Pedersen conductivities above the layer in relation to those inside, and relatively large ambient electric fields would explain why type 1 echoes are so rare in midlatitude E region backscatter.

THE GENERATION OF IONOSPHERIC IRREGULARITIES DUE TO INSTABILITY OF ACOUSTIC-GRAVITY WAVES IN THE ELECTRIC FIELD

Valery SOROKIN and Vitaly Chmyrev (both at: Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Russian Academy of Sciences, IZMIRAN, Troitsk, Moscow Region, Russia, 142092, email: sova@izmiran.rssi.ru)

The generation mechanism of small – scale ionospheric irregularities is presented. The critical factor of the mechanism is excitation of super threshold DC electric field in the lower ionosphere initiating the AGW instability and the formation of periodic structure of Pedersen conductivity, field – aligned electric currents and the related plasma density inhomogeneities in the upper ionosphere. The electric field energy transforms to the energy of acoustic oscillations without a change in the medium thermal balance. The instability increment is proportional to the square of external electric field. In the presence of external DC electric field the conductivity variations in E-layer lead to an appearance of polarization electric fields propagating into the upper ionosphere and generating the plasma density variations at these altitudes. Estimates of the space-time and amplitude characteristics of the excited ionospheric disturbances and their comparison with the satellite data show that the developed mechanism can be applied to explanation of some properties of auroral ionosphere irregularities, as well as to generation model of earthquake related small-scale plasma inhomogeneities in the upper ionosphere.

DIFFERENCES AND CHARACTERISTICS IN THE FORMATION OF DIFFERENT TYPES OF THE IONOSPHERIC E-REGION SPORADIC LAYERS FROM INOSPHERIC SOUNDING DATA OBTAINED IN THE EAST-SIBERIAN REGION

V.F.Petrukhin, E.A.Ponomarev and N.A.Sutyrin (Institut of Solar-Terrestrial Physics, Irkutsk, Russia, email: nasut@iszf.irk.ru)

Presented are results derived from analyzing the data on the ionospheric Es-layer behavior over East Siberia for the time interval 1975-1996. The analysis was carried out by using a filter separating the data into daytime and nighttime intervals (from the solar zenith angle), as well as without it. It is shown that the formation conditions of type "1" and "f" Es differ from those for type "c" Es. The highest formation probabilities of type "1" and "f" Es coincide with the passage time of the morning and evening terminators, and the formation probabilities are higher in the case of the evening terminator when compared with the morning terminator. The formation conditions of type "1" and "f" Es are largely associated with the annual variation of the solar zenith angle. Also, the formation probabilities and heights of type "f" and "1" Es are differ from each other. The formation conditions of type "c" Es are different. The height-time variation of its formation probabilities is similar to that of the semi-diurnal temperature component in the ionospheric E region obtained in terms of the MSIS model.

NONEQUILIBRUM PROCESSES AND ORGANIZED STRUCTURES IN NEAR COSMIC SPACE

Vjacheslav M. Somsikov (Institute of Ionosphere, Kameskoe Plato, 480068 Alma-Ata, Republic of Kazakstan, email: nes@kaznet.kz) Gennadiy V. KHREBTOV and Ibragim E. Suleimenov (both at Institute of Ionosphere, Kameskoe Plato, 480068 Alma-Ata, Republic of Kazakstan, email: gn@ionos.alma-ata.su)

Transition processes in Near Cosmic Space during magnetic storms and in sunrise-sunset hours of day has been investigation by the methods of nonequilibrium dynamics. By joint processing of experimental records of variations of a magnetic field, cosmic rays and ionosphere of parameters the occurrence of dynamic chaos final Hausdorff dimension in variations of a magnetic field and ionosphere of concentration in transitive periods is established. It was found that at transitive hours in ionosphere parameters the additional oscillatory mode has appeared. The comparative analysis of results of processing of records of cosmic rays and magnetic fields, has allowed to assume that the variations, registered on ground, of a magnetic field and variations of cosmic rays in a minute range of frequencies arise on ionosphere heights. Therefore our results testify to presence of the determined chaos in Near Cosmic Space in transitive periods of days.

TURBULENT FLUCTUATIONS OF ELECTRON DENSITY GRADIENT IN THE LOWER IONOSPHERE

Olga G. KHUTOROVA, Dmitry V. Paponov (both radioastronomy dep., Physics fac., Kazan State University, 18, Kremlevskaya st., Kazan, Russia, 420008, e-mail: olga@erae.kazan.ru)

The numerical model of spectrum of turbulent fluctuations of gradient of electron concentration at various heights from 80 to 110 km is carried out versus of the irregularities horizontal size. The model takes into account the seasonal and geophysical changes in ionosphere. The analytical kind of the spectrum is found with using of the theory of dimensions. The spectrum has a maximum near the internal scale of turbulence. Spectrum model is based on empirical ionospheric models.

FORMATION OF FAST IONOSHERIC PLASMA FLUCTUATIONS CAUSED BY METEOR IONIZATION.

Nicolay S. Andrianov, Guerman M. TEPTIN (both radioastronomy dep., Physics fac., Kazan State University, 18, Kremlevskaya st., Kazan, Russia, 420008, e-mail: teptin@erae.kazan.ru)

Meteor ionization makes significant contribution to dynamics of plasma irregularities at heights 80-100 km. Several thousands of meteor particles penetrate during one hour with space velocities, leaving after themselves plasma trails with electron densities 10 fi 10 per meter, several kilometers by length and with diameter by the order of the one meter. Our theoretical investigations and simulation have shown that these irregularities are explained by the influence of turbulent winds and it is well confirmed by experiment. Parameters of turbulent motions and parameters of meteor trails are accounted in the model when dissipative processes are operative (attachment, ambipolar and turbulent diffusion). Estimates were fulfilled by Monte-Carlo method.

NEUTRAL WIND DRIVEN GRADIENT DRIFT INSTABILITY IN THE MIDLATITUDE E REGION

Ludmila Kagan (Radiophysical Research Institute, B.Pecherskaya 25, Nizhny Novgorod 603600, Russia, e-mail: kagmil@nirfi.sci-nnov.ru) Michael Kelley (School of Electric Engineering, Cornell University, Ithaca, NY 14853, USA, e-mail: mikek@ee.cornell.edu)

We propose a new explanation for medium- to small-scale irregularities in the mid-latitude E region. We show that the very wind field that forms thin layers of ionization can also create plasma instabilities. To date, the application of gradient drift instability theory has been restricted to free energy sources involving the ambient electric field. We show that a vertical shear in the zonal wind not only leads to layer formation, but also to unstable regions on both sides of the layer. The mechanism thus does not suffer from the problem inherent in electric field-driven processes, namely, that the mapping of electric fields along magnetic field lines leads to stabilizing conditions on one side of the layer, even if the other side is unstable. Evidence is given that anomalous diffusion due to such waves affects the evolution of the layers.

SPECTRAL AND FLOW ANGLE CHARACTERISTICS OF BACKSCATTER FROM DECAMETRE IRREGULARITIES IN THE AURORAL ELECTROJETS

S E MILAN, M Lester (Both at Department of Physics and Astronomy, Leicester University, Leicester LE1 7RH, UK. Email: Steve.Milan@ion.le.ac.uk)

Measurements are presented of backscatter spectra from 15 m ionospheric irregularities in the auroral electrojets by the CUTLASS Iceland coherent HF radar. The scanning nature of the radar allows the flow angle dependence of the spectral characteristics to be determined and interferometric techniques allow the altitude of the scatter volume (E-, upper E-, or F-region) to be estimated. Several populations of backscatter spectra are observed, each with distinct velocity-spectral width and velocity-flow angle behaviours. At E-region altitudes, two populations appear to correspond to the type I (two-stream instability) and type II (gradient drift instability) spectra observed with VHFradars. However, two E- or upper E-region spectral populations with velocities up to 1000 m/s, above the typical ion-acoustic speed, are also observed. Furthermore, a population with Doppler shifts of the opposite sense to the main body.

STATISTICAL ANALYSES OF ELECTRON DENSITY DISTRIBUTION AT HIGH LATITUDE

Yasuyuki Sato, Hiroaki MISAWA, Akira Morioka (all at Upper Atmosphere and Space Research Laboratory, Tohoku University, Sendai, 980-8578, Japan, email: misawa@stpp2.geophys.tohoku.ac.jp) Hiroshi Oya (Department of Astronomy and Geophysics, Tohoku University, Sendai, 980-8578, Japan, email: oya@stpp1.geophys.tohoku.ac.jp) Toshifumi Mukai (Institute of Space and Astronautical Science, Sagamihara, 229-8510, Japan, email: mukai@fujitubo.gtl.isas.ac.jp)

Statistical profiles of electron density distribution have been derived for the high latitude regions by using the data measured with Plasma Wave and Sounder experiment (PWS) on board the EXOS-D (AKEBONO) satellite. We have analyzed the data of 1989 to 1994 for the altitude range of 300 km to 10,000 km and the invariant latitude range of 50 to 90 degrees. An electron density was derived by detecting upper hybrid resonance frequency and/or cut-off frequency of whistler mode waves. The data of electron density were classified according to local-time, season and geomagnetic activity, then, statistical profiles have been determined as averaged values for the bins of every 50 km height and every 1 degree in invariant latitude. The major results of this study are as follows. 1)There is little difference between the density profiles of summer and winter for the invariant latitude below 60 degrees, while, the densities in winter are smaller than that in summer for the latitude over 60 degrees and the altitude below 6,000 km. This result suggests a possibility of the close relation of back-ground electron densities with the seasonal variations of occurrence of auroral electron accelerations and AKR events.2)There is a density enhancement region particularly in day-side at the altitude of thousands km and the invariant latitude around 80 degrees. The region corresponds to that of downward electron flux with hundreds eV observed with the LEP instrument on board AKEBONO. 3)A set of fitting functions of electron density profiles is empirically

FLOW ANGLE PROPERTIES OF THE 1-M IONOSPHERIC PLASMA WAVE TURBULENCE

E E TIMOFEEV (Polar Geophysical Institute of the Russian Academy, Murmansk, Russia); M K Vallinkoski, J Kangas, P Pollari (Department of Physics, University of Oulu, Finland); T Virdi, P J Williams (Department of Physics, University of Aberystwyth, Wales, U.K.); E Nielsen (Max-Planck-Institute fuer Aeronomie, Katlenburg-Lindau, Germany)

The coordinated STARE-EISCAT data stored for the multi-event ERRRIS campaign are used to study the flow angle properties of threshold ionospheric parameters controlling the STARE radar echo appearance. The selected data with 0db<SNR<1db contain 64 and 128 cases observed by the Finnish (F-radar) and Norwegian (N-radar) STARE radar, respectively. The echo is supposed to come from different echo-layers corresponding to the zero aspect angles: from100_6 km and 108_6 km altitudes over Tromso for the N-radar and F- radar, respectively. Electron and current densities are averaged over the echo-layer altitudes and over 30-degree flow angle bins. It is found that: 1) for the F-radar the threshold E-field strength is drift-aligned, and therefore anisotropic. Besides, there is a systematic decrease of the strength when going from positive to negative flow angles. For the N-radar the threshold E-fields are practically independent of flow angle, and therefore isotropic; 2) the average threshold E-fields are systematically lower but the threshold electron densities are higher in the westjet than within the eastjet for either radar. The difference of the fields is about 25% (50%) but of the densities is factor of 2.25 (1.5) for the N- and the F- radar; respectively; 3) the threshold electron density level is higher in the F-radar than in the N-radar echo layer by a factor of 3 (4) within the westjet (eastjet), respectively.
The nonlinearity of the dynamo layer plasma waves responsible for the F-radar echo is concluded even for small near-threshold E-fields. It is conjectured that the plasma wave turbulence level is enhanced (damped) due to the gradient-drift mechanism within the eastjet (westjet), respectively.

THE THERMAL EFFECTS IN THE EXCITATION OF THE FARLEY-BUNEMAN WAVES

E E TIMOFEEV (Polar Geophysical Institute of the Russian Academy, Murmansk, Russia); M K Vallinkoski, J Kangas, P Pollari (Department of Physics, University of Oulu, Finland); T Virdi, P J Williams (Department of Physics, University of Aberystwyth, Wales, U.K.); E Nielsen (Max-Planck-Institute fuer Aeronomie, Katlenburg-Lindau, Germany)

Properties of the threshold E-fields of a radar echo appearance are analyzed from statistics of the coordinated STARE-EISCAT measurements stored during the multi-event ERRRIS campaign. The selected data pool with 0 dB <SNR <1dB contains 64 cases observed by the Finnish STARE radar (F-radar). The radar echo is supposed to come from the zero-aspect angle layer (echo-layer):108_6 km altitudes over Tromso. Electron (Te) and ion (Ti) temperatures are analyzed as being averaged over the echo-layer width and over 30-deg flow angle bins. Properties of the threshold ratio of the electron drift to-ion-acoustic velocities (Vd/Cs) dependence on the Te/Ti ratio are analyzed for the following set of the half-widths of the flow angle cone: 15, 30, 45 and > 45 degrees. It is found that: 1) In about 90% of all threshold cases the Vd/Cs is less than 1; 2) the properties are essentially different within and beyond _45 degree flow angle cone that is interpreted as a primary cone of the modified FB-waves. Within the cone Vd/Cs achieves its maximum for Te/Ti of about 0.8 and has a tendency to decrease both for Te/Ti>1 and for Te/Ti<1. Beyond the cone Vd/Cs is minimum for Te/Ti of about 0.8 and has a tendency to increase both for Te/Ti>1 and for Te/Ti<1; 3) within (beyond) the cone the properties of the histograms of the threshold radar echo occurrences as a function of Te/Ti are similar to the bi-Maxwellian (Maxwellian) population distribution function, respectively.
The results are quantitatively compared with the modern theory of the electron thermal diffusive instability. It is concluded that within the primary cone of the modified FB-waves the ionospheric plasma permanently is in the stage of the termodynamical non-equilibrium.

DETERMINATION OF TEC OF IONIZATION OVER ARGENTINE WITH DIFFERENTIAL DOPPLER MEASUREMENTS AND COMPARISON WITH IRI

VICTOR H. RIOS (1) and Cesar Valladares (2), Lab. de Técnicas Satelitales (1), (1) Instituto de Física, Universidad Nacional de Tucumán Av. Independencia 1800, (4000) San Miguel de Tucumán - Argentina (2) Institute for Space Research, Boston College, Newton, MA

Differential Doppler measurements of signals from NNSS Navigational Satellites can be used to give the electron content of the ionosphere . Measurements carried out using data from four stations on Argentine. Differential Doppler data from two station are combined, resulting in considerably more reliable results , particularly when there is strong horizontal structure in the ionosphere, as is often the case in Equatorial and polar regions. Examples of model calculations and experimental measurements are also included. In applications of the trans-ionospheric propagation of radio waves first order range errors are proportional to (slant) electron content of the ionosphere, second order errors to the square of this quantity. The results are compared with the IRI model and typical examples are used to demonstrate the differences between model values and observed values. We have tried to highlight the global nature of such discrepancies aiming at providing an eventual basis for incorporating needed modification the predictive capability of the IRI for the equatorial and low latitude ionosphere. In many applications range differences are more important than range itself and this especially true for all interferometric methods. Range difference measurements are influenced by differences of electron content or "horizontal gradients"

HF RADAR OBSERVATIONS OF SMALL SCALE PLASMA TURBULENCE PARAMETERS AT THE MAGNETIC EQUATOR

K.S. VISWANATHAN (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum 695 022, India, email: spl_vssc@vssc.org)

The small scale turbulence parameters of electron density irregularity strength, anomalous electron collision frequency, the corrected E-W electron drift velocity and their spatial/temporal changes are derived in the equatorial electrojet location of Trivandrum (dip 0.5 deg. N), using 18 MHz HF radar observations conducted during daytime in the altitude region of 90-115 km mostly on quiet days. The effects of plasma turbulence on the altitude maximum of electron drift velocity and the shape of the profile are presented. The temporal variations of these parameters are examined in the light of the scattered signal power and drift velocity. Specifically the dependence of irregularity strength on power during weak and strong electrojet times is presented and the underlying physical processes are discussed.

A COMPARATIVE STUDY OF THE COLOCATED HF AND VHF RADAR EASUREMENTS IN THE EQUATORIAL ELECTROJET

K.S. VISWANATHAN (Space Physics Laboratory, VikramSarabhai Space Centre, Trivandrum - 695 022, India, email: spl_vssc@vssc.org)

A comparative study of the lower order spectral moments, obtained from the electrojet altitudes by means of 18 and 54.95 MHz coherent backscatter radars, operating at Trivandrum (dip 0.5 deg N) is carried out. The advantage of using HF data for specific studies like plasma turbulence parameters, longitudinal variability of electron drift velocity, zonal and vertical drifts during spread F conditions is emphasized. The altitude extent of the signal is larger in HF than that of VHF, in view of HF power aperture being nearly two orders of magnitude greater than VHF system. HF spectral information is obtained as low as 80 km, which is regarded as due to zonal winds and this value, in turn, is used to get the estimates of the winds upto 120 km. Also HF radar is used to study effectively the turbulence parameters and their spatial/temporal variation, in view of the absence of type I irregularities, unlike the VHF case. The HF radar signal presence in a larger altitude region is used by considering higher degree polynomial, even when the velocity profiles are distorted. The diurnal behaviour of electric fields by HF observations is clearly brought out. The derived parameters, by both the systems are compared and the observed similarities/differences are discussed in the light of the structured spectral shapes and the behaviour of the two scale sizes of the irregularities probed.

QUASI-PERIODIC BEHAVIOUR OF TYPE II IRREGULARITIES IN THE E REGION OFF THE MAGNETIC EQUATOR

K.S. VISWANATHAN, Sudha Ravindran, K.S.V. Subbarao (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum - 695 022, India, email: spl_vssc@vssc.org)

Observations of E region FAI of 2.8 m scale size are made on several days in summer and equinoctial months during nighttime using the Indian MST radar at Gadanki(dip 12.5 deg.N). Observations made at altitude interval of 1.2 km and time interval of mostly five min in the altitude region of 90-120 km are used for the present study. The Doppler spectra are of type II quasi Gaussian, ranging from a narrow single peak to wide multiple peak, showing variability in time and altitude. The drift of the irregularities does not generally exceed 40 m/s. The drifts in the altitude range of 100-115 km are mostly downward at night and upward occasionally. The intensity and drift of the signals are oscillatory in nature showing quasi-periodic behaviour

with periods in the range 25-35 min. The amplitude of the wave is found to increase from lower to higher altitudes with phase propagation downwards, indicating gravity wave activity. This is attributed to the formation of irregularities due to gradient drift instability mechanism in the presence of sporadic E layers with sharp gradients modulated by gravity waves, as discussed by Woodman et al. (1991) for midlatitude observations. The observations are discussed in the light of local treatment of the instability mechanism.

EQUATORIAL SPREAD-F LONGITUDINAL BEHAVIOUR

Anna DEPUEVA (IZMIRAN, Troitsk, Moscow Region, 142092, Russia, email: depueva@izmiran.rssi.ru)

Simultaneous bottomside and topside ionograms were analysed for the two different longitudinal positions (Djibouti and Huancayo) prior to and during equatorial spread-F and non-spread-F conditions. Generalized collisional Rayleigh-Taylor (GRT) instability growth rates were estimated, the term «generalized» being reffered to inclusion of electric fields and neutral winds as destabilizing factors, as well as the classic gravitational term. Electron density gradient values were taken from the real experimental N(h)-profiles, neutral ionosphere parameters were calculated by the Kohnlein model. It was shown that the observed spread-F longitudinal behaviour could be hardly explained in frames of GRT instability action. This result should be useful for distinguishing global and local triggering spread-F mechanisms.

HF AND VHF RADAR OBSERVATIONS OF EQUATORIAL SPREAD F

R. SEKAR and E.A. Kherani (both at Physical Research Laboratory,Ahmedabad 380 009, India, email: rsekar@prl.ernet.in) A.K. Patra (Department of Physics, K.O. College, Gumla 835 207, India) P.B.Rao (both at National MST Radar Facility, P.O. Box 123,Tirupati 517 502, India, email: nmrf@isro.ernet.in) K.S. Viswanathan, C.V. Devasia and K.S.V. Subbarao (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum 695 022,India, email: spl_vssc@vssc.org)

A coordinated observational campaign, involving simultaneous operation of the 18 MHz HF and 53 MHz VHF radars located respectively at Trivandrum (8.5 deg.N, 77 deg.E; dip 0.5 deg.N) and Gadanki (13.5 deg.N, 79.2 deg.E, dip 12.5 deg.N), has beenconducted during March-April 1998. The bservations are presented in the form of height-time variations of signal intensity, mean Doppler velocity transverse to the magnetic field and velocity spectral width. The Doppler spectra at both HF and VHF are found to be of simple Gaussian to multi-peak complex characteristics. The signal intensity variations at the two frequencies are found to be, in general, well correlated. The topside multiple plume structures observed at VHF on most of the intense ESF events are found to resemble that simulated by Haung and Kelley (J. Geophys. Res., 101, 293, 1996) through gravity wave seeding. The Doppler velocities at 18 MHz are typically less than 50 m/s, while they could be as high as 200 m/s at VHF in the topside, indicating the dispersive nature of ESF irregularities. The velocity spectral widths are found to be as large as or even larger than the mean Doppler velocitiesobserved at the two frequencies.

PRODUCTION OF ELECTRIC FIELD PERTURBATIONS BY GRAVITY WAVE WINDS IN THE E REGION SUITABLE FOR INITIATING EQUATORIAL SPREAD F IRREGULARITIES

Satya Prakash and H.S.S. SINHA, Research Laboratory, Navrangpura, Ahmedabad -380 009, INDIA, email: hsinha@prl.ernet.in

We present here a mechanism where the electric field perturbations, which can map up to the F-region base, are produced through the interaction of the electric field perturbations with sporadic-E layers and a thin E layer. The mechanism operates in two steps. In the first step, the thickness of the E layer is reduced due to the downward transport of plasma by the downward electric fields. These downward electric fields, which map down from the F region to the E region, are generated by the eastward winds in the F region through dynamo action. In the second step the electric field perturbations is produced through interaction of the electric field perturbations having vertical wavelengths similar or larger than the thickness of these layers. These electric field perturbations are produced through Hall conductivity and their amplitudes can be much larger than those produced through the mechanisms proposed earlier. These electric field perturbations are very well suited for the growth of seed irregularities in the base of the F region. The characteristics of these seed irregularities are such that they can account for the growth of multiple equatorial spread F plumes, through the Rayleigh Taylor Instability, observed in the equatorial F region during late evening hours. In the mechanism proposed earlier, the electric field perturbations are produced when the wave front of gravity wave in the meridian plane is parallel to B. The proposed mechanism is effective practically at all latitudes as there is no such restriction on the orientation of the wave front of the gravity wave with respect to B.

OPTICAL IMAGING OF PLASMA DEPLETIONS FROM SHAR

H.S.S. SINHA, Shikha Raizada and R.N. Misra, Physical Research Laboratory, Navrangpura, Ahmedabad -380 009, INDIA

A multi-wavelength all sky optical imaging instrument developed at PRL was operated from a low latitude station SHAR (13?N, 82?E). The purpose of the experiment was to study the nature of very large-scale irregularities using airglow emissions at 630 nm and 777.4 nm. One of the very interesting features which emerged from this study is the eastward tilt of the depletions which lies between 10 - 15?. This is a significant result as the earlier observations from the American sector showed that the plasma depletions are tilted in westward direction. Our data suggests that these tilts might be associated with the altitudinal increase of nighttime plasma drifts.
The airglow images display multiple depletions, which are characterized with varying degree of depletions. It is observed that the E-W extent of the depletions varies with depletion depth. Shallower depletions appear to be associated with smaller zonal width as compared to deeper depletions. This might be probably the manifestation of the fact that deeper bubbles, characterized by large amplitudes, represent well-developed irregularities.
The distance between adjacent depletions i.e. the inter depletion distance (IDD) is found to vary between 100 km to about 950 km suggesting that gravity waves might be the seeding agency for generating such large scale structures.

SEASONAL AND SEMIANNUAL CHANGES IN THE F2-LAYER

Henry RISHBETH (Department of Physics and Astronomy, University of Southampton, Southampton SO17 1BJ, UK, email: hr@phys.soton.ac.uk)

The seasonal, annual and semiannual variations of the quiet F2-layer represent a challenging problem in ionospheric physics. It is now becoming possible to construct a unified picture which is closely linked to the global circulation in the thermosphere, which is driven by solar XUV radiation and inputs from the solar wind and magnetosphere. This paper outlines the present understanding and reviews some unsolved questions.

IMAGING THE HIGH-LATITUDE IONOSPHERIC COVECTION PATTERN

Raymond A. GREENWALD, J. M. Ruohoniemi, and R. J. Barnes (all at Johns Hopkins University, Applied Physics Laboratory, Johns Hopkins Rd., Laurel, MD, 20723, USA,
email: mike_ruohoniemi@jhuapl.edu)

Many important advances in ionospheric research have resulted from the advent of spacecraft-borne imagers that effectively take snapshots of the global pattern of auroral luminosity. When connected in temporal sequence, the images dramatically demonstrate the dynamical behavior of auroral processes. With the realization of the SuperDARN concept in the northern and southern hemispheres, it has become possible to similarly 'image' the high-latitude pattern of ionospheric convection velocity. Although the field of view of each radar is limited to about 10% of the high-latitude one, combining the information from all six radars in the northern hemisphere results in coverage of nearly _ of the entire convection pattern. The temporal resolution available is 1-2 minutes. This global, instantaneous view has been needed to elucidate the manner in which the global pattern responds to IMF variations. We outline the technique for deriving snapshots of the convection pattern and present examples of comparison with imager and low-altitude satellite data. With the increasing emphasis on now-casting and fore-casting the state of the ionosphere, we have developed an extensive on-line facility for accessing SuperDARN products. This includes near real-time maps of the global convection pattern and time series of the cross-polar cap potential variation. These products may be thought of as space weather reports and are available to the general community at the Internet address: http//superdarn.jhuapl.edu/html. We will discuss the critical science topics that are being addressed with the unique capabilities of SuperDARN, describe the upgrades to the system that are underway, and the availability of SuperDARN products.

THE FORENOON IONOSPHERIC ELECTRON DENSITY VARIATIONS OVER THE MU RADAR

S.-R. ZHANG, S. Fukao, and Y. Otsuka (Radio Atmospheric Science Center, Kyoto University, Japan, email: shunrong@kurasc.kyoto-u.ac.jp; fukao@kurasc.kyoto-u.ac.jp; otsuka@kurasc.kyoto-u.ac.jp)

This paper deals with the diurnal variations of electron density profile measured by the MU radar during 1986-1995 period, nearly a full solar cycle. We focus on the so-called forenoon "bite out" of ionization, which is characterized with a lower electron density occurring around 8-11 LT. The statistic study shows that it appears more clearly in summer than in other seasons and for lower solar activity (LSA) than for higher solar activity (HSA). The density depletion becomes increased with increasing height. To understand the involved physical mechanism, a theoretical model is applied, in corporation with MU radar measurements of the ion drift and plasma temperatures during the period, so that the relative importance of the O/N2 ratio, the neutral wind, the vertical component of electric field induced drift, the plasma temperatures, and the topside O+ flux can be analyzed. It is found that (1) in summer at higher solar activity, a higher electron temperature is a necessity to produce a lower forenoon electron density through increasing the plasma diffusion and the O+ loss rate; the poleward neutral wind is favorable to the lower density, but it alone can not significantly deduce the electron density. (2) in summer at lower solar activity, both the poleward neutral wind and the higher electron temperature play significant roles to cause the forenoon bite out. (3) there is no indication for a lower O/N2 ratio to account for the bite out. (4) the effect of the vertical drifts induced by the local eastwest electric field tends to cancel the bite out. (5) the forenoon decrease of O+ flow at 500 km is favorable for a lower density around the F2 peak but its importance is not essential for the bite out.

SPACE OBSERVATIONS OF ION CYCLOTRON WAVES EXCITED BY A ULF RADAR

K. MURSULA, T. Bösinger, and T. Kivisaari (Department of Physical Sciences, University Of Oulu, P.O. Box 3000, FIN-90401 Oulu, Finland, email: Kalevi.Mursula@oulu.fi); P. P. Belyaev (Radiophysical Research Institute, Nizhny Novgorod, Russia); Sobchakov and A. B.Vasiliev (Russian Inst. of Powerful Radiostructure, St.Petersburg, Russia); L. Blomberg (Alfvén Laboratory, Royal Institute of Technology, Stockholm, Sweden)

The first ULF radar experiment was carried out in Kola Peninsula in September 1993. During the experiment the current (Imax = 150-200 A) of a 60 km long power line was modulated in a sinusoidal fashion at frequencies between 0.3 and 5.2 Hz. The magnetic signal of this varying line current was recorded in several ground-based magnetometers at variable distances ranging from 300 km to 2000 km. In this paper we discuss the spectral and polarization properties of the signal received by the Finnish chain of pulsation magnetometers. Moreover, we have analyzed the electric field observations made simultaneously by the Freja satellite within and slightly above the ionosphere. Freja observes ion cyclotron waves with the frequency of the radar modulation frequency far away from the footpoint of the ULF radar. This

provides direct evidence for the fact that the ULF radar signal can excite a propagating wave in the ionosphere.

TRAVELING IONOSPHERIC DISTURBANCES OBSERVED IN THE 630NM NIGHTGLOW IMAGES AT MULTI-STATIONS IN JAPAN

Kazuo SHIOKAWA, Mitsumu Ejiri, and Tadahiko Ogawa (Solar-Terrestrial Environment Laboratory, Nagoya University, 3-13, Honohara, Toyokawa, Aichi 442-8507, Japan, Email: shiokawa@stelab.nagoya-u.ac.jp); Minoru Kubota (Communication Research Laboratory, 4-2-1, Nukuikita, Koganei 184-8795, Japan, Email: mkubota@crl.go.jp); Akinori Saito (Department of Geophysics, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan, Email: saitoua@kugi.kyoto-u.ac.jp); Shoichiro Fukao (Radio Atmospheric Science Center, Kyoto University, Uji 611-0011, Japan, Email: fukao@kurasc.kyoto-u.ac.jp); Shinichi Miyazaki (Geographical Survey Institute, Kitagou, Tsukuba 305-0811, Japan, Email: miyazaki@gsi-mc.go.jp); Kenichi Nakajima and Takeshi Sakanoi (Graduate School of Science, Tohoku University, Aoba-ku, Sendai 980-8578, Japan, Email: ken@pat.geophys.tohoku.ac.jp)

We have conducted imaging observation of 630nm airglow using five all-sky cooled-CCD cameras in Japan during the F-region Radio and Optical measurement of Nighttime TIDs (FRONT) campaign on May 16-24, 1998. The cameras are located at Moshiri (44N, 142E), Zao (38N, 141E), Kiso (35N, 138E), Shigaraki (35N, 136E), and Bisei (35N, 134E). Traveling ionospheric disturbances (TIDs) have been observed as wave structures in the images on May 19-23. Most of the structures have a wave front with a direction of NW-SE and move toward SW with a velocity of about 100 m/s. Typical wavelength of the structures was 200-400 km. The wavelength tends to decrease with decreasing latitudes from Moshiri to Bisei. Similar wave structures are also seen in the two-dimensional distribution of total electron content (TEC) obtained by more than 900 GPS receivers of the GPS Earth Observation Network (GEONET) in Japan. Based on these observations, we discuss possible production and propagation mechanisms of the mid-latitude TIDs.

DAY-TO-DAY CHANGES IN THE SQ IONOSPHERIC CURRENT SYSTEM

Robert STENING (School of Physics, University of New South Wales, Sydney 2052, Australia, email: R.Stening@unsw.edu.au)

During times of magnetic quiet there are still large day-to-day changes in the amplitude and shape of the daily magnetic variations at various observatories. These variations include such large changes as the reverse equatorial electrojet and the "invasion" of the winter current system by the summer system. One presumes that these changes are brought about by changes in the upper atmosphere (tidal) wind systems. In order to confirm this, comparisons need to be made between changes in the global current systems and changes in the global wind systems.

GA2.03/W/06-B3 1200

AN AUTOMATIC PROCEDURE FOR DETECTION OF IONOSPHERIC STORMS

Lj.R. CANDER (Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX, UK, email: l.cander@rl.ac.uk) M.M. Milosavljevic (Faculty of Electrical Engineering, Belgrade University, Belgrade, Yugoslavia, email: emilosam@ubbg.etf.bg.ac.yu)

Many space weather applications require knowledge of the ionospheric F region response to the great geomagnetic storms, particularly its commencement and duration. The precise detection of the ionospheric storm periods in off -line mode can be performed using a new so-called modified generalised likelihood ratio (MGLR) algorithm. This algorithm has been applied on the critical frequencies of the ionospheric F2 layer, foF2 time series measured at Slough, Juliusruh, Rome and Belgrade ionospheric stations during the February 1986 storm. It is found that MGLR algorithm enables not only fully automatic detection of abrupt changes in foF2 variations but inspection of different kind of ionospheric variability before and after the storms.

BISTATIC RADAR OBSERVATIONS OF THE E-REGION IRREGULARITIES DURING TROMSO HEATING EXPERIMENTS

Nataly BLAGOVESHCHENSKAYA, Tatyana Borisova, Viktor Kornienko (all at Department of Geophysics, Arctic and Antarctic Research Institute, 38 Bering str., St. Petersburg, 199397, Russia, Email: nataly@aari.nw.ru); Michael Rietveld (Max-Plank-Institut fur Aeronomie, D-37191 Katlenburg-Lindau, Germany, Email: rietveld@linmpi.mpg.de)

Results of Tromso heating experiments in the night-side auroral Es region from bistatic radar measurements combined with multi-instrument observations at Tromso are presented. Experiments were carried out during Tromso heating campaign in February 1996 from 20 to 23 UT when the pump wave was reflected from auroral Es-layer. The bistatic HF radar was sensitive to irregularities having spatial dimensions of 12-15 m across the geomagnetic field lines. We show that dynamics of the auroral Es layer as well as the development of some geophysical phenomena in the ionosphere-magnetosphere system are affected by the powerful HF radio waves. The action of the ionospheric heating is found in modifications of the particle precipitation, visible auroral forms, field-aligned currents, and magnetic pulsations around the heated volume. The conclusion is made that the strong positive feedback in the substorm current wedge is set as a result of the heater action. Two general categories of the artificial field-aligned irregularities (AFAIs) in the auroral Es region are recognized from heating experiments. The first type of AFAIs has the small growth and relaxation times in response to the HF heater action. The velocities of these AFAIs are near 0 m/s suggesting that the scattered signals are coming from some stationary bulk feature of the heated plasma. The second type exhibits the large phase velocities up to 800 m/s. Their motion was consistent with the background plasma drift. Possible generation mechanisms of AFAIs are discussed.

FIRST GEOPHYSICAL ULF (0.1-10 HZ) GROUND-BASED FACILITY

L.A.Sobchakov, A.V.Vasiljev and N.L.Astakhova (Russian Institute of Powerful Radiostructure (RIPR), 68, 11-Line, 199161, St.-Petersburg, Russia); P.P.BELYAEV, S.V.Polyakov, M.N.Yakunin and S.V.Isaev (Radiophysical Research Institute (NIRFI), B.Pecherskaya St., 25, N.Novgorod, 603 600, Russia, e-mail: belyaev@nirfi.sci-nnov.ru); A.G.Litvak and A.I.Smirnov (Institute of Applied Physics of Russian Academy of Science (IAP RAS), Uljanov St., 46, N.Novgorod, 603600, Russia)

After the first successful artificial ULF experiment in September 1993, three Russian Institutes, RIPR, St.-Petersburg, NIRFI and IAP RAS created the easy flexible ULF facility for geophysical applications. The first testing of this facility, located on the Kola Peninsula, Russia, the region with very small conductivity, was carried out during July 1998. The ULF facility consists of 108-km powerline grounded at both ends with using of river power station buildings (Kola peninsula powerline Company). The portable 50 kW amplifier provided a radiation current of 60-100 A in the line. The crust conductivity under powerline achieves the value of 10-4 – 5*10-5 mho/m. The measurements of far field were carried out at distances 500 (RIPR) and 1500 km (NIRFI) for magnetic and electric field components. The near magnetic field measurements were carried out by Finnish scientific groups from University of Oulu and Sodankjula Laboratory.
The good signal/noise ratio allows us to obtain valid characteristics of ULF signals. The measured amplitude-frequency dependence (proportional to f -1/2 , where f – frequency in Hz), polarization and space distribution (R-2 , R-distance in km) of ULF fields were in line with theory predictions for daytime conditions. For the nighttime one, dramatic discrepancy was observed due to the influence of anisotropy of ionosphere and its temporal variations.

FLEXIBLE PRIOR MODEL, THREE-DIMENSIONAL IONOSPHERIC TOMOGRAPHY

RICHARD CORNELY, Walter Kuklinski, (University of Mass. Lowell, Department of Electrical Engineering, One University Avenue, Lowell Mass. 01854)

An ionospheric reconstruction system, that use constraints from knowledge of ionospheric physics, to produce a set of advanced and unique solutions, consistent with available TEC measurement data, to the underdetermined set of equations resulting from the ionospheric density reconstruction problem, will be presented. A major obstacle to implementing wide-scale ionospheric monitoring systems, is caused by the geometry of the ground based under-determined receiver and orbiting satellite measurement techniques. The resulting TEC data, will contain limited information about variation of electron density with altitude. Recently, a class of iterative algorithms that allow to incorporate additional information, have been successfully used to provide solutions, without a great deal of additional computational complexity. In addition, the nature of the solutions obtained is known to be close to an initial density solution model in the Kullback-Liebler sense. It is also known that, current state of the art prior density models can only simulate a representative ionosphere. As a result, daily and sudden variations in ionospheric electron density will not be represented in these models. This presentation, will focus on a three-dimensional ionospheric density reconstruction system, that uses a set of geometrical transformations to produce updated prior models, containing additional information not well represented in current state of the art ionospheric density models. The updated priors are consequently used as initial solution models to, a specific set of iterative algorithms, which provide a spatially constrained density solution, consistent with the available data and our knowledge of ionospheric physics.

ANALYSIS OF IONOSPHERIC PLASMA PATCH CHARACTERISTICS OBSERVED BY DGS-256 IN MIDDLE AND SOUTH CHINA DURING SPREAD-F PROCESS

JIAN-SHAN GUO(Center for Space Science and Applied Research, Chinese Academy of Sciences, P.O.Box 8701, Beijing 100080,P.R.China, Email: guojs@center.cssar.ac.cn) Hong Zheng, She-ping Shang, Nana Liu(idem)

This paper describes two processes of spread-F development observed at Hainan(110°E,19°N on Feb.1,1990) and Beijing(116°E,40°N on Jun.22,1989) Ionospheric Observatories, and shows how the amplitude and status panels of ionogram varies during the periods, and from which the size and drift velocity of the plasma patches can be estimated approximately by making use of the data of Doppler shift, polarization and amplitude on the panels of ionogram. The simulation of the processes has been made for illustrating the method of the estimation . In both cases , the spread-F*s develop very similar and quiet as usual: beginning at well known F trace with resolved satellite trace above, then the satellite trace winder more and more so that the normal F trace could be no longer identified, and finally the resolved satellite trace appears again. the status panels on the corresponding ionograms, however, shows wave like motion characteristics. The Doppler shift identified from status value on the satellite trace varies quasi-periodically from plus to minus three times for Hainan and two times for Beijing during the patches passing overhead. the passing period of the patches is about 1.5 hours for the tow cases. The characteristics of the patch in Hainan are as follows: drift velocity is about 50m/s (estimated roughly by the Doppler shift and virtual height from the status value of satellite trace). The horizontal wavelength is about 180-270km. The horizontal size of the patch is about 540-810km. A simulation results of a amplitude and status panels of ionogram and patch structure in spatial and velocity space(assumed weak fluctuation) for the patch with similar average characteristics as measured show very similar manner as appeared in the measurement

RESPONSE OF GLOBAL ION COMPOSITION IN THE TOPSIDE IONOSPHERE ON THESOLAR ACTIVITY CHANGES

V. TRUHLIK, L. Triskova, and J. Smilauer (all at Institute of Atmospheric Physics, 141 31 Praha 4, Czech Republic, email: vtr@ufa.cas.cz)

Mass spectrometer data base resulting from the Active mission for the maximum of solar cycle 22 completed by available data from the Goddard Comprehensive Ionosphere Data Base for the minimum of solar cycle 21 was used to study the solar cycle influence on the behavior of major and minor ions in the topside ionosphere up to 3000 km. Attention is focused on changes in the distribution of O+, H+, He+ as major ions; occurrence of minor NO+, N2+, O2+, N+ ions is considered as well. Experimental and modeled distributions are compared, discrepancies between them are discussed.

GA2.03/L/02-B3 1520

FIRST MEASUREMENTS OF ARTIFICIAL ULF (0.3-5 HZ) SIGNALS FROM GROUND-BASE FACILITY AT THE LONG DISTANCE 1500 KM

L.A.Sobchakov, A.V.Vasiljev and N.L.Astakhova (Russian Institute of Powerful Radiostructure (RIPR), 68, 11-Line, 199161, St.-Petersburg, Russia) P.P.BELYAEV, S.V.Polyakov and S.V.Isaev (Radiophysical Research Institute (NIRFI), B.Pecherskaya St., 25, N.Novgorod, 603 600, Russia, e-mail: belyaev@nirfi.sci-nnov.ru)

During Sept., 18–19, 1993, RIPR and NIRFI performed the first unique artificial experiment devoted to an excitation of large-scale ULF fields and measurements at the long distance 1500 km from ULF facility. The ULF facility was located at the Kola peninsula, near Murmansk, Russia and consisted of 55-km powerline grounded at both ends and current source with output current of 100-120 A. The crust conductivity in this region achieved the value 10-4 – 5*10-5 mho/m. The operating frequencies were 0.32, 1.3, 2.6 and 5.2 Hz (20 min "on", 10 min "off") during three cycles over day, night and early morning conditions. The measurements of two horizontal N-S(H) and E-W(D) magnetic components were performed at the distance of 1500 km from facility, near N.Novgorod and were accompanied in Finland by University of Oulu (J.Kangas and T.Bosinger) with using of Finnish pulsation magnetometers chain. The measured amplitude-frequency dependence and polarization of magnetic fields were found to be in line with simple waveguide-cavity theory predictions for daytime conditions and to be in a dramatic discrepancy for nighttime ones. The observed distinctions can be explained by a strong influence of a signal ducted into the slow MHD-ionospheric waveguide and, in the same time, by ionospheric resonance properties in the ULF range (Ionospheric Alfven Resonator, IAR) for electromagnetic waves excited in the cavity Earth-ionosphere. Simultaneous measurements of natural electromagnetic background confirm this consideration.

GA2.03/W/05-B3 1600

IN SITU MEASUREMENT OF THE PHASE RELATIONSHIPS BETWEEN F-REGION ELECTRON DENSITY AND ELECTRIC FIELD FLUCTUATIONS

P. MURALIKRISHNA, M.G.S. Aquino and S.M. Soares (all at Instituto Nacional de Pesquisas Esapaciais - INPE/MCT, C.P. 515, 12201-970, São José dos Campos - SP, Brazil, email: murali@dae.inpe.br)

In-situ measurement of the height variation of the ionospheric electric field and electron density variations were made with a rocket-borne double probe and two different types of electron density probes, namely a conventional Langmuir Probe and a High Frequency Capacitance probe. A Brazilian made SONDA III rocket launched on 18-th December, 1995 at 2117 hrs (LT) from the equatorial rocket launching station, Alcantara reached an apogee altitude of 557km and covered a horizontal range of 589km. Several ground equipments were operated during the launch campaign with the specific objective of knowing the ionospheric conditions at the time of launch and thereby to launch the rocket into an F-region prone to the presence of plasma bubbles. The rocket in fact passed through several medium scale plasma bubbles and the electric field double probe and the electron density probes detected the presence of a wide spectrum of electric field and electron density irregularities. In the base of the F-region the electric field double probe measurements clearly indicated the presence of large amplitude fluctuations, closely associated with large amplitude electron density irregularities But in the height region close to the rocket apogee though the electron density profile showed the presence of large scale spatial structures, the electric field measurements did not show fluctuations of similar amplitude. A study of the relationship between the phases of the electron density and electric field fluctuations at different height regions is reported here. The phase relationship between these two parameters is not only an indication of the nature of the electric field fluctuations but also depends on the specific plasma instability mechanism responsible for the generation of the plasma irregularities.

GA2.03/P/02-B3 1620

THE EFFECT OF SOLAR X-RAY FLARES ON EARTH'S IONOSPHERE AND TELE-SERVICES

M. A. Mosalam SHALTOUT, and S. El-Genedi (National Research Institute of Astronomy and Geophysics, Helwan - Cairo - Egypt Phone (202) 2630833; Fax (202) 5548020 Email: mamshaltout@frcu.eun.eg)

Solar x-ray flares causing a sudden ionospheric disturbance (S I D) affecting on telecommunications and Tele-services. Solar x-rays flares measured during the period 1981 - 1995 by GOES x-ray detector and published by Solar - Geophysical Data of NOAA, Bouldor, Colorado, USA are analysed. Also, sudden ionospheric disturbances SID'S, which world - wide observed during the same period (I981-1995) and published in Solar - Geophysical Data of NOAA, Boulder, Colorado, USA are analysed. The used technique is the time series analysis for non - equal spaced data for the both solar x-rays flares and SID's. The analysis shows a short and long term periodicities in the solar x-ray flares similar to that of SID's.
Also, evaluation for some solar active regions which produced high energetic flares and consequently sudden ionospheric disturbances of high importance during (I981 - 1995) was carried out. The method of cumulative summation curves was made to predict the occurrence of high energetic flares in the solar active region by two or three days before the releasing of the flare energy. It is interested for predicting the sudden disturbances in the telecommunications and Tele-services.

GA2.03/P/01-B3 1640

NEW ELECTRON ENERGY TRANSFER AND COOLING RATES BY ELECTRON IMPACT EXCITATION OF N2 O2 AND O(3P)

A V PAVLOV (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russia Academy of Science, Troitsk, Moscow Region, 142092, Russia)

The electron energy transfer and cooling rates by vibrational excitation of N2 and O2 and cooling rate of thermal electrons by electron impact excitation of fine structure levels of atomic oxygen have been calculated and fitted to new analytical expressions as functions of the electron temperature by use the revised excited cross sections. These new analytical expressions available to the researcher for quick reference and accurate computer modeling with a minimum of calculations. The newO2(v) rates are up to a factor of 5-18 larger than those of Prasad and Furman (J. Geophys. Res., 78, 6701-6707, 1973). The difference between the new electron cooling rate due to N2(v) and those of Stubbe and Varnum (Planet. Space Sci. , 20, 1121-1126, 1972) is up to a factor of 1.7. We found that at the F region altitudes of the ionosphere the new fine structure O(3P) cooling rate is less than the currently used fine structure cooling rate of Hoegy (Geophys. Res. Lett., 3, 541-544, 1976) by a factor of 2-4 for 400-700 ≤ Te- Tn ≤ 3000-3080 K and Tn = 800-1200 K where Te is the electron temperature and Tn, is the neutral translation temperature. We have shown that the vibrational levels v=1-4 (O2) and v=1-7 (N2) are enough to calculate the O2 (v) and N2 (v) electron cooling rates. Our results provide sufficient evidence to neglect the effects of the excitation of the a1Dg. and b1Sg+ electronic states of O2 with thermal electrons on the calculation of the electron temperature. It is also shown that the currently accepted rate of electron energy loss associated with rotational transitions in O2 must be decreased by a factor of 13 and electron energy loss associated with rotational transitions in N2 must be multiplied by a factor of 1.255.

GA2.03/W/08-B3 1700

IS IT POSSIBILE TO SOLVE THE PROBLEM WITH INSUFFICIENCY OF THE INPUT PARAMETERS IN THE RE-TIME IONOSPERIC MODELS

N.A. KILIFARSKA, D.P. OUZOUNOV (Geophysical Institute, Bulgarian Academy of Sciences, Sofia 1113, Bulgaria)

The great temporal and spatial variability of the ionosphere, especially during the magnetic disturbances, is the one of the main reasons for ionospheric modelling failure till this time. Standard statistical methods become helpless because of missing or bad quality of measurements during disturbed periods. The theoretical ionospheric models, on their turns, become more and more sophisticated. However, creation of fully-coupled self-consistent 3-dimensional time dependent models of the ionosphere-thermosphere system, are only partly successful in reproducing the observed irregularities in ionospheric storm reactions, because they rely heavily on a realistic picture of the magnetospheric input (global spatial-temporal variations of the magnetospheric electric fields, particle precipitation, etc.). Its turn out that sophistication of the models can not solve the problem with input parameters and only shift it toward higher levels of dependence. The present study presents an original approach to solve the problem with insufficiency of the input parameters when the spatial real time distribution of foF2 is simulated. A theoretical ionospheric model (TiM) is combined with a special procedure for updating the input parameters (thermospheric constituents and winds) on the base of the currently measured hourly values of foF2 and hmF2 ionospheric parameters. This means auto-correction of the model according to the current ionospheric conditions detected in a meridional chain of ionospheric stations. The accuracy of TiM model in foF2 simulation (presented by spatial relative errors between measured and calculated values) is ±10% during the most hours of the disturbed period.

GA2.03/W/03-B3 Poster 1400-01

MODELING OF THE RESONANCE SPECTRAL STRUCTURE OF ATMOSPHERIC NOISE BACKGROUND IN PC~1 FREQUENCY RANGE

A. G. DEMEKHOV (Institute of Applied Physics, Nizhny Novgorod, Russia; email: andrei@appl.sci-nnov.ru); P. P. Belyaev, S. V. Isaev (both at: Radiophysical Research Institute, Nizhny Novgorod, Russia); J. Manninen, and T. Turunen (both at: Sodankyla Geophysical Observatory, Sodankyla, Finland)

We calculate the frequency spectrum of the electromagnetic background noise in frequency range 0.1-5 Hz based on the model attributing its formation to the ionospheric resonant filtration of the radiation from lightning discharges (Belyaev et al., 1989). Characteristics of the resonance spectral structure (RSS) formed due to the ionospheric Alfven resonator are obtained and their dependence on ionospheric parameters is considered. RSS variation during a day and during a solar cycle is discussed. The calculations are compared to the ULF ground based observations at Sodankyla and mutual consistency of both is demonstrated. Opportunities to use such data to determine some of ionospheric parameters are discussed.

GA2.03/W/05-B3 Poster 1400-02

IN SITU MEASUREMENT OF THE PHASE RELATIONSHIPS BETWEEN F-REGION ELECTRON DENSITY AND ELECTRIC FIELD FLUCTUATIONS

P. MURALIKRISHNA, M.G.S. Aquino and S.M. Soares (all at Instituto Nacional de Pesquisas Esapaciais - INPE/MCT, C.P. 515, 12201-970, São José dos Campos - SP, Brazil, email: murali@dae.inpe.br)

In-situ measurement of the height variation of the ionospheric electric field and electron density variations were made with a rocket-borne double probe and two different types of electron density probes, namely a conventional Langmuir Probe and a High Frequency Capacitance probe. A Brazilian made SONDA III rocket launched on 18-th December, 1995 at 2117 hrs (LT) from the equatorial rocket launching station, Alcantara reached an apogee altitude of 557km and covered a horizontal range of 589km. Several ground equipments were operated during the launch campaign with the specific objective of knowing the ionospheric conditions at the time of launch and thereby to launch the rocket into an F-region prone to the presence of plasma bubbles. The rocket in fact passed through several medium scale plasma bubbles and the electric field double probe and the electron density probes detected the presence of a wide spectrum of electric field and electron density irregularities. In the base of the F-region the electric field double probe measurements clearly indicated the presence of large amplitude fluctuations, closely associated with large amplitude electron density irregularities But in the height region close to the rocket apogee though the electron density profile showed the presence of large scale spatial structures, the electric field measurements did not show fluctuations of similar amplitude. A study of the relationship between the phases of the electron density and electric field fluctuations at different height regions is reported here. The phase relationship between these two parameters is not only an indication of the nature of the electric field fluctuations but also depends on the specific plasma instability mechanism responsible for the generation of the plasma irregularities.

GEOMAGNETIC STORMS: A STATISTICAL STUDY

G.I. Gordienko and S.N. Mukasheva (both at Institute of Ionosphere, Academy of Sciences, Almaty 480020, Kazakstan, email: gord@ionos.alma-ata.su) Lj.R. CANDER (Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX, UK)

A statistical method is applied to test the efficiency of some geophysical factors for geomagnetic storm forecast. Values of daily 2800 MHz solar flux F10.7, geomagnetic field intensity and Alma-Ata neutron monitor pressure-corrected values in the period 1965-1989 are used to analyze their variations in different frequency ranges, to detect some peculiarities in the variations and to determine a statistical connection degree between the peculiarities and storm probability. It has been obtained that the probability is greater when the first derivative values, for example in F10.7 (t), are more than some thresholds.

LIMIT ACCURACY OF HF-DIAGNOSTICS OF THE IONOSPHERIC PLASMA

Natalia V. NASTASYINA, Pavel F. Denisenko and Dmitry A. Noranovich (Institute of Physics, Rostov State University, 194, Stachky Ave., 344090, Rostov-on-Don, Russia, e-mail: denis@iphys.rnd.runnet.ru)

The modern investigations of physic-chemical processes in the ionosphere brings more strong requirements to accuracy of the ionospheric parameters diagnostics. For this aim the new technique of experiment is developed. However, the possibilities of traditional diagnostic methods not always are used to a total degree. In particular, this fact take place in topside ionospheric soundings. In present paper three problems are described: 1) real heights determination under vertical satellite sounding; 2) diagnostics of effective electron collision frequency by method A1; 3) vertical Doppler diagnostics. In all described cases for determination of the ionospheric parameters it is necessary to inverse the Volterra integral equations of first kind. The computer simulation shown that the root-mean-squares errors of determining values depend on signal polarisation, frequency range, geomagnetic latitude of observation point and on radius of frequency correlation of signal fluctuations. Under using waves of ordinary polarisation for experimental measurements the errors in diagnostics of searching ionospheric parameters (vertical velocity of plasma motions, real heights or electron collision frequency) increase from magnetic pole to equator. The applying extraordinary polarising waves for diagnostics gives opposite dependence, i.e. errors are minimal on magnetic equator and maximal in polar ionosphere. On the middle latitudes the root-mean-squares errors of real heights make about 25% from the errors of group paths measurements. Under accuracy of measurements of radio wave absorption 1dB the errors of effective electron collision frequency reach. Under errors of Doppler frequency shift determination in 0,01 Hz the errors of determination of vertical velocity of plasma motion make about 2 m/s. Obtained estimators allow to carry out the optimal choice of polarisation of sounding signals for getting minimal confidential intervals for diagnosing parameters.

THE DETERMINATION OF NON-MONOTONE N(H)-PROFILES FROM IONOSPHERIC VERTICAL SOUNDING DATA USING REGULARISATION METHOD

Natalia V. NASTASYINA and Pavel F. Denisenko (Institute of Physics, Rostov State University, 194, Stachky Ave., 344090, Rostov-on-Don, Russia, e-mail: denis@iphys.rnd.runnet.ru)

The main difficulty under research of temporal variations of N(h)-profiles from ground based vertical ionospheric sounding data relates with existence of gaps on the ionograms caused by radio wave absorption in the D-region by existence of valley. Using the radio wave absorption in Beynon-Rangaswamy's method allows to determine the real heights in the E-region with the errors no more than 2£3 km. Under reconstruction of non-monotone N(h)-profiles upper of E-region from the ordinary and extraordinary traces of the ionograms the errors in real heights reach 10£20 km at the F-region beginning. At present paper the method is described for calculation of non-monotone N(h)-profiles based on using regularization algorithm. Under non-monotone N(h)-profiles determination the ionogram traces of both ordinary and extraordinary polarising waves were used. The application of purposed regularisation scheme reveals two interesting peculiarities. Firstly, the regularising solution is weakly depend on random errors of experimental measurements while the Least-Squares-Method-solution is strongly depend on these errors. Secondly, the regularisation method for middle latitudes conditions gives the confidential intervals for real heights in 3 times smaller than Least Squares Method (LSM). Under errors of virtual heights in 1 km the errors in regularising solution make from 1 km to 3 km while errors in LSM-solution make 10 km. These results conform with theoretical estimating errors of monotone N(h)-profile reconstruction.Under determination of non-linear parameter, valley depth, the error makes 2 %. It is shown that due to the regularization method the real heights are determined with errors about 10% of errors in virtual heights.

NONEQUILIBRUM PROCESSES AND ORGANIZED STRUCTURES IN NEAR COSMIC SPACE

Vjacheslav M. Somsikov (Institute of Ionosphere, Kameskoe Plato, 480068 Alma-Ata, Republic of Kazakstan, email: nes@kaznet.kz); Gennadiy V. KHREBTOV and Ibragim E. Suleimenov (both at Institute of Ionosphere, Kameskoe Plato, 480068 Alma-Ata, Republic of Kazakstan, email: gn@ionos.alma-ata.su)

Transition processes in Near Cosmic Space during magnetic storms and in sunrise-sunset hours of day has been investigation by the methods of non equilibrium dynamics. By joint processing of experimental records of variations of a magnetic field, cosmic rays and ionosphere of parameters the occurrence of dynamic chaos final Hausdorff dimension in variations of a magnetic field and ionosphere of concentration in transitive periods is established. It was found that at transitive hours in ionosphere parameters the additional oscillatory mode has appeared. The comparative analysis of results of processing of records of cosmic rays and magnetic field, has allowed to assume that the variations, registered on ground, of a magnetic field and variations of cosmic rays in a minute range of frequencies arise on ionosphere heights. Therefore our results testify to presence of the determined chaos in Near Cosmic Space in transitive periods of days.

EXTRACTING IONOSPHERIC INFORMATION USING GPS MEASUREMENTS.

Claudio BRUNINI (Facultad de Ciencias Astronomicas y Geofisicas, Universidad Nacional de La Plata, Buenos Aires, Argentina; e-mail: claudio@fcaglp.fcaglp.unlp.edu.ar); Maria Andrea Van Zele (Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires y CONICET, Buenos Aires, Argentina, e-mail: avanzele@tango.gl.fcen.uba.ar); Amalia Meza (Facultad de Ciencias Astronomicas y Geofisicas, Universidad Nacional de La Plata, Buenos Aires, Argentina; e-mail : ameza@fcaglp.fcaglp.unlp.edu.ar) Mauricio Gende (Facultad de Ciencias Astronomicas y Geofisicas, Universidad Nacional de La Plata y Conicet, Buenos Aires, Argentina; e-mail: mgende@fcaglp.fcaglp.unlp.edu.ar)

Signals from GPS satellites received at the surface of the earth have passed through the terrestrial atmosphere and are therefore affected by refraction in the ionosphere and the lower neutral atmosphere. In Geodesy and in Astrometry these refraction effects are typically seen as a nuisance and are removed from the measurements using appropriate models. The complementary point of view is that the refraction effects in GPS measurements contain useful information accumulated by passing through the atmosphere. In this scenario, the ionospheric and tropospheric delay are seen as remotely sensed data related to atmospheric parameters, with the possibility to recover some or all of these parameters through proper data analysis. The main goal of this kind of ionosphere research is to make use the capability of these observations to continuously and routinely ionosphere monitoring at global scale. In particular, we will focus in the estimation of parameters describing the distribution of free electrons in the ionosphere and their changes along time. We describe the algorithms used to produce ionospheric global maps automatically. We analyse the GPS observations collected in some years by around forty earth stations globally distributed and we discuss the correlation between some estimators obtained from the ionospheric model and the geomagnetic and solar activity.

TOWARD A REFERENCE TIMEFRAME FOR MAGNETOSPHERIC SUBSTORM ONSET AND DYNAMICS RESEARCH

Ching-I. MENG and Kan Liou (both at The Johns Hopkins University Applied Physics Laboratory, Laurel, MD 20723-6099, USA, email: Ching.Meng@jhuapl.edu)

Since we first made the report at the ICS-4 meeting a year ago there is a growing awareness that the timing of substorm onset determined from many substorm onset indicators can lead to error. The importance of the onset timing that may adversely affect substorm researches will be reviewed. In addition a summary of our statistical result on calibrating substorm onset signatures will be given to strengthen the need of consensus on unifying the timing of substorm onset. Specifically we used auroral breakups as the substorm onset to compare the timing of onset with other onset signatures: low-latitude Pi 2 pulsations, dispersionless energetic particle injections at the geosynchronize orbit, and auroral kilometric radiations (AKR). Statistically none of the three onset signatures alone can reliably time the substorm onset. This is mainly because substorms are not the only means in producing these signatures. In addition most of the onset signatures are not observed at the initial onset location in the magnetotail. As a result, propagation effects may cause an inevitably inconsistent result from one case to another. This expectation is confirmed by our statistical result even though onset signatures are identified with the use of auroral breakups. It is found that substorm associated Pi 2 pulsations lag behind auroral breakups by 1 - 2 min, on average, depending on the relative location of the ground magnetometer and the onset location. Geosynchronous energetic particle injections were found to lag behind auroral breakups by a various amount (from 0 to more than 10 min). A slightly delay (less than 1 min) of AKR onset relative to auroral breakups is also found, suggesting the most reliable timing tool among the three surveyed onset indicators. Implications of this investigation result will be discussed.

GA3.02/W/43-B2 **0920**

SUBSTORM TIMING USING PIL PULSATIONS FROM HIGH LATITUDE MAGNETOMETER ARRAYS

J L POSCH, K N Erickson, and M J Engebretson (Physics Department, Augsburg College, Minneapolis, MN 55454; ph. 612-330-1040; e-mail: posch@augsburg.edu) A T Y Lui (JHU/APL, Laurel, MD 20723), R L Arnoldy (Space Science Center, University of New Hampshire, Durham, NH 03824); H Fukunishi (Faculty of Science, Tohoku University, Sendai, 980-77, Japan)

The accurate timing of onsets continues to be an important issue in substorm studies. Pi2 pulsations (40 - 150 second period) have been widely used to time substorm onsets. This study explores the use of Pi1 pulsations (1-40 second period) as an alternative indicator. The use of high time resolution magnetometer data from numerous high latitude stations, including a search coil magnetometer in Sondrestromfjord, Greenland, and the US and British AGO arrays in Antarctica at 65° - 80° MLAT has made Pi1 activity a viable possibility for such timing. We have examined a set of substorm onsets identified at JHU/APL by visual inspection of global auroral images from the Polar UVI for selected periods from March 1996 through October, 1997. These onsets have been compared to Pi1 activity seen on the ground at high latitudes. Our results indicate that Pi1 onset times often agree with those of the POLAR identified events when the Antarctic ground stations are between 2200 and 0200 MLT. This Pi1 often is simultaneous across all Antarctic stations and is nearly simultaneous with the Pi2 pulsations. Pi1 may be a more accurate way to time the substorm onset since the period is much shorter than that of Pi2 pulsations and allows for less error when determining the start time. In addition, unlike Pi2 pulsations, Pi1 pulsations weaken in amplitude as they propagate away from the footpoint of the source region.

GA3.02/E/11-B2 **0935**

ON THE FALLACY IN EXISTING METHODS OF SUBSTORM TIMING

V.M. MISHIN, T.I. Saifudinova, A.D. Bazarzhapov, L.V. Minenko, and P.A.Sedykh (all at Institute of Solar-Terrestrial Physics, P.O.Box 4026, Irkutsk, 664033, Russia, email: mishin@iszf.irk.ru),

In a classic NENL model of substorms, the commencement of the substorm active phase is called the expansion onset and is identified with the start of the open tail reconnection. The expansion onset time is determined as the time of the first observed substorm onset, and this tradition has persisted to date. However, it has become clear in recent years that first substorm onsets are produced not by the open magnetic flux reconnection but by instabilities in the near (closed) tail. Hence traditional methods of timing have to be supplanted by others. Examples of a misleading timing by traditional methods are given. To ensure a correct timing, we suggest methods based on using the plot of variation, in the course of the substom, of the open magnetic flux determined by means of MIT2 (Mishin et al., JGR, 1997, p. 19845).

GA3.02/W/42-B2 0950

OBSERVATIONS OF SUBSTORM-LIKE SIGNATURES IN AN NEAR GROUND STATE MAGNETOSPHERE

Peter R SUTCLIFFE (Hermanus Magnetic Observatory, P O Box 32, Hermanus 7200, South Africa; E-mail: psutclif@csir.co.za)

Substorm-like signatures have been observed under conditions with which substorms are not normally associated, namely, extremely quiet solar wind conditions when the magnetosphere is in a near ground state. A number of years of data were scanned for extremely quiet intervals on the basis of ap indices and solar wind parameters. During many of these quiet intervals Pi2 pulsations, which had amplitudes similar to those typically observed during substorm expansion phases, were observed at low latitudes. A variety of other ground based and satellite data sets were inspected for the presence of associated substorm signatures. The occurrence, magnitude, and localization of the substorm-like signatures observed are discussed. Studies of these less complex events should facilitate a better understanding of the mechanisms responsible for substorm onsets and intensifications.

GA3.02/W/15-B2 1005

THE ROLE OF SOLAR WIND IN SUBSTORM TRIGGER MECHANISIM: A REVISIT WITH POLAR UVI IMAGERY

K. LIOU, D. G. Sibeck, P. T. Newell, C.-I. Meng (all at The Johns Hopkins University Applied Physics Laboratory, Laurel, MD 20723-6099, USA, email: kan.liou@jhuapl.edu)

One of the outstanding issues in magnetospheric physics is that of the trigger mechanism(es) of substorm expansion phase onset. Past studies have shown that variations in solar wind magnetic field and/or plasma can trigger substorm onset. In contrast, the occurrence of substorm onsets during steady solar wind conditions has been reported and suggests a triggering mechanism that is internal to the magnetosphere. In a recent study of substorm timing, we found that most of the commonly used substorm onset indicators are subject to delay with respect to auroral breakups. We therefore suspect that this highly controversial issue of a possible solar wind onset trigger may be due to large uncertainties in the onset determination from previous studies. In the present study we re-investigate the influence of sudden changes of the solar wind magnetic fields on substorm onsets by using a list of about 1000 auroral breakups determined from Polar UVI imagery. To further improve the accuracy of our correlative study we use the near Earth solar wind data from IMP-8, GEOTAIL, and INTERBALL-TAIL spacecraft. We will present detailed results and discuss the implications of these findings.

GA3.02/W/56-B2 1020

SUPERIMPOSED EPOCH ANALYSES OF SOLAR WIND CONDITIONS AROUND ONSET FOR VARIOUS DIPOLE TILT ANGLES

N.J. FLOWERS, (Address not available at time of going to press) A.D. Johnstone

Periods of southward interplanetary magnetic field load the magnetotail with energy that is subsequently unloaded into the magnetosphere by a sequence of processes collectively termed a substorm. The mechanism responsible for this unloading of energy and how this is triggered is a source of ongoing controversy.
Caan et al. [1977, 1978], McPherron et al. [1986], Lyons [1996], and Henderson et al. [1996], debate the possibility that a northward turing of the IMF, or a reduction in the induced electric field, is responsible for the triggering of substorms. This work investigates the possiblity that IMF changes may be responsible for triggering onset by using superimposed epoch analyses of solar wind data from around onsets. Identifying nearly 200 substorm onsets with CRRES data, a superimposed epoch analysis of IMP-8 solar wind variables around onset is made. Separating data contibuting to the analyses by dipole tilt angle to the Sun results in differing typical IMF component signatures being seen around the grouped onset time. This may indicate the dipole tilt effects the onset mechanism, or the 15 MeV inner radiation belt formed during CRRES's lifetime effected the onset mechanism, or the long-term seasonal changes occurring in the solar wind over CRRES's lifetime were significant (tilt is a selector for season). It is hoped that work using IMP-8 and WIND data from an extended multi-year epoch will be ready to present at the meeting, indicating which conclusion is correct and providing insights into the triggering debate.
For the general, no tilt discrimination case, no significant structure in IMF vectors is seen prior to event onset, other than a Bz reduction. This indicates that although some events are undoubtedly triggered by changes in the IMF, reductions in the solar wind electric field are not mandatory for event occurance. It is concluded that the substorm onset is an internal process susceptible to external perturbation.

GA3.02/L/03-B2 1055

A STATISTICAL INVESTIGATION OF SUBSTORM TRIGGERING

Tung-Shin SHU and R L McPherron (IGPP & ESS/UCLA, Los Angeles, CA 90024-1567; 310-825-2441; email: thsu@igpp.ucla.edu; rmcpherr@igpp.ucla.edu)

An outstanding problem in magnetospheric physics is deciding whether substorms are always triggered by external changes in the interplanetary magnetic field (IMF) or solar wind plasma, or whether they sometimes occur spontaneously. Over the past decade, arguments have been made on both sides of this issue. In fact, there is considerable evidence that some substorms are triggered. However, equally persuasive examples of substorms with no obvious trigger can also be found. It is evident further works required to determine whether there is a physical relation between IMF triggers and substorm onset. In the work reported here a substorm list was created by using two independent substorm signatures: AL index and Pi 2 pulsations. Possible IMF triggers were determined by ISEE-2 and Imp-8 observations. These lists allow us to consider several questions. First we can assess the frequency of occurrence of potential IMF triggers and calculate the probability that the observed association with substorm onset is due to chance. Second, with the ISEE observations near local noon immediately upstream of the bow shock there can be little question about propagation delay to the magnetopause, or whether a particular IMF feature hits the magnetopause. It thus eliminates the objections that the calculated arrival time is erroneous and that the monitor missed a potential trigger incident at the subsolar point. Finally the joint observations can be used to determine the probability that a signature detected at one spacecraft will be missed by the other.

GA3.02/W/39-B2 1110

CAN PSEUDOBREAKUPS BE PREDICTED?

ZHOU, X.-Y., B.T. Tsurutani, J.K. Arballo (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109) D. Berdichevsky, and R.P. Lepping (Goddard Space Flight Center, Code 695.0, Greenbelt, MD 20771)

We statistically analyze many interplanetary shock events where there are both WIND interplanetary data and POLAR UV imaging data. We find that the shock compression events trigger pseudobreakups (PBs), substorm onsets, or enhance (pre-existing) substorm intensities. Using WIND interplanetary data and ground-based data, it is now believed that we can predict when PBs will occur and when substorm expansion phases will occur.

GA3.02/L/01-B2 Invited 1125

THE SUBSTORM ONSET AS SEEN IN GROUND-BASED OBSERVATION - IMPLICATIONS FOR SUBSTORM MODELS

Hermann OPGENOORTH (Swedish Inst of Space Physics, Uppsala Divison, S-75591 Uppsala Sweden,) and Paul Eglitis (both also at: Finnish Meteorological Institute, Geophysical Division Helsinki, Finland (Tel +46-18-3036661, fax +46-18-403100, E-mail: opg@irfu.se; paul@irfu.se)

The magnetospheric substorm is a large scale instability which converts magnetospheric excess energy stored in current systems and magnetic field deformations into particle energy and heat production in the ionosphere and ring current. Inspite of intensive studies during the last 30 years the exact mechanism for the onset of this instability has not exactly been identified. The reason for this is the global character of the observed disturbance pattern, involving a vast region of space. Detailed in situ observations have so far not been able to solve the exact temporal sequence and consequently the causal relation of the different observed processes in the near Earth space plasma.
The only method which can simultaneously monitor processes in the near-Earth and more distant plasma sheet is the observation of aurora, electric field and current systems in the nightside ionosphere, which within a few degrees of latitude is connected to all relevant regions of near-Earth space. Temporal sequences of processes in different latitude regions of the nightside ionosphere are indicative of consecutive processes in the near Earth and distant plasmasheet. Exact timing of ground-based observations in both latitude and longitude, can solve some of the remaining questions of causality in space plasma processes associated with substorms. We will present recent observations from the Scandinavian network of stations, which includes 3 incoherent scatter radars (EISCAT UHF, VHF and ESR), two coherent radar systems (CUTLASS and STARE) and networks of magnetometers and digital all-sky cameras. Our observations around substorm onsets will be discussed on the background of different substorm models.

GA3.02/W/09-B2 1145

JOINT SUPERDARN AND POLAR OBSERVATIONS OF SUBSTORM EXPANSION PHASE ONSET

M.LESTER (Department of Physics and Astronomy, University of Leicester, Leicester, LE1 7RH, UK, Email: mle@ion.le.ac.uk); and N.J. Fox (Goddard Space Flight Center, mail Code 695, Greenbelt, Maryland 20771, USA).

The global nature of ionospheric convection at expansion phase onset and its relation to the auroral activity remains a topic of much uncertainty. For example, if reconnection in the tail begins at expansion phase onset, signatures are expected in the ionospheric convection. The SuperDARN radars are well placed to image the ionospheric flow over much of the northern hemisphere, while the auroral imagers on the Polar spacecraft can provide simultaneous global images of the aurora. This paper presents observations of ionospheric convection by SuperDARN during 2 expansion phase onsets separated by two hours.

GA3.02/E/13-B2 1200

MODELLING OF SUBSTORM ONSET PROCESSES USING RADIOWAVE ABSORPTION OBSERVATIONS, CONVECTION ANALYSIS AND XRSTED SATELLITE DATA

Peter STAUNING (Solar-Terrestrial Physics Division, Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen X, Denmark. E-mail: pst@dmi.dk)

Substorms are global phenomenacontrolled by the interactions of the ionospheric and magnetospheric regions separated by distances of several tens to hundreds of thousands of km. In view of the propagation delays involved in the magnetosphere-ionosphere communication the explosive brightening of aurora and the sudden development of magnetic bays may appear contradictionary. A possible explanation is offered by theories which invoke the development near the ionosphere of large field-aligned potential structures that could accelerate the magnetospheric plasma particles to generate the sudden and highly variable energetic auroral particle radiation which are characteristic features of ionospheric substorm onsets. We have analyzed the onset processes seen in our high-latitude magnetometer and riometer recordings. The combination of the time-varying AMIE potential patterns to describe the polar convection, and high-resolution, localized observations of substorm activity using, among others, imaging riometer recordings, have been used as the basis for modelling substorm onset processes. We find that field-aligned potential structures can have positive feed-back to the ionospheric potentials affected by conductivity changes caused by the accelerated particles. We suggest that such coupled potential systems may provide a general acceleration mechanism. The ground-based observations will be augmented by data from Xrsted and other satellites.

GA3.02/W/60-B2 1215

TO INVESTIGATE THE CONVERGENCE OF THE SUBSTORM ONSET SIGNATURES

A.G.YAHNIN (Polar Geophysical Institute, Apatity, Russia, E-mail: ahnin@pgi.kolasc.net.ru); V.A.Sergeev, M.V.Kubyshkina (Institute of Physics, University of St-Petersburg, Russia, E-mail: sergeev1@snoopy.phys.spbu.ru); N.L.Borodkova (Space Research Institute, Moscow, Russia, E-mail: nbor@afed.iki.rssi.ru); T.Bosinger (Dept of Physical Science, University of Oulu, Oulu, Finland, E-mail: Tilmann.Bosinger@oulu.fi); T.I.Pulkkinen (Finnish Meteorological Institute, Helsinki, Finland, E-mail: Tuija.Pulkkinen@fmi.fi)

To investigate the convergence of the substorm onset signatures and their reliability to describe adequately magnetospheric processes we study the substorm commencing at 2053 UT on Dec 15, 1996. It was observed by a number of ground based instruments and by two ISTP spacecraft Interball-1 and Geotail. Clear auroral breakup has been detected by several TV cameras situated on Kola Peninsula and Scandinavia. Simultaneously several magnetic stations recorded the onset of magnetic bay and Pi2/PiB pulsations. Interbal-1 situated in the

tail lobe at X=-10 Re registered sharp decrease of the magnetic field strength, and a little bit later Geotail detected fast tailward flow and bipolar variation of the magnetic field Bz component near the neutral sheet at X=-23 Re. The study showed that when the observations are made in appropriate place both auroral and magnetic onset signatures occur at the same time. The observed sequence of magnetotail phenomena agrees with the onset scenario in which the current disruption occurs in the near-Earth plasma sheet in close relation to econnection process and generation of tailward moving plasmoid. The results are confirmed by consideration of several other substorms selected on the basis of good conjunction between the ground-based network and mid-tail satellite.

GA3.02/W/12-B2 1230

SIMULTANEOUS OBSERVATIONS OF DIPOLARIZATIONS IN THE NEAR TAIL PLASMASHEET/LOBE BOUNDARY AND SUBSTORM ACTIVITY ON THE GROUND

NAIGUO LIN, C. A. Cattell, (School of Physics and Astronomy, University of Minnesota, Minneapolis, MN 55455, USA Email: lin@waves.space.umn.edu); M. J. Engebretson, (Dept. of Physics, Augsburg College, Minneapolis, MN 55454-1338 , USA); R. P. Lepping, (NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA); R. P. Lin (UC Berkeley, SSL-305 (Space Sciences Laboratory), CA 94720, USA)

A sudden dipolarization followed by long period (about 25 minutes) compressional magnetic fluctuations with shorter period waves superimposed on them was observed by the Wind spacecraft in the magnetotail near midnight on Sep 17, 1995, at a position of (-15, 0, 2)Re in GSE coordinates. The spacecraft was near the boundary between the northern tail lobe and the plasmasheet. Signatures of several dipolarizations are observed during the fluctuations. Observations of anticorrelation between the variations of the magnetic field and of the energetic electrons are consistent with alternating plasma sheet thinning and expanding. Ground data from stations located near the footprints of the magnetic field lines crossed by the spacecraft during the event showed negative bays occurring near local midnight, which indicate substorm activity. The onset times of Pi2 on the ground varied for different stations. Simultaneous observations from Geotail, which was near local noon at about 20 Re upstream from the Earth, showed similar fluctuations in IMF Bz, with an amplitude of about 5 nT. It is suggested that the periodic southward-northward turning of the IMF may have caused the periodic plasma sheet thinning and the compressioanal fluctuations, which carried the disturbance to the near tail and triggered substorms. The relationship between the onset of a substorm on the ground and the dipolarization in space will be discussed.

MAGNETOSPHERIC SUBSTORM ONSET: OBSERVATIONS, THEORIES, MODELS-2

GA3.02/E/14-B2 Invited 1400

HOW AND WHERE AURORAL BREAKUP BEGINS

Y. KAMIDE (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Aichi-ken 442-8507, Japan, email: kamide@stelab.nagoya-u.ac.jp)

The auroral substorm is one of the elements of the magnetospheric substorm, and an auroral breakup is the first indicator of substorm expansion onset. It is thus crucial to use auroral breakups to time various substorm phenomena in the magnetosphere. This paper discusses observational constraints on substorm initiation theories by differentiating the necessary and sufficient conditions that lead to the sudden expansion processes that occur in conjunction with auroral breakups. It is important to realize that an auroral breakup begins from a preexisting auroral arc; it does not start from "nothing." The strong statistical dependence of the latitude of auroral breakups and the probability of substorm occurrence on the southward component of the interplanetary magnetic field (IMF) is also discussed. The IMF orientation controls the strength of substorms as well.

GA3.02/W/62-B2 Invited 1420

IMPLICATIONS OF IONOSPHERIC CONVECTION OBSERVATIONS DURING THE 24 NOVEMBER GEM SUBSTORM EVENT

L. R. LYONS (Department of Atmospheric Sciences, UCLA, Los Angeles, CA 90095-1565, USA, email: larry@atmos.ucla.edu); J. M. Ruohoniemi (Johns Hopkins University, Applied Physics Laboratory, Johns Hopkins Rd., Laurel, MD 20723-6099, USA,
email: mike_ruohoniemi@spacemail.jhuapl.edu)

Here we present data from the GEM substorm interval that provides strong evidence that such convection reductions lead to substorm onset and that substorms do not occur during conditions of steady enhanced convection. This GEM interval has unusually good coverage of global ionospheric convection from the SuperDARN radars, and unusually ideal IMF conditions (sharp southward turning followed first by ~1.25 hr of steady southward IMF and then by a small and a large northward turning). Convection is found to be quite steady during the 1.25 hr interval of steady southward IMF, and substorms are not seen during this interval. This is consistent with earlier observations during convection bays and implies that internal magnetotail instabilities during periods of enhanced convection do not generally lead to substorm onset. Two onsets are clearly identified in auroral zone data during the period of the two IMF northward turnings, each at a time consistent with IMF triggering. The time of magnetopause impact of individual IMF changes cannot be precisely determined from IMF measurements, so that IMF triggering of the onsets cannot be proofed using the IMF measurements alone. However, convection responses to the IMF changes can clearly be identified in the SuperDARN data. It is found that the reductions in global convection associated with the two northward turnings initiate ~1 min prior to each of the two onsets. The first (smaller) northward turning is found to give a small convection reduction and the onset of a small substorm, while the second (much larger) northward turning is found to give a large reduction is global convection and the onset of a large substorm. This implies that substorm triggering by the IMF does not push the magnetotail over an instability threshold. If so, the smaller northward turning, which followed a prolonged growth-phase period with strongly southward IMF, should have lead to a large substorm. It suggests that substorms result from an adjustment to conditions of reduced convection, small reductions leading to small substorms and large reductions leading to large substorms.

GA3.02/E/06-B2 Invited 1440

TAIL CURRENT DISRUPTION: OBSERVATIONAL CONSTRAINTS ON SUBSTORM TRIGGER MODELS

Shin-ichi OHTANI (The Johns Hopkins University Applied Physics Laboratory, Johns Hopkins Road, Laurel, MD20723-6099, USA, Email: ohtani@jhuapl.edu)

The formation of a Near-Earth neutral line (NENL) and the trigger of tail current disruption are two important concepts of substorm physics. The objective of this paper is to address the cause-effect relationship between these two processes from the observational viewpoint of tail current disruption. Such an approach should be a good complement to the recent studies of plasma sheet plasma flow, which tend to place an emphasis on the formation of a NENL. The list of issues to be addressed include (1) the role of tail current disruption in the global substorm dynamics, (2) the relative timing of the NENL formation and tail current disruption, and (3) the temporal and spatial characteristic scales of tail current disruption. A special emphasis will be placed on observations that are difficult to implement in the so-called pile-up model, which explains dipolarization and the apparent reduction of the tail current intensity in terms of the transfer of magnetic flux from the near-Earth reconnection site. The paper seeks to list observational constraints to be considered in modeling the substorm trigger.

GA3.02/E/09-B2 Invited 1500

KINETIC CHARACTERIZATION OF PLASMA SHEET DYNAMICS

G. K. PARKS, L. J. Chen, M. McCarthy Geophysics Program, University of Washington, Seattle, WA D. Larson and R. P. Lin Space Sciences Laboratory, UC Berkeley, Berkeley, CA H. Reme, CESR, Toulouse, France T. Sanderson, ESTEC, Noordwijk, The Netherlands

The plasma data provided by the Wind 3D instrument are of high quality sufficient to formulate a kinetic picture of the plasma sheet dynamics. This will augment our current understanding which is based primarily on fluid description using the plasma bulk parameters. A kinetic picture is needed because observations clearly show that the plasma distributions consist of more that one population across the central plasma sheet to the lobe regions. Thus describing the dynamics using the bulk parameters alone will be incomplete and can lead to incorrect conclusions. This talk will focus on kinetic properties of both ions and electrons. We will compare, evaluate and discuss new features including possible sources of bursty bulk flows.

GA3.02/W/21-B2 Invited 1520

MODELING OF TIME-EVOLVING MAGNETIC FIELDS DURING SUBSTORMS

G. LU (High Altitude Observatory, National Center for Atmospheric Research, Boulder, CO 80301; 303-497-1554); N. A.; Tsyganenko (Raytheon STX Corporation, NASA GSFC, Greenbelt, MD); A. T. Y. Lui (Applied Physics Laboratory, Johns Hopkins University, Laurel, MD); H. J. Singer (Space Environment Center, National Oceanic and Atmospheric Administration, Boulder, CO); T. Nagai (Tokyo Institute of Technology, Tokyo, Japan); and S. Kokubun (Solar-Terrestial Environment Laboratory, Nagoya University, Japan)

An attempt has been made to model the dynamics of the magnetospheric magnetic field during substorms, by modifying the 1996 version of the data-based model by Tsyganenko [1996]. The modified model incorporated an adjustment to the intensity and thickness of the near-tail current sheet and a contribution from the substorm current wedge. These improvements made it possible to use the model to represent the evolution of the magnetic field during the entire substorm sequence of growth, expansion, and recovery. The modeled magnetic fields have been tested against satellite observations during three isolated substorms. According to the model results, during the substorm growth phase, the thickness of the tail current sheet was graduallydecreased while the intensity of the tail current was gradually increased; by the end of the growth phase, a thin current sheet of 190-1340 km in half thickness was formed in a narrow region around X ~ -7.5 RE, with a maximum westward current density of 9-23 nA/m2. During the substorm expansion phase, an eastward current associated with the substorm current wedge started to develop around X ~ -12 RE, resulting in a collapse of the previously stretched field configuration. At the peak of an intense substorm, the net tail current flow became eastward between X = -11 and X = -13 RE, accompanied by a negative (southward) Bz tailward of -13 RE.

SIMULATION OF DISPERSIONLESS INJECTIONS OF ENERGETIC PARTICLES ASSOCIATED WITH MAGNETOSPHERIC SUBSTORMS

XINLIN LI and D. N. Baker (LASP, University of Colorado, 1234 Innovation Drive, Boulder, CO 80303-7814, USA; 303-492-3514, email: lix@kitron.colorado.edu): M Temerin (SSL, UC Berkeley, CA 94720, USA) G D Reeves and R D Belian (MS D-436, LANL, Los Alamos, NM 87545)

Energetic particle (tens to hundreds of keV) injections into the inner magnetosphere are typical indicators of the onset of expansive phase of magnetospheric substorms. It is generally understood that the expansive phase corresponds to a rapid change of the magnetic field, described as dipolarization, which is associated with a strong inductive electric field predominantly in the dawn-to-dusk direction. We have conducted test particle simulations in order to understand how electric and magnetic fields change during substorm onset and how such changes can produce dispersionless injections of electrons [Li et al., 1998] and ions and other particle features observed in the inner magnetosphere. The dipolarization process was modeled with only one component of the electric field which is westward and a consistent magnetic field. Our simulation results reproduce observed electron and proton injections and subsequent drift echoes. We found that the temporal profile of injected fluxes is determined by the temporal profile of the time-varying magnetic field. Modeling these frequently observed dispersionless injections of energetic particles in the inner magnetosphere will help us to understand the reconfiguration of magnetotail during the expansive phase of magnetospheric substorms.

GA3.02/W/54-B2 1615

OCCURRING IN THE NIGHTSIDE NEAR-EARTH TAIL AFTER SUBSTORM EXPANSION PHASE ONSET

Z.X. CHEN, A. Korth, C. Mouikis (all at: Max-Planck-Institut fuer Aeronomie, D-37191 Katlenburg-Lindau, Germany, Email: chen@ciscos.mpae.gwdg.de); Z.Y. Pu (Department of Geophysics, Peking University, Beijing 100871, China, Email: zypu@pku.edu.cn)

Inspired by the qualitative picture of earthward expansion of tail current disruption, we propose in the beginning of this paper that there may occur an earthward propagating abnormal magnetic field configuration in the nightside near-Earth tail after substorm expansion phase onset. This abnormal magnetic field configuration is characterized by an earthward declining

equatorial curvature radius of the magnetic field lines. In the following parts, we provide an indirect evidence for this abnormal configuration. Since the plasma processes are usually related to magnetic field variations during substorm development, it is expected that there exist some special plasma processes which are subject only to the abnormal magnetic field configuration. The first possible process we can think of is the field-aligned acceleration of energetic ions during substorm expansion phase. We use ions and electrons pitch angle distribution data from the particle spectrometer S321 on board GEOS 2 satellite in this paper. Data analysis shows that there are two kinds of field-aligned distribution variations for energetic ions after substorm onsets: the toward-equator acceleration and off-equator acceleration. By examination of the parallel substorm-period Lorentz equation of ions, we find that magnetic field configuration is the dominant factor in determining the energetic ions field-aligned acceleration directions during the course of the substorm expansion phase. Two kinds of field-aligned distribution variations originate from two kinds of substorm-period magnetic field configurations. The toward-equator field-aligned acceleration of energetic ions results from the normal configuration, while the off-equator field-aligned acceleration of energetic ions can only result from the abnormal configuration.

GA3.02/W/13-B2 1630

RADIAL EXTENT AND PROPAGATION OF ENERGETIC PARTICLE INJECTIONS AT SUBSTORM ONSET

R. H. W. FRIEDEL, G. D. Reeves, M. G. Henderson (all at Los Alamos National Laboratory, Los Alamos, NM, USA); J. F. Fennell and J. L. Roeder (both at The Aerospace Corporation, P.O. Box 92957, Los Angeles, CA 90009); A. Korth Max Planck-Institute, Lindau, Germany)

Near-Earth energetic particle injections have become a reliable and widely used indicator of substorm onset. Dispersionless injections indicate onset location; and timing the same injection on two radially separated spacecraft allows the determination of radial propagation. Data from CRRES and LANL have show such injections far off midnight and as close as 4.5 Re. LANL/CRRES studies have established earthward propagation of the injection front with speeds 24 km/s between L=6.6 and L=5.
Here we intend to extend this study to AMPTE altitudes: this may yield the first direct evidence of ``breaking flows". Recent observations and simulations suggest a scenario in which substorm injections are connected to bursty bulk flows originating at a near-Earth neutral line (NENL). The breaking and diversion of the flows may produce a compressional wave which leads to dipolarization and also reverses the local magnetic gradient and allows energetic particles to surf the wave. The resulting transport and acceleration injects particles into the trapping region which they would otherwise not have been able to reach, including regions where there was little or no filed stretching during the growth phase. If this connection can be established observationally this would point to the classical NENL model, in which the trigger is equivalent to whatever starts off reconnection at the NENL.

GA3.02/W/18-B2 1645

GLOBAL MULTISPECTRAL IMAGING OF AN ISOLATED SUBSTORM

S. A. CUMMER, R. R. Vondrak, R. F. Pfaff (Laboratory for Extraterrestrial Physics, NASA/GSFC, Greenbelt, MD 20771, USA, Email: steve.cummer@gsfc.nasa.gov); N. Ostgaard, J. Bjordal, J. Stadsnes (Department of Physics, University of Bergen, Bergen, Norway); D. L. Chenette (Lockheed Martin Advanced Technology Center, Palso Alto, CA 94304, USA); M. J. Brittnacher, G. K. Parks (Geophysics Program, University of Washington, Seattle, WA 98195, USA); J. B. Sigwarth, L. A. Frank (Department of Physics and Astronomy, University of Iowa, Iowa City, IA 52242, USA;) C. W. Carlson (Space Sciences Laboratory, University of California, Berkeley, CA 94720, USA)

The suite of global auroral imagers on the Polar satellite offers the first simultaneous view of the aurora at visible (the VIS instrument), ultraviolet (the UVI instrument), and x-ray (the PIXIE instrument) wavelengths. These instruments provide not only an opportunity to study substorm morphology at these wavelengths simultaneously but also provide the capability for quantitative remote sensing of the ionospheric effects of the observed energetic particle precipitation. To utilize and test these capabilities, we searched for a relatively isolated and simple substorm which was viewed fully by the three Polar imagers. Such an event occurred on 25 Jan 98 beginning at approximately 0410 UT. We compare the apparent substorm onset times seen in the various emissions (visible, ultraviolet, 3-12 keV x-rays, and 10-25 keV x-rays), and we examine the spatial and temporal morphology of the observed emissions throughout the substorm to understand the different particle populations responsible for them. We also compare estimates, based on images from the three instruments, of the total ionospheric conductance in a number of regions and compare these to direct calculations of ionospheric conductance from energetic electron measurements.

INTRODUCTION TO DEBATE 1700

GA3.02/W/52-B2 1705

A DEBATE ON WHICH SUBSTORM MODEL BEST EXPLAINS EXPANSIVE PHASE ONSET

Wolfgang BAUMJOHANN (Max-Planck-Institut fur extraterrestrische Physik, D-85740 Garching, Germany, email: bj@mpe.mpg.de); Gordon ROSTOKER (Department of Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2J1, email: rostoker@space.ualberta.ca)

At the present time, few space scientists doubt that magnetic field line merging in the magnetotail plays an important role in substorm activity. Since the mid 1970's, the near-earth neutral line (NENL) model has provided a framework in which most researchers try to understand their data. However, over the years several other models have been proposed which differ in many ways from the NENL paradigm. In the past decade, these several models have had their better features combined in a framework which differs significantly from the NENL picture in many important ways. At the same time, the NENL model itself has evolved significantly to meet objections based on ground based and satellite observations. There now are two competing frameworks in which substorm activity can be understood and this paper seeks to compare the two in a presentation which takes the form of a debate between the two authors and which will, towards the latter stages, involve participation by the attendees. The debate will focus on which model allows one to best understand the onset of the substorm expansive phase.

MAGNETOSPHERIC SUBSTORM ONSET: OBSERVATIONS, THEORIES, MODELS-3

GA3.02/W/14-B3 Invited 0830

SUBSTORM ONSET AT A PREBREAKUP ARC: "MINIMUM-B" MODEL

Galperin Yuri (Space Research of Institute of RAS, 84/32 Profsoguznaya St, Moscow, 117810 Russia, Email: ygalperin@iki.rssi.ru)

An excellent example of ground-based monochromatic optical measurements of prebreakup arc and substorm onset as typical for 35 cases was published by J.Deehr (SUBSTORMS 2, 229, 1994). This event and some other evidence are interpreted as showing the existence of an extended magnetic field minimum in the near- Earth plasma sheet at the "root" of the prebreakup arc, and effects of its deepening before the onset.
The "Minimum-B" theory (Galperin et al., GRL, 19, 2163, 1992) for generation of FA double-sheet current loop feeding a stable homogeneous auroral arc predicted a minimum in the radial magnetic field profile in the neutral sheet as a steady double-sheet FA current generator. For a prebreakup arc this generator is located at the inner edge (or at an outward gradient) of the cross-tail linear current density. Such aminimum was deduced by Sergeev et al., Space Sci. Rev.,1996 in a unique case oflong duration Stationary Magnetospheric Convection on November 24, 1981.
Simultaneous satellite data from AUREOL-3 and DE-2 have shown the double-sheet FAC/arc at the predicted place.
An extension of the "Minimum-B" theory to substorm onset (Galperin and Bosqued,Cosmic Research, 1998) supposed a deepening of the magnetic field minimum. For a sharp deepening the inferred increase of FA current will lead to auroral activation or onset according to the "M-I coupling?" theory by Kan et al., JGR, 1988. A neutral line can form if the magnetic field in the minimum reverses sign. Or, the deepening can gradually proceed till a "critical" low value at which CCI or other instabilities lead to a local cross-tail "current disruption?". The ground-based optical data mentioned above in many details give strong support for such a scenario.

GA3.02/E/18-B3 Invited 0850

A SYNTHESIS OF THE NEUTRAL LINE AND CURRENT DISRUPTION MODELS FOR SUBSTORM ONSET

Z.Y. PU, K.B. Kang, S.Y. Fu, and Z.X. Chen (Department of Geophysics, Peking University, Beijing, China, email: zypu@pku.edu.cn); A. Korth, Q.G. Zong, C.G. Mouikis, R.W.H. Friedel (Max-Planck-Institute for Aeronomy, Katlenburg-Lindau, Germany, email: korth@sprotte.mpae.gwdg.de); M. H. Hong (Institute of Geophysics, Academia Sinica, Beijing, China, email: kytang@mail.c-geos.ac.cn); Z. X. Liu (Center for Space Science and Application Research, Academia Sinica, Beijing, China, email: liu@sun20.cssar.ac.cn); T. Pulkkinen (Finnish Meteorological Institute, Helsinki, Finland, email: tuija.pulkkinen@fmi.fi)

It is found that the presence of a decelerated earthward flow destabilizes the drift ballooning mode (DBM) in both equatorial and off-equatorial regions near the inner edge of the plasma sheet (IEPS). The unstable DBM excites coupled Alfvenic slow magnetosonic waves, which carry field-aligned currents into and out of the ionosphere, forming a quasi-periodic current wedge. The total Wedge current may be comparable to the DP 1 current in a large substorm if the azimuthal electric field of the waves is about 5 mV/m. The interplay of the coupled Alfvenic slow magnetosonic waves with the magnetosphere and ionosphere provides the means to the magnetosphere-ionosphere coupling and field line resonance. A synthesis of the near-Earth neutral line model and near-Earth current disruption models for the onset of substorm expansion phase seems to exist. While an earthward flow resulting from reconnection in the midtail is braking near the IEPS, it compresses the plasma populations ahead of its front and pushes them further earthward. This may lead the DBM to explosively grow, causing cross-tail current disruption/diversion and dipolarization of the magnetic field. The expansion onsets would be initiated in the near-Earth tail in the 6 to 13 Re range and preferentially in the premidnight sector. Substorm injection can yield a domino effect in the potentially unstable region. This substorm scenario covers the midtail, the near-Earth tail, and the ionosphere. It integrates current disruption with magnetic reconnection, and might also integrate with the magnetosphere-ionosphere coupling and field line resonance. Decelerated tailward flows may also initiate substorms through generation of the DBM in the near-Earth tail. Instabilities other than the DBM can trigger the substorm expansion phase as well.

GA3.02/W/38-B3 Invited 0910

KINETIC BALLOONING INSTABILITY AS A MECHANISM FOR SUBSTORM ONSET OBSERVED BY AMPTE/CC

C. Z. CHENG (Princeton Plasma Physics Laboratory, Princeton University, Princeton, NJ 08543; 609-243-2648)

The underlining physical processes of substorm onset which leads to substorm explosive growth phase and subsequent current disruption observed by AMPTE/CCE are presented. Toward the end of late growth phase before the onset of current disruption a low frequency global instability with a wave period of $50-75$ seconds is excited and grows exponentially to a large amplitude with $\delta B / B \geq 0.3$ at the onset of current disruption. The plasma β reaches to a high value of 50. Just before the onset an enhanced duskward ion drift of ion distribution is observedand lasts only about one half of the wave period of the low frequency instability. The enhanced duskward ion drift at the onset is correlated with the excitation of higher frequency instabilities (with wave periods 15 sec, 10, sec, etc.) so that the plasma evolves into a turbulence state. During he current disruption phase plasma transport causes plasma pressure profiles (averaged over the turbulent fluctuation scales) to evolve so that the magnetic field configuration changes from a tail-like to a dipole-like geometry. Thus, to correctly model the substorm onset it is necessary to understand the observed low frequency instability wich occurs at high β (≈ 50) and the associated duskward ion drift. We have proposed a new theory of kinetic ballooning instability which can explain the observed plasma features before the substorm onset. The kinetic ballooning instability can become unstable due to the free energy associated with nonuniform plasma pressure with gradient in the same direction as the magnetic field curvature. There are other theories of substorm onset based on the ballooning instability, i.e., the MHD ballooning instability theory and the nonlinear MHD ballooning instability theory. In order to improve our modeling of the substorm onset we will assess the strength and weakness among these theories based on the ballooning instability by comparing their prediction with the observed features of plasma and magnetic field.

GA3.02/E/01-B3 0930

IONOSPHERIC EFFECTS IN THE FORMATION OF AURORAL ARC LINKED TO THE CROSS-TAIL CURRENT DISRUPTION

MANJU PRAKASH(Department of Physics and Astronomy, Suny at Stony Brook, Stony Brook, New York 11794-3800, USA, email: mprakash@nuclear.physics.sunysb.edu)

Recently Lui and Murphree [1998] have proposed a substorm onset model which combines the field line resonance (FLR) model for arc formation with the cross-field instability for current disruption. The model accounts for the observations that the substorm onset begins by brightening of the pre-existing auroral arc which derives its energy from the current disruption in the near-Earth region. Since the evolution of FLRs (which cause auroral arc) and the threshold for the excitation of cross-field instability (which leads to current disruption) are modified due to the modified ionospheric boundary conditions during substorms, it is worthwhile to examine the role ionosphere plays in the various predictions of this model. The present work will examine the role of feedback instability and the propagation of Alfv\'{e}n waves (along the dipole field lines) in the development of various components of this model. The initial analytical studies will be extended to numerical calculations. \vskip 5mm \ni Lui, A. T. Y. and J. S. Murphree, A substorm model with onset location tied to an auroral arc, {\it Geophys. Res. Lett., 25, } 1269, 1998.

GA3.02/W/17-B3 0945

LOCALISED RECONNECTION AND THE DISRUPTION OF THE NEAR EARTH PLASMA SHEET

P L PRITCHETT and F V Coroniti (both at Department of Physics and Astronomy, University of California, Los Angeles, CA 90095-1547, USA, email: pritchet@physics.ucla.edu)

In recent years a number of spacecraft conjunction studies have provided clear evidence for the limited longitudinal extent of activations in and disruptions of the near-Earth plasma sheet. These observations are inconsistent with the traditional view that substorm onset involves a tearing instability along an extended neutral line. The ballooning mode instability in the near-Earth plasma sheet has also been proposed as a trigger mechanism for substorm onset.
Previous 3-D electromagnetic particle simulations [Pritchett and Coroniti, 1999] have suggested that this mode saturates at a fairly benign level when the spatial scale of its nonlinear development reaches that of the ion gyroradius. It produces only modest changes in the magnetic topology and plasma distributions and stimulates relatively slow flows. Thus it fails to produce the typical onset signatures of high-speed earthward flows and tailward expulsion of a plasmoid. As an alternative mechanism, we are investigating the possibility that a localized region of weak B_z, produced by either a peaked convection electric field or by mirrored energetic ions, could lead toisolated reconnection at neutral points and produce the characteristic features of breakup.

GA3.02/E/05-B3 1000

ONSET OF TAIL RECONNECTION IN THE COURSE OF MAGNETOSPHERIC SUBSTORMS: NUMERICAL SIMULATIONS

JOERG BUECHNER (Max-Planck-Institut fuer Aeronomie, Max-Planck-Str. 2, D-37191 Katlenburg-Lindau, Germany)

Reconnection takes place in the course of magnetospheric substorms. The question is, whether it is a cause or consequence of substorm onsets and current disruptions. While the large scale dynamics of reconnection is well described agnetohydrodynamically with some ad hoc assumptions about a certain plasma non-ideality, MHD cannot explain the reason for the onset of reconnection and its inherent three-dimensional structure.
We present current results of numerical simulations of collisionless reconnection through thin current sheets and discuss them in the context of the substorm onset problem.

GA3.02/W/06-B3 1015

EXPLOSION TYPE DYNAMICS OF THE MAGNETOTAIL CURRENT SHEET: SUBSTORM ACTIVATIONS

A.P.KROPOTKIN, (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow 119899, Russia)

Traditionally, fast substorm processes in the magnetosphere are considered as manifestations of large-scale (tearing-mode) instability of the magnetotail current sheet (CS), with characteristic time scales on the order of minutes. However, this concept is controversial: if the CS equilibrium is unstable, how does it manage to stay quiet for a long time preceding the substorm onset? Inversely, if it stays stable for that time but is only developing towards marginal stability due to quasi-static evolution, how can it become extremely unstable in a short time afterwards?
The clue to the problem lies in the nonlinear dynamics of the system. A catastrophe of equilibrium takes place at the marginal stability point. In a generic situation, the nonlinear dynamics of equilibrium loss is described by a single equation for the amplitude of the marginal mode. The equation involves both nonlinear saturation of the mode and its spontaneous symmetry violation. The latter results in the fact that in the course of quasi-static evolution, in advance of the fast equilibrium loss, the system becomes metastable. The (slowly varying) linear term which would fully determine the process time scale in the standard linear approach, plays a quite different role here. Its balance with the highest-order nonlinear term determines the (slowly-varying) saturation level for the disturbed vector potential amplitude A. The fast stage of evolution appears to be of "explosion instability" type, A ~ 1/(t0-t), being independent of the linear growth rate. The moment of the "explosion" t0 is shifted to later times from the moment tM when the system reaches marginal stability. That shift depends on the scale of the initial (fluctuation, seed) disturbance A0: for smaller A0 it is greater, so that the system stays in the metastable state for longer times.

GA3.02/W/40-B3 1050

A GLOBAL SIMULATION STUDY OF THE NOVEMBER 24, 1996, GEM SUBSTORM CHALLENGE EVENT

J RAEDER (Institute of Geophysics and Planetary Physics, University of California, 405 Hilgard Ave, Los Angeles, CA 90095, USA, email: jraeder@igpp.ucla.edu); L A Frank and J Sigwarth (The University of Iowa, Iowa City, IA 52242, USA); S Kokubun (STELAB, Nagoya University, 3-13 Honohara, Toyokawa, Aichi 442, Japan); R P Lepping and K W Ogilvie (NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA); H Singer (NOAA R/E/SE, Space Environment Center, 325 Broadway, Boulder CO 80303, USA)

The GEM (Geospace Environment Modeling program) substorm challenge event provides a unique opportunity to test magnetospheric models and to elucidate what they can tell us about the substorm process. The event in question occurred on November 24, 1996, around 2230 UT, and was observed by a wide variety of instruments, including the Polar-VIS auroral imager, several magnetospheric spacecraft, and ground magnetometers. This substorm is an isolated event that follows several hours of quiet magnetospheric conditions. In this talk we present the results from our global simulation of this event and discuss in detail the timing of the substorm signatures and the possible onset triggers.

GA3.02/W/32-B3 1105

PARTICAL ENERGIZATION AND PRECIPITATION DURING SUBSTORM EXPANSION PHASE IN DUNGEY'S MODEL MAGNETOSPHERE

Michael SCHULZ (Lockheed Martin Advanced Technology Center, Dept H1-11, Bldg 255, 3251 Hanover Street, Palo Alto, CA 94304, e-mail: schulz@agena.spasci.com)

Dungey's model magnetosphere consists of a dipole field plus uniform southward Delta B parallel to the dipole moment. A magnetospheric substorm can be simulated with this model by making the "tail" field Delta B and the cross-magnetospheric convection electric field suitably time-dependent. A gradual increase in Delta B from 7.8 nT (nominal quiet-time value) to 51 nT (for example) simulates substorm growth phase, during which the boundary between closed and open field lines shifts equatorward from 18° to 25° magnetic colatitude in the ionosphere. (Trapped particles escape into the "tail" during the growth phase of this model substorm.) Expansion phase is simulated by letting Delta B relax quickly back to 7.8 nT. The resulting (induced) electric field energizes charged particles (whether originally present or newly introduced across the neutral line), especially those on field lines that map to colatitudes between 18° and 25° in the ionosphere. This process can supply trapped relativistic electrons (mirroring near the magnetic equator) for radiation belts [as with Birn and Hesse, JGR, 99, 109-119, 1994] and also lower-energy precipitating auroral electrons (modeled here as being in strong pitch-angle diffusion). Particle energy gain is estimated in each case by expressing the Hamiltonian as a function [Schulz and Chen, JGR, 100, 5627-5633, 1995; Schulz, 103, 61-67, 1998] of the respectively conserved (i.e., adiabatically invariant) quantities in the limits of vanishing and strong pitch-angle scattering. Representative results for equatorially mirroring particles barely trapped at expansion-phase onset: 9.4-keV electrons become 640-keV electrons at L = 5.594; 3.2-keV protons become 67-keV protons at L = 5.58. Representative results for particles in strong pitch-angle diffusion, barely trapped at expansion-phase onset: 9.4-keV electrons become 48.6-keV electrons at L = 5.594; 3.2-keV protons become 12-keV protons at L = 5.58, all these results having been deduced from analytical expressions.

GA3.02/W/34-B3 1120

AN INVESTIGATION OF THE PI2 TRAVEL TIME IN THE MAGNETOTAIL DURING THE SUBSTORM ONSET

Yan SONG, Robert L. Lysak (both at School of Physics and Astronomy, University of Minnesota, 116 Church St. SE, Minneapolis, MN 55455, USA, e-mail: yan@aurora.space.umn.edu & bob@aurora.space.umn.edu), Dong-Hun Lee (Kyung Hee University, Yongin, Kyunggi 449-701, Korea, e-mail: dhlee@nms.kyunghee.ac.kr)

The quantitative calculation of the Pi2 travel time in the tail is important to help to clarify cause and effect during substorm expansion onset. A systematic numerical calculation of the MHD wave travel time of a magnetic perturbation (such as Pi2) from the neutral sheet in the tail to the ionosphere will be presented. For different stretched tail topologies, the travel time of the fast mode and shear mode MHD waves from different tail locations (-5 Re to -30 Re) to the ionosphere will be given. The travel time of fast flows caused by mid-tail (~ 15-30 Re) reconnection from the reconnection site to the near-Earth region (~ 6-10 Re) and the travel time of the rarefaction wave from the near-Earth region to the mid-tail region are also calculated. The results will be compared with observational facts.
Wave-related and convection-related phenomena must be distinguished. The previous theories of reconnection and the generation of field-aligned current are basically based on a convection picture. Establishment of new theoretical concepts of reconnection and the generation of field-aligned current is necessary to understand the mechanisms of the substorm onset.

GA3.02/L/07-B3 1135

MEASURING THEORIES FOR TRIGGERING SUBSTORM EXPANSION WITH OBSERVATIONAL CONSTRAINTS

Anthony LUI (The Johns Hopkins University Applied Physics Laboratory, Laurel, MD 20723-6099, USA, email: Tony.Lui@jhuapl.edu)

A number of theories are documented in the literature for the onset of substorm expansion. The prominent plasma instabilities include tearing, ballooning, drift-kink, cross-field current, and Kelvin-Helmholtz. Many of these theories are proposed on the basis of some selective observational indications. In this paper, we shall first identify some essential observational constraints on the substorm expansion onset process. We then evaluate briefly the strength and weaknesses of these theories and assess how well they satisfy the observational constraints identified above.

GA3.02/W/37-B3 1150

ROBUSTNESS OF SANDPILE/AVALANCHE MODELS FOR AGNETOSPHERIC ENERGY STORAGE AND RELEASE

Nicholas W. WATKINS (British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET, UK, Email: NWW@bas.ac.uk); Sandra C. Chapman and George Rowlands (both at Physics Department, University of Warwick, Coventry, CV4 7AL,UK, Email: sandrac@astro.warwick.ac.uk); Richard O. Dendy and Per Helander (EURATOM/UKAEA Fusion, Culham Science Centre, Abingdon, Oxfordshire, OX14 3DB, UK, Email: richard.dendy@ukaea.org.uk)

Most investigations of the substorm problem have focused on single substorm episodes or event groups. An alternative is to analyse the overall statistics of magnetospheric energy release, and thereby constrain the underlying physics. This usually requires definition of a substorm "event" via a thresholding process. In contrast, self-organised criticality (SOC) predicts that certain open dissipative systems will evolve to a critical state where all energy release statistics display both power law frequency spectra and power law distributions for event occurrence, size and duration. The demonstration of such a distribution for a measured geomagnetic index, and the proposal on theoretical grounds that the magnetosphere may be in an SOC state, have motivated cellular automaton ("sandpile") simulations of magnetospheric energy confinement and release ("avalanches"). Previous models have taken the limit where energy inflow ("fuelling") is slow relative to dissipation, and either uniform or random. However the magnetospheric system of interest has both slow and fast periods, mixed together in the observed indexes, and its fuelling is naturally modulated.

We have developed a sandpile model which accommodates both constant and fluctuating fuelling at a broad range of rates, and have studied the resultant distribution of energy release events. The power law form of the probability distribution is remarkably robust, except under extreme loading.

GA3.02/W/27-B3 **1205**

THE ROLE OF SELF ORGANISED CRITICALITY IN THE SUBSTORM PHENOMENON AND ITS RELATION TO LOCALISED RECONNECTION IN THE PLASMA SHEET

A J KLIMAS (Laboratory for Extraterrestrial Physics, Code 692, NASA/GSFC, Greenbelt, MD 20771; 301--286--3682; e-mail: alex.klimas@gsfc.nasa.gov); D Vassiliadis (USRA; at Code 696, NASA/GSFC, Greenbelt, MD 20771; 301--286--9060; e-mail: vassi@lepgst.gsfc.nasa.gov); J A Valdivia (National Research Council; at NASA/Goddard Space Flight Center, Greenbelt, MD, 20771; 301--286--3545; e-mail: alejo@roselott.gsfc.nasa.gov); D N Baker (Laboratory for Astrophysics and Space Physics, University of Colorado, Boulder, CO 80309; 303--492--4509; e-mail: baker@lynx.colorado.edu)

Recent observations of the magnetotail plasma sheet have shown it to be a dynamic and turbulent region. Borovsky et al. [J. Plasma Phys., 1997] have found strong turbulence in the plasma sheet at ~ 20 RE tailward of Earth; the turbulence is observed at all activity levels. The existence of strong turbulence in the plasma sheet in the region associated with substorm onset might be thought difficult to reconcile with the coherence and repeatability of the substorm cycle. We review a variety of evidence that strongly suggests the magnetotail is driven, through magnetic flux transfer, into a state of "self-organized criticality" (SOC). It is an important property of physical systems that evolve into SOC that they self-organize into a unique lobal dynamic state. This global state is inevitable, and repeatable. In this state, however, small- spatiotemporal-scale system fluctuations are unpredictable and can be only described statistically. This is the basis, we think, for the global coherence and repeatability of the substorm phenomenon in the turbulent plasma sheet. At, or near, substorm onset the plasma sheet can be described by a global SOC state containing significant small scale turbulence. In several recent studies, "sandpile" models were driven into SOC and then shown to reproduce various measures of substorm activity. We discuss the plasma physical foundation of these sandpile models. The evolution of simple continuum plasma sheet models into SOC-like states will be demonstrated. We view the substorm phenomenon as an avalanche of many small econnection events in the turbulent plasma sheet under the assumption that the plasma sheet is in a SOC state.

SEPARATION OF THE SCALING PROPERTIES OF THE DIRECTLY DRIVEN AND UNLOADING COMPONENTS OF THE MAGNETOSPHERE

Mervyn P FREEMAN and Nicholas W Watkins (British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET, UK, email: M.P.Freeman@bas.ac.uk)

It has been proposed that the magnetosphere can be naturally driven to a scale invariant state that is insensitive to the driver. This state is known as Self-Organised Criticality (SOC). So far, evidence to support this is mainly based upon scale invariant properties of the Auroral Electrojet (AE) index including the broad power law distribution of energy dissipating burst events. However, it is well known that a component of the AE index is directly related to the solar wind driver which itself has scale invariant properties. Thus, in this paper, we compare the scaling properties of the solar wind driver with those of the AE indices in order to evaluate to what extent the latter provide evidence that the magnetosphere, rather than the solar wind, is an SOC system.

MAGNETOSPHERIC SUBSTORM ONSET: OBSERVATIONS, THEORIES, MODELS-1

GA3.02/E/12-B3 Poster **0900-01**

RECURRENT SUBSTORMS AT THE EARTH AND HOMOLOGOUS FLARES ON THE SUN

P.A. SEDYKH, L.V. Minenko, V.I. Sidorov, S.S. Adelkhanov,and V.M. MISHIN (all at Institute of Solar-Terrestrial Physics,P.O.Box 4026, Irkutsk, 664033, Russia, email: mishin@iszf.irk.ru)

For the time interval (00-11) UT, May 3, 1986 (CDAW9C), the MIT2 method (Mishin et al. [JGR, 1997, p.19845]) was used in calculating, at steps of 6 min, the values of the open magnetic flux Psi, the magnetospheric tail length L, and the potential difference Upc1 on the dayside throat of the polar cap boundary. We assumed Upc1~M, where M is the dayside magnetopa use reconnection rate. For the interval considered, the plot of M(UT) shows a nearly monotonic decrease of Upc1 values, that are the characteristics of the solar wind geoeffectivness. From this plot, it is obvious that four recurrent substorms were observed in the interval considered, with corresponding changes of the parameters AE, Upc1, Psi, and L. Such a recurrence suggests the existence of the external energy source of substorms, which persisted at a supercritical level during ~11 hours. It is pointed out that homologous solar flares in terms of models such as CSHKP leave room for a similar interpretation. In CSHKP models, the flare is produced as a consequence of the reconnection of the open magnetic flux created by the external energy source. Therefore, the homologenity of the flares presupposes a long persistence of their external energy source.
This conclusion is not trivial because it is generally believed that the "opening" of the magnetic flux occurs suddenly due to the rise of a filament.

THE RECONNECTION POWER AND RATE IN THE COURSE OF EACH OF THE TWO ACTIVE PHASES OF MAGNETOSPHERIC SUBSTORMS

V. MISHIN, T. Saifudinova, A. Bazarzhapov, P. Sedykh (all at Institute of Solar-Terrestrial Physics,P.O.Box 4026, Irkutsk, 664033, Russia, email: mishin@iszf.irk.ru)

Broadly speaking, the "magnetospheric substorms - solar flares" analogy has become public knowledge, without its quantitative characteristics, however. Obtaining such characteristics is one of motivations of this work, which is a continuation of papers of Mishin et al. ((a) and (b), this issue). We are based on existing substorm models (models with Current Disruptions, CDs), assuming a two-stage development: first active phase - reconnection in the near, closed, tail; and second active phase - open magnetic flux reconnection in the middle tail. Mishin et al. [1997] used the magnetogram inversion technique to determine the open magnetic flux Psi in the tail lobes. In this paper, time profiles of Psi have been used as the main addition to the traditional data base to estimate the Poynting flux to the magnetosphere, and the reconnection power and rate in the course of each of the two active phases of the two magnetospheric substorms being investigated (CDAW6 and CDAW9C events). It is evident from the calculated results that power and rate of the open magnetic flux reconnection exceed those for the first active phase, as in the case of solar flares (see Mishin et al. (GA4.02), this issue).

PLASMA SHEET TURBULENCE AND SUBSTORM EXPANSION ONSET

Elizaveta E. ANTONOVA and Ilya L. Ovchinnikov (both at Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: oi@taspd.npi.msu.su)

Plasma sheet experimental observations supported the hypothesis about the existence of the medium scale developed turbulence and quasi-diffusion particle transport. The measured diffusion coefficient is very close to predicted one and is much larger then Bohm diffusion coefficient. The theory of the plasma sheet with medium scale developed turbulence explains the existence of a quite stable plasma sheet and its substorm dynamics, including plasma sheet thinning during substorm growth phase and plasma sheet thickening during substorm expansion phase. Plasma sheet with minimal thickness is formed in the near to Earth plasma sheet regions where dawn-dusk electric field has maximal amplitude. The growth of plasma sheet thickness in the developed approach is connected with the growth of the level of turbulence. The external source of Bz<0 magnetic field can destroy the plasma sheet stability and lead to the formation of neutral line and plasmoid. The connection of tail processes with the inner magnetosphere processes and the inner magnetosphere substorm onset is discussed.

PHYSICS-BASED 2D RUNNING CELLULAR AUTOMATA AS MODELS OF MAGNETIC FIELD NEAR NEUTRAL SHEET

Jouni TAKALO (Department of Physics, Un. of Jyvaskyla, P.O.Box 35, FIN-40351, Jyvaskyla, Finland, now at GSFC, Code 692, Greenbelt, MD 20771, USA, email: jouni@roselott.gsfc.nasa.gov); Jussi Timonen (Department of Physics, Un. of Jyvaskyla, P.O.Box 35, FIN-40351, Jyvaskyla, Finland, email: timonen@snafu.phys.jyu.fi); Alex Klimas, Juan Valdivia and Dimitris Vassiliadis (All at GSFC, Code 692, Greenbelt, MD 20771, USA, email: alex@bokeh.gsfc.nasa.gov)

Magnetic field models based on cellular automata (CA) are presented. These models feature self-organized critical behavior with power-law scalings both in durations and sizes of avalanches. The models have also nonlinear energy dissipation. Sometimes a large scale avalanche has external reason, sometimes the avalanche is internal without any external trigger. The present models, isotropic and anisotropic, are two dimensinal running CAs, such that the models are feeded at every round, not just in the state of relaxation. Both models have full physical interpretation in terms of magnetohydrodynamic equations. The heights of the CA are magnetic flux densities, and the change of the heights are the time derivatives of the flux densities.

SUBTRORM AS A GLOBAL MAGNETOSPHERIC INSTABILITY

I.I.ALEXEEV and S.Yu.Bobrovnikov (Institute of Nuclear Physics, Moscow State University, Moscow, Russia)

The substorm onset was theoretically studied. It was described as a global transition from a metastable magnetospheric state to another stable state with lower energy. In contrary to the usual approach we investigate not local instability in the tail but global magnetospheric instability. Based on paraboloid model the magnetospheric dynamics during substorm growth phase was investigated.
A key role of the Region 1 filed-aligned currents was revealed. Critical values of the model parameters depend on intensity of field-aligned currents was calculated. It was shown that at growth phase, when the IMF has southward direction, the Region 1 filed-aligned currents serve as a stabilization factor which permits the magnetosphere to go to the metastable configuration. And after IMF turns northward or a sudden pulse in solar wind dynamic pressure this stabilization factor disapeares. The criteria of the transition of the magnetosphere from metastable configuration to expansion was presented. On the basis of this criteria the scenario of substorm which take into account an influence of field-aligned currents was constructed. This scenario is based on global magnetospheric model. Parameters of this model have obvious physical sense and can be calculated from the satellites and on-ground measurements. As a results a new explanation of substorm onset was presented.

ON THE STABILITY OF CHARGED PARTICLE ORBITS IN A SHEARED MAGNETIC REVERSAL MODELLING THE QUIET TIME GEOTAIL.

M. TSALAS, (Dept of Physics, Uni of Warwick, Coventry, Email: maximost@astro.warwick.ac.uk); S. C. Chapman and G. Rowlands

The motion of charged particles in a simple model for the geotail with a shear component has been investigated. It was found that as the value of by (in GSE) is increased, the position of the integrable region varies accordingly. This variation is analytically predicted using a multiple timescale perturbation technique. It was also observed that for a certain interval of by, the whole of the phase space becomes chaotic via a bifurcation sequence. We investigate this region of global chaos by looking at the stability of the periodic orbits. Since each type of orbit contributes differently to the cross tail current distribution, knowing how the introduction of a shear component influences the topology of the phase space could help in the understanding of the currents observed in the region.

A POSSIBLE ROLE OF ION DEMAGNETIZATION IN SUBSTORM GENERATION

Wladislav LYATSKY (Polar Geophysical Institute, Apatity, 184200, Russia,
email: lyatsky@pgi-ksc.murmansk.su)

A new model for the substorm generation based on stimulated ion diffusion across magnetic field lines in the magnetotail plasma sheet is studied. The essence of the model is: the ion demagnetization in the plasma sheet produces a radially-directed ion diffusion which leads to a charge separation and the formation of field-aligned currents eliminating these charges. The magnitude of these currents depens on the ionospheric conductivity. The effect of field-aligned currents on the ionospheric conductivity produces the instability of this system consisting in a sharp increase of the ion diffusion, the dipolarization of the magnetic field in the plasma sheet and the substorm beginning. The model includes the following issues: (1) Before the substorm onset, the magnetotail plasma sheet approaches to the Earth and magnetic field lines are stretched from the Earth. (2) Partially demagnetized (because of their large Larmor radius)

ions in the magnetotail plasma sheet move from the Earth. This produces a radially-directed electric field which limits the ion escape and produces a system of field-aligned currents with upward current at the boundary of the ion demagnetization and downward current poleward of this boundary. (3) The magnitude of field-aligned currents is controlled by the ionospheric conductivity. For quiet conditions the ionospheric conductivity is small and field-aligned currents are weak. The increase of the ion diffusion before a substorm leads to increase of field-aligned currents. This stimulates an increase of the ionospheric conductivity which leads to a new increase of the ion diffusion and the substorm beginning.

HALL-MHD SIMULATIONS OF THE DRIFT KINK INSTABILITY IN THE MAGNETOTAIL

R. V. REDDY and G. S. Lakhina (both at Indian Institute of Geomagnetism, Dr. Nanabhoy Moos Road, Colaba, Mumbai - 400 005, India, email: vreddy@iig.iigm.res.in)

The stability of the current sheets of the Harris type against the drift kink mode is studied using two dimensional Hall-MHD simulations, in which we include the effects of the electron pressure gradient and the Hall current. These Hall-MHD effects allow the relative electron-ion cross field streaming, which is necessary to obtain the drift kink mode. The simulation experiments are carried out to find the growth rates and the real frequencies for near-Earth magnetotail parameters. The obtained simulation results of the drift kink instability are compared with other cross-field current instabilities in the magnetotail. Implications of these results for the disruption of the near-Earth plasma sheet and the triggering of substorms are discussed.

CURRENT DISRUPTION AT SUBSTORM ONSET: BREAKDOWN OF THEALEXANDER-ORBACH CONDITION FOR THE CRITICAL PERCOLATION

Alexander V. MILOVANOV and Lev M. Zelenyi (both at Space Research Institute, Profsoyuznaya street, 84/32, 117810 Moscow, Russia, e.mail: amilovan@mx.iki.rssi.ru) Pierluigi Veltri and Gaetano Zimbardo (both at University of Calabria, 87036 Arcavacata di Rende, Italy, e.mail: zimbardo@fis.unical.it)

Self-organized critical states of the Earth's magnetotail are analyzed. The local stretching and thinning of the tail is associated with the site of the substorm current disruption just prior to the onset when the critical states are characterized by the metastable magnetic field structures. We show that the self-organized geometry of such structures is that of a critical percolating network exhibiting some universal topological features. We quantify these features in terms of the improved Alexander-Orbach (AO) condition [1] which relates the Hausdorff fractal dimension of the network to its basic topological characteristic, the index of connectivity.
Application of the AO condition has led us to prove that the self-organized states can be described by the power-law magnetic energy density spectrum, with the slope close to -7/3; this slope has been earlier recognized in the AMPTE satellite experiments as reported by Ohtani et al. [2]. In our study, the AO relation is treated as the structural stability condition of the critical state. We speculate that the cross-tail current disruption at the substorm onset could be understood as the violation of the AO stability condition followed by the breakdown of the critical (metastable) percolating network.
We analyze the structural properties of the magnetic field and plasma turbulence at the substorm onset with use of such unconventional methods as fractal geometry, percolation theory, fractional differentional calculus, and homotopic topology. The specific feature of our study is basically geometric approach which assumes a self-consistent relationship between the topology of the system and main "physical" characteristics of the turbulence.
We model numerically the self-organized critical states in the Earth's magnetotail by the so-called fractional Brownian surfaces whose topological properties recover well the main assumptions of our approach. The particle dynamics on the fractional Brownian surfaces with the imposed transversal electric field is simulated. The anomalous heating, diffusion, and acceleration rates of the particles are analyzed in relation with the fractal geometry of the turbulence; we show that these anomalous rates appear in unconventional scaling laws depending on the connectivity properties of the fractal. Some observational manifestations of our study are discussed in view of the recent spacecraft measurements of the magnetotail.

NON-ADIABATIC PARTICLE DYNAMICS AND MAGNETIC FIELD RECONNECTION BY THE LINEAR MAGNETOSONIC WAVE EXCITATION IN THE CURRENT SHEET OF THE EARTH'S MAGNETOTAIL

A.P.KROPOTKIN and O.O.Trubachev, (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia)

In the stability theory of a current sheet (CS) it is usually adopted that plasma is fully confined in the CS. As a result, possible unstable modes are evanescent outside CS. It is argued that since normally there is a uniform cold plasma background outside CS, the specific CS-bound mode may be linearly coupled to spatial modes of that uniform medium. Waves propagating away from the CS may provide a means of energy dissipation being necessary for tearing process in the CS, and this results in magnetic field reconnection. Linear excitation is considered of a fast magnetosonic wave in such a non-uniform medium. That linear excitation has a low threshold, and does not need any preliminary turbulence level. The wave being excited, interacts with particles dynamically, resulting in a non-adiabatic and dissipative force due to the wave-particle momentum exchange. The force does not exist in the Hamiltonian dynamics of test particles but is an important point of self-consistent plasma systems analysis. As a result, the limitations imposed earlier on the tearing-like instabilities are weakened.

NON LINEAR DYNAMICS OF THE EQUILIBRIUM LOSS IN THE GEOMAGNETOTAIL PLASMA SYSTEM BASED ON A "COMBINED" PLASMA KINETIC EFFECT

A.P.KROPOTKIN and O.O.Trubachev, Skobeltsyn (Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia); A.T.Y. Lui, Johns Hopkins University, Applied Physics Lab., Laurel MD 20723-6099 USA

The substorm onset instability combines features of "macro" scale electromagnetic disturbance of the tearing mode type, and the "micro" scale plasma turbulence which is generated by the cross-field current instability (CCI) and modulated in coherence with the large scale disturbance. Both components are involved in a feedback loop. It is assumed that the current sheet (CS) is thin enough for CCI turbulence to already exist. Current density variations of the large scale disturbance result in additional CCI generation; on the other hand, that additional plasma turbulence provides, in quasilinear approximation, a flow of electrons which violates the frozen-in condition for magnetized electrons, and thus destabilizes the tearing mode. The process is nonlinear. However the threshold amplitude diminishes as the CS thins during the substorm growth phase, so that the instability sets in when the threshold gets smaller than the background fluctuations or externally driven disturbances.

STATISTICAL OBSERVBLES FOR TESTING MAGNETOSPHERIC SANDPILE MODELS

Nicholas W. WATKINS and Mervyn P. Freeman (both at British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET, UK, Email: NWW@bas.ac.uk.) Richard O. Dendy (EURATOM/UKAEA Fusion, Culham Science Centre, Abingdon, OX14 3DB, UK, Email: richard.dendy@ukaea.org.uk)

Earth's magnetosphere is a complex, open, driven, dissipative system . Generically, such systems often display various forms of "simple" behaviour - examples include low dimensional chaos and "sandpile" phenomenology. However, not all observables derived from such systems are independent, and care must be taken to uncover implicit linkage and avoid redundant information. We illustrate this problem with reference to current interest in self-organised criticality (SOC) sandpile models of the magnetosphere, which have been used to interpret geomagnetic index time series. In particular, we evaluate the information contained in power spectra, structure functions, amplitude probability distribution functions (PDFs), burst size PDFs, and inter-burst interval PDFs. We consider recent progress in relating power law slopes to the decade range covered by instabilities, and show how this illuminates which types of substorm data can usefully be compared with the output of SOC sandpile models.

TIME-SPATIAL CHARACTERISTICS OF AURORAL LUMINOSITY DURING DOUBLE BREAKUPS

ILIA KORNILOV, Tatyana Kornilova (both at Polar Geophysical Institute, Apatity, Murmansk region, 184200, Russia, E-mail: kornilov@pgi.kolasc.net.ru); Oleg Kornilov (Institute of Physics, St.Petersburg State University, St.Petersburg, Petrodvorets, 198904, Russia)

During strong magnetic disturbances the phenomenon named as double breakups (DB) is sometimes observed in the region of auroral oval. DB represent simultaneous poleward expansion in two regions separated by latitude in the same longitudinal sector. A typical feature of double breakups is correlation of luminosity of the northern and southern breakups. Correlation characteristics were studied on the base of TV auroral data. It was shown that the close interaction of auroras in the region of the north and south breakups exists. In the time of strong magnetic disturbances lasting for several hours the repeated in 30-50 minutes sequences of DB are observed. At the time scale of the order of any sequence duration a correlation between auroral intensity of the northern breakups and southern ones occur. Maximum intensity of the north breakup in average 5 minutes leads the same of the southern breakup. Inside the small time scale of the order of 100-200 s the stable correlation of the luminosity has been registered: fast auroral luminosity variations in the region of north breakup 2-5 s lead ones of the southern breakup.

MULTI-POINT OBSERVATIONS OF SUBSTORM SERIES UNDER CONTINUOUS SOUTHWARD IMF ON DECEMBER 22-23, 1996

Yu. I. YERMOLAEV, L. M. Zelenyi, A. A. Petrukovich (Space Research Institute, Moscow 117810, Russia, Email: yermol@afed.iki.rssi.ru), V. A. Sergeev (St.Petersburg University, Russia), T. Mukai (ISAS, Japan), S. Kokubun (STEL, Japan), K. Liou, C.-I. Meng (APL/JHU, USA), G. Parks (Un. ofWashington, USA), J.-A. Sauvaud (CESR/CNES, France)

Multi-point observations by ground-based stations and a fleet of ISTP satellites allow us to study plasma processes in different regions of near-Earth space during an interesting interval on December 22-23, 1996 which was characterized by ~ 20 hour southward IMF and almost constant solar wind pressure ~ 1.2 nPa. Five substorm events were observed during this period of continuous external driving. Several global effects of these substorms are described. Our results demonstrate the principle importance of prehistory of magnetotail activity on the development of each of subsequent substorm. In particular, comparison of measurements in the plasma sheet on both flanks showed (1) similar loading/unloading processes in the tail correlated with substorm development, and (2) a strong bursty convection concentrated in a narrow (dY ~ 15 Re) channel.
The work was supported in part by INTAS grant 96-2346.

AN EIGEN MODE ANALYSIS OF THE AURORAL ELECTROJET

WEN-YAO XU (Institute of Geophysics, Chinese Academy of Sciences, Beijing 100101, China, email: wyxu@mail.c_geos.ac.cn)

A substorm involves "directly driven" and "loading-unloading" processes, which have different temporal-spatial features and are correlated respectively with the large-scale magnetospheric convection and substorm current wedge. In order to quantitatively separate these two components, a new technique of eigen mode analysis, Method of Natural Orthogonal Components (MNOC) is used to analyze the ionospheric equivalent current systems. The results show that the current pattern of the first eigen mode exhibits a two-cell construction, characterizing the large-scale magnetospheric convection and directly driven process, while the secondeigen mode shows a concentrated westward electrojet at midnight sector, characterizing the substorm current wedge and the loading-unloading process . The first mode consistently exists whenever during quiet periods or at substorms, and its intensity increases from the beginning of the growth phase of substorms, then quickly intensifies in the expansion phase. On the other hand, the intensity of the second mode remains to be near zero during both quiet time and the growth phase of substorms, its rapid enhancement occurs in the expansion phase. These characteristics in the current patterns and the intensity variations coincide with the defined physical processes of the directly driven and loading-unloading components. On the basis of these results a suggestion about a modified AE index is proposed.

PREDICTION OF SUBSTORMS FOLLOWING SHARP NORTHWARD TURNINGS OF THE IMF

Gerard BLANCHARD (Department of Chemistry and Physics, Southeastern Louisiana University, SLU 10878, Hammond, LA 70402-0878, Email: gblanchard@selu.edu) Larry Lyons (Department of Atmospheric Sciences, University of California, Los Angeles, CA, 90095-1565,
Email: larry@atmos.ucla.edu) James Spann (Space Plasma Physics Branch, Space Science Laboratory, NASA/Marshall Space Flight Center, NASA Mail Code ES83, Huntsville, AL 35812, Email: jim.spann@msfc.nasa.gov)

It has been shown that there is an association between changes of the interplanetary magnetic field (IMF) that are expected to lead to a reduction in magnetospheric convection (northward

turnings, reductions in |By|) and the onset of the expansion phase of substorms. This has been previously demonstrated by analyses of IMF data during time intervals associated with identified substorm onsets.. Here we examine whether observations of northward turnings of the IMF can be used to predict the occurrence of substorms We first identified sharp northward turnings that follow an interval of steady, southward IMF using measurements from the Wind spacecraft during the first 180 days of 1997. We also required that the northward turning be observed by either IMP-8 or GEOTAIL, in addition to Wind, and that one of the observing satellites be sufficiently close to the Earth-Sun line, or that the two observing satellites be sufficiently separated in YGSE, that we are reasonably certain that the northward turning affected the magnetosphere. We also used the dual observations to estimate the arrival of the northward turning at the Earth. Using these criteria, we predicted 17 substorms. We then searched for the following signatures of substorm onset around the time of the predicted onset: auroral brightening followed by auroral bulge expansion observed by Polar UVI, geosynchronous particle injection, geosynchronous magnetic field dipolarization, and an appropriate magnetic disturbance at the surface of the Earth. Of the 17 predictions of substorms, 10 were successful in that a substorm onset was observed within +/- 12 min of the predicted onset, 1 is indeterminate due to a lack of data at the Earth, 1 had unusual activity that we have not been able to identify, and 5 were unsuccessful. The 5 failures fall into two groups that we can eliminate through modification of our selection criteria for northward turnings. Two of the northward turnings that failed to produce substorms were preceded by the lowest average |BzGSM| of the set; The remaining 3 were the only cases in which the northward turning was accompanied by a simultaneous sharp increase in |ByGSM|. The increase in |ByGSM| would be expected to prevent the decrease in convection that would otherwise be expected to be associated with a northward turning. These results indicate that it is an IMF change that leads to a reduction in convection, rather than just a northward turning or reduction in |By| that is associated with substorms, and that at least some substorms can be predicted by measurements of the IMF that affects the magnetosphere.

THE TRIGGRING MECHANISM OF RANDOM SUBSTORMS

Chen SHEN (Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing 100080, China, e-mail: sc@center.cssar.ac.cn); Zhenxing Liu (Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing 100080, China, e-mail: liu@center.cssar.ac.cn)

The triggering mechanism of random substorms has been studies by using an equaivalent circuit method. It is found that, during the growth phase, if there is an interplanetary discontinuty approaching the dayside magnetopause, the interplanetary and magnetopause current sheets will interact with each other, the magnetic reconnection is enhanced greatly, and the dawn-dust potential drop increases considerably within short time. The simulation shows that, the cross tail current will reach its critical value shortly after the north turning of the IMF, the current disruption occurs, and the expansion phase of substorms takes place.

DEVELOPMENT OF THE DAYSIDE AURORA DURING MAGNETOSPHERIC SUBSTORMS

R. P. RIJNBEEK and P. N. Smith (both at Space Science Centre, School of CPES, University of Sussex, Brighton BN1 9QH, UK, email: R.P.Rijnbeek@sussex.ac.uk); M. I. Pudovkin (Institute of Physics, State University, St. Petersburg, 198904 Russia, email: Mikhail.Pudovkin@pobox.spbu.ru); G. V. Starkov (Polar Geophysical Institute, Murmansk Region, Apatity, 184200 Russia, email: starkov@pgi.kolasc.net.ru)

We have analysed optical data obtained from Spitzbergen during the winter periods of 1980-1983. This study has shown that there are three maxima in the intensity of dayside auroral luminosity during the course of a substorm in the nightside magnetosphere: the first maximum is observed during the preliminary/growth phase, the second immediately after the onset of the breakup, and the third during the maximum of the substorm. The poleward motion of the dayside aurora increases after the beginning of the preliminary phase. The intensity of the ionospheric electric field, deduced from the auroral velocity, is in the range 30-50 mV/m (for comparison, during quiet magnetic conditions the value of the electric field is about 10 mV/m). This increase in the electric field coincides with the first maximum of the auroral luminosity. Short-lived fading of the aurora is observed on both the dayside and nightside before substorm onset. A brief intensification of the luminosity in the green line appears after the substorm onset. The intensity of the ionospheric electric field decreases around the time of onset, but the value is still enhanced compared to that observed during quiet conditions. The primary maximum in the luminosity coincides with the maximum of the nightside substorm, and with a renewed increase of the electric field in the dayside ionosphere.

COUPLING BETWEEN SUBSTORMS AND ULF DISTURBANCES IN THE DAYSIDE CUSP

Viacheslav PILIPENKO, Natalia Kleimenova, Olga Kozyreva (Institute of the Earth Physics, B.Gruzinskaya, 10, 123810, Moscow, Russia, e-mail: vpilipenko@uipe-ras.scgis.ru) Mark Engebretson (Augsburg College, Minneapolis, MN55454, USA, e-mail: engebret@augsburg.edu)

The recently deployed magnetometer network MACCS in Arctic Canada and the extension of the "210 Magnetic Meridian" array of stations to Siberia provide an opportunity for the study of a possible coupling between the nighttime substorm activity and the behavior of ULF pulsations in the dayside cusp. Several events with a response of the dayside long-period magnetic pulsations to substorms and to IMF variations have been revealed. An onset of a substorm can result in the suppression of the IPCL/Pc5 activity in the dayside cusp. At the recovery phase of a substorm the pulsation activity returns back to the pre-onset level. The essential role of By component of IMF has been elucidated: the effect is revealed only during periods of negative By. Several interpretation of the effect found are possible, among them is that the behavior of pulsation's intensity as the occurence of an ULF precursor of a substorm.

PLASMA PRESSURE IN THE HIGH LATITUDE MAGNETOSPHERE AND SUBSTORM EXPANSION PHASE ONSET

Maria O. RIAZANTSEVA (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia; email: maria@orearm.msk.ru)

The results of high latitude plasma pressure observations are interpreted as the proof of high latitude quasi-ring current existence. The current carries are mainly the auroral ions of plasma sheet origin. Such ions form the plasma structure surrounding the Earth at all local times. Plasma pressure in the ring is near to isotropic and constitute of the order of 1 nPa. Measured plasma pressure meanings are comparable with the solar wind dynamic pressure. High latitude quasi-ring current growth may lead to real or effective eastward current formation. Such current produce positive magnetic field disturbance near the Earth and negative magnetic field disturbance in the geomagnetic tail. The simple model is developed giving the possibility to evaluate the contribution of the magnetic field of high latitude ring current in the near Earth and near tail magnetic field. It is shown that eastward ring current can be considered as the course of near tail current disruption and substorm expansion phase inset.

ENERGETIC PARTICLE INJECTIONS AND MAGNETIC FIELD PERTURBATIONS FROM CRRES DATA

Kozelova T.V., Lazutin L.L., KOZELOV B.V. (Polar Geophysical Institute, Apatity, Russia, e-mail: kozelov@pgi.kolasc.net.ru) Rasinkangas R. (Unirversity of Oulu, Oulu, Finland)

The dynamical variability of particle fluxes, associated with substorm processes, is the subject of intensive study of many years. A key feature of substorm 'dispersionless' injections is that the particle fluxes increase nearly simultaneously over a very broad range of energies (including both electrons and ions). Lezniak and Winckler (1970) showed the correlation of increases in the electron fluxes with increases of local magnetic field. Moore et al (1981) proposed that the injections correspond to some kind of compressional wave that propagates Earthward and may be associated with westward current of perturbation. However, the increase in the magnetic field strength (dipolarization) after substorm onset may indicate, that the total westward current intensity decreases suddenly (i.e. current disruption) or the eastward current of perturbation appears. We investigated changes in the magnetospheric cross-field current during the proton and electron injections on the CRRES spacecraft. The differential vectors of the magnetic field have been used to identify the current perturbations. The line current model have been used to interpret equivalent currents, associated with these magnetic field perturbations. Analysis of current perturbations showed that the current of perturbation in the injection front may be directed both westward and eastward depending on the spacecraft position in respect to the site of active region.

GROUND AND SPACECRAFT OPTICAL OBSERVATIONS OF SUBSTORMS

V. TAGIROV (Polar Geophysical Institute, Apatity, 184200, Russia, Email: tagirov@pgi.kolasc.net.ru); V.Arinin (Russian Federal Nuclear Center, Sarov, 607190, Russia, Email: root@gdd.vniief.ru); C.-I.Meng, K. Liou, D. Sibeck, and A.T.Y. Lui (all at the John Hopkins University, Applied Physics Laboratory, Laurel, MD 20723, USA, Email: david.sibeck@jhuapl.edu); L.A.Frank and D.Morgan (both at University of Iowa, Iowa City, IA 52242, USA); G.Parks (University of Washington, Seatle, WA 98195,USA)

In conjunction with NASA's Polar satellite program, we have conducted a campaign of auroral substorm observations using a low-light-level all-sky TV observations at Loparskaya (68.6º N, 33.3º E geographic, 65.0º N, 114.2º E geomagnetic) located at Kola Peninsula, North-West of Russia. The satellite optical observations were made both in UVI and visible ranges of wavelengths. We present substorm activity on December 9, 1996. We used keogram presentation of satellite UVI and ground based TV data to compare the dynamics of auroral display at different ranges of wavelengths in time interval more than three hours. Although TV observations began about an hour later than the satellite ones the rest parts of keograms coinciding in time demonstrated strong similarity in both ranges of emissions. The onsets occurred periodically and duration of each substorm was about 75 minutes. The first onset which was registered only by UVI camera was very weak and took place at 66-68º geom. latitude at 2020 UT, the next one was more intensive and occurred at 64-67º at 21.32 UT and the last one was very strong and started at 63-65º at 2250 UT. The common feature of all onsets was a poleward leap of the aurora and then slow equatorward moving. Such behavior showed that the more closer to the Earth onset takes place the more intensive it is. The first onset was registered only by POLAR UVI camera, there was no any signature of disturbance seen by visual camera or ground based magnetic stations. No disturbance was registered also in IMF or solar wind characteristics prior to this onset. The second onset started just above Loparskaya, where all-sky camera was located. According to WIND satellite data it was probably triggered by a northward turning of the IMF Bz component and an increase of the solar wind dynamic pressure about 8 minutes prior to onset. Ground optical, magnetic and POLAR satellite data show that the onset covered a very limited area and lasted about 15 minutes without further developing to the recovery phase. The third onset did not exhibit any noticeable external triggering factors. The IMF was stable and strongly southward, and the solar wind dynamic pressure did not exhibit any changes. But contrary to the previous onsets this one developed into a very intense substorm expanding from the region located slightly westward from Loparskaya towards both the evening and morning sectors as it widened and finally covered the entire oval.

MAGNETOSPHERIC ENERGETICS DURING MODERATE SUBSTORMS: IMP8 AND GEOTAIL OBSERVATIONS

Anna BELEHAKI (Institute of Ionospheric and Space Research, National Observatory of Athens); Ioanna Tsagouri (Nuclear and Particle Physics Section, Physics Department, University of Athens)

The energy budget of the magnetosphere during moderate sunstorms is estimated, using IMP8 observations from the interplanetary medium and GEOTAIL from the deep tail phase of the mission. It is assumed that the energy, that entered the magnetosphere due to electromagnetic coupling with the solar wind, is described by the epsilon parameter, proposed by Akasofu. The estimation of the energy input and the energy dissipated in the magnetotail during a substorm process was based on two specific events occurred during 1993. The analysis of energetic particle, magnetic field and plasma data from the EPIC, MGF and CPI experiments on board GEOTAIL gave us the possibility to estimate the position of the Near Earth Neutral Line location, the time of plasmoid release, the size of the plasmoid, its convection velocity and finally the energy dissipated for the plasmoid formation and acceleration downtail. Our results suggest that the energy dissipated in the ionospheric Joule heating is comparable to the energy dissipated in accelerating the plasmoid, and these two are the most prominent modes of dissipation of the input solar wind energy into the Earth's magnetosphere.

GEOTAIL SPACECRAFT OBSERVATIONS OF ENERGETIC ION SPECTRAL AND COMPOSITIONAL VARIATIONS NEAR SUBSTORM ONSET

S.P. CHRISTON, G. Gloeckler (Dept. of Physics, Univ. of Maryland, College Park, MD 20742), A.T.Y. Lui, R.W. McEntire, E.C. Roelof, D.J. Williams (JHU/APL, Laurel, MD 20723), T.E. Eastman (Plasmas International, Silver Spring, MD 20910), and S. Kokubun (STEL, Nagoya University, Toyokawa, Japan).

Measurements of energetic hydrogen and oxygen ions in the near-Earth (X > -30 Re) magnetosphere obtained by Geotail during the ISTP interval are used to investigate the energy spectra and relative composition before and after abrupt flux increases associated with

A

magnetic field dipolarizations (characteristics generally associated with substorm onsets). Measurements of charge state composition from EPIC/STICS at ~9.4-210 keV/e and mass composition from EPIC/ICS at >50 keV to 3 MeV are used. The relative abundance of energetic high-charge state oxygen ions of solar wind origin to low-charge state oxygen ions of ionospheric origin provides a measure of the relative importance of these two plasma sources. Although it has been shown that the relative abundance of ionospheric oxygen generally increases with geomagnetic activity, substorm-related changes in the oxygen spectral shape remain to be determined in a statistically meaningful manner. Such changes in spectral shape can be identified with different acceleration scenarios. We investigate differential flux variations of the energetic ion populations (at a minimum for protons and oxygen) for a large sample of occurrences and compare their relation to other locally and globally determined parameters (noting their assocaition to published tabulations of substorm onsets) with the intent to determine "typical" variations and, if any, classes and ranges of differences from this determined norm.

QUASI-PERIODIC FIELD AND ENERGETIC PARTICLE STRUCTURES: SIMULTANEOUS OBSERVATIONS BY GEOTAIL AND INTERBALL IN THE NEAR MAGNETOTAIL

George KARAGEVREKIS*, D. V. Sarafopoulos and E. T. Sarris (Demokritos University of Thrace 67100 Xanthi, Greece email: postdoc@creator.space.noa.gr); I. A. Daglis and A. Belehaki (national Observatory of Athens, Institute of Ionospheric and Space Research, 15236 Athens, Greece); V. Lutsenko (Space Research Institute, Profsoyuznaya 84/32, Moscow 117810, Russia); S. Kokubun (Solar-Terrestrial Environment Laboratory, Nagoya University, 442 Toyokawa, Japan); *Also at National Observatory of Athens

On November 1, 1995 a strong negative Bz component of the IMF as recorded on board the Wind spacecraft was followed by recurrent quasi-periodic and intense tailward fluxes of energetic particles in the central plasma sheet (GEOTAIL/EPIC measurements at X=-23Re), as well as by energetic particle fluxes in the plasma sheet boundary layer (INTERBALL/DOCK-2 measurements). Thanks to the location of Interball, which differs only in the Z direction with respect to the location of Geotail, a better understanding of the morphology associated with the near magnetotail during substorm activity is obtained. At the same time the tailward detected bursts of energetic particles were associated with corresponding negative bays of ground-based magnetograms at midnight local time, as well as with energetic particle injections at geosynchronous orbit (LANL 1987-097 spacecraft). We suggest that during this event the energy was not dissipated through the ejection of a single plasmoid/flux rope, but rather through the creation of multiple plasmoids/flux ropes.

LOCATIONS OF DUSK-TO-DAWN CROSS-TAIL CURRENT DEDUCED FROM THEMAGNETIC VARIATIONS AT GOES-5 AND AMPTE-CCE DURING THE SUBSTORM ONSETS

Kouta OKADA (Kyushu University, Hakozaki, Fukuoka, 812-8581, Japan,
email: okada@geo.kyushu-u.ac.jp)

It has been widely accepted that during substorm expansion onsets Pi 2 pulsations are observed globally at the dipequator, and magnetic field changes are often detected at the nightside geosynchronous orbit. Using high-time resolution magnetic field data from the geosynchronous satellite GOES 5 during the interval from March 1 to June 20, 1986, we examined the dynamical field changes in the nightside agnetosphere.The first peak in space are found to show a peculiar feature. In order to explain the peculiar feature, we propose that the current disruption region should be set up in the inner magnetosphere than 6.6Re during the substorm expansion onset. Furthermore, we will show a local time distribution of the events of the magnetic field change at the substorm expansion onset in the nightside magnetosphere.

GA3.02/L/06-B3 Poster **0900-27**

FIELD-ALIGNED CURRENTS PRIOR TO A SUBSTORM EXPANSION PHASE ONSET

V. A. VELICHKO, R. N. Boroyev and D. G. Baishev (Institute of Cosmophysical Research and Aeronomy,31 Lenin Ave., Yakutsk 677891, Russia, email: lae@sci.yakutia.ru)

We have selected a set of substorms, a center location of which at the moment of an expansion phase has been determined on the magnetograms from the auroral stations. During a substorm growth phase at middle and low latitudes the bays in the geomagnetic field D-component are found: the negative bay was observed westward of the future substorm center, the positive bay - eastward. The magnetograms of mid-latitude stations extended in longitude allowed to rebuild directions and to estimate the longitudinal scale size of the downward and upward field-aligned currents, arising in the expected substorm center a few minutes prior to the expansion phase onset. At the beginning of expansion phase the field-aligned currents reverse their direction on each side from the substorm center.

IMF CONTROL OF STORM AE ACTIVITY

Tadanori ONDOH (Space Earth Environment Laboratory, Kitano, Tokorozawa 359-1152, Japan, (email: 77771903@people.or.jp)

Since solar wind parameters simultaneously observed by separate satellites show the same variation on time scales above 30 minutes or more, hourly values of AE and Dst indices during small geomagnetic storms are compared with those of IMF-BZ and solar wind pressure to study the cause of storm AE activity. All storm AE increases occur during Dst decreases for the southward IMF-BZ, and storm AE minima coincide with northward IMF-BZ maxima. At least, two large storm AE increases above 600 nT occur and the first storm AE activity develops together with the Dst, decrease, southward IMF-Bz increase, and solar wind pressure increase. The second larger storm AE activity occurs with a larger southward IMF-Bz, but not with a solar wind pressure increase. The storm AE activity is primarily controlled by the IMF-Bz polarity, and the dayside magnetosphere before the storm AE increase recovers from its distorted state. The storm AE activity explosively begins with the auroral electrojet caused by the tail reconnection. Since closed magnetic field lines in the tail are stretched more tailward with increasing the southward IMF-Bz, curvature drifts of hot ions may produce a partial eastward ring current near the tail equatorial plane beyond X =-10 RE. However, gradient drifts of hot ions injected from the tail are dominant within X =- 8 RE in the equatorial plane and form an westward ring current. This is a favorable condition for generating the reconnection in the near-Earth tail, since the partial eastward ring current locally weakens the west-ward cross tail current in the near Earth tail.

GA3.03/W/03-B4 Invited **0930**

MAPPING THE HIGH-LATITUDE, HIGH-ALTITUDE EXTENSION OF THE PLASMA SHEET USING POLAR ENERGETIC PARTICLE OBSERVATIONS

HARLAN E. SPENCE (Boston University Center for Space Physics, 725 Commonwealth Avenue, Boston, MA 02215, email: spence@bu.edu), J. F. Fennell and J. L. Roeder (both at The Aerospace Corporation, P.O. Box 92957, Los Angeles, CA 90009), R. Friedel (Los Alamos National Lab, Mail Stop D-436, Los Alamos, NM 87545), T. A. Fritz, K. L. Hirsch, and M. Alothman (all at BU), M. Grande (Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire, OX11, OQX, England), M. Kivelson and J. Green (Institute for Geophysics and Planetary Physics, University of California Los Angeles, CA 90095)

For the past several years, the NASA/POLAR spacecraft has been exploring the high-altitude, high-latitude magnetosphere. This region has not been well-sampled in the past and certainly not with such comprehensive instrumentation. In this review presentation we highlight recent studies using POLAR data that have explored the nature of the open/closed magnetic field boundary at high altitudes. These analyses have focussed on the location of the energetic particle trapping boundary and its control by parameters such as dipole tilt, solar wind dynamic pressure, interplanetary magnetic field orientation, and geomagnetic activity levels. In this study, these analyses will be extended by comparing the observed boundary encounters to simple, parameterized phenomenological models of the expected magnetic field geometry, under a variety of conditions. Finally, the local measurements of particle boundaries will be compared to auroral boundaries deduced from coincident global auroral imaging from the POLAR spacecraft.

THE STATISTICAL POLAR CAP BOUNDARY AND DYNAMICS: ENERGETIC PARTICLE RESULTS FROM SAMPEX

S.G. KANEKAL (Code 696, NASA GSFC and RTISS, Greenbelt Rd, Greenbelt,MD 20904, USA, e-mail:kanekal@lepsam.gsfc.nasa.gov) D.N.Baker (Laboratory for Atmospheric and Solar Physics, UNiversity of Colorado, Boulder, CO, 80309) J.B.Blake (The Aerospace Corporation, MS259, Los Angeles, CA 90009) B.Klecker (Max planck Institut for Extraterrestriche Physik, Garching,Germany) G.M. Mason (Dept. of Physics, Univ. of Maryland, College Park, MD 20742) R.A. Mewaldt (California Institute for Technology, Pasadena, CA 91125)

We use instruments aboard SAMPEX to determine energetic particle boundaries in the polar regions. These boundaries are related to the polar cap, namely, the region of open magnetic flux tubes. SAMPEX is in a low earth polar orbit and executes about 15 orbits per day and has almost continuous data coverage from August 92 to present. The energetic particle boundaries are determined from particle measurements of energy thresholds ranging from about 30 keV to 0.50 MeV. We discuss the statistical features of the energetic particle boundaries and study the boundary dynamics under the influence interplanetary parameters such as the Interplanetary magnetic field and the solar wind velocity.

GA3.03/E/07-B4 Invited **1020**

DYNAMICS OF THE AURORAL LUMINOSITY BOUNDARY OF THE POLAR CAP DURING SUBSTORMS

M. BRITTNACHER, D. Chua, M. Fillingim, G. Parks, and R. Wellman (all at Geophysics Program, Box 351650, University of Washington, Seattle, WA 98195, USA, Email: britt@geophys.washington.edu); J. Spann (NASA Marshall Space Flight Center, Huntsville, AL 35812, USA); and G. Germany (Center for Space and Astronomy Research, University of Alabama in Huntsville, Huntsville, AL 35899, USA)

The area of the polar cap during substorms has been measured using images from the Polar Ultraviolet Imager (UVI) for different interplanetary magnetic field (IMF) conditions. Changes in the poleward boundary of auroral luminosity have been analyzed in relation to substorm phase and IMF orientation. Reconnection models of flux transport into the polar cap during the substorm growth phase, and loss from the polar cap during the expansion phase, provide a framework by which these UVI observations can be analyzed. By comparison of the observations with the model predictions we can determine to what extent these models accurately predict the polar cap dynamics, and also where anomalous behavior calls for a new understanding of the dynamics beyond what these models provide. It was found that the polar cap boundary near noon and midnight usually shifted down in latitude by 1-2 degrees and 3-4 degrees respectively, increasing the area of the polar cap during the substorm growth phase as predicted. However, this growth phase phenomenon also unexpectedly occurs independently of the IMF Bz component. The polar cap area also increased due to motion of the dawn and dusk aurora to lower latitudes, although the latitudinal shifts were asymmetric, not always concurrent, and continued well into the substorm expansion phase. What is not explained by the models is that the poleward auroral boundary in the nightside region sometimes reached very high latitudes (greater than 80 degrees MLat) greatly decreasing the polar cap area, independent of the magnitude of the substorm.

GA3.03/W/05-B4 **1110**

OPTICAL DETERMINATION OF THE POLAR CAP AREA AND OPEN MAGNETIC FLUX WITH THE VISIBLE IMAGING SYSTEM

J. B. SIGWARTH and L. A. Frank (Both at: Department of Physics and Astronomy, The University of Iowa, Iowa City, IA 52242, E-mail: sigwarth@iowasp.physics.uiowa.edu).

The Visible Imaging System (VIS) on the Polar spacecraft acquires global images of Earth's northern auroral oval at multiple wavelengths and at a temporal resolution of approximately one minute. The wobble compensated or "despun" images of the VIS Earth Camera have a spatial resolution of approximately 100 km at the apogee altitude of 51,000 km. The VIS Earth Camera is sensitive predominantly to the atomic oxygen emissions at 130.4 nm and 135.6 nm.

The images acquired with the VIS Earth Camera are used to determine the poleward boundary of the auroral oval. From the identified boundary, the polar cap area and total open magnetic flux in the polar cap are calculated. The rate of change of the observed open magnetic flux in the polar cap is the net result of the source of open flux due to merging on the dayside and the loss of open flux to reconnection in the magnetotail. In addition, with knowledge of solar wind parameters it is possible to estimate the magnetic energy stored in the lobe fields of the magnetosphere. Several example sequences of VIS images that show the variation of the polar cap area, total open magnetic flux, and estimated energy stored in the magnetotail lobe fields will be presented. These will include the substorm that occurred on January 12, 1997 where the polar cap area and open magnetic flux continued to increase for 30 minutes after the onset of the substorm at 0725 UT.

GA3.03/E/06-B4 Invited **1130**

DETERMINATION OF POLAR CAP BOUNDARY FROM GUMICS RUNS

Pekka JANHUNEN (Finnish Meteorological Institute, Geophysical Research, POB 503, FIN-00101, Helsinki, Finland, email: Pekka.Janhunen@fmi.fi)

The GUMICS ionosphere-magnetosphere coupling simulation is a global MHD code coupled with an electrostatic ionosphere. Techniques such as adaptive hierarchically refined Cartesian grid and temporal subcycling are used to speed up processing, which would otherwise be too involved for existing computers. The emphasis in GUMICS is a good modeling of the ionosphere and good resolution in the near-Earth region.
An MHD simulation suits well for the determination of the polar cap boundary, since from an MHD simulation, one can determine the open-closed field line boundary by numerically integrating many magnetic field lines starting from the ionosphere and seeing whether they return to the Earth (closed) or hit the boundary of the simulation box (open). This method corresponds directly to thedefinition of open and closed field lines.
We study the dynamical behavior of the polar cap boundary in GUMICS runs in varying IMF conditions. We also study how the polar cap boundary is related to the Region-1 current system and the ionospheric potential pattern, to see if these can be used as observational proxies of the polar cap boundary.

FAST AND POLAR OBSERVATIONS OF THE POLAR CAP BOUNDARY, FIELD-ALIGNED CURRENTS AND CONVECTION ELECTRIC FIELDS DURING CME EVENTS

CYNTHIA CATTELL, A. Bowser, C. McBrady, K. Sigsbee and J. Wygant (School of Physics and Astronomy, University of Minnesota, Minneapolis, MN 55455, USA, Email: cattell@belka.space.umn.edu); C. Carlson, R. Ergun, J. McFadden, F. Mozer, W. Peria (Space Sciences Lab, University of California, Berkeley, CA 94720, USA); G. Le, C. Russell, R. Strangeway (IGPP, University of California, Los Angeles, CA, USA); R. Elphic (Los Alamos National Lab, Los Alamos, NM 87545, USA); M. Brittnacher and G. Parks (Geophysics Program, University of Washington, Seattle, WA 98195, USA)

There have been many CME encounters with the earth's magnetosphere since the launch of FAST in August, 1996. The short orbital period and data coverage for almost every auroral zone crossing allow us to determine the changes in field-aligned currents, convection electric fields and particle boundaries with time to determine the effects of solar wind plasma and magnetic field properties. In this paper, we present observations of the polar cap boundary as determined from four different methods- convection reversal, location of field-aligned currents, particle signatures and optical signatures from the Polar UVI imager. In addition, observations of field-aligned currents and convection electric fields from Polar perigee passes will be used to provide auxiliary observations which, for most events, are at different local times than the FAST observations. The resulting polar cap sizes will be compared to solar wind parameters observed by WIND. This results of this study will enhance our understanding of the coupling of the solar wind and the magnetosphere during CME events. The comparison of multiple techniques to determine the polar cap boundary will aid in estimating the accuracy of these methods for different loca.

GA3.03/W/10-B4 **1220**

THE POLAR CAP BOUNDARY DURING NORTHWARD IMF

J.C. GREEN (University of California, Los Angeles, Department of Earth and Space Sciences, 405 Hilgarde, Los Angles, CA, 90048, email: jgreen@igpp.ucla.edu); M.G. Kivelson, R.J. Walker, K.K. Khurana(all at the University of California, Los Angeles, Department of Earth and Space Sciences, 405 Hilgarde, Los Angles, CA, 90048); H.E. Spence(Boston University, Dept of Astronomy and Space Physics, Boston, MA), J.B. Blake(The Aerospace Corporation, Los Angeles,CA)

The configuration of the polar cap during northward IMF is still debated. Both single event studies and large statistical studies have been employed in an attempt to understand how solar wind parameters affect the movement of the polar cap boundary. Xu (1995) and Newell et al (1997) investigated several events of prolonged duration of northward IMF using DMSP data. Both found that the polar cap closes with duration of northward IMF but complete closure can be inhibited by a finite By component. Large statistical studies have been less successful at finding correlations. A recent statistical study by Kanekal et al (1998) using SAMPEX data found that the polar cap actually increased with increasing magnitude or northward IMF.
We have investigated the nightside energetic ion boundary using POLAR CEPPAD energetic ion data. The boundary was determined by noting the drop off in flux of ions corresponding to the high energy tail of the plasma sheet. It's not unambiguous that this is the open/closed field line boundary but changes in this energetic particle boundary give an indication of the configuration and dynamics of the magnetosphere during northward IMF. Our initial results show that, like the Kanekal et al (1998) study, the nightside energetic ion boundary appears to move equatorward with increasing duration of northward IMF and magnitude of Bz. This may indicate a complete shift of the polar cap towards the nightside during northward IMF. We will further investigate the cause of this finding and also what role the Bx component of the solar wind may have play in controlling the polar cap boundary.

DETERMINATIO OF OLAR CAP BOUNDARY: IMLICATIONS FOR MAGNETOSPHERIC ENERGETICS

GA3.03/W/12-B4 Invited **1400**

MONITORING THE OPEN–CLOSED BOUNDARY OF THE POLAR CAP USING PARTICLE PRECIPITATION OBSERVATIONS

THOMAS SOTIRELIS, Patrick T. Newell, Joseph P; Skura and Ching-I. Meng (The Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland)

The location of the open-closed boundary of the polar cap varies greatly, as does the quantity of open flux it encloses. The amount of open flux is central to describing the magnetospheric state. Reliably monitoring this boundary would permit an explicit ongoing diagnostic for the amount of energy stored in the lobes of the magnetotail. Observations of precipitating particles by low altitude polar orbiting satellites can be used to identify individual points on the open-closed boundary. A fleet of such spacecraft can provide several nearly simultaneous points. Hence, boundary shapes and the enclosed flux can be estimated. Factors impacting the accuracy of such estimates will be discussed, such as the number of points available and the definition of nearly simultaneous. The status of an ongoing effort to automate such determinations using observations from the fleet of DMSP and NOAA satellites, and so to provide a time history of the open-closed boundary and the open flux starting from 1984, will be presented.

GA3.03/W/13-B4 **1430**

AUTOMATED DETERMINATION OF THE POLAR CAP BOUNDARY FROM POLAR UVI IMAGES

J.B. BAKER, C.R. Clauer, J.M. Daida, V.O. Papitashvili (all at Space Physics Research Laboratory, University of Michigan, Ann Arbor, MI 48109-2143, USA, email: bakerjb@zasu.sprl.umich.edu) A.J. Ridley (Southwest Research Institute, San Antonio, TX 78238-5166, USA, email: ridley@worf.space.swri.edu) M.J. Brittnacher (Geophysics Program, University of Washington, Seattle, WA 98195-1650, email: britt@geophys.washington.edu)

The POLAR UVI instrument can instantaneously image the entire auroral distribution at good spatial and temporal resolution. It thus provides a suitable dataset with which to investigate the dynamics of the polar cap on a global scale without the need for extrapolation or statistical fitting. It is important to have good temporal and spatial resolution of polar cap variations in order to better understand the coupling of the magnetosphere to the ionosphere and solar wind. To this end, an automated technique has been developed to obtain polar cap boundaries from POLAR UVI images. The technique has been calibrated against DMSP particle precipitation and ground magnetometer data, and we present the results of this calibration. Relationships between electron precipitation, auroral intensity, and field-aligned currents which emerged during the calibration process are discussed. We also present preliminary results of a study of how the polar cap area behaves during periods of both steady and time-varying IMF conditions.

GA3.03/W/07-B4 **1450**

EFFECTS OF THE ENERGY INPUT DURING SUBSTORM EXPANSION PHASE TO THE SUBSTORM SIZE

E.I.A. KALLIO, T.I. Pulkkinen, H.E.J. Koskinen*, A. Viljanen (Finnish Meteorological Institute, Geophysical Research, P.O.Box 503, FIN-00101 Helsinki, email: Eija.Kallio@fmi.fi; * also at University of Helsinki; Department of Physics, P.O.BOX 9, FIN-00014 University of Helsinki J. A. Slavin, K. Ogilvie NASA Goddard Space Flight Center, Greenbelt, MD, USA

During the substorm cycle, energy is extracted from the solar wind, stored in the magnetotail, and later explosively dissipated in the magnetosphere-ionosphere system. While the energy input and dissipation must balance over longer time periods, factors that contribute to the exact moment of the onset of the explosive expansion and the size of the substorm are still largely unknown. In this study, we have identified substorms from the local electrojet index created from the IMAGE magnetometer chain in Scandinavia and Finland during the entire year of 1997. Each of the substorms has been tagged with an onset time and start of growth phase time. The WIND magnetic field and plasma measurements are then used to compute the epsilon-parameter, that characterizes energy input to the magnetosphere, and its time integral from the start of the substorm growth phase. These two parameters are compared with ionospheric dissipation, namely the local electrojet index and its time integral, which represent the ionospheric Joule heating. We compare and contrast cases when the energy input stops at or close to the substorm expansion onset with events where the energy input continues to the expansion phase. Our aim is to evaluate to which extent the substorm expansion dissipates previously stored energy and how much of the energy comes directly from the solar wind.

GA3.03/W/04-B4 **1510**

THE LATITUDE OF THE AURORAL ELECTROJET - LONG-TERM VARIATION AND DEPENDENCE ON THE SOLAR WIND VELOCITY

VENNERSTROEM, Susanna (Dannish Space Research Inst, Juliane Maries Vg 30, Copenhagen, Denmark, Email: sv@dsri.dk)

By using the H/Z-ratio of the groundbased magnetic observations at high latitudes, it is possible to determine the latitudinal position of the auroral electrojet. For a few high-latitude observatories records of hourly values of H and Z exist back to around 1920. We use these long-time series to investigate the long-term and solar cycle variation of the latitude of primarily the westward auroral electrojet. We find that in the late declining phase of the solar cycle, where the geomagnetic activity is mainly due to high speed streams from coronal holes, the electrojet is located at relatively higher latitudes than during solar maximum for similar geomagnetic activity levels. We compare with satellite measurements of the solar wind, especially the solar wind velocity.

DYNAMICS OF THE POLAR CAP BOUNDARIES AND AREA IN THE COURSE OF SUBSTORMS

V.M. MISHIN, A.D. Bazarzhapov, T.I. Saifudinova, and D.Sh. Shirapov (all at Institute of Solar-Terrestrial Physics,P.O.Box 4026, Irkutsk, 664033, Russia, email: mishin@iszf.irk.ru)

The polar cap can be determined as an area inside the high-latitude boundary of FAC Region 1. Such a method was introduced on the basis of magnetogram inversion technique MIT2, tested through comparison with auroral imaginery from the Viking and DE2 spacecrafts, and used in timing and analyzing substorms [Mishin et al., 1997, p.19845; and Ref's therein].
During the past >10 years, data on the dynamics of the polar cap boundaries and area (i.e., on the open magnetic flux dynamics) has been amassed by above authors for >20 substorms including those studied in frames of CDAW6 and CDAW9. This paper summarizes the main results on the entire set of accumulated data. It also presents results derived from comparing the boundaries and area of the northern polar cap by the MIT2 method, with those obtained recently using other methods by Lyons et al., and Baker et al.

IONOSPHERIC SIGNATURES OF THE POLAR CAP BOUNDARY AND APPLICATION TO MEASUREMENT OF RECONNECTION

Gerard BLANCHARD (Department of Chemistry and Physics, Southeastern Louisiana University, SLU 10878, Hammond, LA 70402, Email: gblanchard@selu.edu); Larry Lyons (Department of Atmospheric Sciences, University of California, Los Angeles, CA, 90095-1565, Email: larry@atmos.ucla.edu)

The polar cap boundary corresponds to the surface separating open and closed field lines in the magnetosphere. Magnetospheric reconnection is equivalent to a plasma flow through this surface at altitudes down to the ionospheric F region. It is thus possible to calculate the reconnection rate from measurements of ionospheric flow, provided that the location and velocity of the polar cap boundary are determined. Sharp differences in precipitating electron characteristics across the boundary create detectable ionospheric signatures of the boundary. On the nightside of the Earth, the location of the polar cap boundary in a magnetic meridian can be monitored continuously using a meridian scanning photometer or incoherent scatter radar. With a meridian scanning photometer, we seek the increase in auroral emission at the boundary. The ratio of 6300 A emission to 5577 A favors 6300 A at the poleward edge ofthe auroral zone. We show that there is a sharp increase in 6300 A intensity at the polar cap boundary and present criteria for identifying the boundary. The signature of the polar cap boundary observed by incoherent scatter radar is an increase in the E-region electron density, and the polar cap boundary is identifiable by placing a threshold on density. We demonstrate that the boundaries determined by these two methods (radar and photometer) agree to within 0.6 degrees. On the dayside, the increase in electron density is masked by photoionization. We show, however, that by accounting for the photoionization, a threshold on the ionization rate identifies the polar cap boundary.
Once the location and velocity of the polar cap boundary in a meridian in known, the reconnection rate in that meridian can be computed from radar measurements of ionospheric flow. We present examples of measurements.

GA3.03/W/06-B4 **1640**

THE RELATIONSHIP BETWEEN HF RADAR BACKSCATTER AND THE NIGHTSIDE POLAR CAP BOUNDARY

M. LESTER, S.E. Milan (both at Department of Physics and Astronomy, University of Leicester, Leicester, LE1 7RH, UK, Email: mle@ion.le.ac.uk), V. Besser and R. Smith (both at Geophysical Institute, University of Alaska, Fairbanks, 903 Koyukuk Drive, Fairbanks, Alaska 99755-7320, USA)

The SuperDARN radars often observe in the nightside scatter a gradient in the spectral width parameter as a function of latitude, with high values at higher latitudes. This gradient has been related in one case to the boundary between the Central Plasma Sheet and the Boundary Plasma Sheet. In this paper we discuss data from the CUTLASS Finland radar which indicates that the gradient is co-located with the poleward boundary of the red line (630.0 nm) emission, which in turn has been suggested as an indicator for the polar cap boundary. We discuss these interpretations of the spectral width gradient in terms of the dynamic behaviour of the magnetotail, demonstrating when the polar cap boundary can be identified by this technique.

GA3.03/W/08-B4 **1700**

ON THE USE OF SUPERDARN HF RADAR BACKSCATTER CHARACTERISTICS FOR DETERMINING THE NOON POLAR CAP BOUNDARY

M PINNOCK, A. S. Rodger British Antarctic Survey, Madingley Road Cambridge CB3 0ET, UK (email: M.Pinnock@bas.ac.uk) SuperDARN PIs.

Previous work has demonstrated a link between the equatorward edge of cusp particle precipitation, detected by satellites and ground based optical measurements, and the occurrence of large Doppler spectral widths in SuperDARN HF radar data sets. The radar Doppler spectral width data, obtained on meridional pointing beams, has been used as a proxy for the location of the polar cap boundary (PCB), and this data used to measure the flow of plasma across the PCB and hence derive the reconnection electric field in the ionosphere. However, the precise cause of the Doppler spectral width enhancement, usually interpreted as the signature of small scale (< 45 km) electric field variations, is not known. The earlier work has also used only single radar data sets with a field of view limited to ~2 of MLT. In a case study using 4 of the SuperDARN radars we examine the Doppler spectral width boundary determined over 6 h of MLT around the noon sector and its relationship to the convection pattern, also determined from the radar data. A clear link between variations in the poleward velocity component and the offset of the Doppler spectral width boundary from the likely location of the PCB is observed for many, but not all, of the radar scan periods. This reinforces the intimate link between cusp particle precipitation and the Doppler spectral width data, in particular when time-of-flight effects on the cusp ions are taken in to account. Progress towards calibrating the offset between the Doppler spectral width boundary and the true PCB will be reported. Illustrations of the dynamic behaviour of the boundary will also be shown.

STATISTICAL ANALYSIS OF HIGH-LATITUDE IONOSPHERIC FLOWS ASSOCIATED WITH THE ASYMMETRIC EFFECT OF THE Y COMPONENT OF THE INTERPLANETARY MAGNETIC FIELD.

H. KHAN and S. W. H. Cowley. (University of Leicester, University Road, Leicester, LE1 7RH, UK.)

Ionospheric flow velocities, measured by the EISCAT UHF radar located at Tromsø, Norway, together with solar wind measurements of the interplanetary magnetic field (IMF) By component, have been studied in a statistical manner. It has been suggested that the flow asymmetries on closed field lines ascribed to the effects of the IMF By can be explained using the simplistic 'dipole plus uniform field' model. Previous studies of the ionospheric flow onset after the North-South (BZ) turnings of the IMF revealed the typical twin vortical flow pattern was produced ~5-15 min after perturbations were incident at the ionosphere. Cross correlations between simultaneous ionospheric vector velocities, observed on closed field lines, and the IMF By component were calculated using nominal lags of 0, 5, 10 and 15 min to illustrate the overall asymmetric trends in the data sets. The flow asymmetries observed using the positive northward vector velocity in particular, clearly illustrate flows indicating a shift in the polar cap position as a whole, in the opposite sense to that of the direction of the IMF By. Simultaneously the flow pattern centre is displaced towards increasing local time from noon and midnight for positive IMF By, and conversely for negative By, in the northern hemisphere. Both these features are consistent with the asymmetric shifts proposed by the 'dipole plus uniform field' model, where the first indicates the latitudinal tilt of the ionospheric footprints of field lines that lie in the dawn-dusk meridian, and the second describes the displacement in longitude of those field lines in the noon-midnight meridian.

GA3.03/W/09-B4 **1740**

EVIDENCE OF ANTI-SUNWARD FLOW ON CLOSED FIELD LINES IN THE IONOSPHERE: POSSIBLE EXISTENCE OF A VISCOUS CELL

Adalbjorn THOROLFSSON, Jean-Claude CERISIER (both at Centre d'étude des Environnements Terrestre et Planétaires, 4 avenue de Neptune, 94107 Saint-Maur, France, Email: thorolfs@cetp.ipsl.fr) and Mike Pinnock (British Antarctic Survey, High Cross, Madingley Rd., Cambridge CB3 0ET, UK)

There is still an ongoing debate about whether the low-latitude boundary layer (LLBL) on the flanks of the magnetosphere is open or closed. Using satellite and SuperDARN ionospheric radar data, we carry out a case study of the flow in the afternoon ionosphere with respect to particle boundaries obtained with satellite data. We find evidence for anti-sunward flow near the convection reversal boundary that is associated with closed field lines. This indicates that at least a part of the LLBL is on closed field lines. These results are discussed and the possibility of a viscous cell on the flanks is evoked.

SIZE OF THE AURORAL OVAL AS INFERRED FROM GEOMAGNETIC VARIATIONS AT THE ANTARCTIC LOCATIONS, TRANS-AURORAL ITALIAN STATION TERRA NOVA BAY, AND SUB-AURORAL INDIAN STATION MAITRI

G.Rajaram, A.N.HANCHINAL, and T.arun (all Indian Institute of Geomagnetism, Dr.Nanabhai moos Road, Colaba, MUMBAI-5,INDIA. E-mail: arun@iig.iigm.res.in); M.Candidi(CNR-IFSI, CP 27 FRASCATI, 00044- ITALY. E-mail: candidi@ifsi.rm.cnr.it)

It is generally known that the auroral oval shifts equatorward during magnetically disturbed conditions(high Kp and AE indices). What is less known is the extent of broadening of the auroral oval, which is also known to occur during magnetic disturbance. This work tries to focus on this aspect by examining the X,Y and Z geomagnetic variations at the trans-auroral location Terranova bay(geog.74o 41'S,164o 07'E,geomag.-77.34o,279.41o E) and Maitri(geog.70o 46' S,11o 44' E,geomag.-66.8 S,56.3oE). Characteristics of the variations indicate wheather the location does or does not experience the signature of the auroral electrojet events i.e. wheather it is within the auroral oval or not.
Events during Nov-Dec 1994 are chosen for this study; IMF data and AE data are also available for the same periods. An attempt is made to relate information on the size of the auroral oval(inferred as discussed above) to conditions of polarity and intensity of the IMF.

GA3.03/E/02-B4 Poster **1400-02**

THE EARTH'S MAGNETOSPHERE AS A NON-LINEAR ELECTRODYNAMIC SYSTEM

Vladimir SHELOMENTSEV and Sergey Sheshukov (both at Institute of Solar-Terrestrial Physics, 664033, P.O.Box 4026, Irkutsk, Russia, email: vshel@iszf.irk.ru)

Results of the prediction filter technique applied to the solar wind parameters (used as an input data) and the magnetospheric parameters (used as an output data) strongly support a supposition about a non-linearity of the magnetospheric response to changes of the external conditions. Forms of the filters depend on a general level of the magnetospheric disturbancy as well as on a disturbance type. Thus, a ratio of the contributions of the fast magnetospheric response (driven processes) and the delayed response (unloading processes) varies from an initial (isolated) substorm to the subsequent (non-isolated) ones. Additional analysis testifies about an importance of the inner state of the magnetosphere for the development and the energetics of a single disturbance. It appears that the magnetospheric-ionospheric electric circuit contains the non-linear elements. The analogue of this circuit gives an insight into the observed regularities of the electric fields, currents, and energetics during a substorm development. This study is supported by the RFBR grants 95-05-14385, 98-05-65120.

THE NORTHERN POLAR CAP AREA IN THE COURSE OF THE CDAW-9C SUBSTORM AS DEDUCED FROM DE-1 DATA AND UPDATED MIT-2

D.Sh. Shirapov, A.D. Bazarzhapov, T.I. Saifudinova, and V.M. MISHIN (all at Institute of Solar-Terrestrial Physics,P.O.Box 4026, Irkutsk, 664033, Russia, email: mishin@iszf.irk.ru),

The magnetogram inversion technique-2 (MIT-2) is useful for calculating the density distribution of field-aligned currents in the geomagnetic frame of reference and for determining the polar cap boundaries and area S as the area of the region poleward of Iijima and Potemra's zone 1 currents [Mishin V.M. et al., J.Geophys.Res., 1997, v.102, p.19845]. This paper is based on using a new version of MIT-2 with a nearly twice as high spatial resolution. Assuming that F = B_S (where F is the open magnetic flux across the area S, and B is the mean value of the geomagnetic field strength in the polar cap) we calculated the values of F at steps of five minutes for the time interval (0000-3000)UT, May 3, 1986 (CDAW-9C substorm) and compared results obtained with similar data from DE-1 reported by Baker D.N. et al. [Geophys. Monogr. Ser., v. 84, ed. By H.Waite, Jr., 1994, p.101]. The difference between the two data does not exceed 13% of the mean value of F.

A LATITUDINAL DISPLACEMENT OF THE OPTICAL AURORA CONJUGANCY ON THE POLEWARD EDGE OF AN AURORAL BULGE

V.G. VOROBJEV, O.I. Yagodkina (Polar Geophysical Institute, Apatity, Murmansk region, Russia, 184200, Email: vorobjev@pgi.kolasc.net.ru), D. Sibeck, K. Liou, C.-I. Meng (Applied Physics Laboratory, Johns Hopkins University, Laurel, MD 20723-6099 USA, Email: david.sibeck@jhuapl.edu)

Simultaneous optical observations at the Antarctic station Mirny (F'=-77.320) and UVI images of the northern auroral oval from POLAR satellite were used to examine the high-latitude aurora conjugacy during the substorm development. It was found the signif icant discrepancy between the location of the poleward edge of the auroral bulge in two hemispheres up to 50 of the corrected geomagnetic latitude. A value and direction of the conjugacy displacement are not connected with the tilt angle of the magnetic d ipole but rather depend on the interplanetary magnetic field (IMF) orientation in the ecliptic plane. Aurorae were observed at more high latitudes in northern hemisphere when Bx<0 and By>0 and on the contrary the aurorae were registered at more high latit udes in south hemisphere when Bx>0 and By<0. The similar asymmetry was observed as well at the magnetic activity level in the conjugated high latitude areas. The latitude of aurorae in both hemispheres well coincided when the IMF changes the orientation a few times before and during the substorm or when the IMF orientation is differed from the spiral structure. However, actually in these events the local bright auroral forms were often observed only in one of hemispheres and were not registered in the other one. Obtained

results can testify the high efficiency of the interplanetary Bx penetration into the magnetosphere.

ALFVEN RESONANCES AND ALFVEN EIGEN MODES IN THE MAGNETOSPHERE

A. GUGLIELMI (Institute of Physics of the Earth, B.Gruzinskaya, 10, Moscow, 123810 Russia, Email: gugl@uipe-ras.scgis.ru)

Thereport is devoted to the theory of Alfv'en waves as related to the magnetospheric physics with theoretical results compared against the ground and satellite based data. In the case of Alfv'en resonances, attention focuses on the problem of the remote diagnostics of the magnetosphere using the so-called ULF ranger technique. It is based on the known lateral structure of the resonances, and on the additional information which is contained in the impedance relations on the Earth's surface. This allow us to widen the range of diagnostic tools when we use an observation of the waves in Pc 3 - 5 frequency band. The prospects for remote sensing of the plasmapause position are discussed. In the case of Alfv'en eigen modes, the linear and nonlinear aspects of the theory are outlined. The emphasis is on the structure induced nonlinearity of the medium. Particular attention has been given to the energy and mass transport in the ionosphere-magnetosphere coupled system.

GA3.04/E/03-B1 0900

PC3S AND DC TRAINS: A CAUSAL CONNECTION?

Gary D. EGBERT (College of Oceanic and Atmospheric Sciences, Oregon State University, 104 Ocean. Admin. Bldg, Corvallis, OR 97331, e-mail: egbert@oce.orst.edu); Markus Eisel (GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany, e-mail: eisel@gfz-potsdam.de); Sierra Boyd and H.F. Morrison (both at Engineering Geoscience, University of California, Berkeley, CA, e-mail: em@seismo.berkeley.edu)

To study possible electromagnetic (EM) precursors to earthquakes, magnetotelluric (MT) stations have recorded EM data almost continuously (at 40 hz sampling rate) since late 1995 at two sites along the San Andreas fault 150 and 300 km south-east of San Francisco, California. (Geomagnetic dipole latitude: 43 degrees, L approximately 1.8). Using classical and multivariate transfer function (TF) methods we show that the usual MT assumption that external magnetic fields are spatially uniform (over a distance of 150 km) is violated to a significant degree in the period range 10-30 seconds. We furthermore show that inter-station TFs vary significantly in time, with systematic variations due to time of day, and day of week. The overall spatial and temporal pattern of EM field variations implied by the TF estimates and related statistics (for periods from 10 to 300 s) is consistent with a combination of two distinct sources:
Pc3 geomagnetic pulsations, and cultural EM noise due to the San Francisco Bay Area Rapid Transit (BART) DC electric railway. Several aspects of the association between the two sources suggest that at least some of the PC activity may be causally related to the BART signal, but this issue needs further investigation. Our study also highlights some of the advantages of a TF approach (normally used for solid earth EM induction studies to eliminate external source variations) for some aspects of ionospheric studies. In particular we obtain clean estimates of Pc3 resonance frequencies (fundamental, plus the second and third harmonics) with our approach.

GA3.04/L/02-B1 0920

DENSITY DEPENDENCE OF ALFVEN EIGENFREQUENCIES IN THE GLOBAL CORE PLASMA MODEL

R.E. Denton (Physics and Astronomy Department, Wilder Laboratory, Dartmouth College, Hanover, NH 03755-3528, email: richard.denton@dartmouth.edu)L. Gallagher and Paul D. Craven (NASA Marshall Space Flight Center, Mail Code ES83, Building 4481, 382, Huntsville, Alabama 35812, USA, email: dennis.gallagher@msfc.nasa.gov)

There has been some interest in the possibility of using ULF to diagnose the magnetospheric plasma. One possible application to remotely sense the field line distribution of mass density using measurements of frequencies of toroidal field line resonance(global scale Alfven waves with magnetic oscillations in the direction). It is of interest, therefore, to know what has been inferred about the magnetospheric density from other. Here we use a simplified version of the Global Core Plasmato examine the effect of parallel density dependence on toroidal line resonance modes. The magnetospheric density dependence is on observations by DE-1; the model couples at low altitudes to International Reference Ionosphere. We find that in the outer, the toroidal field line resonance modes have spacing to that obtained with a density dependence of 1/R along field, where R is the radial distance from the Earth. Closer to the, the effective radial dependence steepens since the steep density dependence is in nearer proximity to all locations the field line.

GA3.04/L/03-B1 Invited 0940

DISPERSIVE FIELD LINE RESONANCES

R. RANKIN, J. C. Samson, I. Voronkov (all at Department of Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2J1, email: rankin@space.ualberta.ca) V. Tikhonchuk (P. N. Lebedev Physics Institute, Russian Academy of Sciences, Moscow 117924, Russia)

Field line resonances (FLRs) are standing shear Alfven waves in the dipole-like region of the Earth's magnetosphere. With dispersive effects of electron inertia, electron thermal pressure, and ion gyroradius, FLRs can form intense field aligned currents, parallel and perpendicular electric fields, and deep field aligned density cavities. The low conductivity in cavities can also lead to enhanced electric fields in the low altitude magnetosphere below 1Re, as observed in satellite missions such as FAST. We shall discuss observations of FLRs in satellite and ground data, and present a self-consistent model which describes the interaction between fundamental mode standing shear and density waves. Using specified field aligned variations of density, magnetic field, electron and ion temperatures, we classify the interaction of the waves as electron dispersive (ED) or ion dispersive (ID). In the ED case, we identify conditions under which enhanced parallel electric fields and density perturbations can be generated, and consider the energies to which auroral electrons might be accelerated. In the ID case, the interaction of the waves evolves through the generation of coupled shear-Alfven-ion-acoustic solitons. It is found that dispersion and nonlinearity can drive electric fields and density fluctuations that are much larger than in the non-dispersive case, with very short perpendicular scales comparable to the inertial length and ion gyro-radius, respectively. The processes involved may go some way to explaining recent observations of density cavities and strong electric fields by the Freja and FAST spacecraft, and in predicting their temporal and spatial nonlinear evolution.

GA3.04/E/02-B1 1010

EVOLUTION AND TRANSFORMATION OF STRONG MAGNETOHYDRODYNAMIC (MHD) DISTURBANCES IN MAGNETOSPHERIC RESONATOR

N.A. BARKHATOV (Nizhniy Novgorod State Pedagogical University, 1, Ulyanova str., Nizhniy Novgorod 603005, Russia, e-mail: nikolay@barkh.sci-nnov.ru); N.S. Belliustin (Radiophysical Research Institute, 25, Bolshaya Pecherskaya str., Nizhniy Novgorod, 603600, Russia, e-mail: nick@nbell.sci-nnov.ru); P.G. Khurlapov (Institute of Applied Physics, 46, Ulyanova str., Nizhniy Novgorod, 603600, Russia, e-mail: pasha@sci-nnov.ru)

The peculiarities of developmental dynamics of strong magnetohydrodynamic disturbance in magnetosphere are investigated. The effects of transformation of Alfven wave propagating along the Earth magnetic field into fast and slow magnetosound waves at collision of opposing impulses are considered. The dependence of effects on angle of Alfven wave declination to magnetic field and on ratio of sound velocity in plasma to Alfven velocity is analysed. Non-linear Alfven wave transformation in a magnetosound ones is also investigated for various inclination angles of Earth magnetic field at the reflecting boundaries of the magnetospheric resonator. The special attention is given to effects, which increase with decreasing of temperature and sound velocity in plasma. The analytical evaluations, matched with considered effects in case of average nonlinearity are made, and peculiarities of limit approach of cold plasma are also studied. The role of near Earth space ionosphere-atmosphere in these phenomena is investigated. It is marked, that strong Alfven wave can induce the essential plasma concentration redistribution in the Earth ionosphere, dependence of this effect on the ratio of Alfven velocity to sound one is considered.

GA3.04/W/20-B1 Invited 1100

ELECTROMAGNETIC WAVES FROM 0.1 TO 4 HZ OBSERVED BY POLAR

B.J. ANDERSON (JHU/APL, Laurel, MD, 20723, USA, e-mail: brian.anderson@jhuapl.edu); C T Russell (IGPP, UCLA, Los Angeles, CA, 90024, USA, e-mail: ctrussell@igpp.ucla.edu); R Pfaff (GSFC, Greenbelt, MD, 20771, USA, e-mail: rob.pfaff@gsfc.nasa.gov); C A Cattell (Department of Physics and Astronomy, University of Minnesota, Minneapolis, MN, 55454, USA, e-mail: cattell@belka.spa.umn.edu); S A Fuselier (Lockheed/Martin Advanced Technology Center, Palo Alto, CA, 94304, USA, e-mail: fuselier@agena.spasci.com)

The Polar orbit is ideal for studies of electromagnetic ion cyclotron (EMIC) waves because it samples magnetic field lines in the magnetosphere over a wide range of latitudes offering the opportunity to study the propagation characteristics as never before. Here we present initial results of analysis of electromagnetic waves recorded by the Polar magnetic and electric fields experiments. Magnetometer data have been processed for 0.1 to 4 Hz fluctuations with <0.1 nT sensitivity from March 1996 through April 1998. Hundreds of instances of electromagnetic waves in this frequency range occur and fall into three categories: (1) EMIC waves in the magnetosphere, (2) broadband fluctuations associated with boundary layers and the cusp, and (3) band-limited EMIC-like fluctuations poleward of the cusp on open field lines. The magnetospheric EMIC waves occur primarily on field lines that map to the afternoon magnetosphere beyond 5 Re, consistent with previous analyses. The broadband fluctuations are most intense in the cusp proper where the magnetic field strength is depressed due to diamagnetic effects. The polar cap EMIC-like waves may be related to the polar cap Pc 1 events reported by Dyrud et al. [1997]. We selected a total of 42 events with strong magnetic signatures for comparison with electric field data. Poynting flux and wave vector determination analyses will be reported for each class of events to identify the direction of energy flow and their wave mode.GA3.04/E/01

GA3.04/W/11-B1 1130

CAN ION CYCLOTRON WAVES PROPAGATE FROM THE EQUATORIAL MAGNETOSPHERE TO THE GROUND?

J.R. JOHNSON and C. Z. Cheng (Princeton University, Plasma Physics Laboratory, Princeton, NJ 08543, E-mail: jrj@pppl.gov, fcheng@pppl.gov)

Ion cyclotron waves are important for transferring energy from protons to heavy ions, as remote indicators of proton dynamics, and in regulating proton anisotropy. However, for over a decade it has not been understood how these waves could be generated in the equatorial magnetosphere and be observed on the ground so reliably. Theoretical results based on ray-tracing, in fact, predicted that these waves are reflected at the Buchsbaum resonance (ion-ion hybrid resonance due to helium or oxygen) and cannot reach the ground. We present solutions of the coupled full wave equations for ion cyclotron waves propagating along auroral field lines and predict Poynting fluxes, wave amplitudes, and polarizations along a field aligned coordinate. Our results suggest that even for significant concentrations of oxygen and helium substantial wave power can reach low altitudes due to mode conversion and tunnelling. The waves reflect off the ionosphere and are strongly absorbed as they propagate back toward the magnetosphere leading to substantial wave absorption. Reflection and absorption coefficients are presented for waves incident from the equatorial magnetosphere, and windows of wave transmission and absorption can be predicted for ion cyclotron waves in the magnetosphere depending on azimuthal wave number and frequency. The ionosphere can also significantly affect wave propagation because the waves are at relatively high frequency. Significant amounts of wave energy can be dissipated at the ionosphere in addition to the energy that is absorbed at the ion resonances.

GA3.04/W/08-B1 1150

NON-STATIONARY ALFVÉN RESONATOR: NEW RESULTS ON PC1 PEARLS AND IPDP EVENTS

K. MURSULA, T. Bräysy, J. Kangas, R. Kerttula, P. Pollari, and T. Pikkarainen, (Department of Physical Sciences, University of Oulu, P.O. Box 3000, FIN-90401 Oulu, Finland, e-mail: Kalevi.Mursula@oulu.fi); K. Prikner (Geophysical Institute, 14131 Praha, Czech Republic); F. Z. Feygin, and O. A. Pokhotelov (Institute of Physics of the Earth, Moscow, Russia)

On December 15, 1984, a series of Pc1 pearls was observed by the Finnish search-coil magnetometer network, which subsequently increased in frequency and developed to a structured IPDP after substorm onset. The EISCAT radar was simultaneously monitoring the mid- to high-latitude ionosphere. We have calculated the ionospheric resonator properties during the different phases of the event using EISCAT observations. Contrary to earlier results, we find that the Pc1/IPDP wave frequency observed on ground corresponds to the maximum of the transmission coefficient rather than that of the reflection coefficient. This casts strong doubts on the bouncing wave packet model of Pc1 pearls. Instead, we present evidence for the alternative model of pearl formation by ULF waves modulating the Pc1 growth rate. The wave source was seen to move to lower latitudes during the IPDP event. Also, the properties of the ionospheric resonator could be modified so as to allow the observed increase in wave frequency. Therefore, we propose a new model for the IPDP formation, whereby the ionosphere acts as an active agent in forming the IPDP signal on the ground

GA3.04/L/04-B1 **1210**

OBSERVATIONAL TEST OF ION CYCLOTRON WAVE PROPERTIES IN THE VICINITY OF THE BI-ION HYBRID RESONANCE FREQUENCY

R E ERLANDSON (The Johns Hopkins University Applied Physics Laboratory, Laurel, MD 20723 USA, email: erlandson@jhuapl.edu); A J Ukhorsky (Moscow Institute of Physics and Technology, Russia); B L Giles and J A Slavin (NASA/GSFC, Greenbelt, MD 20771 USA)

The purpose of this study is to investigate the propagation of electromagnetic ion cyclotron (EMIC) waves in the vicinity of the bi-ion hybrid resonance frequency. Specifically, evidence of wave reflection, attenuation, and transmission will be sought for EMIC waves generated near the equator in the frequency range above the helium gyrofrequency. Observations using the Dynamics Explorer-1 (DE-1) satellite magnetic field experiment and Retarding Ion Mass Spectrometer (RIMS) will be used in this study. DE-1 was launched on August 3, 1981 and operated for nearly 10 years. DE-1 was placed in an elliptical-polar orbit with an apogee altitude of 4.6 Re. DE-1's orbit is ideally suited to study wave propagation as the satellite orbit follows nearly the same L-shell at low magnetic latitudes. Preliminary results based on observations acquired off the equator near L=4.5 in the dusk sector suggest that there is little change in EMIC wave amplitudes near the bi-ion hybrid frequency. These observations suggest that the waves tunnel through the stop band region or are simply unaffected. The later may occur in cases when the helium ion concentration is low. Observations from RIMS will be used to constrain the possibilities.

Magnetic pulsations in the Pc 1 and 2 frequency range (0.1 to ~1 Hz), have been studied both in space and on the ground for decades, and are known to be generated by wave-particle instabilities in the outer magnetosphere. While earlier studies near the plasmapause revealed a temporal association with magnetic storms, increasing evidence suggests that events at higher L shells in the dayside magnetosphere show a quite different dependence. The increasing availability of ground observations from high latitude sites in Antarctica and Arctic Canada, along with the consistent availability of solar wind and interplanetary magnetic field (IMF) data during the ISTP era, has led to a new appreciation of the significant control of such events by variations in the solar wind and IMF; the most prominent of these is the triggering of intense events, both sustained and transient, by enhancements in solar wind pressure. Comparison of Pc 1-2 events with the Dst geomagnetic activity index during 1996 and 1997 shows a strong correlation between Pc 1-2 activity and positive Dst (or sharp increases in Dst), consistent with the solar wind pressure effect. We also observed a modest anticorrelation between Pc 1-2 occurrence and negative Dst and with geomagnetic storms or their recovery phases. These results are also consistent with earlier unpublished studies of data from the AMPTE CCE satellite. Of the 20 Pc 1-2 events observed during good conjunctions between the elliptically-orbiting POLAR satellite and Antarctic ground stations during these two years, 17 were associated with moderate or large solar wind pressure increases. These observations suggest that the outer magnetosphere is frequently marginally unstable to ion cyclotron wave emissions, regardless of the occurrence of storms. Our continuing investigations of these events will focus on local plasma conditions on the flux tubes where these waves are observed.

GROWTH, PROPAGATION AND DAMPING OF ULF WAVES IN PLANETARY MAGNETOSPHERES

Carsten OTHMER, Karl-Heinz Glassmeier (Institut fuer Geophysik und Meteorologie, TU Braunschweig, Germany)

Planetary magnetospheres arenatural laboratories for many plasma physical processes one of which are ULF pulsations. Together with magnetic storms and substorms, they constitute the most important signatures of magnetospheric dynamics. Numerous observations of ULF waves in the terrestrial magnetosphere have been reported, and they have also been found in the magnetospheres of Mercury, Jupiter and Saturn. The special environments that the different planetary magnetospheres present us with, have major consequences for the behavior of ULF waves. Possible excitation mechanisms, propagation characteristics and damping processes for ULF waves and their relation to magnetospheric parameters such as size, background magnetic field, plasma sources, properties of the ionosphere, multi-ion effects etc. are discussed. Special emphasis will be paid to a comparative view of ULF waves under these different conditions.

ULF WAVES IN THE JOVIAN MAGNETOSPHERE

C. T. RUSSELL, K. K. Khurana and M. G. Kivelson (All at Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA, USA, e-mail: ctrussell@igpp.ucla.edu)

The main energy and mass source in the jovian magnetosphere is Io at a radial distance of 5.9 jovian radii. The immediate vicinity of Io contains strong ion cyclotron and mirror mode waves but more than 20 Io radii away the magnetosphere is largely quiet even on field lines connected to Io. The plasma circulation in the jovian magnetosphere is largely corotational with a radial component that moves outward, slowly at first and then ever more quickly. The wave phenomena seen in the magnetosphere seem to be controlled by this radial transport. The waves increase in amplitude with radial distance in the dipolar magnetosphere and are stronger transverse to the field off the equator and more strongly compressional near the equator. At about 24 RJ the magnetic field switches from being quasi-dipolar to being magnetodisk-like. Near the inner edge of this region the level of wave turbulence is highly variable. In the lobes of the magnetodisk the field is generally quiet, in the current sheet it is more turbulent and the amplitude of this turbulence increases with radial distance. The surface of the magnetodisk itself appears to ring with a period of about 10 minutes. Russia, e-mail: leon@iszf.irk.ru)

NONLINEAR INTERACTION OF ORDINARY ELECTROMAGNETIC AND ALFVEN WAVES

Adam Yukhimuk, Lena SIRENKO (both at Department of Space Plasma Phisics, Main Astronomical Observatory NASU, Kyiv, 252650, Ukraine); Olga Falko (Department of Astronomy and Space Physics, Kyiv National University, Kyiv, 252022, Ukraine)

The scattering of ordinary electromagnetic wave on the kinetic Alfven wave in the magnetized plasma with small plasma parameter (b=8pnT/B02) is investigated. Nonlinear dispersion equation and instability growth rates are found on the basis of two-fluid magnetohydrodinamics. It is shown that ordinary electromagnetic wave can decay on the kinetic Alfven wave and other ordinary electromagnetic wave. Parametric instability considered in the paper could take place in the ionosphere and magnetosphere of Earth, where plasma parameter is small. The analysis of the satellite measurements point out that scattering of ordinary electromagnetic wave on the kinetic Alfven wave more effective then ion cyclotron wave.

EXCITATION OF PS6 PULSATIONS AND FORMATION OF AURORAL STRUCTURES STRETCHED ALONG THE MERIDIAN DURING DISTURBANCES

S.I. SOLOVYEV, D.G. Baishev, N.E. Molochushkin and A.A. Fedorov (all at: Institute of Cosmophysical Research and Aeronomy, 677891 Yakutsk, Russia, E-mail: s.i.solovyev@sci.yakutia.ru); K. Yumoto (Kyushu University 33, Fukuoka 812-81, Japan, e-mail: yumoto@geo.kyushu-u.ac.jp); M.J. Engebretson (Department of Physics, Augsburg College, Minneapolis, MN 55454, USA, e-mail: engebret@augsburg.edu); W.J. Hughes (Department of Astronomy and Center for Space Physics, Boston, MA 02215, USA, e-mail: hughes@buasta.bu.edu)

This paper reports on the results of statistical study of Ps6 pulsations and their relationship to N-S aurora and omega bands using data of geomagnetic observations from magnetometer networks and optical data for 1994-1998. We investigated main properties of Ps6 pulsations and characteristics of auroral structures, their relationship to types of magnetospheric disturbances, and also the dynamics of ionospheric Ps6 currents. It is found that intense Ps6 pulsations accompanied by N-S aurora and omega bands which are observed in the premidnight and morning sectors, respectively, are a fine structure of SMC events or convection bays although they can be observed also in the course of a substorm. Ionospheric Ps6 currents flow predominantly northward (southward) for auroral structures drifting along the azimuth to the west (the east) before (after) the midnight. On Geotail data during N-S aurora the fluctuations of electric field Ey component and BBF-events in the plasma sheet are observed. Possible sources of auroral structures and currents responsible for Ps6 pulsations are discussed.

GIANT PULSATIONS: A NONLINEAR PHENOMENON

O.A.Pokhotelov and Yu.G.KHABAZIN (both at Institute of Physics of the Earth, 123810 Moscow, Russia, E-mail: khabazin@uipe-ras.scgis.ru); K.Mursula and J.Kangas (both at Department of Physical Sciences, University Oulu, Linnanmaa, FIN-90570 Oulu, Finland, E-mail: Kalevi.Mursula@oulu.fi); P.K. Shukla (Institut fur Theoretische Physik IV, Ruhr-Universitat Bochum, D-44780 Bochum, Germany, E-mail: ps@tp4.ruhr-uni-bochum.de); L.Stenflo (Department of Plasma Physics, Umea, University S-90187 Umea, Sweden, E-mail: lennart.stenflo@physics.umu.se); I.Mann and D.Milling (both at Department of Physics, University of York, Heslington, York YO1 5DD, UK)

The theory developed up to the present to account for giant pulsations (Pgs) has been dominated by the linear approximation. Nevertheless, exceptionally high amplitudes and purely monochromatic features of the pulsation wave trains indicate the importance of nonlinear effects. Among a great variety of different nonlinear mechanisms, the nonlinear phase mixing of the resonant particles due to the finiteness of the pulsation amplitude is of great importance. We present a simple approach to this problem and provide a certain experimental background in favour of a nonlinear behaviour of the wave packets. We demonstrate that many intriguing peculiarities, e.g., exceptionally long duration of the giant pulsations, can be explained in terms of monochromatic modes exhibiting strong nonlinear wave-particle interactions in the presence of quasi-stationary injection of resonant particles during magnetic storms.

GROUND-BASED AND POLAR SPACECRAFT OBSERVATIONS OF A GIANT (PG) PULSATION AND ITS ASSOCIATED SOURCE MECHANISM.

D.M. WRIGHT, T.K. Yeoman, J. Storey and I.J. Rae (Department of Physics & Astronomy, University of Leicester, University Road, Leicester, UK. LE1 7RH)

A study of a giant pulsation event has been undertaken. The wave was observed at the ground on the Scandinavian IMAGE magnetometer network where the amplitude maximised in the vicinity of Tromsø (TRO), Norway (66.4° N geomagnetic). The ionospheric signature of the wave, which exhibited an azimuthal wave number (m) of about 30, was simultaneously recorded by a high-latitude HF Doppler sounder operating near Tromsø. This was possible due to the high spatial resolution of the sounder measurements. In addition, the CAMMICE instrument on the POLAR spacecraft, located east of Tromsø, detected a dispersed proton population on closed field lines shortly before the ULF wave was observed by the ground-based instrumentation. The role played by these particles, which were injected on the nightside during a substorm several hours earlier, in the generation mechanism of the wave will also be discussed.

INFLUENCE OF A DRIFT-BOUNCE INSTABILITY ON THE ALFVEN WAVE STRUCTURE IN THE MAGNETOSPHERE

Dmitri Yu. KLIMUSHKIN (Institute of Solar-Terestrial Physics, Irkutsk 33, P.O.Box 4026, 664033, Russia; e-mail: klimush@iszf.irk.ru)

This report discusses the influence of a drift-bounce instability on the MHD wave structure in the magnetosphere. It is assumed that the magnetospheric plasma consists of two components: (1) the low-energy core component that determines the structure of the wave, and (2) the high-energy low density component which determines the instability of the wave. The field line curvature, non-zero plasma pressure, and finite resistance of the ionosphere are taken into account. The drift-bounce instability that develops due to the resonance of energetic particles with the electromagnetic field of the hydromagnetic wave, is often treated as the mechanism for generation of geomagnetic pulsations with high azimuthal wave number (m>>1) in the magnetosphere. A combined action of finite pressure of the core component and field line curvature leads to the propagation of Alfven waves across the magnet

THE SOLITARY STRUCTURES IN OVERDENSE IONOSPHERIC PLASMA

A.V. KOCHETOV and B.A. Mironov (both at Institute of Applied Physics, N.Novgorod, Russia, e-mail: kochetov@appl.sci-nnov.ru); G. I. TERINA and V.N.Bubukina (both at Radiophysical Research Institute, N.Novgorod, Russia, e-mail: ter@nirfi.sci-nnov.ru)

The results of the modelling of nonlinear dynamic effects arising in the ionospheric plasma under the action of the powerful radio waves are presented. Numerical solutions of nonlinear Schredinger equation in the linearly inhomogeneous plasma layer excited by the heating radio wave were obtained. The processes of the formation of the solitary structures of the electric field and disturbances of plasma density and processes of their relaxation for different values of density gradient and the amplitude of the heating wave were analyzed. The spatial evolution of the electric field and disturbances of the plasma density and time dependencies of the reflected signal were obtained. With the heater turn-on the penetration of the solitary structure into the overdense plasma takes place which increases under the heating power increase and the decrease of the plasma density gradient. The decreasing of the scale of the spatial soliton structure, the periodic and chaotic solitons generation during the heater time are observed. When the heater is turned off, the solitons continue to travel into the overdense plasma for some time, increasing in the amplitude, until they reach the turning point. Then they reflect and propagate into the underdense plasma, decreasing in the amplitude, and disappear. The obtained results allow to interpret the appearance of the scattered signal after the heater turn-off - "after effect plasma signal" (AEPS). This work was supported by the Education Department of Russia. (grant N 97-0-5.3-113).

FRACTAL DYNAMICS OF HIGH-LATITUDE LONG-PERIOD IRREGULAR PULSATIONS IN A FREQUENCY BAND (2,1-5,5) MHZ

KLAIN, B.I., Kurazhkovskaya, N.A. (both at Geophysical Observatory "Borok" of the United Institute of Physics of the Earth of Academy of Science of Russia, 152742 Borok, Yaroslavl, Nekouz, Russia, e-mail: klain@borok.adm.yar.ru)

The dynamics of fractal dimension (D) of high-latitude long-period irregular pulsations of np-type in a frequency band (2,1-5,5) mHz have been studied. The study was performed based on the data obtained by the observations of magnetic field of high-latitude observatories of Northern and Southern hemispheres of a magnetosphere. It was shown, that the fractal dimension of np-pulsations depends from a degree disturbance of a magnetosphere and geomagnetic latitude of an observatory. The increase of geomagnetic activity lead to magnification of fractal dimension of pulsations. During intense geomagnetic storms the linear relation D from a Dst-variation and duration of an initial phase of storms was discovered.
For moderate - perturbed conditions the latitudinal profile of fractal dimension of np-pulsations was constructed. It was revealed, that in a narrow interval of latitudes 69-710 quantities D are less, than in lower and high latitudes. It is supposed that the fractal dimension reflects change structure of pulsations and the chosen interval of latitudes corresponds to a standing of boundary of the magnetospheric resonator. The possibility of application D as the indicator of a degree perturbation of a high-latitude magnetosphere, and also for monitoring its structure is considered.

SUNRISE EFFECT ON VERY LOW-LATITUDE PC3 PULSATIONS

Y.M. TANAKA, K. Yumoto, A. Yoshikawa, T.I. Kitamura (Department of Earth and Planetary Sciences, Kyushu University, Fukuoka, 812-8581, Japan, E-mail: tanaka@geo.kyushu-u.ac.jp; E-mail: yumoto@geo.kyushu-u.ac.jp); B.J. Fraser (Department of Physics, University of Newcastle, Newcastle, NSW 2308, Australia, E-mail: phbjf@cc.newcastle.edu.au); D. Cole (IPS Radio and Space Services, Learmonth Solar Observatory, Exmouth, W.A. 6707, Australia, E-mail: david@ips.oz.au)

We statistically investigated wave characteristics of Pc 3 pulsations observed at very low-latitude stations, GUA (Mlat=5.6û, Mlong=215.6û), and CRI (Mlat=3.1û, Mlong=273.5û). When both the two stations were located in the interval from 0800 to 1700 LT, very small phase differences of Pc 3 were found to be observed in the H component, indicating a nearly zero azimuthal wave number. Moreover, a 180û phase shift of Pc 3 across 0730 LT was newly found in the H component, which may be related to the change of the ionospheric conductivity in the sunrise region. The sunrise effect on low-latitude Pc 3 pulsations was also examined by analyzing data from the 210û magnetic meridian network. At low latitudes (L= 1.2-2.1), a 180û phase shift across the sunrise was found in the D component , while no phase shift in the H component. This phase variation is consistent with the previous result, a 90û rotation of polarization major axis around the sunrise. The phase variation of low-latitude Pc 3 pulsations across the sunrise suggests that a secondary electric field built up by the charges at a terminator on the sunrise

THE PHASE STRUCTURE OF EQUATORIAL AND VERY LOW LATITUDE ULF WAVES ACROSS DAWN

Colin WATERS, Murray Sciffer, Brian Fraser, Kristie Foulkes (all at Department of Physics, University of Newcastle, Callaghan, 2308, NSW, Australia, e-mail: colin@physics.newcastle.edu.au); Kate Brand (Physics Department, The University of Birmingham, Edgbaston, Birmingham B15 2TT, UK); O. Sakaand, K. Yumoto (Department of Earth and Planetary Sciences, Kyushu University 33 6-10-1 Hakozaki, Fukuoka 812-8581, Japan, e-mail: yumoto@geo.kyushu-u.ac.jp)

Most Pc3 ULF waves observed at low latitudes have been associated with toroidal mode hydromagnetic wave resonances in the plasmasphere. In the near equatorial regions, a band of Pc3-4 ULF wave activity is often seen and usually has enhanced amplitude at the equator. Due to the difficulty in exciting toroidal resonances at very low latitudes, this wave energy has been attributed to fast mode ULF waves. The phase difference between data recorded at longitudinally spaced equatorial magnetometers show a marked change at dawn when one station is in sunlight and the other in darkness. The phase structure with latitude is also seen to show a large phase shift near the equator, in agreement with previous studies.
A model of ULF wave propagation through the equatorial ionosphere has been developed. Using IRI data and parameters relevant to the local conditions, the observed phase structures are modelled and compared with the experimental data. It is shown that the phase shifts at dawn and with latitude are probably due to two mechanisms. The first is of ionospheric origin as refilling occurs and the other involves propagation of the waves.

GEOMAGNETIC RESPONSE TO THE EARTH'S ARRIVAL OF A SOLAR MASS EJECTION

Stefania LEPIDI, Antonio Meloni (both at Istituto Nazionale di Geofisica, Roma, Italy; E-mail: stefania.lepidi@aquila.infn.it); Patrizia Francia, Umberto Villante (both at Dipartimento di Fisica, Universita' de L'Aquila, L'Aquila, Italy; E-mail: patrizia.francia@aquila.infn.it); Alan J. Lazarus (Center for Space Research, MIT, Cambridge, USA; E-mail: ajl@space.mit.edu); Ronald P. Lepping (Lab. for Extraterrestrial Physics, NASA/GSFC, Greenbelt, USA; E-mail: rpl@leprpl1.gsfc.nasa.gov)

An analysis of the low frequency geomagnetic field fluctuations at an Antarctic (Terra Nova Bay) and a low latitude (L'Aquila, Italy) station during the Earth's passage of a coronal ejecta on April 11, 1997 shows that major solar wind pressure variations were followed at both stations by an high fluctuation level. During northward interplanetary magnetic field conditions and when Terra Nova Bay is close to the local geomagnetic noon, coherent fluctuations, at the same frequencies (3.6 mHz) and with a polarization pattern indicating an antisunward propagation, were observed simultaneously at the two stations. The appearance of similar features at a wide latitudinal and longitudinal separation suggests that the observed waves might be interpreted as global magnetospheric modes triggered by an external stimulation.

GA3.04/E/10-B1 Poster **1520-11**

POSSIBLE CONTAMINATION OF GEOMAGNETIC PULSATION DATA BY ELECTROMAGNETIC INDUCTION EFFECT

Baldev R. ARORA (Indian Institute of Geomagnetism, Colaba, Mumbai 400 005, India, e-mail: bra@iig.iigm.res.in); Nalin B. Trivedi, Antonio L. Padilha and Icaro Vitorello (all at Instituto Nacional de Pesquisas Espaciais, Sao Jose dos Campos,Brazil, e-mail: trivedi@dge.inpe.br)

The quantification of wave polarization characteristics of ULF waves from the geomagnetic field variations is done under 'a priori' assumption that fields of internal induced currents are in-phase with the external inducing fields. Such approximation is valid only in areas where internal electrical conductivity distribution varies only as a function of depth. Lateral conductivity variations, either in the form of land-ocean contrast or those associated with crustal structures, perturb the flow pattern of induced currents. The amplitude and phase changes that these perturbations produce in the resultant fields recorded at Earth's surface, make the determination of polarization and phase of the oscillating external signals problematic. In this paper, with the help of magnetovariational data from an array of magnetometers in the equatorial belt of Brazil, we present examples of geomagnetic micropulsation events contaminated by anomalous induction effects. These induction effects, if not properly guarded for, lead to highly over estimates of the equatorial enhancement and also suggest changes in the azimuth of ULF waves as they propagate through the equatorial electrojet. Given this observational evidence, guidelines to identify and estimate the extent of induction effects in geomagnetic pulsations data are briefly outlined.

GA3.04/L/06-B1 Poster **1520-12**

A MAGNETOSPHERIC MHD DISTURBANCE, TRIGGERED BY AN IMPULSIVE SOURCE IN THE IONOSPHERE

Anatoly S. LEONOVICH (Institute of Solar-Terrestrial Physics, 664033, Irkutsk, P.O.Box 4026,

A theory has been constructed for standing quasi-Alfven waves excited in the magnetosphere by a broad-band source localized in the ionosphere. A detailed study is made of the oscillations generated by a narrowly localized (across geomagnetic field lines) impulsive source. It is shown that oscillations from such a source can occur in two different regimes. The initial regime is characterized by the fact that the excited standing wave oscillates throughout the space with the same frequency equal to the frequency of toroidal Alfvenic eigen-oscillations of the magnetosphere on the magnetic shell where the source is localized. In the asymptotic regime, the oscillation field of the standing Alfven wave occupies a distinctly delineated (across field lines) region. In every point of the region the waves are oscillating with their eigenfrequency.
A numerical calculation is made of the total field of standing quasi-Alfven waves excited in the magnetosphere by an impulsive source localized in the ionosphere. It is shown that the fundamental harmonic of standing waves reaches an asymptotic regime already after the first oscillation period. All other harmonics oscillate in the initial regime during many oscillation periods of the fundamental harmonic. Such a picture of the oscillations adequately depicts the MHD disturbances recorded as part of active MASS experiments aboard the AUREOLE-3 satellite. The point at which the leading edge of a strong electromagnetic impulse was recorded, is quite well associated with the southern boundary of localization of the fundamental harmonic of standing waves. The form and duration of the impulse recorded aboard the satellite is also adequately described.

A MODEL FOR ULF WAVE PROPAGATION THROUGH THE IONOSPHERE

Murray SCIFFER and Colin Waters (both at Physics Department and CRC for Satellite Systems, University of Newcastle, Callaghan, 2308, NSW, Australia, e-mail: colin@physics.newcastle.edu.au)

ULF waves from the magnetosphere interact with the ionosphere and are detected by ground based magnetometers. Furthermore, the role of ULF waves in Doppler data obtained from HF radars is being re-examined with the increasing number of SuperDARN radar studies. Central to these investigations is the understanding of ULF wave structure and particle motion as a function of altitude through the ionosphere. Most studies that look at ULF waves and their interaction with this region, treat the ionosphere as an infinitely thin sheet with height integrated quantities. In this paper we present a more detailed model of ULF wave propagation through the ionosphere that allows the incident wave modes to be specified.
The model assumes constant horizontal wave structure with variation in the vertical direction only. Using realistic particle populations with altitude and an anisotropic complex conductivity

tensor, the ULF wave is modelled as an electromagnetic wave so that the electric and magnetic field perturbations may be obtained as a function of height. The incident wave mode mix between the fast and shear Alfven modes may also be specified and the inclination of the magnetic field or dip angle is a free parameter. Results for various dip angles, ionospheric conditions and incident horizontal wave structure and wave mode mixes are discussed within the context of experimental magnetometer data.

ULF WAVES AND IONOSPHERE: MULTI-STEP MODE CONVERSION BETWEEN DIVERGENT AND ROTATIONAL ELECTRIC FIELD BY THE IONOSPHERIC HALL EFFECT

A.YOSHIKAWA and K.Yumoto (both at Department of Earth and Planetary Sciences, Kyushu University, Hakozaki, Fukuoka 812-8581,JAPAN, e-mail: yoshi@geo.kyushu-u.ac.jp)

Natures of reflection and mode conversion of MHD waves at the inductive ionosphere are investigated by using the reflection and mode conversion tensor of MIAS system. In the MIAS system, 8 wave elements (FAC and rotational current of magnetosonic mode in the magnetosphere, divergent and rotational Hall and Pedersen current in the ionosphere and divergent and rotational displacement current in the neutral atmosphere) are coupled through the ionospheric multi-step Hall effect. To clarify the differences between inductive and electrostatic response of ionosphere for reflection process of shear Alfven wave, various physical quantities are compared in both treatments. Inductive ionosphere requires the renormalization of rotational electric field to the divergent one, and generates the divergent Hall current, which directly closed via the FAC. The existence of divergent Hall current brings about the redistribution of 8 wave elements are very different from in the electrostatic ionosphere. It is shown that the ionospheric currents associated with the ULF pulsations at high conducting ionosphere are almost borne by Hall current both rotational and divergent parts of ion

AN IONOSPHERIC MECHANISM OF COMPRESSIONAL-SHEAR ALFVEN WAVE TRANSFORMATION

P. NENOVSKI, B. Andonov, P. Muhtarov (Geophysical Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria)

The experimental evidence of a compressional-shear wave transformation events recorded simultaneously at geostationary orbit and the foot of the same field lines (Lanzerotti and Tartaglia, 1972) is examined in view of the recent theoretical findings for an elliptization effect produced directly by the ionosphere. It is found that due to the ionosphere dissipation effect compressional waves could be transformed into nearly transverse wave seen at the ground. According to theoretical findings the elliptization effect emerges under certain ionospheric/wave conditions. The Lanzerotti and Tartaglia results for a left-hand elliptization of 0.7 (nearly circular) and a polarization plane rotation of 45 degree could easily be produced in winter conditions and subauroral ionosphere. The effect depends on a wave parameter proportional to the squared horizontal wavenumber, the Hall region thickness and the wave period. Thus the ionosphere dissipation effect is possibly an effective mechanism for an elliptic polarization with left- hand sense (in the northern hemisphere) and a 45 degree rotation angle (when the elliptization effect is maximum) seen by Lanzerotti and Tartaglia's experiment.

THE SPATIAL STRUCTURE OF HIGH LATITUDE PC5 GEOMAGNETIC PULSATIONS: IMAGING RIOMETER OBSERVATIONS

Pavlo PONOMARENKO, Brian J Fraser, Michael B Terkildsen, Sean T Ables, and Fred W Menk (all in Department of Physics, CRC for Satellite Systems, University of Newcastle, Callaghan, NSW, 2308 Australia, E-mail: phpp@alinga.newcastle.edu.au); Ray J Morris (Australian Antarctic Division, Channel Hwy, Kingston, TAS, 7050 Australia)

Geomagnetic pulsations observed on the ground indicate the signatures of MHD plasma waves propagating in the magnetosphere and ionosphere. Due to their large field of view, the magnetometers provide relatively low spatial resolution, which in many cases exceeds the characteristic horizontal scale size of the wave. One of the possibilities to improve the resolution is connected with the use of multibeam imaging riometers. These measure cosmic noise absorption (CNA) at low ionospheric altitudes due to the high electron collisional frequency and allow the study of the spatial structure and dynamics of CNA events. Previous magnetometer measurements at high latitudes have shown that resonant Pc5 pulsations sometimes are accompanied by similar variations in CNA. The question about the mechanism of such a correlation is open, and different mechanisms can be considered. The current study attempts to use the imaging riometer SHIRE at the Australian Antarctic cusp station Davis to investigate the spatio-temporal structure of Pc5 pulsations at high latitudes. The CNA events were selected using several steps. Firstly, Pc5 events with a pronounced spectral maximum were identified in the magnetometer data from Davis. Secondly, a co-located broadbeam riometer was used as a reference to look for the coincident spectral maxima in CNA variations. Thirdly, for the correlated events we used SHIRE data to determine the spatial distribution of the pulsations' intensity and phase for the dominant spectral component. The phase shift between neighbouring beams was used then to restore the vector of the horizontal propagation velocity of the waves.

POLARIZATION STRUCTURE OF MIDDLE-LATITUDE PC3-4 PULSATIONS DERIVED FROM THEIR ELECTRIC FIELD SIGNATURE

D. DANOV (1), J.Vero (2), B.Zieger (2), and P. Nenovski (3) ((1) Solar-Terrestrial Influences Laboratory, Sofia, Bulgaria, (2) Geodetic and Geophysical Research Institute, Sopron, Hungary, (3) Geophysical Institute, Sofia, Bulgaria)

We have analyzed one month data of the electric field of Pc3-4 geomagnetic pulsations recorded at middle-latitude station (Nagycenk, Hungary). In addition to the spectral analysis a polarization study of the geomagnetic pulsations under quiet and disturbed conditions is performed. The purpose of this study is to examine the electric field signature of the well-registered sunrise changes of the polarization plane rotation. The polarization plane rotation change at sunrise has been documented by magnetic field measurements. The electric field signature of Pc3-4 pulsations yields however such sunrise effect occasionally and it does not exist regularly. An explanation of the results is presented provided that the geomagnetic pulsations in selected frequency ranges are of magnetosonic type. The interpretation is based on the electric /magnetic field asymmetry in the polarization changes through the ionosphere-atmosphere system. Influences from the atmosphere- lithosphere system are additionally accounted for.

THE STUDY OF THE IONOSPHERIC SOURCES OF THE GEOMAGNETIC PULSATIONS BY THE MAGNETIC GRADIENTOMETRIC METHODS

KOPYTENKO, Yury; Ismagilov, Valery; Kopytenko, Eugene; Zaitsev, Dmitri; Voronov, Pavel; (SPbF IZMIRAN, 191023, Box 188, Muchnoj per.2, St. Petersburg, RUSSIA, E-mail: ek@eak.izmi.ras.spb.ru)

Values of phase velocities of the geomagnetic wave front propagating along the Earth surface were received using data of a magnetic gradientometer during experiment in subauroral zone in autumn of 1997. The gradientometer consists of 3 three component magnetovariation complex MVC-1DG situated in tops of a triangle and spaced at a distance, 6 - 8 km. Original algorithms of the data processing were used. Typical values of the geomagnetic wave fronts velocities are 20 – 60 km/sec, normal to wave front magnetic gradients of geomagnetic pulsations are about 0.01 nT/km and depend from a distance to ionospheric source and amplitude of the geomagnetic pulsations. The directions to the ionospheric sources of the geomagnetic pulsations were calculated during periods of different geomagnetic activity using a method of magnetic location in ULF frequency range.

MONITORING SPATIAL AND TEMPORAL VARIATIONS OF THE PLASMAPAUSE REGION USING GEOMAGNETIC FIELD LINE RESONANCES

D.K. MILLING, R.A. Mathie and I.R. Mann (Department of Physics, University of York, York YO10 5DD); F.W. Menk (department of Physics, University of Newcastle, Callaghan, N.S.W., 2308, Australia).

The use of cross-phase and related techniques can yield the field-line resonance frequency between latitudinally spaced pairs of magnetometers. This data can then be used to estimate the temporal and spatial variations in plasma mass density. Such analysis has been applied to the data from a dense array of temporary stations in Fenno-Scandinavia with the aim of studying the plasma density variations across the plasmapause region as a function of geomagnetic activity, LT and UT.
An attempt is made to specify the minimum instrumentation which would be required for near real-time monitoring of the plasmasphere and plasmapause.

MONITORING SPATIAL AND TEMPORAL VARIATIONS IN THE DAYSIDE PLASMASPHERE USING GEOMAGNETIC FIELD LINE RESONANCE

Fred W. MENK and Colin L. Waters (both at Department of Physics, CRC for Satellite Systems, University of Newcastle, Callaghan, NSW, 2308, Australia, e-mail: physpuls3@cc.newcastle.edu.au); David Orr and David Milling (both at Department of Physics, University of York, Heslington, York, Y010 5DD, UK, e-mail: dave@samsun.york.ac.uk); Mark A. Clilverd and Andy J. Smith (both at British Antarctic Survey, Madingley Road, Cambridge, CB3 0ET, UK, e-mail: MACL@pcmail.nerc-bas.ac.uk)

It is well known that the resonant frequency of geomagnetic field lines is determined by the magnetic field and plasma density. Using ground magnetometer arrays and cross-phase and related methods, the field line resonance frequency was determined across L=2.8-4.5 in the northern hemisphere, and 9-10 hours away in local time at L=2.8 in the southern hemisphere, for several days in October and November 1990. The temporal and spatial variation in plasma density was thus evaluated and compared with VLF whistler measurements of electron densities at similar times and locations. The plasma mass loading was also estimated. Other features that were examined include the plasma mass density power law, diurnal variations in plasma density at low latitudes, substorm refilling effects, and a longitudinal asymmetry in plasma density.

EXCITATION OF HARMONIC CYCLOTRON WAVES IN THE EARTH'S MAGNETOSPHERE

Oleg POKHOTELOV, Felix Feygin and Vladimir Gladychev (all at Institute of Physics of the Earth, 123810 Moscow, Russia, E-mail: pokh@uipe-ras.scgis.ru); Dmitrii Pokhotelov (Thayer School of Engineering, Dartmouth College 800 Cummings Hall, Hanover, NH 03755-8000, USA, E-mail: dmitrii.pokhotelov@dartmouth.edu); Michel Parrot (LPCE/CNRS, 3A, Avenue de la Rechercher Scientifique 45071 Orleans Cedex 2, France, e-mail: mparrot@cnrs-orleans.fr); Jorma Kangas and Kalevi Mursula (both at Department of Physical Sciences, University of Oulu, FIN-90570 Oulu, Finland, e-mail: jorma@sgo.fi; kalevi.mursula@oulu.fi)

A theoretical model for the generation of ion cyclotron harmonic waves observed in the deep plasmasphere both during disturbed and quiet conditions is presented. It is shown that during quiet magnetic conditions these waves are generated by a weak kinetic instability involving hot helium ions with a ring like distribution. The existence of such ions in the magnetosphere during quiet magnetic conditions is confirmed by the satellite data. A simple analytical model of this instability accounting for the longitudinal inhomogeneity of the ambient magnetic field is used. During magnetic storms there is a transition to a strong hydrodynamic instability involving the oxygen ions of ionospheric origin. The development of kinetic instability during this time is suppressed by the field aligned inhomogeneity of the dipole magnetic field. Such a scenario of harmonic cyclotron wave excitation is in a good agreement the ULF/ELF wave observations on board the AKEBONO satellite during disturbed and quiet times.

A MECHANISM OF PC1 PEARL FORMATION BASED ON ALFVEN SWEEP MASER

A.G. DEMEKHOV, V.Y. Trakhtengerts (both at: Institute of Applied Physics, Nizhny Novgorod, Russia; e-mail: andrei@appl.sci-nnov.ru); S.V. Isaev, S.V. Polyakov, P.P. Belyaev, V.O. Rapoport (all at: Radiophysical Research Institute, Nizhny Novgorod, Russia)

A self-consistent model for the generation of Pc~1 pearl emissions based on the nonlinear magnetosphere/ionosphere coupling is considered. Formation of pearls is attributed to the pulsating regime of the Alfven sweep maser (ASM) with nonlinear selective mirrors. Such mirrors are formed by the conjugate ionospheres: their reflection coefficient has an oscillatory frequency dependence due to eigenmodes of the ionospheric Alfven resonator; nonlinear magnetosphere/ionosphere feedback is provided by the dependence of the value and frequency of the reflection maxima on the flux of energetic protons precipitated into the ionospheres in the course of Alfven wave generation in the magnetosphere. A nonlinear soliton-like solution of the ASM model is found which corresponds to a single wave packet having the positive frequency drift and oscillating between the conjugate ionospheres. Properties of this solution are shown to explain many observational characteristics of Pc1 pearls, such as their morningside predominance, correlation with low magnetic activity, spatio-

temporal and spectral patterns. Results of numerical simulations of the ASM equations are presented.

THE PONDEROMOTIVE INFLUENCE OF ION CYCLOTRON WAVES ON THE FIELD-ALIGNED DISTRIBUTION AND MOTION OF IONS IN THE EQUATORIAL ZONE OF THE MAGNETOSPHERE

Anatol GUGLIELMI (United Institute of Physics of the Earth, B. Gruzinskaya, 10, Moscow, 123810 Russia, e-mail: gugl@uipe-ras.scgis.ru); Kanji Hayashi (Department of Earth and Planetary Physics, University of Tokyo, 7-3-1 Hongo, Bunkyo, Tokyo, Japan 113, e-mail: hayashi@sunep1.geoph.s.u-tokyo.ac.jp); Rickard Lundin (Swedish Institute of Space Physics, BOX 812, S-98128 Kiruna, Sweden, e-mail: rickard@irf.se); Alexander Potapov (Institute of Solar-Terrestrial Physics, P.O.B. 4026, Irkutsk, 664033 Russia, e-mail: potapov@iszf.irk.ru)

The effects of ponderomotive forces of ion-cyclotron waves in the near-equatorial region of the magnetosphere have been investigated using hydrodynamic, quasi-hydrodynamic and "test-particle" approaches. Main attention was paid to the application of general theory to the magnetospheric physics. It has been shown that the problem of the ponderomotive impact of the waves upon the plasma density may be formally reduced to a problem of phase transition of the second kind. In such a formalism, the plasma distribution is altered dramatically as the imaging point in the plane of governing parameters crosses some demarcation line. The magnetic equator turns out to be an attractor for a heavy ion. Heavy ions congest near the magnetic equator provided the waves are comparatively strong. This suggests that the ponderomotive effects play a role in formation of structure and dynamics of the magnetosphere.

THE ION CYCLOTRON RESONATOR

A. V. GUGLIELMI (Institute of Earth Physics, Moscow, Russia
e-mail: gugl@scgis.fisgeos.iitp.ru); C. T. Russell (Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA, USA, e-mail: ctrussell@igpp.ucla.edu)

Ion cyclotron waves travelling parallel to the magnetic field away from the equator in a planetary magnetosphere may be reflected back toward the equator in a multi-ion plasma restricting the ion cyclotron waves to the near equatorial region. This process occurs because the local gyrofrequency increases away from the equator and the wave frequency that is constant in Hz, approaches the cut-off frequency where it is reflected. Structure in the spectrum of ion cyclotron waves published by Fraser et al. [JGR, 1992] suggests that the ion cyclotron resonator may occur in the magnetosphere at least on occasion. On the other hand if the waves propagate slightly off angle, they can become right handed and propagate into the ionosphere and be lost. We examine more recent POLAR data to determine if frequency structure is present in the ion cyclotron waves near the equatorial plane.

POYNTING VECTOR MEASUREMENTS OF ELECTROMAGNETIC ION CYCLOTRON WAVES WITH FREQUENCIES ABOVE THE HELIUM CYCLOTRON FREQUENCY: CRRES OBSERVATIONS

P. Manusiu, and B.J. FRASER, (Physics Department, CRC for Satellite Systems, University of Newcastle, NSW, 2308, Australia, e-mail: phbjf@cc.newcastle.edu.au)

Previous studies of electromagnetic ion cyclotron (EMIC) waves in the equatorial middle magnetosphere using Poynting vector calculations from the CRRES spacecraft dE and dB wave fields have shown that the waves propagate essentially in field-aligned directions. Ray angles are typically less than 30 degrees with respect to the magnetic field direction. This study was only concerned with wave frequencies below the helium cyclotron frequency f (He+). A new study underway considers the energy propagation characteristics of a number of EMIC wave events from CRRES with f > f(He+). Included in the study are examples of events showing harmonic structure and an association with cold plasma density cavities or gradients.

RELATION BETWEEN PC1 PEARLS AND ULF WAVES STUDIED BY THE POLAR SATELLITE AND GROUND OBSERVATIONS

T. BRÄYSY, K. Mursula, R. Rasinkangas, and P. Tanskanen (Department of Physical Sciences, University of Oulu, P.O. Box 3000, FIN-90401 Oulu, Finland, E-mail: Timo.Braysy@oulu.fi) F. Mozer (Space Science Laboratory, University of California at Berkeley, Berkeley, CA 94720, USA)

The electromagnetic ion cyclotron (EMIC) waves are among the most common wave forms inside the magnetosphere. One special type of EMIC waves, particularly typical for the inner magnetosphere, are the Pc1 pearls consisting of regularly repeating emissions of EMIC waves observed on ground. The standard model of pearls assumes that they are due to a wave packet bouncing along the field line from one ionosphere to another (BWP model). However, there are several facts that are problematic for this model. For example, a recent event study using Viking satellite observations excludes the BWP model as a cause to the observed EMIC burst structure (Mursula et al., JGR 102, 17611, 1997) and verifies that ULF waves modulate EMIC wave growth (Rasinkangas and Mursula, GRL 25, 869, 1998). Also, an earlier case study using simultaneous ground and Polar satellite observations of EMIC and ULF wave activity seems to support the modulation model as a cause for repetitive structure of Pc1 pearl pulsations (Mursula et al., Adv. in Space Res., in print, 1999). Here we look for further evidence for ULF modulation of EMIC wave growth using several pearl events observed on ground by the Finnish magnetometer chain and simultaneously monitored by the electric field instrument (EFI) onboard Polar spacecraft.

NEW CONSTRAINTS ON THEORIES OF PC1 PEARL FORMATION

K. Mursula, J. Kangas, R. KERTTULA, T. Pikkarainen (Department of Physical Sciences, University of Oulu, P.O. Box 3000, FIN-90401 Oulu, Finland, E-mail: Raine.Kerttula@oulu.fi); A. Guglielmi and O. Pokhotelov (United Institute of Physics of the Earth, 123810 Moscow, Russia); A. Potapov (Institute of Solar-Terrestrial Physics, Irkutsk, Russia)

We study structured Pc1 pulsations (also called Pc1 pearls) observed on ground, concentrating on the relation between the pearl repetition period t and the wave frequency f. Earlier studies suggest that the product tf is roughly constant. We re-examine this relation and show that a simple inverse law is excluded. Instead, our observations suggest the relation t μ f -p with p=0.59±0.06, posing a new, strict constraint on theories of Pc1 pearl formation. We also study the L-dependence of various combinations of t and f using a model L-value, and extract additional constraints from these combinations. We discuss these constraints in the bouncing wave packet model of pearl formation, and determine the range of allowed parameter values in this model. We present two models of energetic ions with different L-distributions, and show that one of them can be excluded by the constraints derived. We also discuss how to further improve on these constraints to better test the bouncing wave packet model and other theories of Pc1 pearl formation.

STORM-TIME PC1 ACTIVITY AT HIGH AND MID-LATITUDES

R. KERTTULA, K. Mursula, T. Pikkarainen, J. Kangas (Department of Physical Sciences, University of Oulu, P.O. Box 3000, FIN-90401 Oulu, Finland, E-mail: Raine.Kerttula@oulu.fi)

We study Pc1 pulsations observed at a high-latitude station (Sodankylä) and a mid-latitude station (Nurmijärvi) during magnetic storms. We have analyzed altogether 18 storms occurring in low sunspot years (1976-78 and 1984-88). The Dst minimum of the strongest (weakest, respectively) storm was -226 nT (-77 nT), and the mean (median) Dst value was -133 nT (-110 nT). Pc1 activity was studied from the day of sudden storm commencement (denoted by day 0) onwards during six consecutive days. The two main types of Pc1 pulsations, the structured and unstructured Pc1's, were studied separately.
Structured pulsations strongly depend on the evolution of storms. Their activity increases from day 0 to day 4 by a factor of about five, reaching a maximum occurrence on day 4 at both stations. Slightly more events are seen at Sodankylä than at Nurmijärvi. Also the diurnal distribution of structured Pc1's suffers a dramatic change during the storm process. On days 1 and 2 structured pulsations are strongly concentrated in the evening sector. During the later recovery (days 3-5) the activity shifts to the morning sector. On the other hand, unstructured pulsations show only weak dependence on the storm evolution. The daily occurrence of unstructured Pc1's remains nearly constant, reaching weak maxima on day 1 or 2. The diurnal distribution with a noon maximum is nearly unchanged. We also study the changes of Pc1 activity with the intensity of the storm.

STATISTICAL STUDY OF ION CYCLOTRON WAVES BY FREJA SATELLITE

T. KIVISAARI, K. Mursula, and T. Bräysy (Department of Physical Sciences, University of Oulu, P.O. Box 3000, FIN-90401 Oulu, Finland, E-mail: Tarmo.Kivisaari@oulu.fi)

The Swedish Freja satellite was launched in 1992 and it ceased to operate in 1996. The orbital inclination was 63 degrees and period 109 minutes with apogee and perigee heights of 1750 km and 600 km, respectively. The F1 electric field instrument of Freja was a spherical double probe instrument, which measured the two orthogonal components of the electric field in the spin plane.
We have used an automated system to search for and view electromagnetic ion cyclotron (EMIC) waves in Freja F1 instrument data. Using that system, we have analysed one full apogee rotation period of Freja satellite data from August to December, 1993. Based on these observations we have collected statistical information of occurrence and characteristic of EMIC waves. Wave occurrence seems to be organised according to the development of magnetic storms. During the approximately 100 days studied, one major, one intermediate and eight minor storms occurred. The maximum number of waves was found during the major storm. Waves with lowest latitudes (below 50° CGMLat) were only found during the two largest storms. The diurnal distribution of waves also followed the storm development with increase of night-side wave activity during the main phase of largest storms. Waves with largest amplitudes occurred preferentially during the storm main phase. The results suggest that ion cyclotron waves are an important factor in the decay of the ring current after storm onset.

ACTIVITY OF PC1 GEOMAGNETIC PULSATIONS FOR 1957 - 1992

Emma T. MATVEYEVA, Vladimir F. Ruban (Geophysical Observatory Borok, Institute of Physics of the Earth RAS,Borok, Nekouz, Yaroslavl, 152742, Russia, e-mail: emma@borok.adm.yar.ru)

The index of Pc1 activity suitable for a computer analysis is suggested on a basis of a detailed catalogue of Pc1 (0.2-5.0 Hz) pulsations obtained as a result of processing of continuous observation from 1957 till 1992 at the observatory Borok (geomagnetic latitude 54.05 degrees N and longitude 113.44). As a unit of activity a 15-minutes interval is accepted during which the pulsations are observed no less than 5 minutes. The index of activity N is a sum of such intervals in each day by UT. The use of the index N is illustrated dy the results of the study of seasonal and cyclic Pc1 activity, its relationship with the cases of magnetic storms and sector boundaries of IMF. Along with a geophysics the index can be used for a wide range of disciplines for which the effect of natural electromagnetic field in this frequency range can be of practical or scientific interest.

A NEW APPROACH ON THE INTERPRETATION OF COMPRESSIONAL MHD WAVES IN THE MAGNETOSPHERE

Dong-Hun LEE (Dept of Astronomy & Space Science, Kyung Hee University, Yongin, Kyunggi, 449-701, Korea, e-mail: dhlee@nms.kyunghee.ac.kr)

Previous theoretical and numerical studies for cavity/waveguide modes assume perfectly reflecting boundary conditions at the outermost boundary whether the system is 1-D, 2-D or 3-D. The perfect boundary condition mathematically corresponds to the infinite potential wall (or the infinite Alfven speed), which assumes that the system should lie in the region surrounded by two infinite "walls" both at the inner and outer boundaries. In order to investigate how compressional waves differently behave in the presence of realistic Alfven speed gradient at the outer boundary, we newly adopt a quantum mechanical approach to obtain the wave solution. By using an analogy with the Schrodinger's equation, dynamics of compressional MHD wave propagation is theoretically studied in the dayside and nightside magnetosphere. The wave solutions are obtained for dayside and nightside Alfven speed profiles, respectively, without any arbitrary boundary condition at the magnetopause or the bow shock. The result shows that the previous cavity/waveguide models are found to be inappropriate for studying compressional wave properties in the magnetosphere. We introduce the role of virtual resonances which generally represent any possible compressional modes in the magnetosphere.

THE NATURE OF MAGNETOSONIC RESONANCE

A.D.M. WALKER (University of Natal, Durban)

The nature of field line resonances in the magnetosphere associated with standing transverse Alfvén waves is well understood. Another type of resonance is associated with the slow magnetosonic wave. It occurs when the plasma b is near unity. The theory of how this resonance is excited is developed. Its possible relevance to storm type pulsations and to long period oscillations observed near the magnetopause is discussed.

PHASEMIXING AND PHASE MOTION OF ALFVEN WAVES IN THE PLASMA SHEET BOUNDARY LAYER

A.N. WRIGHT (Mathematical Institute, University of St. Andrews, St. Andrews, Fife KY16 9SS, Scotland, U.K., e-mail: andy@dcs.st-and.ac.uk); W. Allan (NIWA, P. O. Box 14-901, Kilbirnie, Wellington, New Zealand, e-mail: w.allan@niwa.cri.nz); R.D. Elphinstone and L.L. Cogger (both at Department of Physics and Astronomy, University of Calgary, Calgary, AB, Canada T2N 1N4, e-mail: rob@hobbes.phys.ucalgary.ca, cogger@phys.ucalgary.ca)

The time-dependent phase structure of Alfven waves on tail-like field lines is studied. Alfven waves generated on field lines threading the PSBL have received little attention compared to those on dipole-like field lines, but may be shown to have an equatorward phase motion. Phasemixing in the magnetotail proves to have a much richer behaviour than that on near-Earth (dipole-like) field lines as not only the Alfven frequency varies across the background field lines, but the field-aligned wavenumber varies too. The two contributions tend to cancel each other partially for typical tail equilibria. Observations are given of a double oval configuration showing long period pulsations on the poleward portion of this oval. Equatorward phase motion is observed and supports the theory presented here. These observations illustrate that Pc 5 pulsation activity can be more complicated than thought previously, and can occur at locations not in the dipole-like region as is commonly supposed. The concepts presented in this paper provide a powerful framework with which to interpret observations related to auroral arcs, substorms and magnetospheric equilibria.

EXCITATION OF RESONANT ALFVEN WAVES IN THE MAGNETOSPHERE BY NEGATIVE ENERGY SURFACE WAVES ON THE MAGNETOPAUSE

M.S. RUDERMAN and A.N. Wright (both at School of Mathematical and Computational Sciences, University of St. Andrews, St Andrews, Fife KY16 9SS, Scotland, U. K.)

The instability of the magnetopause caused by the resonant interaction of a negative energy surface wave with Alfven waves localised in the vicinity of the resonant magnetic surface is considered. The most important property of this instability is that it takes place for flow velocities in the magnetosheath below the Kelvin-Helmholtz (KH) threshold velocity, i.e., when there is no KH instability of the magnetopause. The magnetopause is modelled by an MHD tangential discontinuity with a magnetic-free plasma on the magnetosheath side and cold plasma on the magnetospheric side. It is shown that one of the two surface waves that propagate along the discontinuity when the shear velocity is smaller than the KH threshold velocity is a negative energy wave when the shear velocity is larger than a critical velocity. This negative energy wave propagates tailward in the magnetospheric frame, although it propagates sunward in the magnetosheath frame. When, in addition, a resonant condition is satisfied, the negative energy surface wave resonantly interacts with localized Alfven waves. This interaction results in growth of both the surface wave and the Alfven waves. The resonant condition can only be satisfied when the plasma density increases and, consequently, the Alfven velocity decreases in the direction toward the magnetopause in its vicinity. The increment of the resonant instability is calculated under the assumption that the plasma density changes only in a slab in the vicinity of the magnetopause with the thickness much smaller than the wavelength. The possible observational signatures of the resonant instability are discussed.

THREE-DIMENSIONAL SIMULATIONS OF POLOIDAL AND COMPRESSIONAL PC4-5 MAGNETOSPHERIC WAVES

Richard E. DENTON and Mary K. Hudson (Department of Physics and Astronomy, 6127 Wilder Lab, Dartmouth College, Hanover, NH 03755, USA, e-mail: richard.denton@dartmouth.edu); Elena V. Belova (Princeton Plasma Physics Laboratory, Princeton, NJ 08543, USA, e-mail: ebelova@pppl.gov).

A three-dimensional hybrid MHD/gyrokinetic simulation code has been constructed in order to study the self consistent generation and effects of wave-particle induced poloidal and compressional Pc 4-5 magnetospheric waves. These are global scale Alfven-like waves with large azimuthal mode number; they are usually thought to be driven by a combination of the drift mirror and drift bounce resonance modes. In the simulation, the high energy ring current is represented as gyrokinetic particles, while the bulk plasma is represented by MHD-like equations. A nonlinear delta f scheme is used to reduce the numerical noise. Our model uses cylindrical co-ordinates with the magnetic field along the direction of the gradient in the polar angle. This allows inclusion of the radial variation of fields and curvature without the complications of dipole geometry. Results to date will be presented.

AN EXPLANATION OF THE PC5 PULSATION POLARIZATION PUZZLE OBSERVATION AT SOUTH POLE STATION

E.A. Bering (1), P. NENOVSKI (2) ((1)Space Physics Department, University of Houston, Houston, (2)Geophysical institute, Bulgarian Academy of Sciences, Sofia)

The Bering et al's experiment during the austrial summer 1985-1986 (1995) has revealed a strange opposite handedness in Pc5 pulsastion electric and magnetic field polarization. This experimental puzzle proves to be unexplained till now. The main peculiarities comes from the fact that while the magnetic field polarization remains practically unchanged, the electric field changes its polarization when the South Pole station crosses the local noon (1330 UT). This polarization reversal is closely related to the auroral Pc5 pulsation phenomenology seen at dawn and dusk meridians. The Pc5 pulsation magnetic field polarization at cusp latitudes seems to behave differently. Two explanations of this discrepancy are suggested. The first suggests a coexistence of waves of different nature/polarizations and different wavelengths. The second - compressional/magnetosonic waves event. The latter are of left-hand polarization before noon and of right-hand after noon similar to the usual high-latitude Pc5 pulsations. According to the Nenovski's polarization model (1994) the ionosphere in the southern hemisphere should induce a considerable right-hand polarization effect. This polarization effect reduces/increases the initially left/right-hand polarization. A situation exists when the initial Pc5 pulsation left-hand polarization cannot cancel the right-hand effect from the ionosphere. Then the magnetic field polarization at the ground appears to be opposite to the initial. We have examined both the ionosphere/atmosphere and the wave parameter conditions under which such an effect could take place. The ice-ground conditions are also considered.

POLAR CUSP PC3-5 RANGE GEOMAGNETIC PULSATIONS TRIGGERED BY SSC

KLEIMENOVA N.G., Kozyreva O.V., Bitterly M., Short J.-J.

The digital 2-second and 1-minute data at antarctic observatory Dumont d`Urville ("=80.5ø) for 36 daytime and 9 night SSC events in quit geomagnetic activity have been analyzed. It was found that all of the SSC events as usual were accompanied by long period (1-5 mHz) and two narrow bands of Pc4 (~8-11 mHz and ~18-20 mHz) geomagnetic pulsations. In daytime Pc3 (25-60 mHz) could be also exited. The SSC occurrence leads to subsequent long lasting (several hours) continue "regime" of these irregular pulsations in which the Pc4 and Pc3 wave packets are noncoherent in time and shape. But the simultaneous Pc4 wave packets near cusp and at subauroral Kerquelen station located about 120ø to the West have been found. We suppose that Pc4(SSC) pulsations represent the global cavity mode and Pc3`s are connected with different local sources at cusp and subauroral latitudes.

GA3.04/W/42-B1 Poster **1520-38**

A PC5 ULF WAVE WITH LARGE AZIMUTHAL WAVENUMBER OBSERVED WITHIN THE MORNING SECTOR PLASMASPHERE BY SAMNET

G.CHISHAM (British Antarctic Survey, Cambridge, UK); I.R.Mann (Department of Physics, University of York, York, UK)

We present details of an unusual Pc5 ULF wave with a large azimuthal wavenumber (m) which is observed within the plasmasphere by ground-based magnetometers. In a previous statistical study, 129 Pc5 events were identified at mid-latitudes by the U.K. Sub-Auroral Magnetometer Network (SAMNET), but only three displayed large azimuthal wavenumbers (m>10). Analysis of the variation of wave parameters during one of these events using a novel complex demodulation technique is presented. The technique reveals the temporal variation of wave characteristics including the azimuthal wavenumber and wave frequency, and allows us to study the azimuthal dispersion characteristics of the wave and estimate the azimuthal phase and group speeds. The method used to estimate the azimuthal wavenumbers resolves the ambiguity resulting from aliasing, which can occur for large-m waves observed at stations more than one azimuthal wavelength apart. The drift-bounce resonance mechanism is discussed as a possible wave excitation mechanism for this event, and resonance with H+ and/or O+ ions at the inner edge of the ring current is presented as a possible excitation scenario.

DAYSIDE MAGNETOPAUSE ULF WAVES OBSERVED BY GEOTAIL

Tohru SAKURAI, Yutaka Tonegawa, Takuya Kitagawa (Department of Aeronautics and Astronautics, School of Engineering, Tokai University, 1,117 Hiratsuka 259-1292, Japan, e-mail: sakurai@ms.u-tokai.ac.jp); Kiyofumi Yumoto (Department of Earth and Sciences, Kyusyu University, 6-10-1 Hakozaki, Fukuoka 812-8581, Japan, e-mail: yumoto@geo.kyusyu-u.ac.jp); Susumu Kokubun (Solar Terrestrial Environmental Laboratory, Nagoya University, 3-13 Honohara, Toyokawa 442-8507, Japan, e-mail: kokubun@stelab.nagoya-u.ac.jp); Toshifumi Mukai, Koichiro Tsuruda (both at The Institute of Space and Aeronautical Science, 3-1-1 Yoshinodai, Sagamihara 229-8510, Japan, e-mail:mukai@stp.isas.ac.jp)

The Geotail satellite took the orbits of skimming the dayside low-latitude magnetopause since December 1994. These orbits present a good opportunity for the study of excitation and propagation of ULF waves near the dayside magnetopause. The instrumentation on board Geotail is good for such a task since the satellite measured simultaneous magnetic, electric fields and low-energy plasma. Based on these data we have studied the excitation and propagation characteristics for the ULF waves, Pc3/4 and Pc5. The most interesting study concerns Poynting fluxes for both modes of resonance and propagation of these ULF waves.

GA3.04/W/01-B1 Poster **1520-40**

PROPAGATION OF PC3-4 PULSATIONS AT HIGH LATITUDES

Tim A. Howard and Fred W. MENK (both at Department of Physics, CRC for Satellite Systems, University of Newcastle, Callaghan, NSW, 2308, Australia, e-mail: physpuls3@cc.newcastle.edu.au)

It is well known that at high latitudes field line resonances (FLRs) fall in the Pc5 (<7 mHz) range, and that the Pc3-4 (7-50 mHz) range includes burst-like signals with very short coherence lengths. However, the generation and propagation mechanisms of stable, sinusoidal Pc3-4 pulsations at these latitudes have not yet been established. Using 19 stations of the Arctic IMAGE magnetometer array, we have examined the variation in amplitude, phase and coherence with latitude and longitude for Pc3-4 waves seen across the entire array. Amplitudes decreased exponentially with decreasing latitude and frequency of the pulsations was closely related to the strength of the IMF and the solar wind cone angle. High coherence was observed over large spatial distances. There is no evidence that these Pc3-4 pulsations are harmonics of FLRs. The interstation meridional and azimuthal phases, when mapped into the equatorial plane of the magnetosphere, relate to fast mode waves propagating Earthward and away from the noon meridian. Accordingly, we believe the pulsations are due to forced field line oscillations driven by inward propagating compressional waves generated in the upstream solar wind.

CHARACTERISTICS OF PI2 MAGNETIC PULSATIONS OBSERVED AT THE CPMN STATIONS: A REVIEW OF THE STEP RESULTS

Kiyohumi YUMOTO (Department of Earth and Planetary Sciences, Kyushyu University 33, Fukuoka 8912-8581, Japan, Email: yumoto@geo.kyushu-u.ac.jp),The CPMN group.

From analyses of magnetic data from the CPMN stations, we can find the following observational results; (1) Pi 2 magnetic pulsations observed on the ground are an ensemble of various hydromagnetic modes excited at high, middle, low and equatorial latitudes. Each mode exhibits its own propagation (timing) and spatial illumination. (2) Although there are

apparent longitudinal propagation and latitudinal time delay of Pi 2's, the difference of the timing of maximum Pi 2 wave energy among the CPMN stations is within 100sec in the latitudinal and longitudinal directions. (3) When a low-latitude single station is located in the sector of 00-24 hr LT, 20-03 hr LT, and 23-01 hr LT, respectively, 62%, 79%, and 100% of auroral breakups identified by the POLAR satellite have associated Pi 2's. 66% of the low-latitude Pi 2's occur within 1 min of the auroral breakups, and 85 Bs (B within 2 min). It is concluded that when a ground single station is located at the midnight sector of 23-01 LT, we can see almost 100% one-to-one correspondence between auroral breakups and low-latitude Pi 2's. But the ground station is located outside the midnight sector, we can expect only 60-80% correspondence of the relation with 1-2 min time delays of Pi 2 onsets to auroral breakups. The Pi 2's is still a good indicator of substorms, however, the use of them should be with care.

PROPAGATION MECHANISM OF PRELIMINARY REVERSE IMPLUSE OF SC/SI

Kentarou KITAMURA and Kiyohumi Yumoto (both at Department of Earth and Planetary Sciences, Kyushu University, 6-10-1 Hakozaki, Fukuka, Japan, E-mail: kentarou@geo.kyushu-u.ac.jp); the CPMN Group (E-mail: yumoto@geo.kyushu-u.ac.jp)

A negative impulse just before onset of sc/si main impulse, called PRI (Preliminary Reverse Impulse), is often observed on the ground in daytime. PRI is considered to be caused by a twin-vortex type ionospheric current (DP-field), which is generated by the electric field penetrating into the polar ionosphere, during a compression of the magnetosphere by passage of the interplanetary shock or discontinuity. In this paper, characteristics of sc/si magnetic variations are studied to investigate propagation mechanism of PRI of the DP-field. By analyzing the magnetometer network data along the 210 deg. magnetic meridian, we can get some new aspects of magnetic variations of the DP-field. A good linear relation is found between the peak time when the negative impulse of PRI is maximum and the ratio of negative impulse (PRI range) to the step-like variation (DL-field range). The latitudinal delay of the PRI peak time had been explained by using the signal propagation of sc/si from high latitude to the equatorial region. However, the present result indicates that the latitudinal time delay of PRI apparently appears in the relation of the ratio between.

LONGITUDINAL PROPOGATION CHARACTERISTICS OF PI2

UOZUMI, T. (Dept of Earth & Planetary Sciences, Kyushu University, Japan.
Email: uozumi@geo.kyushu-u.ac.jp)

To examine longitudinal propagation characteristics of Pi 2 observed in auroral and low-latitude regions, magnetic energy variation defined as dH^2 + dD^2 + dZ^2 were calculated for Pi 2 events occurred during the interval between Feb.11th to Mar.31st 1996. And the time when the variation of energy became maximum and their magnitude were compared among stations. The main results of statistical analysis are summarized as follows (1) In the auroral region, the Pi 2 wave energy shows the maximum at the pre-midnight meridian (PMM). And the eastward and westward propagations are recognized in the dawn and dusk sector, respectively. (2) The longitudinal dependence of amplitude in the auroral region become approximately exp(-x^2), where x is the difference of longitude measured from the PMM. (3) At higher latitude in the auroral region (Kotel'nyy : phi=69.94), Pi 2 wave energy become the maximum earlier than at lower latitude stations (Kotzebue : phi=64.52, Chokurdahk : phi= 64.67). (4) In low-latitude stations at Kagoshima (L=1.22) and Ewa beach (L=1.17), it is recognized that eastward Pi 2 propagation in dawn sector, on the other hand, westward propagation is not clear in dusk sector.

PROPAGATION OF GEOMAGNETIC SUDDEN COMMENCEMENT (SC)

T. ARAKI (Dept. of Geophysics, Graduate School of Science, Kyoto Univ., Kyoto 606-8502, Japan, e-mail: araki@kugi.kyoto-u.ac.jp); K. Yumoto (Dept. of Earth Science, Faculty of Science, Kyushu Univ., Fukuoka 812-81, Japan); K. Shiokawa (STE Lab., Nagoya Univ., Toyokawa 442-8507, Japan); D. Orr and Physics, Univ. of York, York Y01 5DD, UK.)

The geomagnetic sudden commencement (SC) is initiated by an eastward magnetopause current increase due to sudden compression of the dayside magnetosphere. It is transmitted to the day side equatorial ionosphere by a compressional HM wave with an averaged speed of about 600 km/sec. A westward electric current flows in the equatorial ionosphere to shield the magnetic field increase on the ground and initial rise may apparently delay from that of above the ionosphere. The compressional HM wave propagates from day side to night side above the ionosphere with a time delay of 20-40 sec and causes night side SC on the ground. There is another mode of instantaneous transmission from day side to night side in the space between the ionosphere and the ground. This mode is nearly evanescent and does not transmit much energy. If the onset of SC is sufficiently sharp, however, detectable geomagnetic increase is observed almost simultaneously both in day side and night side. These characteristics of SC propagation is described by showing results of data analysis.

THEORY OF LOCALIZED RESONANT OSCILLATIONS IN THE NIGHTSIDE MAGNETOSPHERE EXCITED BY TIME-DEPENDENT PARALLEL CURRENTS OVER THE AURORAL IONOSPHERE

A.E. ANTONOVA, Yu. I. Gubar' and A.P. Kropotkin (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia)

Theory of transverse-small-scale Alfven resonant waves is modified in order to use it for substorm phenomena modeling. Poloidal disturbances are considered, for which field-aligned currents are of substorm origin (belong to the substorm current wedge system), and polarization corresponds to the effects of magnetic "dipolarization" and increased plasma radial convection. Nonresonant components of the substorm disturbance in the near-Earth portion of the magnetotail plasma sheet are assumed to serve as an external source for Alfven resonance generation. This occurs in the form of "extraneous" field-aligned currents on the poloidal resonant surfaces (PRS) arising due to spreading over the ionosphere of those disturbances which are brought there from the dipolarization region. Nonresonant constituent of the impulsive disturbance with continuum frequency spectrum excites simultaneously and in a coherent manner a lot of resonances at different PRS. During radial propagation, different resonant waves overlap, and their phase velocity differences result in phase mixing leading to the disturbance amplitude decrease without dissipation in the ionosphere.
Results are applied to interpretation of the time-dependent substorm current wedge and Pi 2 pulsations. Another application is related to intense short-term inductive electric field of the resonant disturbance. Such a field may effectively accelerate energetic particles. Analysis of observational data (Baker and Pulkkinen, 1998) suggests that strong low-frequency (2-20 mHz) waves may be indeed responsible for such acceleration.

ION CYCLOTRON WAVES IN JUPITER'S MAGNETOSPHERE

Panagiota PETKAKI and M. K. Dougherty

Magnetometer data from the Ulysses Jupiter flyby is examined, and in particular middle magnetosphere observations near the magnetodisk. Ion cyclotron waves are searched for in the heavy ion gyrofrequency regime (SO^+_2, SO^+, S^+, O^+ and S^{++}). Power spectral peaks in the ion cyclotron frequency range in the Ulysses magnetometer data have been found in the past. Here we thoroughly examine the high resolution 1 sec data, with ion cyclotron waves signatures being observed on several occasions both close to the magnetic equator and at some distance from it. Rippling and warping of the magnetodisk, as observed by Ulysses, could be the cause of such ion cyclotron signatures arising some distance from the magnetic equator. Lower mass ions are observed further away from the planet and the heaviest mass ion signatures only appear close to the Io torus. Polarisation analysis of the observations are also presented and theoretical implications of the wave signatures discussed.

POLAR SPACECRAFT OBSERVATIONS OF ELECTRIC ULF WAVES

J. H. CLEMMONS, F. S. Mozer, Berkeley, H. Laakso, R. F. Pfaff, P. J. Chi, C. T. Russell,

Fields measurements from the Polar spacecraft of magnetospheric ultra-low frequency (ULF) waves in the Pc3-5 frequency range are analyzed to provide new insights into the properties and evolution of the waves. Polar's high altitude, high-inclination orbit gives a new perspective on the waves, and the combination of electric and magnetic measurements provides a powerful analysis tool for the determination of wave nodal structure, standing wave character, polarization, and energy flow. Results from a survey of more than two years of Polar data are presented. Preliminary analyses indicate that power in the electric component is peaked near noon, with lower frequencies having narrower peaks. In keeping with previous results from geosynchronous orbit, the electric component generally has more power in the azimuthal direction than in the radial direction, indicating the prevalence of poloidal modes. Further analyses and comparison to the magnetic perturbations are discussed.

ULF/VLF/ELF OBSERVATIONS DURING THE SOLAR TOTAL ECLIPSE.

Keyun TANG, Fenglin Peng, Zuoli Ning and Shaofeng Yang, Y.Tanaka and K.Yumoto

During the period around the total solar eclipse of March 9, 1997, coordinated observations including optical, radio, gravity, acoustic, ionospheric, geomagnetic, ULF/VLF waves observations, as well as Schumann Resonance bservation were conducted in Mohe area near the north-east border between China and Russia.
Pi 2 and Pc 4 geomagnetic pulsation were observed. Obvious jumps during the solar eclipse could be found. Polarization analyses were completed, and we found that mirror effects of polarization orientation for Southern Hemisphere and Northern Hemisphere were destroyed. Observations of VLF waves show a clear decreasing on amplitude during the solar eclipse. We had also measured the frequency and amplitude variations of the first Schumann resonance mode. The records and analyses show significant variations away above the usual daily variation. On March 9, 1997, the day of the solar eclipse occurred, the amplitude of the first SR mode dropped dramatically. For the three-quarters just after the first contact, the amplitude dropped 94%, and reached the minimum at the middle eclipse, then gradually recovered to the normal level at the last contact. The amplitude variation of the first SR mode was well consisted with the solar eclipse process. We could conclude that the significant amplitude variation of the first SR mode was caused by the solar eclipse process. The measurements during the total solar eclipse suggest us that the local ionosphere environment is very important to influent the propagation and receiving of SR waves. A model to describe the propagation mechanism of SR waves will be discussed.

ULF WAVES AND THE INDUCTIVE IONOSPHERE

Akimasa. YOSHIKAWA (Department of Earth and Planetary Sciences, Kyushu University, Hakozaki, Fukuoka 812-8581,Japan, e-mail: yoshi@geo.kyushu-u.ac.jp)

Natures of reflection and mode conversion of MHD waves at the inductive ionosphere are investigated. The most important view obtained in the course of study was the "divergent Hall current" (DHC), which directly closes the FAC in the ionosphere. It is well known that when a shear Alfven wave is incident on the ionosphere, the 90 degree rotation of the wave's magnetic field across the ionosphere is caused by the Hall effect. The rotation is a guiding principle in the diagnostics of geomagnetic pulsations at high latitudes. However, such a rotation is only a result of one-step mode conversion. On the other hand, the DHC is an ionospheric divergent current driven by the rotational electric field that is produced as a result of multi-step mode conversion between divergent and rotational electric fields arising from the Hall effect in the ionosphere. The DHC is shown to be a primary source of physical phenomena arising from the multi-step mode conversion. The ionospheric currents associated with the ULF pulsations at the inductive ionosphere are almost borne by Hall current both rotational and divergent parts in quantity, and causes a frequency shift and horizontal dispersion of standing field line oscillation. In this paper, various aspects of the DHC are analyzed and its physical background is elucidated.

PHASE STRUCTURE OF DAMPING STANDING ALFVÉN WAVES IN THE MAGNETOSPHERE

Margaret KIVELSON (Department of Earth and Space Sciences and Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095-1567, USA, e-mail: mkivelson@igpp.ucla.edu); David J. Southwood (European Space Agency, Headquarters, 8-10 rue Mario-Nikis, F75738 Paris Cedex 15, France, e-mail: dsouthwo@hq.esa.fr)

There are various damping mechanisms for magnetospheric Alfvén waves. The most significant damping mechanism for the waves is usually absorption in the ionospheres at the feet of field lines. We work through a simple model of damped standing waves and use it to

investigate the changing phase relations between electric and magnetic perturbations along the background field. We show how the phase variation relates to the energy flux into the ionosphere. The work not only improves our understanding of the behaviour of magnetospheric waves, but also explicitly characterises key aspects of eigenoscillations of the system. In an era when correlations between ground and space are common and can be critical elements in timing geophysical phenomena, it is important to understand this aspect of the field-aligned structure.

GA3.04/E/06-B2 0950

INFLUENCE OF IONOSPHERIC CONDUCTIVITY ON MIDDLE AND LOW LATITUDE PC3-4 PULSATIONS

Nadezhda YAGOVA, Viacheslav Pilipenko, Evgenij Fedorov (Institute of the Physics of the Earth, Moscow 123810, Russia, e-mail: vpilipenko@uipe-ras.scgis.ru); Kiyohumi Yumoto (Kuyshu University 33, Fukuoka 812-81, Japan, email: yumoto@geo.kyushu-u.ac.jp)

Longitudinal and latitudinal variations of the parameters of the magnetospheric Alfven resonator have been calculated using a semi-empirical model of the ionosphere-magnetosphere plasma distribution. The calculated values of damping rates of Alfven oscillations at mid-latitudes during the dark period are too high for the "free-end" and "quarter-wave" oscillation regimes to be realized. At low latitudes relatively high quality factors are expected both at day and night-time conditions. A drastic change of a field-aligned structure of Alfven oscillations during the transition from day-side to night-side ionospheric conditions might not happen due to conjugated variations of plasma density in the ionosphere and in the magnetosphere. The analysis of the experimental data recorded at middle and low latitude stations of the "210 Magnetic Meridian" magnetometer network and the station l'Aquila gives the following results: (a) the pulsation amplitude in a frequency band near fundamental harmonic of Alfven field line resonance has the strongest dependence on the ionospheric conductivity; (b) the influence of day/night ionospheric conditions on the Pc3 amplitudes at low geomagnetic latitudes is weaker in comparison with the one at mid-latitudes; (c) the ionospheric conductivity control of the Pc3 amplitude at middle latitudes weakens with the harmonic number. The experimental observations are in accordance with the predictions of the numerical model.

HIGH-LATITUDE OBSERVATIONS OF ULF WAVES WITH LARGE AZIMUTHAL WAVENUMBERS

T. K. YEOMAN, D. M. Wright (Department of Physics and Astronomy, University of Leicester, University Road, Leicester, LE1 7RH, U.K.); A. B. Stockton-Chalk (School of Physics and Astronomy, University of Birmingham, Edgbaston, Birmingham, B15 2TT)

DOPE (The Doppler Pulsation Experiment) is an HF Doppler sounder deployed at Tromsø, Northern Norway for the investigation of the ionospheric signatures of ULF wave phenomena of magnetospheric origin. This high-latitude Doppler sounder has been demonstrated to be a highly sensitive instrument for the investigation of ULF waves of large azimuthal wavenumber. These waves are assumed to be driven by magnetospheric wave-particle interactions, and are difficult to study by other means due to their strong spatial integration between the ionosphere and the ground. The occurrence and characteristics of these waves will be discussed, and their ground and ionospheric characteristics compared for various values of azimuthal wavenumber.

GA3.04/L/12-B2 Invited 1100

PI2 PULSATIONS

Prof. Margeret KIVELSON

Pi 2 pulsations (impulsive signals with periods of 40-150 seconds) are widely used to time substorms and to track geomagnetic activity. Despite the utility of this type of pulsation for substorm studies, the mechanisms that generate the wave signals is not well established. We present the first detailed observations that directly relate Pi 2 pulsations to flow bursts in the magnetotail. We describe the steps in the generation of mid- and low-latitude Pi 2 pulsations by flow bursts. On the ground, the first indication of activity is a linearly increasing (precursor) perturbation that lasts ~90 seconds, which is due to inward convection from the distant magnetotail. An abrupt change of slope of the analyzed wave amplitude corresponds to the true start of the wave signal. Mid-latitude Pi 2 are generated when the flow reaches the inner magnetosphere, where it is braked by the rapidly rising magnetic pressure. Pulsations arise from the transient response of the ionosphere to currents generated by the braking. The braking also generates compressional waves that directly drive low-latitude (monochromatic) Alfvenic oscillations. We show that low-latitude, flank Pi 2s are directly correlated with temporal oscillations of the flow velocity, delay

GA3.04/W/32-B2 1130

PI2 PULSATIONS IN THE THREE-DIMENSIONAL DIPOLE MAGNETOSPHERE

Dong-Hun LEE (Dept of Astronomy & Space Science, Kyung Hee University, Yongin, Kyunggi, 449-701, Korea, e-mail: dhlee@nms.kyunghee.ac.kr); Robert L. Lysak and Yan Song (School of Physics and Astronomy, University of Minnesota, 116 Church St. SE, Minneapolis, MN55455, USA, e-mail: bob@aurora.space.umn.edu, yan@aurora.space.umn.edu)

Pi2 pulsations have been numerically studied in a new 3-D dipole model, which allows a realistic Alfven speed profile for the plasmasphere and outer magnetosphere in the tailward region. This model includes a reasonable inner/outer boundary condition, which is differentiated from the previous numerical models. When an impulse associated with the substorm onset is assumed, we investigate how Pi2 modes are developed in time as well as how field-aligned currents are produced and distributed over the whole nightside magnetosphere. The results are compared with current theoretical and observational characteristics. The effects of non-axisymmetric geometry around the tailward magnetosphere have also been examined and discussed in detail.

GA3.04/E/12-B2 1150

UARS OBSERVATION OF A PI2 PULSATION AT 600 KM ALTITUDE

Kazue TAKAHASHI and Brian J. Anderson (both at Johns Hopkins University Applied Physics Laboratory, Laurel, MD 20723-6099; e-mail: kazue.takahashi@jhuapl.edu); James B. Gary (University of Texas at Dallas, e-mail: gary@utdallas.edu); Kiyohumi Yumoto (Department of Earth and Planetary Sciences, Kyushu University; e-mail: yumoto@geo.kyushu-u.ac.jp)

Satellites in low-altitude orbits provide unique opportunities to study the ionospheric screening effects on ULF waves propagating from the magnetosphere. This paper reports an observation of a Pi2 pulsation at an altitude of approximately 600 km from the Upper Atmosphere Research Satellite (UARS). The Pi2 pulsation occurred on November 18, 1993 when the satellite was over the western Pacific near the three ground magnetometer sites, Chichijima (L = 1.14, MLT = 23), Ewa Beach (L = 1.17, MLT = 03), and Guam (L = 1.07, MLT = 23). On the ground the Pi2 was visible in the H component from 1337 to 1343 UT at all locations with the same period of 43s but with an amplitude ranging from 3 nT (Guam) to 1 nT (Ewa Beach). At the satellite the same pulsation was detected in the northward component (parallel to the ground H component) of the magnetic field with an amplitude of 3 nT. The phase delay between space and ground was very small. Overall, the wave observed by UARS appear to have reached the ground with little modification in amplitude and polarization. The results support the idea that low-latitude Pi2 pulsations originate from fast mode oscillations in the inner magnetosphere.

GA3.04/L/13-B2 1210

CPMN GROUP, LOCAL TIME DEPENDENCE OF PI2 PULSATIONS; A STATISTICAL STUDY

Li Yan and Kiyohumi YUMOTO (both at Department of Earth and Planetary Sciences, Kyushyu University 33, Fukuoka 8912-8581, Japan, Email: yumoto@geo.kyushu-u.ac.jp), The CPMN group

Local time dependence of Pi 2 pulsations is studied statistically using the 210 MM data at the various latitudes. 249 Pi 2 events are recognized in one month data of February, 1995. 68% Pi 2 events are observed at night time within this month at a low-latitude station MSR. For both occurrence and wave amplitude, there are three maxima at premidnight, slightly post midnight, and prenoon; two minima at late afternoon and just after sunrise. The three maxima decrease at significantly different rate with decreasing latitude. The wave frequency show different contents and different local time dependence at auroral latitude and mid- to low-latitudes. Mid- and low-latitude Pi 2'~'have an additional frequency component than auroral-latitude Pi 2's. The local time dependence of the "equatorial enhancement" is also obtained, which agrees with previous studies at most local time except for the large ratio in the few hours after sunrise that has not been reported.

DIAGNOSING PC5 MAGNETOSPHERIC WAVEGUIDE MODE EXCITATION MECHANISMS

I.R. MANN (Dept. of Physics, University of York, Heslington, York, YO10 5DD, U.K., email: ian@aurora.york.ac.uk) A.N. Wright (Mathematical Institute, University of St. Andrews, St. Andrews, Fife, Scotland, KY16 9SS, U.K., email: andy@dcs.st-and.ac.uk)

We show how the compressional modes supported by a waveguide with a free magnetopause boundary have characteristics which are strongly local time and solar wind speed dependent, being either leaky, trapped, or energised by magnetopause instabilities. These waveguide modes are believed to excite Pc5 field line resonances (FLRs) in the magnetosphere. We show how the characteristics of the resulting FLRs can be used to probe the energy sources responsible for driving the compressional waveguides modes, and hence be used to determine the pathway for energy transport from the solar wind to the resonances. In particular, the characteristics of multiple harmonic FLRs can be used to diagnose their energy sources and to distinguish between resonances excited by solar wind non-uniformities or through the development of magnetopause instabilities. Using observations previously reported in the literature, we show examples of this diagnostic analysis and conclude that the dawn/dusk asymmetry in Pc5 FLR characteristics may be linked to different excitation mechanisms operating either side of noon. In particular, we suggest that the majority of dawn-side FLRs may be excited by waveguides modes which are amplified through the development of instabilities on, and through the action of over-reflection at, the magnetopause. Wave excitation by this mechanism generates a spectrum displaying preferred azimuthal wavenumbers, similar to that observed, and which is previously unexplained. Moreover, this mechanism is likely to generate quarter-wavelength modes which have lower frequencies than the standard (magnetopause velocity node) half-wavelength modes. This may provide an explanation for the very low (millihertz) eigenfrequency spectrum required to drive the FLRs which are observed at these frequencies by HF radars and ground-based magnetometers, especially on the flanks.

GA3.04/W/38-B2 1430

COUPLING BETWEEN FIELD LINE RESONANCES AND LEAKY CAVITY MODES

A.D.M. WALKER (University of Natal, Durban)

If a wave is incident on the magnetopause from the solar wind then, if its frequency matches that of a leaky cavity mode, it is captured and causes oscillation of the cavity mode. If its frequency does not match a cavity mode frequency then it is essentially reflected from the magnetopause without penetrating the magnetosphere. Those waves which are captured may excite field line resonances. The mechanism of this process is discussed using WKBJ methods and other analytic techniques. This approach, while only approximate, has the advantage of allowing easy visualisation of the physical processes.

GA3.04/L/15-B2 1450

PC5 ULF PULSATIONS ASSOCIATED WITH WAVEGUIDE MODES OBSERVED WITH THE IMAGE MAGNETOMETER ARRAY

R. A. MATHIE, I. R. Mann, Department of Physics, University of York, York YO10 5DD, England, (e-mail: rod@aurora.york.ac.uk; ian@aurora.york.ac.uk); F. W. Menk, Department of Physics, University of Newcastle, Newcastle, NSW 2308, Australia. (email: physpuls3@cc.newcastle.edu.au); D. Orr, Department of Physics, University of York, York YO10 5DD, England, (e-mail: david@aurora.york.ac.uk)

Several recent publications have reported high latitude radar observations of field line resonances (FLRs) displaying discrete and very stable frequencies in the Pc5 range. It is believed that these quantized frequency FLRs may be associated with cavity/waveguide harmonics of the outer magnetosphere but the prevalence and reported stability of the frequencies remain controversial. We examine the statistics of 137 Pc5 pulsation events identified from three months of IMAGE magnetometer data and show that these discrete frequencies are also prominent in ground-based data. We also examine amplitude, phase and polarization characteristics and show that these FLRs have features which are strongly local time dependent.

GA3.04/W/07-B2 **1510**

HIGH-LATITUDE ULF WAVES OBSERVED BY THE POLAR SPACECRAFT

P J CHI, C T Russell and G Le (All at Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095, USA; e-mail: pchi@igpp.ucla.edu); J H Clemmons (Aerospace Corporation, El Segundo, CA; e-mail: James.H.Clemmons@aero.org)

High-latitude ULF waves have been extensively studied by ground-based observations but very few ULF-wave studies have been made at these latitudes in the magnetosphere. The Polar satellite provides such an opportunity. The polar cusp is a region rich in ULF waves coming from the magnetopause and boundary layer. The cusp is also thought to be an entry point for waves generated beyond the magnetopause, at the bow shock or in the magnetosheath. To better understand the characteristics of high-latitude ULF waves, we conduct a statistical survey of the occurrence of ULF waves observed by Polar MFE instrument. Continuous wavelet analysis is applied as an objective tool for selecting wave events in one full year of MFE data. Our results show that transverse Pc3 waves are dominant near the cusp region. However, compressional Pc3 waves are more likely to occur in the subsolar magnetosphere. This is consistent with our previous case study which suggests that, in the region near the cusp, the ULF Poynting flux propagates mainly along the field lines and the wave energy does not appear to propagate directly from the cusp into the magnetosphere across field lines. Transverse waves also occur at different L-shells that are consistent with the field line resonance picture. Compressional Pc5 waves have a high occurrence rate on the tail field lines at high latitudes, and they may be caused by perturbations on the magnetospheric boundaries.

GA3.04/L/16-B2 Invited **1600**

LOW FREQUENCY GEOMAGNETIC FIELD FLUCTUATIONS AT A LOW LATITUDE STATION

U. VILLANTE, P. Francia (both at Dipartimento di Fisica, Universita' de L'Aquila, Italy, E-mail: umberto.villante@aquila.infn.it) and S. Lepidi (Istituto Nazionale di Geofisica, Roma, Italy)

The power spectral analysis of the geomagnetic field fluctuations at a low latitude station (L'Aquila, Italy, IGRF95 geomagnetic coordinates 36.2N, 87.5E) shows statistical evidence at discrete frequencies for daytime power enhancements which become more clear during periods characterized by higher solar wind speed. These power enhancements occur at frequencies which approximately correspond to those detected at auroral latitudes both in the F-region drift velocities and in the ground geomagnetic field fluctuations and generally interpreted in terms of field line resonances set up by magnetospheric cavity/waveguide compressional modes driven by external stimulations.
Case studies of selected events show that fluctuations at the same discrete frequencies are observed in correspondence to the Earth's arrival of solar wind pressure pulses. A comparison with observations performed at an Antarctic high latitude station shows that on these occasions the discrete modes appear simultaneously at both stations approximately at the same frequencies. The appearance of similar features at a wide latitudinal and longitudinal separation suggests to interpret these events in terms of global oscillations of the whole magnetosphere. Moreover, the polarization pattern is consistent with an antisunward propagation.

GA3.04/W/43-B2 **1630**

FIELD LINE RESONANCES AND WAVEGUIDE MODES AT LOW LATITUDES: OBSERVATIONS

Fred W. MENK, Colin L. Waters and Brian J. Fraser (all at Department of Physics, CRC for Satellite Systems, University of Newcastle, Callaghan, NSW, 2308, Australia,
e-mail: physpuls3@cc.newcastle.edu.au)

Although Pc 3-4 ULF pulsations are commonly observed at low latitudes, many of their features are poorly understood. A 12-station magnetometer array was operated in eastern Australia specifically to examine these aspects. The following have been investigated and will be discussed: the variation in field line eigenfrequency with latitude, and hence the significance of ionospheric heavy ions; the scale size, Q and damping of the field line resonances; and the propagation characteristics of ULF waves below the local resonance frequency. A remarkable feature of the observed power spectra is the presence of multiple closely spaced peaks across the entire latitude range. The Pc 3-4 pulsations are probably due to field line oscillations driven by incoming compressional mode waves which excite cavity or waveguide modes in the magnetosphere.

GA3.04/E/09-B2 **1650**

LOW LATITUDE PC3-4 PULSATIONS

D.R.K. Rao, B.M. PATHAN and R.S. Udare (all at Indian Institute of Geomagnetism Colaba, Mumbai 400 005, India, e-mail: bmpathan@iig.iigm.res.in)

Employing digital data on ULF geomagnetic pulsations from three latitudinal stations in the Indian longitudinal region, few spatial characteristics of Pc3-4 are studied. Different techniques of analysis on the three identified frequency bands of pulsation signals have been used. At the lowest frequency band (102 to 47 sec), the amplitudes of the signal in both NS and EW directions in the horizontal plane, are noticed to be highly subdued at a station far away from the equatorial electrojet influence as well as the Sq focus. The identified cross phase (or time delay) between the latitudes of extreme northern and southern stations has yielded two frequencies at 35 and 50 mHz,by Gradient technique. The validety of 35 mHz cross phase is discussed in terms of excitation by a broad band source and propagation of signal through cavity resonance mode at low and equatorial regions. The latitudinal propagation is found to be highly variable (mx or my lying between 3 and 12) and the propagation is mostly directed away from the equator. Few hodograph results towards polarization are discussed.

VALIDATION OF THE PHASE GRADIENT TECHNIQUE FOR INFERRING MAGNETOSPHERIC RESONANCES FREQUENCIES

W. GOEDECKE, Colorado School of Mines Golden Colorado, CO, USA
(email: wgoedeck@mines.edu); C. T. Russell and P. J. Chi (both at Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA, 90095-1567, USA)

Simultaneous GPS synchronized one-second triaxial magnetometer data from four stations over a range of 9 degrees in geomagnetic latitude were collected in the Western United States, at Boulder, South Park, the Air Force Academy, Los Alamos, New Mexico and Los Angeles, California. Their equivalent L shells range from 1.7 to 2.3. The ULF horizontal component is nearly unchanged from high to low L shells with the exception of broadband attenuation with some extra loss of high frequency components. Both phase difference and amplitude ratio dynamic spectra help identify resonances. The resonance was found to accentuate certain frequency bands, but the standing modes do not dominate the observed signal enough to mask the non-resonating frequencies.
The observed signal is complex, comprised of several frequencies over a time interval of several periods. The signal's center frequency shifts, not unlike a drifting frequency modulated wave, allowing resonance of several L shells. Phase skipping was also observed. There appeared to be a merging of wave periods from upper to lower L shells along with the selected attenuation of high frequency components.
Additional data have been collected from the north-south station pair in Srobarova, in the Slovak Republic, and Tihany, Hungary. These reveal times when a propagating mode occurs, that is, when the phase gradient changes proportionally with the frequency. This constant time shift independent of frequency is best revealed by a time difference plot, unlike the phase difference plot. In this case, no or appreciable resonance was found. Observatories of lower L shells generally receive the signal first, but on several days at this European pair the higher L shell observed the signal first.
During most intervals appreciable declination component pulsations were also observed, with very little phase gradient or time shift between station pairs.

ENERGIZATION OF RING CURRENT IONS AND RELATIVISTIC RADIATION BELT ELECTRONS DURING GEOMAGNETIC STORMS

J L ROEDER , J F Fennell, R S Selesnick , and J B Blake (The Aerospace Corporation, Los Angeles, CA, 90009, USA, email: James.L.Roeder@aero.org)M. Grande (Rutherford Appleton Lab, Chilton, Didcot Oxon OX11 0QX, UK)S. Livi (Max-Planck-Institute for Aeronomy, 37191 Katlenburg-Lindau, Germany)

Geomagnetic storms are known to cause the energization and transport of ions in the magnetospheric ring current. This process may be described by the change in the total kinetic energy content of the ion populations which is related to the Dst magnetic index through the Dessler-Parker-Sckopke relation. Such events also are related to the energization of relativistic electrons in the radiation belts. The electron acceleration may occur as either a very rapid injection by shock-driven induced electric fields or an increase over several days in the storm recovery phase. The observed storms have a wide range of efficiency for the energization of both ion and electrons. Using data from the Polar CAMMICE and CEPPAD instruments we characterize serveral storms according to the magnitude of the ion and the electron acceleration. We then compare the energization events with the intensity of the storms according to the magnitude and duration of the Dst variations. The kinetic energy content of the measured fluxes integrated over the inner magnetosphere is used to characterize both the ion and electron acceleration. The CAMMICE MICS instrument provides ion composition data in the energy- per-charge range of 1-200 keV/e. The CEPPAD IPS sensor extends the measured ion energy range with proton fluxes in the range 20-1500 keV. The combination of these two instruments provide excellent energy coverage of the ring current ion populations. The data from the CEPPAD HIST sensor over the energy range 0.7-7 MeV are used to characterize the relativistic electrons in the outer radiation belt. For example, the January 1997 magnetic cloud event caused a exhibited a large enhancement in the high energy electrons, but only a moderate response in Dst (-78 nT), with a corresponding increase in the ring current ions. The May 15, 1997 storm (-115 nT), in contrast, caused a more substantial ring current ion variation, but a smaller electron enhancement. The existence of pre-existing "seed" populations in the magnetosphere may account for some of these differences.

GA3.05/E/02-B3 **0850**

LONG TERM VARIATION OF THE LOW-ALTITUDE TRAPPED PROTON POPULATION MEASURED BY SAMPEX/PET

M. KRUGLANSKI, D. Heynderickx and J. Lemaire (BIRA/IASB, Brussels, Belgium) M.D. Looper and J.B. Blake (The Aerospace Corp., Los Angeles, California) E.J. Daly (ESTEC/ESA, Noordwijk, The Netherlands)

It has been firmly established that the low-altitude trapped proton population exhibits strong time variations related to geomagnetic secular variation and neutral atmosphere conditions. The flux measurements of the Proton Electron Telescope (PET) onboard the polar satellite SAMPEX constitute an adequate data set to distinguish different time scales and to characterise the respective variations. We demonstrate the effect of the secular geomagnetic variation by comparing the (I,Bm) distribution of trapped protons measured by SAMPEX/PET with the distribution measured by AZUR satellite in 1969. Using TIROS data spanning two solar cycles, Huston and Pfitzer have studied the variation related to the atmosphere's response to the solar UV flux on a time scale of the solar cycle. The four years (1992-1996) of PET data at our disposal allow us to analyse in more detail the relation between the proton flux variation and solar activity during the most recent descending solar cycle phase. After accounting for the effects described above, the PET data still exhibit a clear systematic variation on a shorter time scale. The residual flux variation, which can be as high as a factor 2, is strongly correlated with the seasonal variation of the MSISE-90 total mass density in the SAA at the altitude of mirroring protons. Our analysis of the SAMPEX data shows that a modern low-altitude proton model must take into account variations on at least three different time scales. This work was funded by ESA's Technology Research Programme, ESA/TOS-EMA, Space Environments and Effects Major Axis.

SPECTRUM CHARACTERISTICS OF THE RELATIVISTIC ELECTRONS IN THE OUTER RADIATION BELT DURING MAGNETIC STORMS

Takahiro OBARA (Hiraiso Solar Terrestrial Res. Ctr., 3601, Isozaki, Hitachinaka, Ibaraki, 311-1102 Japan, email: T.Obara@crl.go.jp)

Once a major magnetic storm takes place, the relativistic electrons in the outer radiation belt disappear entirely. After the disappearance of the relativistic electrons which can last as much

as one day, an increase in the flux occurs and sometimes exceeds the pre-storm levels. The return flux is evident at first in a low L-shell (3-4) region, which propagates to higher L shells. Based on Akebono (EXOS-D) observation, an investigation has been made on the spectrum characteristics of the relativistic electrons. Results demonstrate that there is a systematic tendency in the spectrum from 300 keV to 2.5 MeV; i.e. both decay and growth are severer for higher energy and time delay of recover is apparent for higher energy. On the contrary, fast recover is made for lower energy electrons. We have also studied on a correlation of the electron flux increase and the IMF Bz polarity as well as the polar cap index during the storm recovery phase. Results demonstrate that a large flux enhancement occurred when the IMF was southward and the PC index was quite large. Source particles are effectively supplied due to the enhanced magnetic activity and they may be accelerated up to MeV range by some processes within outer radiation belt. We will discuss possible way(s) to increase the outer belt electrons during the storm recovery phase.

GA3.05/E/07-B3 0930

SOLAR CYCLE CHANGES OF ENERGETIC PARTICLE PROPERTIES IN THE INNER MAGNETOSPHERE

D.N. BAKER and X. Li (Laboratory for Atmospheric and Space Physics, University of Colo-rado, Campus Box 590, Boulder, Colorado, 80309-0590, USA, e-mail: baker@lynx.colorado.edu); J.B. Blake (The Aerospace Corporation, MS 259, Los Angeles, CA 90009); S.G. Kanekal (Goddard Space Flight Center, Greenbelt, MD 20771)

The near-Earth region responds powerfully to changes on the sun and in the solar wind. The Earth's radiation belts and inner magnetosphere show pronounced differences in their character-istics as the sun's magnetic and solar wind properties change. Solar coronal holes produce regu-lar, recurrent solar wind stream interactions in geospace, often enhancing highly relativistic elec-trons (HREs) and causing recurrent magnetic storms. These phenomena are characteristic of the approach to solar minimum. On the other hand, major geomagnetic disturbances associated with a periodic coronal mass ejections occur most frequently around solar maximum. We review the observational and modeling results that demonstrate differences throughout the inner part of geospace during the course of the 11-year solar cycle. We place particular emphasis on long-term, homogeneous data sets from SAMPEX and POLAR missions.

GA3.05/E/16-B3 0950

RELATIVISTIC ELECTRON EVENTS IN THE OUTER ZONE DURING AUGUST-SEPTEMBER 1998: SAMPEX AND POLAR MEASUREMENTS

S.G. KANEKAL (Code 696, NASA GSFC and RTISS, Greenbelt Rd, Greenbelt,MD 20904, USA, e-mail: kanekal@lepsam.gsfc.nasa.gov); D.N.Baker (Laboratory for Atmospheric and Solar Physics, UNiversity of Colorado, Boulder, CO, 80309); J.B.Blake (The Aerospace Corporation, MS259, Los Angeles, CA 90009); B.Klecker (Max planck Institut for Extraterrestriche Physik, Garching,Germany); G.M. Mason (Dept. of Physics, Univ. of Maryland, College Park, MD 20742); R.A. Mewaldt (California Institute for Technology, Pasadena, CA 91125)

The dynamics of the radiation belts seen from the perspective of relativistic electron dynamics exhibit both properties common to such events as well as variations amongst them. In this paper, we study the relativistic electron enhancement events in the outer zone during the months of august and september 1998. we use data from multiple satellites to characterize the interplanetary conditions and relativistic electrons in the earth's magnetosphere. For the latter, detectors onboard POLAR and SAMPEX satellites are used to measure electrons over an energy range of several ev to MeV and covering almost all L-shells. Since SAMPEX and POLAR orbit at ≈ 800 km and 2-9 Re altitudes respectively, pitch angle and spatial information are also obtained. Sensors on WIND provide information about the interplanetary conditions. Observations and comparisons of particle spectra and fluxes covering a large range of L-shells and energies will be presented. This study will also attempt to compare and contrast these case studies with previous measurements.

GA3.05/W/01-B3 1010

OBSERVATIONS OF THE SHOCK INJECTION OF MAGNETOSPHERIC PARTICLES IN MAY AND AUGUST 1998: COMPARISON WITH THE GREAT EVENT OF 24 MARCH 1991

J B BLAKE, M D Looper, R S Selesnick (The Aerospace Corporation, Los Angeles, CA, 90009, email: jbernard.blake@aero.org) X Li and D N Baker (LASP, University of Colorado, Boulder , CO, 80303) M K Hudson (Physics and Astronomy Department, Dartmouth College, Hanover, NH 03755)

The very strong ssc event of 24 March 1991 was observed by CRRES to inject large fluxes of electrons with energies exceeding 15 MeV and protons of several tens of MeV deep into the magnetosphere in a time period of a couple of minutes (Blake et al. 1992). The physics underlying this unprecedented observation was described by Li et al. 1993. On 4 May 1998 and 26-28 August 1998 ssc injections were observed by 1997-068 (in HEO orbit) and by SAMPEX. The energy spectra of protons and electrons, the L value of the peak intensity, the relative intensities of these events and the high-L seed population will be compared and contrasted.

GA3.05/W/30-B3 1100

OBSERVATIONS OF THE OUTER RELATIVISTIC RADIATION BELT USING GPS SATELLITES

R. H. W. FRIEDEL, T. Cayton, C. Ingraham, G. D. Reeves (all at Los Alamos National Laboratory, Los Alamos, NM, USA)

Los Alamos has for many years been flying environmental radiation monitors on the GPS (Global Positioning Satellites) series of spacecraft. Currently three GPS spacecraft carry these monitors. The GPS orbit (12 hour, 4 Re, 45 degree inclination) is ideally suited to sampling the outer radiation belt: Each spacecraft covers the range of L=4 to open field lines four times an orbit, giving a time resolution of three hours per pass. Combining the measurements from three spacecraft gives an unprecedented in-situ resolution in the outer relativistic radiation belt.
The relativistic electron response can be quite different from the main ring current response as observed by Dst. The past history of the relativistic electron population plays a crucial role: Already elevated flux levels can be quite insensitive to storms, and large changes in relativistic electrons can be observed without any visible signature in Dst. We further present some first observations of relativistic radiation belt asymmetries observed before the May 1997 magnetic storm.

GA3.05/W/24-B3 1120

OCCURRENCE OF ELECTROMAGNETIC ION CYCLOTRON WAVES IN ASSOCIATION WITH GEOMAGNETIC STORMS

B J ANDERSON and R E Erlandson (both at The Johns Hopkins University Applied Physics Laboratory, Laurel, MD, 20723, USA, email: brian.anderson@jhuapl.edu)

Electromagnetic ion cyclotron waves are thought to provide significant pitch angle scattering of energetic protons, especially during geomagnetic storms. We use observations from the AMPTE/CCE and DE-1 spacecraft to asses whether ion cyclotron wave occurrence has a systematic correlation with storms. Case studies indicate that low L Pc 1 emissions can persist for long periods of time in a given local time sector, primarily during the main and recovery phases of storms. This result is consistent with modeling in that low L Pc 1 are observed, but the occurrence of the waves relative to storm phase and their sustained character are not understood. Statistical analysis of AMPTE/CCE data throughout the five year mission yields data on 72 storms. Superposed epoch analysis of these events shows that even during storms, wave occurrence is dominated by sources in the outer magnetosphere in the afternoon dayside. There does not appear to be a pronounced overall increase in Pc 1 occurrence during storms although the intensity of the events is higher. The most pronounced effect is a decrease in wave normalized frequency below the equatorial He+ gyrofrequency but above the O+ gyrofrequency, that begins just at main phase onset and lasts between 12 to 24 with the longer duration corresponding to more intense storms. This frequency shift is interpreted in terms of downward shift of maximum unstable wave frequency with increased plasma beta.

GA3.05/E/06-B3 1140

THE TEMPORAL EVOLUTION OF INJECTED ELECTRON DISTRIBUTIONS IN THE INNER MAGNETOSPHERE

Nigel P. MEREDITH and Alan D. Johnstone (both at Mullard Space Science Laboratory, University College London, Holmbury St Mary, Dorking, Surrey,RH5 6NT, UK, Email: npm@mssl.ucl.ac.uk); Richard B. Horne (British Antarctic Survey, Natural Environment Research Council, Madingley Road, Cambridge, CB3 0ET, UK, Email: r.horne@bas.ac.uk); Roger R. Anderson (Department of Physics and Astronomy, University of Iowa, Iowa City, Iowa, IA 52242-1479, USA).

The temporal evolution of injected electron distributions in the energy range 0.1 < E < 30 keV are examined using data from the CRRES satellite. Equatorial electron distributions and concomitant wave spectra on the night-side of the Earth in the range 3.8 < L < 6.8 are studied as a function of time since the end of the previous injection event determined from the AE index. Pancake electron distributions, so-called because of their appearance in velocity space where they peak at the 90 degree pitch angle, are seen to develop from injected distributions that are nearly isotropic in velocity space. Outside L = 6.0 the pancakes are seen to develop on a time scale of approximately 5 hours. Strong ECH and whistler mode wave intensities are associated with the injected distributions and exponential fits reveal wave decay constants of 2.15 +/- 0.13 and 2.4 +/-0.16 hours respectively. Inside L = 6.0 the situation is complicated by the proximity of the plasmapause and inward convection times that increase significantly with decreasing L-value. Outside L = 6.0, in the marginally stable state, the phase space density contours lie approximately along the curves for diffusion by whistler mode waves but inside L = 6.0 the pancakes are more sharply peaked at 90 degrees. These results suggest that whistler mode waves play a dominant role outside L = 6.0, whereas inside L = 6.0 the ECH waves also play a significant role.

GA3.05/E/09-B3 1200

ELECTRON PITCH ANGLE DIFFUSION BY ELECTROSTATIC ELECTRON CYCLOTRON HARMONIC WAVES AS A SOURCE OF PANCAKE DISTRIBUTIONS

RICHARD B. HORNE (British Antarctic Survey, Madingley Road, Cambridge CB3 0ET, U.K., email: R.Horne@bas.ac.uk); Richard M. Thorne (Department of Atmospheric Sciences, University of California, Los Angeles, U.S.A., email: rmt@atmos.ucla.edu)

It has been suggested that highly anisotropic electron pancake distributions are the result of pitch angle diffusion by electrostatic electron cyclotron (ECH) harmonic and whistler mode waves in the equatorial region. Here we present pitch angle diffusion rates for ECH wave spectra centred at different frequencies corresponding to spacecraft observations. The wave spectra are carfully mapped to the correct resonant electron velocities. We show that previous diffusion calculations of ECH waves at (n+0.5)fce, driven by the loss cone instability, result in large diffusion rates over a small range of pitch angles near the loss cone and therefore cannot account for pancake distributions. However, when the wave spectrum is centred at higher frequencies in the band (1.9fce) the diffusion rate is very small inside the loss cone, but peaks just outside and remains large over a wide range of pitch angles up to 60 degrees or more. Since ECH waves near 2fce are cyclotron damped we suggest that pancake distributions can be formed by pitch angle diffusion as the waves are damped, and not as they grow, after propagation in a non-homogeneous medium. The calculated diffusion rates suggest that ECH waves at amplitudes of the order of 1 mV/m can form pancake dsitributions on a timescale of a few hours, which is consistent with recent CRRES observations following substorm injections near geostationary orbit.

GA3.05/W/22-B3 1220

EFFECTS OF BETATORON DRIFT ON THE PLASMASPHERIC PLASMA AND RADIATION BELT PARTICLES

Hiroshi OYA (Department of Geophysics, Graduate School for Science, Tohoku University, Sendai, 980-8578, Japan. email: oya@stpp1.geophys.tohoku.ac.jp)

From the distribution of the plasmaspheric plasma detected from the upper hybrid frequency observed by the plasma wave spectra of PWS experiment on board the Akebono (EXOS-D) satellite, the time variation of the plasmaspheric plasma structure has been studied as the function of the Dst and ASY indices. It has been confirmed that the plasmaspheric plasma is controlled by the drift motion called here the "Betatron drift" that is caused by the induction electric field due to the time variation of the magnetic field associated with the time variation of the ring current. In the period of dB/dt<0, detected on the earth, the plasma makes exodus towards outside of the plasmapause while the hot magnetospheric plasmas immigrate into the inside region of the plasmasphere, in the period of dB/dt>0. Formation processes of the plasmapause is also controlled by this betatron drift; the processes then not simply follow the convection and refilling mechanism as has been accepted to be established mechanism of the plasmasphere and plasmapause formation. The mechanism of the betatron drift can also be applicable to understand recently discovered storm time variations of the radiation belt particles.

GA3.05/W/17-B3 1400

SUBSTORM ACCELERATION OF 0.5 MEV ELECTRONS ON THE RECOVERY PHASE OF RECURRENT MAGNETIC STORMS

A.V. DMITRIEV and Yu.S. Minaeva (Institute of Nuclear Physics, Moscow State University, 119899, Moscow, Russia, email: dalex@srdlan.npi.msu.su)

The dynamics of electrons with energy ~0.5 MeV in the outer radiation belt is studied using CORONAS-I satellite data obtained in March-May 1994. The strong increases of the electron fluxes are observed on the recovery phase of recurrent magnetic storms when the Earth is crossed by fast solar wind streams from large coronal holes on the Sun. The recovery phases of recurrent magnetic storms are accompanied by substorm activity induced by Alfvenic waves in the fast solar wind. The substorm activity is accompanied by effective acceleration of the electrons in the outer radiation belt.

GA3.05/W/34-B3 1420

OUTER ZONE ELECTRON RADIAL DIFFUSION MODEL OF OCTOBER 1991 MAGNETIC STORM

D.H. BRAUTIGAM (Air Force Research Laboratory, Hanscom AFB, MA 01731, email: brautigam@plh.af.mil) J.M. Albert (Institute for Scientific Research, Boston College, Boston, MA 02115)

Using Combined Release and Radiation Effects Satellite (CRRES) data, the response of the outer radiation belt electrons to the 9 October 1990 magnetic storm is analyzed in terms of a radial diffusion model. Electron differential flux from the Medium Electron A instrument (MEA) is transformed into phase space density as a function of the three adiabatic invariants. The invariants are determined by magnetic field data from CRRES and the Tsyganenko 1989 Kp driven model. The radial diffusion equation is solved using time dependent radial diffusion coefficients D(t) and time dependent outer boundary conditions parameterized by data from Los Alamos National Laboratory geosynchronous satellite 1989_046. The diffusion model accounts for both significant flux decreases and increases throughout the region in the several hundreds keV electrons. However, the results suggest that an internal source is required to account for the gradual increase in the >1 MeV electrons throughout the recovery phase. Whistler chorus waves were observed by CRRES to be greatly enhanced throughout the recovery phase suggesting that energy diffusion via cyclotron resonance may be a potential acceleration mechanism.

GA3.05/W/08-B3 1440

MODELING THE INFLUENCE OF CAPITAL EVENTS ON THE HIGH ENERGY PROTON BELT

ANGÉLIQUE VACARESSE, Daniel Boscher, and Sébastien Bourdarie (ONERA, Département dEnvironnement SPatial, 2 Avenue Edouard Belin, P. O. Box 4025, 31055 Toulouse Cedex 04, France, Email: Angelique.Vacaresse@onecert.fr)

Protons in the 10 MeV 100 MeV range are usually very stable in the radiation belt. Such high energy particles are trapped in the belt for years. Nevertheless, strong active periods can modify this population. First, particles can decrease at the outer edge of the belt, in relationship to magnetospheric modifications, due to changes in the magnetic field itself. These magnetospheric variations, traduced by magnetopause and magnetospheric shielding fluctuations, are parameterized with the help of geomagnetic indexes and solar wind parameters. On another hand, high energy solar protons from eruptions can penetrate deeply in the magnetosphere, giving rise to a second proton belt in the 30 MeV range. That has been seen on CRRES (Combined Release and Radiation Effect Satellite), not only during the March, 1991 major event [Gussenhoven et al., 1993], but also during smaller events [Hudson et al., 1998]. Such changes in the magnetospheric boundary conditions have been modeled by particle fluctuations observed on GOES satellites at geostationary orbit. Results of modeling such physical processes using the Salammbô code [Beutier et al., 1995] will be shown in this study. The influence of such a strong dynamics on the high energy proton belt is analyzed, as well as the effects of worst cases (losses and Solar Proton Events). This work can contribute to a reference proton radiation belt model. It also allows to progress towards Space Weather considerations through the study of a parameter signature and a statistical repartition of main events, the prediction still needing better in-flight measurements and solar activity understanding.

GA3.05/W/29-B3 1500

STOCHASTIC ELECTRON ACCELERATION TO RELATIVISTIC ENERGIES BY SUPERLUMINOUS WAVES

Richard M. THORNE and F. Xiao (Department of Atmospheric Sciences, UCLA, Los Angeles CA 90095-1565, e-mail: rmt@atmos.ucla.edu) D. Summers (Department of Mathematics and Statistics, Memorial University of Newfoundland, Canada A1C5S7)

Intense superluminous waves (with phase speeds exceeding the velocity of light) are excited in the auroral cavity during disturbed magnetospheric conditions. Previous ray tracing studies have demonstrated that these waves can propagate into the lower L region of closed magnetic field lines. Here we explore the potential resonant interactions with trapped outer-zone electrons. Relativistic resonant diffusion surfaces are constructed for each superluminous wave mode and we identify waves which could contribute to the acceleration of outer-zone electrons to relativistic energies (>1 MeV) during disturbed conditions.

GA3.05/E/21-B3 1520

ENTRY OF HIGH ENERGY PARTICLES INTO THE EARTH'S MAGNETOSPHERE

Mostafa EL-ALAOUI, Maha Ashour-Abdalla (Both at UCLA-IGPP, Los Angeles, CA 90095-1567, USA, e-mail: mostafa@igpp.ucla.edu)

During the upcoming solar maximum, energetic solar particle events will increase in frequency and severity. Traveling along interplanetary magnetic field (IMF) field lines, they reach the Earth's magnetosphere and enter it, increasing populations of energetic particles and affecting spacecraft operations. We will study the interactions of these particles with the magnetosphere and their access to the inner magnetosphere by using a combination of MHD and large scale kinetic simulations. While we do not expect the particles with the highest energies to be strongly affected by the magnetic fields of the magnetosphere, it is clear that the energetic particle spectrum will be influenced in a complex manner before being trapped by the Earth's field. Starting from the solar wind, we will calculate and follow the orbits of several thousand H+ ions forward in time until they are lost at the edges of the simulation box, precipitate into the ionosphere or become trapped. In addition, we will determine and evaluate the success these highly energetic particles (> 0.1 MeV) from the solar wind have in reaching and penetrating the Earth's magnetosphere. Any energization and transport processes that these ions undergo inside the Earth's magnetosphere will also be examined.

GA3.05/W/26-B3 1600

MULTIPLE SATELLITE STUDY OF THE ENERGETIC ELECTRON RESPONSE TO THE MAY 1998 MAGNETIC STORM

J F FENNELL, J L Roeder , J B Blake, R S Selesnick (The Aerospace Corporation, Los Angeles, CA, 90009, USA, email: joseph.f.fennell@aero.org); R H W. Friedel and G D Reeves (Los Alamos National Laboratory, MS: D436, Los Alamos, NM 87545, United States); M Grande and M Carter (Rutherford Appleton Laboratory, Chilton-Didcot, OX110QX, United Kingdom)

We combine the energetic electron observations from Polar and HEO (94-026, 95-034, and 97-068) to the large magnetic storm of May 2-9, 1998. These observations are taken by high-altitude high-inclination satellites at energies > 100 keV. The HEO (94-026, 95-034, and 97-068) satellites are in ~12 hour orbits at different local times while Polar is in an 18 hour orbit. The HEO coverage occurs roughly in the pre-noon/pre-midnight, post-noon/post-midnight and dawn/ dusk regions of the inner magnetosphere. Polar covers the pre-noon/pre-midnight region. HEO 94-026 and 95-034 provide coverage generally for L * 4 while HEO 97-068 covers L* 2 and Polar covers L*3. These data are combined to provide a picture of the evolution of the energetic electrons with time, local time, L and energy. These combined observations will be presented and discussed in terms of the development of the storm from the electron perspective at mid to high latitude. We will also compare these off-equator observations to the observations taken near the equator by LANL geosynchronous and GPS satellites.

GA3.05/E/11-B3 1620

STORM ASSOCIATED HRE (HIGHLY RELATIVISTIC ELECTRON) EVENTS OBSERVED IN LOW EARTH ORBIT

Richard A. GOLDBERG (NASA Goddard Space Flight Center, Laboratory for Extraterrestrial Physics, Code 690, Greenbelt, MD, USA, email: richard.a.goldberg.2@gsfc.nasa.gov); W. Dean Pesnell (Nomad Research Inc., Bowie, MD 20716, USA, email: pesnell@nomadresearch.com); David L. Chenette, Edward E. Gaines, Michael Schulz (all at Lockheed Martin Advanced Technology Center, Lockheed Martin, Palo Alto, CA 94304, USA, email: chenette@spasci.com) Charles H. Jackman (NASA Goddard Space Flight Center, Laboratory for Atmospheres, Code 916, Greenbelt, MD 20771, USA, email: jackman@assess.gsfc.nasa.gov)

Highly relativistic electrons populate the trapped radiation belts especially during the recovery phases of geomagnetic storms (as indicated by Dst). Their subsequent precipitation can be energetically important for the upper atmosphere and thus needs to be characterized in terms of spectral energy distribution, spatial extent, and frequency of occurrence. We have studied the characteristics of HRE events for E > 0.3 MeV from Oct 1991 through Sept 1994 with data from the High-Energy Particle Spectrometer (HEPS) aboard UARS. Each event has a characteristic signature such that the delay to onset and the event duration seem to increase with particle energy over the indicated range. Energy-time maps of the electron flux have been refined to distinguish between trapped and precipitating electrons and (in this context) to separate measurements by hemisphere (north vs south) in bins of width DL = 1/4. The minimum L at which HRE events could be discerned seemed to increase with time during the 3-year interval studied (i.e., during the declining phase of Solar Cycle 22).

GA3.05/W/42-B3 1640

MULTIPLE DISCRETE-ENERGY ION FEATURES IN THE INNER MAGNETOSPHERE

Xinlin Li and D.N. Baker (LASP, University of Colorado, 1234\\ Innovation Drive, Boulder, CO 80303-7814, USA; 303-492-3514; email: lix@kitron.colorado.edu); M Temerin (SSL, UC Berkeley, CA 94720, USA); W K Peterson (Lockheed Martin, Palo Alto, CA 94304, USA); J Fennell (Aerospace Corporation, Los Angeles, CA 90009-2957, USA);

Recent measurements from the ion composition sensors (CAMMICE/MICS and TIMAS) on board the POLAR satellite often show multiple peaked spectra, which are seen as multiple bands in energy-time plots. Although similar phenomena had also been observed by CRRES satellite around its apogee (r=6.3R$_{\rm E}$) and were interpreted as a possible drift echo effect [Grande et al., 1992].
POLAR data reveal that these multiple bands of ion fluxes are over a very large range of L (L=2.5--7) and energy (a few keV to hundreds of keV) independent of the charge and mass of the ions. Our test particle simulation shows that these multiple bands are a manifestation of drift echoes of different energy ions. Initial injection of these ions into the inner magnetosphere is caused by earthward propagating time-varying fields associated with a dipolarization process during a substorm onset. Modeling these multiple discrete-energy ion features provides valuable new information about how deep into the magnetosphere impulsive electric fields and changes in magnetic fields can penetrate.

SIGNATURES OF MAGNETIC FIELD EFFECTS ON RING CURRENT DEVELOPMENT AND DECAY FOR THE JUNE 4-5, 1991 STORM

M. W. LIEMOHN, J. U. Kozyra (both at: Univ. of Michigan, 2455 Hayward, Ann Arbor, MI 48109, USA, email: liemohn@umich.edu); M. F. Thomsen (Space and Atmospheric Sciences, MS D466, LANL, Los Alamos, NM 87545, USA); J. L. Roeder (The Aerospace Corp., MS: M2/260, P. O. Box 92957, Los Angeles, CA 90009, USA); P. Song (Univ. of Michigan, 2455 Hayward, Ann Arbor, MI 48109, USA); J. E. Borovsky, and T. E. Cayton (both at: Space and Atmospheric Sciences, MS D466, LANL, Los Alamos, NM 87545, USA)

This study investigates the effects of a greatly compressed magnetic field on the development and decay of the ring current during the June 4-5, 1991 geomagnetic storm. Observations from both the LANL geosynchronous orbit satellite 1989-046 and the CRRES satellite show magnetosheath encounters on June 5, indicating that the magnetic field is highly compressed and/or distorted. To study the effects of these distortions on the near-Earth plasma transport, the RAM code is used to simulate the energetic ion motion in the inner magnetosphere, using geosynchronous orbit data for boundary condition inputs. The results are compared with CRRES MICS and LANL MPA data. The effects of various processes on the propagation and precipitation of the particles are examined, including effects of ion demagnetization and non-adiabatic motion, the time-varying geomagnetic field, and dayside compression of the magnetopause. These processes increase the loss rate of the ring current, and their relative importance to ring current dynamics is investigated and discussed.

SCATHA OBSERVATIONS OF DISPERSING ION SIGNATURES IN THE INNER MAGNETOSPHERE

R. J. STRANGEWAY (Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095, USA, Email: strange@igpp.ucla.edu); H. L. Collin (Lockheed Martin ATC Space Physics Lab., 3251 Hanover St., Palo Alto, CA 94304, USA, Email: collin@spasci.com)

The Spacecraft Charging at High Altitudes (SCATHA) spacecraft was launched in the late 1970's into a near geosynchronous orbit. Included in the instrument complement was an ion composition experiment which could measure ions with energies in the range 0.1 to 32 keV/e, and resolve masses up to and including singly charged Oxygen. In this paper we will review SCATHA ion composition observations, emphasizing the occurrence of dispersing ion signatures. Through comparisons with theoretical predictions of the drift path trajectories we will determine the source location of the dispersing ions. We will further address the question of whether these dispersing ions are injected locally, i.e., injected from the ionosphere, or if they correspond to pre-existing magnetospheric plasma populations that have been accelerated by induction electric fields.

THE "MAIN" SUBSTORM AS A MAJOR SOURCE OF STORM-INJECTED RADIATION BELT ENERGETIC ELECTRONS

Lyudmila V. TVERSKAYA (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: tverskaya@taspd.npi.msu.su)

As the author has proposed earlier, the major storm-time injection of energetic radiation belt electrons takes place when west auroral electrojet is shifted to its lowest latitude position during the storm main phase. Particles are injected into the field weakened by the ring current. On the storm recovery phase particle's energy must markedly rise adiabatically. As has been shown recently, an injection of relativistic electrons at L~3 really takes place on a time scale of "main" substorm. That substorm is characterized by the lowest latitude position of auroral electrojets during the storm main phase. The results of coordinated analysis of night-side trapped radiation boundary collapse in the equatorial plane and the ground magnetic data are presented. An appearance of the injected electrons of up to ~5 MeV energy during the "main" substorm was registered on the GLONASS satellite on the several-minutes time scale. Data on several-MeV electrons from RELAY-1 are analysed too. As is shown, position of the intensity maximum of storm-time injected relativistic electrons (Lmax) is in a good consistence with the previously reported formula:|Dst|max = 27500/(Lmax)**4.
The roles of "main" substorms and sudden impulses in formation of the storm "new" radiation belts are compared. The cases of "fast" collective shift of the outer radiation belt are discussed too. It is shown that both recently registered cases and the observed in 60-s may be well explained in a framework of the theory of particle transport under the influence of sudden impulses.

MODELING FIELD-ALIGNED POTENTIALS PRODUECED BY NON-ADIABATIC ION MOTION IN THE PLASMA SHEET

Maha ASHOUR-ABDALLA, Vahe Peroomian (Both at UCLA-IGPP, Box 951567, Los Angeles, CA 90095-1567, USA, e-mail: mabdalla@igpp.ucla.edu); Lev M. Zelenyi (Space Research Institute, Academy of Sciences, Moscow, Russia, e-mail: lzelenyi@iki.rssi.ru)

Previous studies of the effects of ion nonadiabaticity on the magnetotail indicate that, even for steady solar wind conditions, the magnetotail evolves into a quasi-steady state with periodic oscillations. In this study, we employ a self-consistent large-scale kinetic model to evaluate the contribution electrons make to the dynamics of the magnetotail. Because of their small inertia, electrons should have an nearly equilibrium Boltzmann distribution along field lines, and thus parallel electric fields should result, which would assure charge neutrality. The parallel potential has a pronounced disturbing influence on ions, accelerating or decelerating them along field lines and causing drifts across field lines. Including in our model the effects of electron heating during convection enhances this tendency. We discuss the self-consistent pattern of parallel potentials in the magnetotail and the inner magnetosphere that result from the motion of non-adiabatic ions and charge-neutralizing Boltzmann electrons.

CHARGED PARTICLE ACCELERATION BY WEAK AND STRONG ELECTROSTATIC TURBULENCE IN THE INNER AURORAL MAGNETOSPHERE

Peter BESPALOV (Institute of Applied Physics, Russian Academy of Science, 46 Ulyanov st., Nizhny Novgorod, 603600, Russia, Email: peter@appl.sci-nnov.ru)

Magnetic field-aligned electric currents are typical for the auroral magnetosphere. In our opinion, the regions with field-aligned current can be responsible for effective charged particle acceleration in the high-latitude inner magnetosphere for stationary and nonstationary conditions, especially if a plasma turbulence exists. In this work, we analyze the acceleration processes. Accelerations of charged particles by a quasistatic electric field, by weak or strong plasma turbulence are taken into account. Solutions of stationary kinetic equation are found for acceleration by weak and strong plasma turbulence in an inhomogeneous magnetic field for different correlations between system time and space scales. The estimate of energy input shows the efficiency of the acceleration mechanism in such processes in the chosen parts of the energetic spectrum. This model contributes to understanding both the flux distribution of energetic particle at high latitudes and the global energy budget of the inner magnetosphere.

SPATIAL DISTRIBUTION OF ELECTRON FLUXES (>0.08 MEV) AT LOW L-SHELLS MEASURED IN THE EXPERIMENT ON BOARD "MIR-SPECTR" ORBITAL COMPLEX.

A.V.BOGOMOLOV, G.Ya.Kolesov, Yu.I.Logachev, I.N. Myagkova (all at Skobeltsyn Institute of Nuclear Physics, Moscow State University, Vorob'evy Gory, 119899 Moscow, Russia).

Fluxes of electrons with the energies >80 keV were measured in the experiment "GRIF-1" onboard the module "SPECTR" of orbital station "MIR" at altitude ~400 km since October 1995. The complex of instruments "GRIF-1" includes the charged particle detectors with large and small geometrical factor. It permits to measure the variations of electron fluxes both in the Earth's Radiation Belts and in the regions closed to the geomagnetic equator. The higher fluxes of >0.08 MeV electrons were detected near L=1.4, L=1.7 and L=2.2. Maps of electron spatial distribution and L-B diagramms at the altitude 400 km are obtained.

CASE STUDY OF THE INNER MAGNETOSPHERIC CONVECTION DURING TWO RECENT GEOMAGNETIC STORMS

A. BOONSIRISETH and R. M. Thorne (both at Dept. of Atmospheric Sciences, UCLA, 405 Hilgard Ave. MS7127, Los Angeles, CA, 90095, email: amyb@atmos.ucla.edu); G. Lu (NCAR/HAO, P.O.Box 3000, Boulder, CO 80307-3000)

Due to the important role that convection plays in particle and energy transport into the inner region of the magnetosphere during a geomagnetic storm, there has been many past and present attempts of modelling the electric field. But to date, the electric field models for the inner magnetosphere have been unable to reproduce the large variations seen during storms. This project will involve a case study of the convective electric field during two recent storms and Jan. 10 and May 15, 1997. The dependence of the electric field on several solar wind parameters (BIMF, Pdyn) will be carefully analyzed using data from WIND and an electric field mapped from ionospheric potentials generated by AMIE with T96 magnetic field model. The region covered by this study ranges from L=2.5Re to L=6.5Re for all local times. Each major feature of the electric field throughout both storms will be studied in relation to solar wind and IMF changes. The conclusions of this study will hopefully provide some basis for future convection modelling efforts.

PLASMSPHERIC MATERIAL AT THE RECONNECTING MAGNETOPAUSE

Yi-Jiun SU, JOSEPH E. BOROVSKY, Michelle F. Thomsen, David J. McComas, and Richard C. Elphic (Space and Atmospheric Sciences Group, Los Alamos National LAboratory, Los Alamos, New Mexico 87544, USA. Email: ysu@lanl.gov; jborovsky@lanl.gov; mthomsern@lanl.gov; dmccomas@lanl.gov; relphic@lanl.gov)

During geomagnetic storms, cold and dense plasmaspheric material is observed to drain toward the dayside magnetopause when the solar wind pressure is strong and the IMF is southward. What is the fate of draining plasmaspheric material at the magnetopause? Does the plasmaspheric material participate in the dayside reconnection? In this study, we will present observations from Los Alamos Magnetospheric Plasma Analyzers at geosynchronous orbit during such plasmaspheric drainage events. For a set of events where cold plasmaspheric material is observed immediately adjacent to the magnetopause/ low-latitude boundary layer, we examine the detailed ion distributions, from ~1eV to ~40keV, for evidnce that the draining plasmaspheric ions and the entering magnetosheath ions are simultaneously present on the same flux tube, which is a signature that the plasmaspheric flux tubes experience reconnection. In a preliminary examination of 18 such events during 1997-98, four cases were found where the plasmaspheric ions appeared simultaneously with magnetosheath-like plasma. In one of the four cases, the draining plasmaspheric ions appear to be energized by the reconnection process. We will present the results of a more extensive study, extending back to the previous maximum of the solar cycle. The results have significant implications regarding the fate of draining plasmaspheric material at the magnetopause and, indeed, regarding the parameters controlling the operation of dayside reconnection.

THEORY AND MODELING OF RELATIVISTIC ELECTRONS ASSOCIATED WITH SUBSTORM INJECTIONS

ANTHONY A. CHAN, Hee-Jeong Kim, Richard A. Wolf (all at Department of Space Physics and Astronomy, MS 108, Rice University, Houston, TX 77005, USA. Email: anthony-chan@rice.edu); and Joachim Birn (NIS-1, MS D466, Los Alamos National Laboratory, Los Alamos, NM 87545, USA)

The adverse effects of MeV electrons on technology and on humans in space has brought renewed interest to the problem of understanding the sources and dynamics of these energetic particles. Ongoing measurements, often from multiple spacecraft, are enabling the best characterization yet of the phenomenology of the electron flux variations and of the solar wind and magnetospheric conditions which are correlated with the large, potentially-damaging flux increases, but much work remains in order to fully understand the underlying physical mechanisms. Theory and simulation efforts will be reviewed with emphasis on identifying the physical processes responsible for the transport and acceleration of relativistic electrons in Earth's magnetosphere during magnetic storms. Recent calculations of rapid injection of energetic plasma sheet electrons to an outer trapping region, followed by subsequent slow radial transport to the inner magnetosphere, will be presented.

CEP EVENTS DURING THE MAY 2-4, 1998 STORM PERIOD

Jiasheng CHEN, Theodore A. Fritz, and Harlan E. Spence (all at Center for Space Physics, Boston University, 725 Commonwealth Avenue, Boston, MA 02215 USA, http://buspace.bu.edu/EPG/jiasheng/chen.html, email: chen@buasta.bu.edu)

The POLAR spacecraft has observed five large cusp energetic particle (CEP) events in the high altitude dayside polar cusp during the May 2-4, 1998 geomagnetic storm period. Two events were detected on May 2 at about 2:10 and 19:00 UT, two events were detected on May 3 at 13:42 and 17:42 UT, and one event was detected on May 4 at 5:30 UT. They have event durations of about 4.7, 8.4, 3.0, 0.6, and 6.6 hours, in which the time averaged Data values were about -4, -65, -60, -68, and -180 nT, respectively. The second event had the longest CEP event time period since the discovery of the CEP event in 1996 [Chen et al., GRL, 24, 1447, 1997]. It is found that the ion flux in the 5/4/98 CEP event is two to three orders of magnitude larger than that in the 8/27/96 CEP event over the energy range of 20-2000 keV. The simultaneous observations indicated that in the energies of 60-1400 keV the ion fluxes in the

cusp were higher than that in locations including upstream from the bow shock, downstream in the magnetosheath, and magnetopause. These new observations support previous discovery [Chen et al., JGR, 103, p.69, 1998] that the high-altitude dayside cusp is a new acceleration region of the magnetosphere.

EVOLUTION OF PLASMASPHERIC REFILLING: COMPARISON OF OBSERVATIONS WITH AN INTERHEMISPHERIC PLASMASPHERE MODEL

R. H. COMFORT, P. G. Richards, J-H Liao, (all at The University of Alabama in Huntsville, CSPAR, TH S101, Huntsville, AL 35899, USA, Email: comfortr@cspar.uah.edu); P. D. Craven (NASA/Marshall Space Flight center, Space Sciences Laboratory, ES 83, Redstone Arsenal, AL, 35812, USA, Email: Paul.Craven@msfc.nasa.gov.)

The evolution of the plasmasphere is closely coupled to processes governing flux tube refilling and transport. In this study we follow this evolution through a series of sequential ion observations made by the Retarding Ion Mass Spectrometer (RIMS) on the Dynamics Explorer 1 (DE1) satellite and with the intervening time intervals filled in by simulations made with the Field Line Interhemispheric Plasma (FLIP) model. The FLIP model solves the continuity and momentum equations for the major ion species as well as the energy equations for ions and electrons along entire flux tubes from 100 km altitude in both hemispheres. Convection has recently been included in the code, driven by a dawn-dusk electric field model. Since the observations are necessarily restricted to two local time passes through the plasmasphere per orbit, the FLIP code will follow the observed flux tubes as they corotate and convect through the other local times. The period of DE1 (~7 hours) is such that nearly the same flux tubes are observed every second day, or every sixth orbit. The intervening observations provide additional information regarding longitudinal variations. Simulations will use the initial plasmasphere observations to define initial conditions of where the plasmapause is located and the extent of filling in the plasma trough. The composite of observations and simulations allows assessment of the degree to which the FLIP simulations accurately describe the processes which govern flux tube refilling over the two-day period between observations on the same flux tubes. To the extent that the convection electric field model in the FLIP codeis accurate, this composite also provides a global picture of what is happening in and near the plasmasphere during the period. Of particular interest are changes in plasma composition as refilling proceeds.

PRECIPITATION OF THE RING CURRENT IONS DUE TO TURBULENT DIFFUSION AT ION-CYCLOTRON WAVES

A. G. DEMEKHOV, D. L. Pasmanik, and V. Y. Trakhtengerts (all at: Institute of Applied Physics, Russian Academy of Science, 46 Ulyanov st., 603600 Nizhny Novgorod, Russia; e-mail: andrei@appl.sci-nnov.ru)

Results of self-consistent calculations of the pitch angle and energy distribution of the ring current (RC) protons due to the charge-exchange processes and pitch angle diffusion at ion-cyclotron waves are presented. Spatial and temporal dependence of the energetic proton source and background plasma density is taken into account. Energetic ion lifetime is shown to be strongly affected by wave-induced loss processes during both main and recovery phases of a magnetic storm. The important role of the cold plasma evolution for the dynamics of the RC proton precipitation is demonstrated. Relation of the model results to satellite data on trapped and precipitated energetic ion fluxes is discussed.

GA3.05/W/07-B3 Poster **0900-12**

RAY TRACING AND THE POLARISATION OF ELECTROMAGNETIC ION CYCLOTRON WAVES IN THE MIDDLE MAGNETOSPHERE

G. Dowdell, B. J. FRASER, and Y. D. Hu (Physics Department, CRC for Satellite Systems, University of Newcastle, NSW, 2308, Australia, email: phbjf@cc.newcastle.edu.au)

The proton cyclotron instability generates electromagnetic ion cyclotron (EMIC) waves, which propagate in the left-hand (LH) polarised mode. It is therefore expected that LH polarised waves would predominate in the magnetosphere. However this is not the situation, and linear and right-hand (RH) polarised waves have been frequently observed by the GEOS-1/2, AMPTE/CCE and CRRES spacecraft in the equatorial region of the middle and outer magnetosphere. In a multi-ion plasma the existence of a crossover frequency associated with the presence of He+ ions in a predominantly H+ plasma has been invoked in the past to explain these linear and RH polarisations. It is difficult for this mechanism to explain the observation of linear and low ellipticities which are seen over a wide range of geomagnetic latitude. It is shown in this study using ray tracing techniques that the wave normal angle increases rapidly with propagation off the equator in response to the inhomogeneous medium. Polarisation analysis performed in conjunction with ray tracing shows that this model can predict low ellipticities over a wide spatial range of latitude, in general agreement with AMPTE/CCE and CRRES results.

INJECTED ENERGETIC IONS AT L~~3-4 DURING THE EARLY MAIN PHASE OF THE LARGE MAGNETIC STORM ON 24 MARCH, 1991

S.Y. Fu (Max-Planck-Institut f\"ur Aeronomie, D-37191 Katlenburg-Lindau,Germany Email: syfu@linmpi.mpg.de); B. Wilken (Max-Planck-Institut f\"ur Aeronomie, D-37191 Katlenburg-Lindau, Germany Email:syfu@linmpi.mpg.de); Q.G. Zong (Max-Planck-Institut f\"ur Aeronomie, D-37191 Katlenburg-Lindau, Germany Email:syfu@linmpi.mpg.de); Z.Y. Pu (Department of Geophysics, Peking University, Beijing 100871, China Email: zypu@pku.edu.cn)

Substorm-associated ion flux enhancements in the inner magnetosphere during the early stage of the large storm on 24 March, 1991 are investigated in this paper. The ion composition measurements are made by MICS onboard the CRRES satellite at L=3.2 $\sim$ 3.8 and local time 1830 to 1900 LT in the time interval of interest. It is found that there are apparently two groups of ions intensified in the event. The low energy group (E/Q $<$ 80 keV/e)) of ions have a trapped distribution peaked at 90^o (pancake PADs) and exhibit strong energy dispersion effects. In contrast, high energy ions (80 keV/e $<$ E/Q $<$140 keV/e)) have intense fluxes at small pitch angles (butterfly PADs), and show peaks (E/Q $\sim$ 100 keV/e) in the energy spectra (flux vs energy per charge) for all four most abundant ion species. The striking differences in the energy and pitch angle distributions between these two groups of ions suggest different energization and transport processes. The first group of ions is possibly energized before they are convected by the gradient B drift to the dusk side and reach the position of the satellite. The second group maybe accelerated directly by the enhanced electric field (estimated magnitude is about 5 mV/m) and the diffusive process at high latitude moves them into the inner region.

PC1 ULF WAVES...

Dr Kanji HAYASHI (Department of Earth and Planetary Physics The University of Tokyo, Japan)

Pc 1 ULF waves are known to be typically enhanced in intensity and in extent of source distribution in the course of major magnetic storms, especially in the recovery phase. This well known fact, however, is a kind of those ingrained in the minds of researchers based on past statistics or on accumulation of impressive events. These after light shows of magnetic storm being appropriate to be named as PC1 storm are interesting to study how storm time plasma in the outer-inner magnetosphere is accommodated with producing free energy for the electromagnetic waves. In this paper results on spatial and temporal characteristics PC1 regions associated with magnetic storms are reported based on comprehensive analyses of data obtained by the semi-global network operated during the STEP period with induction magnetometers. Also we would like to propose that it is worth to devote some effort to achieve global network more plausibly for detecting PC1 waves especially in the plasmapuase latitudes by linking established sites on Internet and by adding new sites in blank areas.

GA3.05/E/12-B3 Poster **0900-15**

POSSIBLE WAVE MODES FOR RELATIVISTIC ELECTRON SCATTERING AND STOCHASTIC ACCELERATION DURING MAGNETIC STORMS

RICHARD B. HORNE (British Antarctic Survey, Madingley Road, Cambridge CB3 0ET, U.K., email: R.Horne@bas.ac.uk); Richard M. Thorne (Department of Atmospheric Sciences, University of California, Los Angeles, U.S.A., email: rmt@atmos.ucla.edu)

The possibility of electron stochastic energization to relativisitic energies (> 1 MeV) via resonant wave-particle interactions during a magnetic storm is explored. The minimum electron energy Emin for cyclotron resonant interaction with various electromagnetic waves is calculated for conditions representative of storm-times. Since Emin > 1 MeV for resonance with L-mode ion cyclotron waves, intense stormtime EMIC waves could contribute to relativistic electron loss, but not acceleration. Inside the plasmapause whistler mode waves, and highly oblique magnetosonic waves near the lower hybrid frequency, can resonate with electrons over the important energy range from approximately 0.1 to 1 MeV. In low density regions outside the plasmapause, the whistler, RX, LO and Z modes can resonate with electrons over a similar energy range. These waves have the potential to contribute to the stochastic acceleration of electrons up to relativistic energies during magnetic storms.

ACCELERATION OF ENERGETIC ELECTRONS AND PROTONS ON HIGH-LATITUDE FIELD LINES AT HIGH ALTITUDES

Tatyana A. IVANOVA, Elmar N. Sosnovets, Lyudmila V. Tverskaya (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: ivanova@taspd.npi.msu.su)

We analyze the particle data from MOLNIYA-1 and GORIZONT satellites. Increases of tens-keV electron fluxes and fluxes of protons of the energies from tens keV to several MeV on the high latitude field lines are studied. Simultaneous data from on-ground geomagnetic observatories are analysed as well. An appearance of particles in the local time sector of dusk--night--early-dawn typically correlates with an increasing of magnetic disturbances on a corresponding field line on the phase of the substorm expansion. Since there are no significant proton fluxes in the interplanetary medium in that periods, the mentioned effect shows that protons of up to ~1 MeV energy are accelerated on high-latitude field lines in the magnetosphere. The possible mechanisms of acceleration are discussed.
Variations of the energetic particle intensity with a period of several minutes through ~1 hour, measured in both day and late-dawn sectors of the magnetosphere at 5-7 Re are investigated. As is shown, synchronous variations of both proton and electron intensities are connected with the geomagnetic variations of DP-2 type and sudden impulses.

ENERGETIC PARTICLES TRAPPED IN THE HIGH-LATITUDE DAYSIDE CUSP: COMPARISON WITH OTHER POPULATIONS AND THE PROBLEM OF ORIGIN

A. E. Antonova, Yu.I. Gubar' and A. P. KROPOTKIN, (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia)

Model concept of energetic particle trapping in the high-latitude outer dayside magnetosphere associated with off-equatorial magnetic field minima, has been proposed long ago (Shabansky, 1972; Shabansky and Antonova, 1968; Antonova and Shabansky, 1975, 1976). Aside from the observational evidence of energetic particle enhancements in the corresponding regions which was obtained on several (mainly Soviet) spacecraft, and was analysed earlier, recent observations of energetic heavy ions, protons, and electrons in the dayside polar cusp, onboard INTERBALL (Savin et al., 1998) and POLAR (Chen et al., 1997, 1998; Sheldon et al., 1998) are shown to support the model (Antonova et al., 1998).
A plausible origin mechanism for the dayside high-latitude particle fluxes consists of: (a) particle injection (and possible acceleration) during magnetospheric substorm activity on nightside; (b) drift-shell branching effect bringing near-equatorial (at nightside) particles to dayside high-latitude regions; (c) pitch-angle and cross-drift-shell diffusion of particles which eventually produces the locally trapped population. Comparative analysis of particle fluxes and energetic spectra in the cusp population and in the normal outer radiation belt favors such a scenario.

VARIATIONS OF GEOMAGNETIC DISTURBANCE INDICES, CONTROLLING ENERGETIC PARTICLE TRANSVERSE DIFFUSION IN THE RADIATION BELTS

A.V.Dmitriev, D.V. Kalinin, S.N.KUZNETSOV and B.Yu.Yushkov (all at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, 119899, Moscow, Russia, e-mail: kuznets@srdlan.npi.msu.su)

Energetic particle transverse diffusion is one of the main processes responsible for radiation

belt dynamics. The transverse diffusion coefficient is a function of geomagnetic disturbances. Different types of geomagnetic disturbances are observed: sudden storm commencements, magnetic storms and substorms which are characterized by certain indices such as number of SSC, Dst-variation, AE and Ap indices. We analyse these indices in connection with solar activity and tilt of the geomagnetic dipole to the ecliptic plane. Certain time variation of all these indices connected with solar activity 11-year cycle is obtained. Variation of the number of SSC on a shorter time scale were not found. 6-month and diurnal variation of magnetic storm number and AE and Ap indices was found. This variation is connected quantitatively with the tilt of the geomagnetic dipole to the ecliptic plane.

TIME SCALES OF THE EARTH'S RADIATION BELTS VARIATION: ANALYSIS OF THE TIROS/NOAA DATA

Yoshizumi MIYOSHI, Akira Morioka, and Hiroaki Misawa (all at Upper Atmosphere and Space Research Laboratory, Tohoku University, Sendai, 980-8578, Japan,
email: miyoshi@stpp2.geophys.tohoku.ac.jp)

Many studies on the static and dynamic behavior of the earth's radiation belts have been performed. However, the response of energetic particles with respect to the external variations with the wide range of time scales has not been well known in detail except for the case of storm and sub-storm. The variability and its time scales of the radiation belts have important information to investigate generation and dissipation process of energetic particles, and driving parameters of the inner magnetosphere.
Using the data set of the TIROS/NOAA satellites during the long period of 1979-1998, we have performed analysis to derive characteristic time scales of the electron flux variation. As the result, the existence of the variation synchronized with the solar cycle in both the inner and outer radiation belts was confirmed. It was also shown that the radiation belts changed in relation to the various variability of the geomagnetic activity; i.e., annual and semi-annual variations, and the recurrent activity. Correlation studies between solar parameters and electron flux variations indicated that there was L-dependent phase lag between the sun spot number and the electron flux, and this phase lag was shorter compared with the diffusion time expected by the traditional radial diffusion.

SYNCHROTRON RADIATION FROM THE EARTH'S RADIATION BELT: INVESTIGATION OF AKEBONO/PWS DATA

Akira MORIOKA, Hiroaki Misawa, and Yoshizumi Miyoshi (All at: Upper Atmosphere and Space Research Laboratory, Tohoku University, Sendai, 980-8578, Japan,
email: morioka@stpp2.geophys.tohoku.ac.jp,)

The radiation produced by relativistic electrons artificially injected into the earth's magnetosphere had been reported in 1960s. However, the radiation from natural relativistic electrons in the earth's radiation belt has not been detected. The EM waves at 3MHz observed with the Akebono satellite were investigated to search the synchrotron component from the earth's radiation belt. The statistical analysis using the data from 1989 to 1995 showed that the wave activity has a positive correlation with energetic electrons which were detected by the NOAA satellite: the linear relation between the 3MHz EM wave intensities and the flux of relativistic electrons. This result shows the first detection of the natural synchrotron radiation produced in the earth's radiation belt.

DETERMINATION OF THE EFFECTS OF SUBSTORMS ON THE STORM-TIME RING CURRENT USING NEURAL NETWORKS

V MUNSAMI (Hermanus Magnetic Observatory, P O Box 32, Hermanus, 7200, South Africa, E-mail: vmunsami@csir.co.za)

A controversy exists as to whether the injection of particles into the ring current is caused by the induced electric fields associated with the expansive phase of substorms or by the enhanced convection electric fields that are driven by the solar wind. In order to investigate the causal storm-substorm relation, an artificial neural network (ANN) is used to examine the relationship between the definitive, high time resolution (1 minute), auroral electrojet index (AL) and ring current index (SYM-H). The network is trained on data taken from the 10-year period between 1984 and 1994 in which substorm onsets are identified by Pi2 geomagnetic pulsations. The performance of the network and its implication to the effects of substorms on the storm-time ring current is discussed.

A MODEL FOR ENERGY RELEASE DURING BURSTY BULK FLOW

B P PANDEY (Indian Institute of Geomagnetism, Bombay 400 005, India, email: pandey@iig.iigm.res.in); G.S.Lakhina (Indian Institute of Geomagnetism, Bombay 400 005, India, email: pandey@iig.iigm.res.in)

A simple model for bursty bulk flows (BBFs) in terms of bursty type of driven reconnection is developed. A bursty type reconnection may be induced at the magnetopause boundary due to the solar wind forcing. The magnetic energy release during the current sheet reconnection is calculated. In this model, persistent plasma energization is provided by ongoing external driving. Possible implication of this mechanism on plasma acceleration is briefely discussed.

SOME THIN EFFECTS IN ELECTRON PLASMA AT GEOSYNCHRONOUS DISTANCES

Boris V. Marjin, Nickolay N. PAVLOV, Elmar N. Sosnovets, and Michail V. Teltsov (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: nnpavlov@taspd.npi.msu.su)

We analyze the data from GORIZONT-35 for 1992-1994. Two spectrometers of electron plasma measured fluxes in field-align and field-perpendicular directions in the energy range 0.1-12 keV. Somewhat new approach of fitting the spectra with multi-Maxwellian distribution function is applied. The method allows us to recognize several simultaneously existing plasma populations and to trace their characteristic temperatures along time/orbit. Time resolution of 128 seconds disallows working in storm periods. Although in rather quiet geomagnetic conditions, such effect as entering a new population into the observed energy range and traversing the range by the temperature of this population is sometimes seen. Three populations exist in the 0.1-12 keV interval in those periods. In many cases the time of appearance of a new population coincides with an injection identified by A-indices. And in many cases the changing of temperature of the injected population looks like cooling. We discuss possible explanation of this effect as either time- or spatial-based one, as well as either convective or injection nature of a new population. Total energy of each Maxwellian ensemble of plasma-electrons is estimated. Some other effects and results of statistical and correlation analysis performed for the measured data are also reported.

CUSP ENERGETIC PARTICLES OBSERVED BY INTERBALL TAIL PROBE

N.PISSARENKO, S.Savin, V.Lutsenko, I.Kirpichev, E.Budnik, A.Moszhukhina, E.Morozova (Space Researh Institute, 117810, Moscow, Russia I.Sandahl (Swedish Institute of Space Physics, Box 812, 981 28 Kiruna, Sweden)

Observations made by the Interball Tail Probe in the Cusp region have found some events with s.c. Cusp energetic particles (CEP) - protons with energy 1-3 MeV. These increasings continued during some tens minutes and went from the distance 1-2 Earth's radius as far as magnetopause. Most probably this population is trapped inside a diamagnetic cavity which was allowed by the origin of different disturbances in the high latitude geomagnetic field. The comparasion with other phenomena showed the coincidence of such events with low frequence turbulence in the nearby plasma regions.

FINE SPATIAL STRUCTURE OF THE OUTER RADIATION BELT IN QUIET AND DISTURBED CONDITION

George POPOV (Irkutsk State Economics Academy, 11 Lenin str., Irkutsk 664015, Russia, Email: popov@isea.irk.ru); Vitalii Degtjarev, Sergei Sheshukov and Svetlana Chudnenko (all three at Institute of Solar-Terrestrial Physics, P.O.Box 4026,Irkutsk 664033, Russia, Email: shesh@istp.irk.ru); Geoff Reeves (Los Alamos National Laboratory, NIS-2, Mail Stop D-436, Los Alamos, New Mexico, 87545, USA Email: reeves@lanl.gov); Alan Johnstone (Mullard Space Sience Laboratory, Hholmbury St.Mary, Dorking, Surrey RH5 6NT, UK, Email: adj@mssl.ucl.ac.uk)

It is well known, that data from simultaneous measurements of radiation on several geostationary spacecrafts distributed in longitude make it possible to reconstruct the spatial distribution (in magnetic coordinate system) of charged particles measured and L-values scanned ranges approximately from 6.6 till 7.0. Electron fluxes data from LANL geostationary spacecrafts were statistically treated and ordered in a special magnetic coordinate system. The data treating procedure allowed to obtain the dynamics of quasi-trapped electrons of different energies on different L-shells. It was found, that a rather permanent fine spatial structure of the quasi-trapped electrons exists with maximum of fluxes near L = 6.78 and MLT=12. This structure looks like asymmetrical "mini-belt". The position of the maximum depends of the electron energy (the more is the energy, the smaller is the L - value) and changes with magnetic activity. Dynamics of this "mini-belt" for both quiet and disturbed periods is illustrated and discussed. During isolated magnetic storms the mini-belt maximum shifts in regular manner outward and inward; a diffusion wave of quasi-trapped particles propagates from outside of the geostationary orbit and serves as a source of new particles for mini-belt. The asimutal geometry of this diffusion wave extracted from experimental data is illustrated. The possible role of fine spatial structure is discussed in relation with well-known "anomalous" dynamics of the inner radiation belt.

RESONANT ENHANCEMENT OF RELATIVISTIC ELECTRON FLUXES

ILAN ROTH AND Mike Temerin (SSL, UC Berkeley, CA 94720, USA, Email: ilan@ssl.berkeley.edu), Mary Hudson (Dartmouth College, NH 03750, USA

The enhancement in the flux of relativistic electrons during active geomagnetic periods is of major importance as use of the near-earth space environment increases. Enhancement of energetic electron fluxes at L ~ 4-5 were observed during geomagnetic storm intervals, as well as during quieter times following high speed solar wind stream arrival at 1 AU. The HIST instrument on the POLAR satellite measured numerous large enhancements in f(L) at low L shells during active periods. as well as increase at L=4.5 of <1 MeV electrons which precedes increase in the >1 MeV, without significant flux increase initially at higher L values. This observation, and others by HEO spacecraft suggest that a local heating mechanism may be operative. It is suggested that the ubiquitous, obliquely propagating whistler waves interact with electrons which bounce along the geomagnetic field 1ines. The unducted whistler chorus which is a typical signature of the substorm expansion phase, interacts with the seed of sub-relativistic electrons. For an oblique wave propagation the energetic electrons with large gyroradius (larger than the perpendicular wavelength) can interact resonantly with multiple harmonics of the whistler waves on their bounce trajectories along the inhomogeneous magnetic field. Whistler waves, which propagate obliquely to the magnetic field, can interact with energetic electrons through Landau, cyclotron, and higher harmonic resonant interactions when the Doppler-shifted wave frequency equals any (positive or negative) integer multiple of the local relativistic gyrofrequency. This interaction occurs over large spatial distances when an electron is bouncing in the terrestrial magnetic field. The resulting resonant interaction violates the first and the second adiabatic invariants and results in electron energization at relativistic energies. The analysis of the energization with the help of particle and Hamiltonian simulations of these interactions are presented.

A PI2 ONSET AS OBSERVED AT GEOSYNCHRONOUS ALTITUDE.

O. SAKA, (Dept. Phys. Kurume National College of Technology, Kurume, Japan and Dept. Earth and Planetary Sci., Kyushu University, Fukuoka, Japan); D.N. Baker, (Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, CO, USA)

The initial responses of the magnetic field lines at Pi 2 onset are examined in the midnight sector of geosynchronous altitude (L~6.6). The onset of the Pi 2 disturbances at the satellite altitude is determined by employing the ground magnetometer station at the dip-equator (Huancayo, Peru) located in the meridian of the geosynchronous satellites, Goes 5 and 6. The initial disturbances at L~6.6 are characterized by a decrease of the field magnitude B, an increase of the radial component V, and a nearly equal opportunity of increase/decrease of the northward component H. Based on the model calculation, we infer that the formation of the dusk-to-dawn current in the midnight sector at a L close to the geosynchronous altitude could invoke the initial disturbances outlined above.

IONIZATION DYNAMICS OF THE F LAYER IN THE DIFFUSE AURORA AND SAR-ARC REGION

Ievenko I.B., Khalipov V.L., Alexeyev V.N., STEPANOV A.E. (Institute of Cosmophysical Research and Aeronomy, Yakutsk 677891, Russia, email: ikfia@sci.yakutia.ru)

Study results of the subauroral luminosity dynamics and ionisation at heights of F2-layer on the ground-based photometric and ionospheric observation data at the Yakutsk meridian for Kp=3-5 are present. The following features have been related: 1. At the beginning of prolonged magnetic activity (several hours) at latitudes of the brightening SAR-arc the increase of the F2 regular layer height with a velocity up to 30 m/s and the decrease of the electron density by 2-4 times are occured. 2. Under the repeated increase of activity (the expansion phase of the next substorm) in the aftermidnight sector the polar edge is observed already equatorward of the diffuse precipitation boundary and shifted with the velocity of 20-50 m/s to the sounding station zenith. 3. Results of complex measurements suggest that SAR-arc and sporadic ionization motion equatorward of the diffuse precipitation zone is caused by the penetration of the magnetospheric convection electric field into the plasmasphere.

SECOND-ORDER INTERACTIONS IN THE PLASMA SHEET

Elena VILLALON (Northeastern University, Boston Ma 02115, USA, e-mail: villalon@plh.af.mil)

The nearly isotropic fluxes of low energy electrons (< 10 keV), observed above the diffuse aurora can be attributed to interactions between quasi-electrostatic plasma waves and particles in the plasma sheet. Banded electrostatic cyclotron harmonic (ECH) emissions have been detected by the CREES satellite, near equatorial regions at the shells L = 3.5 to 7. The frequency bandwiths of the ECH emissions extend between harmonic intervals of the electron gyrofrequency, and their spectrum can be quite broad. The ECH waves with a sufficiently broad frequency spectrum can satisfy the conditions for second-order resonance interactions with the low energy electrons.
Second-order resonance interactions are characterized by variations of the frequencies as waves and electrons propagate along the field lines. The frequency variations along field lines mantain the resonance interactions for extended distances by compensating for magnetic field inhomogeneities. These concepts were originally applied by Villalon and Burke, J. Geophys. Res., 100 (1995), to the interactions of whistler and electrons, and they were proved to be very efficient to precipitate electrons into theatmospheric loss cone. Because the wave amplitudes that are known just outside the plasmasphere are low, it is not possible to explain electron precipitation with coherent interactions for a single frequency wave since they fall out of resonance due to the inhomogeneities. We investigate the effects that second-order interactions have in the coupling of ECH waves and electrons, and compare them to single frequency coherent electrostatic interactions.

PITCH ANGLE DIFFUSION VIA CHAOS IN THE ELECTRON-WHISTLER MODE WAVE INTERACTION

W J WYKES and S C Chapman, (University of Warwick, Coventry, UK)

We investigate the interaction between electrons gyrating about a uniform background magnetic field and two anti-parallel whistler mode waves as a mechanism for pitch angle diffusion and subsequent scattering into the loss cones as a source of auroral precipitation. For a single whistler wave (in the Earth's magnetosphere, for example), the wave couples with electrons propagating in an anti-parallel direction. There is no stochasticity and the system is Hamiltonian in form. The second whistler wave introduces chaos into the system. Near resonance with either of the waves, particles are still trapped and execute regular motion. Off resonance the orbits are stochastic. For small wave amplitudes the system is Hamiltonian to first order with two degrees of freedom. Numerically integrating the full system of equations we can investigate the growth of the stochastic regions as the wave amplitude increases. For small wave amplitudes regular KAM surfaces dominate phase space. When the wave amplitudes is increased stochastic orbits appear between the two resonances and as the wave amplitude increases further the stochastic region grows, until stochastic trajectories dominate phase space and regular trajectories are confined to close to the resonances. We calculate the Lyapunov exponents averaged over phase space for the full system of equations to quantify the degree of stochasticity in the system as a function of wave amplitude, wave frequency and particle velocity.

MULTIPLE SATELLITE STUDY OF THE MAY 1998 MAGNETIC STORM: RING CURRENT RESPONSE

J F FENNELL, J L Roeder , J B Blake (The Aerospace Corporation, Los Angeles, CA, 90009, USA, email: joseph.f.fennell@aero.org); R. H. W. Friedel, G. D. Reeves and M. Henderson (Los Alamos National Laboratory, MS: D436, Los Alamos, NM 87545, United States); M. Grande (Rutherford Appleton Laboratory, Chilton- Didcot, OX110QX, United Kingdom); T. A. Fritz (Boston University, Boston, MA 02215, United States); S. Livi (Max Planck Institute for Aeronomy, Katlenburg-Lindau, Germany)

One of the problems of performing ring current studies with in-situ data has been the poor spatial/temporal sampling of the inner magnetosphere that has been provided by single satellite studies. Generally, the recent (since 1984) studies of the ring current have relied on singlesatellites in geotransfer or higher apogee orbits with periods of 10 hours or more. The recent observations taken by the Polar satellite in an 18 hour orbit are representative of this problem. For this study we combine the detailed composition observations from Polar CAMMICE experiment with proton observations by HEO (94-026, 95-034, and 97-068) satellites in ~12 hour orbits at different local times. The HEO coverage occurs roughly in the pre-noon/pre-midnight, post-noon/post-midnight and dawn/ dusk regions of the inner magnetosphere. Polar covers the pre-noon/pre-midnight region. The minimum Dst ~ -216 nT occurred on May 4, 1998 near 0530 UT. Polar was outbound through the near noon ring current region from ~0400 UT until it exited the plasma sheet and entered the magnetosheath (during the shock) near 0615 and again near 0645 UT. It did not resample the ring current until after 1920 UT on May 4. Adding the HEO data provides ring current traversals near 0000, 0500, 0600, 0800, 0830,1100, and 1400 UT on May 4 during the DST minimum and early storm recovery. These data are combined to provide a picture of the evolution of the ring current as a map of its peak position and outer and inner edges as a function of time and local time. The combined observations will be presented and discussed in terms of the development of the storm main phase and its initial recovery.

SUBSTORM-ASSOCIATED PARTICLE POPULATIONS IN THE INNER MAGNETOSPHERE AS OBSERVED BY POLAR/CAMMICE AND CEPPAD

N. Y. GANUSHKINA, T. I. Pulkkinen (Finnish Meteorological Institute, Helsinki, Finland); V. A. Sergeev (Institute of Physics, University of St. Petersburg, St. Petersburg, Russia); D. N. Baker, T. E. Turner (Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, CO, USA); M. Grande, B. Kellett (Rutherford Appleton Laboratory, Chilton, Didcot, UK); J. F. Fennell, J. Roeder (The Aerospace Corporation, Los Angeles, CA, USA); and T. A. Fritz (Boston University, Boston, MA, USA)

The Charge and Mass Magnetospheric Ion Composition Experiment (CAMMICE) and the Comprehensive Energetic Particle and Pitch Angle Distribution (CEPPAD) instruments onboard POLAR probes the substorm-associated composition of particle populations in the Earth's magnetosphere over the range of 6 keV/e to 400 keV/e. The periods when POLAR was near magnetic midnight (2200 - 0200 MLT) are considered. The plasma sheet thickness variations during the different substorm phases are examined in a statistical sense. The results are compared with global auroral images and their mappings to the magnetotail. On many passes a spectacular feature was found such as plasma sheet-like (10-50 keV) and radiation belt-like populations overlapped at L=5-6. It also has a sharp earthward boundary. The relationship of appearance of such events to the magnetic activity was examined. As many of these structures appear after substorm onset they could be the midlatitude prints of substorm-related inward injection of plasma material.

DYNAMICS OF ANOMALOUS COSMIC RAY IONS STRIPPED IN THE OUTER ATMOSPHERE

S.N.KUZNETSOV and B.Yu.Yushkov (both at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, 119899, Moscow, Russia, e-mail: kuznets@srdlan.npi.msu.su)

The main problems in analysing the ACR radiation belt are developing of the model of charged particle nonadiabatic motion and finding the adiabatic motion boundary. We propose to use parameter "chi" for analysing the two different modes of motion. Here "chi" is the ratio of the particle gyration radius to the curvature radius of magnetic field line at the equator.
We constructed a Poincare mapping for particle dynamics in a dipole field based on the quasi-adiabatic motion model. This method was applied to motion analysis of particles with variable charge (ions during their stripping). The life-times for particles with different "chi" and the adiabatic motion boundary for different L-shells were found. The probability of trapping for ACR ions stripped in outer atmosphere on different L-shells is analysed.

PARAMETERS OF PARTICLE POPULATIONS IN THE INNER MAGNETOSPHERE, DETERMINED WITH A HELP OF DIFFUSION WAVES OF ELECTRONS

MINEEV Yu.V. (Skobeltsyn Institute of Nuclear Physics, Moscow State University, 119899, Moscow, Russia, e-mail: mineev@srdlan.npi.msu.su)

Onboard several satellites (Intercosmos and Cosmos series) rapid diffusion waves of energetic electrons were obtained with simultaneous shift of maxima within energy range 0.1-2.0 MeV towards low L-shells. These waves have high velocity, which is more than ring current velocity. They are an effective instrument to study the processes of acceleration, transport and losses of particles in the inner magnetosphere. Determing the diffusion wave velocity permites us to calculate the radial diffusion coefficient for outer radiation belt, that can not be easily obtained by other methods (for example, by solving the diffusion equation). The role of injection and fast radial diffusion during disturbed magnetospheric conditions and during the recovery phase of the storm in creating the electron population of the inner magnetosphere is discussed. The new calculated distribution function was used to estimate the electron's source time value corresponding to the definite radial diffusion coefficients and closs term (pitch-angle scattering and energy loss by Coulomb interaction, wave-particle interaction) for the inner radiation belt electrons during maximum and minimum solar activity. The connection between waves and spectral peculiarities of particles observed onboard several satellites are considered. The data of satellites Intercosmos-19 and Cosmos-1686 about energetic electrons fluxes profiles (L<2.5) are also better described by the diffusion under influence of the electric fields fluctuations.

NORMALIZED >50 MEV PROTON FLUX MAPS FOR SPACE OPERATIONS

E.G. MULLEN (Assurance Technology Corporation, Carlisle, MA 01741,
email: mullen@assurtech.com); G. Ginet, M.S. Gussenhoven, D.H. Brautigam (Air Force Research Laboratory, Hanscom AFB, MA 01731); D. Madden (Institute for Scientific Research, Boston College, Newton, MA 02159)

Protons in the Earth's inner radiation belt are the source of Single Event Effects (SEEs) on low altitude satellites. Precise knowledge of the position of the belt in geographic coordinates is hampered by temporal variations, two of which are a) fluctuations in the Earth's magnetic moment and b) enhancements and additional peaks in proton fluxes beyond L = 1.8. The change in position, direction and magnitude of the Earth's magnetic moment has been substantial since the NASA AP8 models were constructed. In addition, a second peak in high energy proton fluxes was created during a very large magnetic storm in March 1991. Data taken on the APEX and CRRES satellites are used to produce three-dimensional contour maps of normalized flux of protons with energies >50 MeV in geographic coordinates. These maps may also be used to give relative probabilities of experiencing Single Event Effects (SEEs) in the Earth's inner radiation belt, and as such, have proven useful to operations on spacecraft such as the Hubble Telescope. To make the maps, the data are averaged in 3 degree by 3 degree bins in geographic latitude and longitude, and in 50 km steps in altitude. All geographic longitudes, and latitudes between +70 degrees and -70 degrees are covered. The altitude range extends from 350 km to 14,000 km. This geographic range includes the complete region of inner belt >50 MeV protons, except in the area of the South Atlantic Anomaly (SAA) below 350 km. The maps easily locate the SAA when ascending in altitude, and an "Indonesian Anomaly" when descending in altitude from above 15,000 km. They also clearly show the second proton peak falling within an envelope determined by the primary peak.

OBSERVATIONS OF QUASI-TRAPPED ELECTRONS FLUXES (>0.5 MEV) UNDER THE INNER RADIATION BELT ON BOARD "CORONAS-I" SATELLITE

S.N. Kuznetsov, I.N.MYAGKOVA(both at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, 119899, Moscow, Russia, e-mail: irina@srdlan.npi.msu.su)

Electrons with the energies >0.5 MeV were observed at altitude about of 500 km in the experiment on board 'CORONAS-I'satellite, launched in March 1994. Significant electrons

peaks at L=2.1-2.3, narrow electron peaks at L=(1.6 and in the western side of Brazilian Magnetic Anomaly significant electron peaks near L=1.3 were observed during March-May 1994. Dependencies of anomalous electron in peaks on L, local and universal time, parameters of interplanetary medium and geomagnetic activity indexes for Northern and Southern hemispheres were studied. Empirical model of anomalous electron fluxes under radiation belt (for L<2.2) based on these studying results was built.

ASSESSING THE ROLE THAT GEOCORONAL CHARGE EXCHANGE PLAYS AS A SOURCE FOR THE PLASMASPHERE

Herbert O. Funsten, Joseph E. BOROVSKY (both at Space and Atmospheric Sciences Group, Los Alamos National Laboratory, Los Alamos, NM 87545, USA, email: jborovsky@lanl.gov), Michael W. Liemohn, and Janet U. Kozyra (both at Space Research Laboratory, University of Michigan, Ann Arbor, MI 48109)

The charge-exchange collisions between plasma-sheet (ring-current) ions and the hydrogen atoms of the geocorona produce cool protons that are trapped in the dipole portions of the Earth's magnetosphere. Theoretical estimates are presented which indicate that the production rate of these cool ions is a few tons per day in the magnetosphere or about 0.5 per cubic centimeter per day at geosynchronous orbit. With the use of computer simulations, the role of these charge-change ions in the refilling of the plasmasphere is studied. It is determined that these ions could be important for early time refilling and consequently could play a role as a catalyst for the late-time refilling.

SIMULATION OF CME-DRIVEN RADIATION BELT PARTICLE ACCELERATION FOR SOLAR MAXIMUM EVENTS

M. K. Hudson, S. R. ELKINGTON, and J. G. Lyon (Department of Physics and Astronomy, Dartmouth College, Hanover, NH 03755, email: mary.hudson@dartmouth.edu); J. B. Blake (Aerospace Corporation, Los Angeles, CA 90009)

The first CME-driven interplanetary shock events with radiation belt particle effects comparable to the 1989-1991 solar maximum have now been observed with the new millennium fleet of spacecraft. A 3-D global MHD simulation of the May 1-4 and Aug 27-28, 1998, events has been used to drive guiding center test particle trajectory simulations for both radiation belt electrons and protons. These are the first events to show clear trapping of solar energetic protons deep in the magnetosphere for this solar maximum, comparable for the case of the Aug 27-28 period with the Great Storm of March 24, 1991, in terms of trapping and acceleration mechanism. Effects of ring current buildup and recovery on the nonadiabatic loss and subsequent energization of protons as the background magnetic field dipolarizes are included in the analysis. While it appears that trapping of solar energetic protons is due to the initial shock compression of the magnetopause (Hudson, et al., 1997), dipolarization due to ring current recovery transports them radially inward increasing their energy above detector thresholds.

VARIATIONS OF IONS O+ AND H+ ENERGY DENSITY IN RING CURRENT DURING MODERATE MAGNETIC STORM

L. A. Dremukhina, Ya. I. FELDSTEIN, A. E. Levitin (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation,Troitsk, Moscow Region, 142092, Russia, email: lgromova@izmiran.troitsk.ru) M. Greenspan (Department of Physics, Univertsity of Maryland, College Park, MD 20742, USA)

Observations of ions O+ and H+ energy density every 3 minutes in the magnetosphere equatorial plane at 2 < L < 7 by AMPTE/CCE satellite are used for analysis of contribution of the ring current and near-Earth plasma sheet to the observed on the ground Dst magnetic field variation in the course of moderate magnetic storm in November 1986. Based on DMSP data on auroral plasma precipitations structural boundaries the location of boundary between the ring current and the current in the magnetospheric tail is determined. Relative contribution of ions O+ and H+ to the energetic of the ring current and adjacent plasma sheet region is evaluated. Characteristic times of the ring current decay at various L-shells for ions O+ and H+ are calculated and compared with values of the ring current decay parameter on the basis of ground geomagnetic data. Energy balance equation in the inner magnetosphere is used for modelling of magnetic field variations on the Earth's ground during magnetic storm in dependence on interplanetary medium parameters.

ASYMMETRIC RESPONSE OF RING CURRENT TO SUDDEN SOUTHWARD TURNING OF IMF

Kumiko HASHIMOTO (Communications Research Laboratory, Koganei, Tokyo 184, JP, email: hashimoto@crl.go.jp), Yusuke Ebihara (The Graduate University for Advanced Studies, JP), Takashi Kikuchi (CRL, JP) and Masaki Ejiri (NIPR, JP)

We have investigated the development of ring currents caused by a sudden southward turning of IMF, by using INTERMAGNET magnetometer data in mid and low latitudes and a simulation of the ring current. A sudden southward turning of IMF Bz from +10 to -17 nT was observed by GEOTAIL at 17:19 UT on September 5, 1995. The southward turning was followed by magnetic H-component decreases at low latitudes in 17-23 MLT and by increases in 9-14 MLT, with a time lag of 9 min after the increase of the convection electric field as inferred from the polar cap magnetometer data. The local time asymmetry of the magnetic H component changed drastically after the northward turning of IMF depressed the convection electric filed at 17:52 UT. The magnetic field decreased from evening to morning hours, and increased in early morning. We simulated the development of the ring current with a convection electric field calculated from the observed solar wind parameters, by applying the ring current model by Ebihara and Ejiri [1998]. The result of simulation shows that the enhanced convection electric filed causes outflow of ring current particles which have been developed before the event. As a result, the ground magnetic field increases in the day-side. Consequently, the ring current condition before the event is crucial for the asymmetric ring current.

GA3.05/E/10-B3 Poster **0900-43**

EFFECT OF RADIATION BELT ORIENTATION AND STRENGTH ON GROUND GEOMAGNETIC FIELD VARIATIONS

James M E, Som Sharma, H Chandra, P S Shah and R G RASTOGI, (Physical Research Laboratory and Gujrat University Ahmedabad 380 009, India, e-mail: parvs@prl.ernet.in)

Using the eqatorial Dst(H) index as the indicator of the intensity of ring current, the relationship have been computed between daily means of Dst(H) and daily means of the northward (X) and eastward(Y) components of the geomagnetic field at world wide stations during 1958. Significant longitudinal and regional inequalities have been isolated related to the corresponding regional anomalies in the earths magnetic field. Quantitative explations are found between the delta X / delta Y and the deviation of dipole meridian with respect to the ground magnetic meridian of the station.

POST-STORM EVOLUTION OF HIGHLY RELATIVISTIC ELECTRON PITCH-ANGLE DISTRIBUTIONS

Michael SCHULZ, David L. Chenette, and Edward E. Gaines (all at Lockheed Martin Advanced Technology Center, Palo Alto, CA 94304, USA, email: schulz@agena.spasci.com) Richard A. Goldberg (NASA/GSFC, Laboratory for Extraterrestrial Physics, Code 690, Greenbelt, MD 20771, USA, email: richard.a.goldberg.2@gsfc.nasa.gov) W. Dean Pesnell (Nomad Research Inc., Bowie, MD 20716, USA, email: pesnell@nomadresearch.com)

This is a theoretical account of UARS electron observations described by Goldberg et al. (this session). Stormtime radial transport tends to increase phase-space densities of trapped relativistic electrons but typically leads to flux increases at specified energies only as the ring current decays. Flux enhancements at this stage are (for kinematical reasons) greatest for equatorially mirroring electrons, and so pitch-angle anisotropies are large. Subsequent pitch-angle diffusion broadens the flux enhancement to particles that mirror off-equator, thus gradually increasing low-altitude electron intensities on time scales ~ 20% of corresponding lifetimes against diffusion into the loss cone. This is because broadening and loss reflect distinct eigenvalues of the same diffusion operator. Corresponding time scales for post-storm growth and decay of off-equatorial electron intensities thus increase with electron energy above an L-dependent critical energy (E* ~ 300 keV at L = 3) for which electron lifetimes are shortest.

MAGNETOSPHERIC ENERGETICS DURING STORMS

Niescja E TURNER and Dan Baker (LASP, Univ. of CO, Boulder, CO 80309-0590 USA, Email: turner@daria.colorado.edu); Tuija Pulkkinen (Finnish Meteorological Institute,Helsinki, Finland); Vania Jordanova (University of New Hampshire); Gang Lu (HAO/ NCAR); Mike Henderson (Los Alamos); Joe Fennell and Jim Roeder (Aerospace Corp.) Ted Fritz (Boston University)

Magnetospheric energy flow is traced through ten storms, with particular focus on the ring current. For each storm, we trace energy input into the magnetosphere, along with ring current energy calculated from POLAR CAMMICE data. We calculate the energy density in the ring current using the MICS detector on the POLAR CAMMICE experiment. Where available, we use a ring current model to correct for azimuthal asymmetry of the current and then multiply by the volume to estimate the total energy. Consideration is also given to ENA data as a proxy for ring current particle measurements in order to provide a more continuous data set. Energy input is estimated with the epsilon parameter. Additionally, AMIE data are used for several storms to trace the energy flow into the ionosphere through joule heating and auroral electron precipitation. The resulting time series of ring current energy, ionospheric joule heating, and auroral electron precipitation are then compared with the input energy, the measured Dst, and the measured AE in order to trace the evolution of the energetics of the system as a whole.

MAGNETOSHEATH OXYGEN AND MAGNETOSPHERE PARTICLE TRANSPORT

B.Wilken, Q.G. Zong, S. Y. Fu, S. Livi, U. Mall (all at Max-Planck-Institut fuer Aeronomie, D-37191 Katlenburg-Lindau, Germany Email: wilken@linmpi.mpg.de); M. Grand (Space Science Division, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, England) T. A. Fritz (Boston University, Boston, USA)

Particle spectrameter HEP-LD onboard Geotail frequently detected impulsive flux enhancement of energetic oxygen ions in the duskside mgnetosheath. These oxygen ions are usually moving in a downstream direction. In all cases the observed events are related to geomagnetic activity such as substorms and magnetic storms. In some favourable cases it was possible to compare the magnetosheath flux level of oxygen ions with the flux level in the adjacent magnetosphere. It was found that the magnetospheric flux was too low to serve as a local source for particle leakage. Occasional observations of anisotropic oxygen ions in the outer magnetosphere during substorm activity may provide a clue for the oxygen transport.

THE RESPONSE OF THE MAGNETOSPHERE TO AN INTERPLANETARY SHOCK: THE MAGNETOSPHERIC COMPRESSION ON SEPTEMBER 24, 1998

C. T. RUSSELL, P. Chi, Guan Le, J. Raeder and R. J. Strangeway (All at Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095-1567, USA, email: ctrussell@igpp.ucla.edu); H. J. Singer (Space Environment Center, NOAA, Boulder, CO, USA); H. Kawano (Kyushu University, Fukuoka, Japan); T. E. Moore (Goddard Space Flight Center, Greenbelt, MD, USA); W. K. Peterson (Lockheed Martin, Palo Alto, CA, USA)

At approximately 2344 UT on September 24, 1998 the nose of the magnetosphere was suddenly compressed by a strong interplanetary shock wave. As evidenced by successive compressions of the magnetic field at GOES 10, POLAR and GOES 8, the compressional wave moved rapidly through the magnetosphere. At POLAR the compression caused the magnetopause to move closer to the spacecraft, causing rapid cross field flows and altering the location of the conjugate point in the ionosphere. The pre-existing flows were heated locally only slightly by betatron acceleration because the flows were mainly field aligned.

Waves also did not lead to much heating because they were small in amplitude. Centrifugal heating may have been a more important local process. Some of the observed change in the plasma observed at POLAR was associated with the motion of the non-uniform polar cap outflow across POLAR. Snapshots of the polar cap by FAST confirm that the outward polar cap flows are non-uniform at this time but also show that strong heating is present and subsequently is very important in determining the outflow of plasma. Ground station recordings, synchronized with GPS signals, enable the disturbance to be followed through the magnetosphere from high latitudes to low. This event teaches us much about how the ionosphere is coupled to the magnetosphere and demonstrates the symbiosis of ground based, ionospheric and magnetospheric observations with modelling in magnetospheric studies.

POLAR IONOSPHERIC OUTFLOW RESPONSE TO SOLAR WIND CONDITIONS AT 2-9 RE

Moore, T.E. and B.L. GILES (both at NASA Goddard Space Flight Center, Greenbelt, MD 20771 USA, Email: thomas.e.moore@gsfc.nasa.gov), M.O. Chandler (NASA Marshall Space Flight Center, Huntsville, AL 35812 USA), M.R. Collier (NASA Goddard Space Flight Center, Greenbelt, MD 20771 USA), H.L. Collin (Lockheed Martin Advanced Technology Center, Palo Alto, CA, 94304 USA), R. Fitzenreiter (NASA Goddard Space Flight Center, Greenbelt, MD 20771 USA), W.K. Peterson (Lockheed Martin Advanced Technology Center, Palo Alto, CA, 94304 USA), C.J. Pollock (Southwest Research Institute, San Antonio, TX 78228 USA), C.T. Russell and R.J. Strangeway(both at University of California, Los Angeles, CA 90024 USA)

We report observations of direct ionospheric plasma outflow response to the incidence of an interplanetary shock and associated coronal mass ejection upon the earth's magnetosphere. Data from the WIND spacecraft, 185 RE upstream of Earth, document the passage of an interplanetary shock at 23:20 UT on 24 Sept. 1998, traveling at 860 km/s. The polar cap plasma environment sampled by the POLAR spacecraft changed abruptly at 23:45 UT, reflecting a displacement of the previously remote plasma mantle to the vicinity of the spacecraft, as the shock propagated through the polar magnetosphere. At about 02:00 UT, POLAR reentered the lobe and polar wind, finding it had changed to a colder, slower, and denser outflow dominated by O+ plasma. The O+-dominated outflow continued as the spacecraft passed through the northern cleft at ~4.5 RE and then the southern cleft at 1.8 RE (geocentric). Such a direct response of the ionosphere to solar wind pressure disturbances is of potential significance to the dynamics of the magnetotail.

GA3.08/W/17-A6 0940

CENTRIFUGAL ACCELERATION OF IONS OBSERVED ON POLAR SPACECRAFT NEAR 9 RE OVER POLAR CAP UPON ARRIVAL OF CME-DRIVEN SHOCK

John B. CLADIS, Harry L. Collin, and William K. Peterson (all at Lockheed Martin Advanced Tech. Center, 3251 Hanover Street, B 255, Palo Alto, CA 94304, USA, email: cladis@spasci.com) Thomas E. Moore (NASA Goddard SFC, Code 692, Bldg. 2, Greenbelt, MD 20771-1000, USA, email: thomas.e.moore@gsfc.nasa.gov) Christopher T. Russell (Inst. of Geophysics and Planetary Physics, UCLA, Los Angeles, CA 90095-1567, USA, email: ctrussel@igpp.ucla.edu)

A shock driven by a coronal mass ejection struck the magnetosphere about 2344 UT on September 24, 1998. The POLAR spacecraft was near apogee over the northern polar cap, at (X,Y,Z)GSM = (-2.3803, -2.7148, 8.1450) in RE. During the following 144 s, from 2345:18 UT to 2347:42 UT, (1) the magnetic field measured on-board with the UCLA magnetometer increased sharply from126.16 nT to 182.00 nT; (2) the field components changed from (BX,BY,BZ)GSM = (84.91, 32.55, -87.45) to (151.11, 50.655, -87.867); (3) the full rotation of B was 19.87o; and (iv) the velocity components of both the H+ and O+ ions increased by about 75 km/s antiparallel to B. We suggest the ions were flung along -B by the "motion" of the magnetic field, according to the centrifugal-acceleration process first described by Cladis [GRL, 13, 893,1986]. A parallel-velocity increase of 35 km/s was computed by integrating the term $dv_{||}/dt = vE \cdot d\hat{e}/dt$, using the local values of vE (the drift velocity) implied by the ion-velocity components perpendicular to the magnetic field and the measured values of $\hat{e}(t) = B(t)/B(t)$. The higher acceleration of the ions was confirmed by a computer simulation of the process along the ion paths.

GA3.08/W/13-A6 0940

FAST OBSERVATIONS DURING THE SEPTEMBER 24TH AND 25TH 1998 MAGNETIC STORM

R. J. STRANGEWAY, C. T. Russell (both at: Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095, USA, Email: strange@igpp.ucla.edu), D. M. Klumpar (Lockheed Martin Advanced Technology Center, 3251 Hanover St., Palo Alto, CA 94304, USA), C. W. Carlson, J. P. McFadden, R. E. Ergun (all at: Space Sciences Laboratory, University of California, Berkeley, CA 94720, USA), T. E. Moore (NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA), and W. K. Peterson (Lockheed Martin Advanced Technology Center, 3251 Hanover St., Palo Alto, CA 94304, USA)

During September 24th and 25th 1998 the FAST spacecraft acquired data over the Northern Polar Cap in the noon-midnight local time sector. This allowed for detailed observations of the dayside cusp at ~ 4000 km altitude. The spacecraft was therefore ideally suited for monitoring the outflow of ionospheric plasma which was also observed at the higher altitude POLAR spacecraft. The interval around the Sudden Impulse (SI) at 23:45 UT on September 24th is characterized by enhanced field-aligned currents in the cusp region. Because the FAST orbital period is ~ 135 minutes, we can provide snapshots of the cusp region, and FAST passes through the cusp at ~ 00:10 UT on September 25th, some 35 minutes after the SI. The field-aligned currents at this time are sig ificantly larger than on the previous orbit. Large fluxes of 100 eV oxygen ions are also observed to be flowing out of the ionosphere, with decreasing energy for increasing latitude. These ions form a conic in pitch angle, consistent with the "pressure cooker" model of ion acceleration, where transverse heating overcomes a downward electric field. As already noted the field-aligned currents are weaker on the previous orbit, and a weaker oxygen conic is also observed. This suggests that the main effect of the increased solar wind dynamic pressure is to enhance already existing ion outflow through an increase in the field-aligned currents and the associated parallel electric fields and ion heating in the cusp ionosphere.

GA3.08/W/05-A6 1040

THE RESPONSE OF THE MAGNETOSPHERE TO AN INTERPLANETARY SHOCK: GROUNDBASED OBSERVATIONS OF THE SUDDEN IMPULSE ON SEPTEMBER 24, 1998

P. Chi, Guan Le, J. Raeder, C. T. RUSSELL and E. Zesta (All at Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA, USA, email: pchi@igpp.ucla.edu); K. Yumoto, H. Kawano and K. Kitamura (All at Kyushu University, Fukuoka, Japan); V. Angelopoulos (University of California, Berkeley, CA, USA); M. Moldwin (Florida Institute of Technology, FL, USA)

The strong interplanetary shock wave that intersected the front of the magnetosphere at about 2344 UT on Sept. 24, 1998, launched a compression of the magnetosphere that was followed around the globe by a new generation of magnetometers with rapid sampling and precise GPS-synchronized timing. Magnetometers of these chains included those in the Circum Pan Pacific Magnetometer Network, those in the IGPP/LANL array, those in the MEASURE array and those in the MACCS array. The event exhibited all the classical signatures of an SI including the preliminary decrease before the main increase in the H-component. The ability to model this event and its induced ionospheric currents using an MHD code allows us to compare the compression as it is seen in the magnetosphere with the response of the ionospheric currents.

GA3.08/W/02-A6 Invited 1100

RECENT ADVANCES IN MAPPING MAGNETOTAIL BOUNDARIES USING SUPERDARN HF RADARS

Mervyn P FREEMAN (British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET, U.K, email: M.P.Freeman@bas.ac.uk)

We review and discuss recent publications which have shown how HF radars can remotely sense magnetotail boundaries and thereby measure how these boundaries respond to changes in the IMF and to substorms. Specifically, we present the following: (1) Evidence for a relationship between the boundary plasma sheet/central plasma sheet (bps/cps) interface in the magnetotail and the equatorward edge of HF radar backscatter from the ionosphere or a latitudinal gradient in the Doppler spectral width of the backscatter. (2) Examples using this empirical relationship to track both rapid (of order 1 min) and slow (of order 1 h) changes in the ionospheric projection of the bps/cps interface. (3) Comparison of the time-varying location of the bps/cps interface observed in these examples with that predicted by a magnetic reconnection-based magnetospheric model using concurrent solar wind observations.

GA3.08/W/25-A6 1130

ELECTRON PRECIPITATION AS A FUNCTION OF MAGNETOTAIL STRETCHING

THOMAS SOTIRELIS and Patrick T. Newell, The Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, 20723

A model for the differential energy flux of precipitating electrons from 32 eV to 30 keV is presented. The model spectra are keyed to the degree of magnetotail stretching as inferred from the precipitation itself. The result is less smeared and more flexible than previous work because a given portion of the oval— such as from the structured/unstructured boundary to the poleward edge of the oval— is averaged only with the appropriate precipitation. Data from twelve years and eight DMSP spacecraft are used. Extensive variations in the energy flux, average energy, and spatial extent of the precipitation are seen for different degrees of magnetotail stretching.

GA3.08/W/31-A6 1150

AURORAL PRECIPITATION BOUNDARIES AND THE MAGNETOSPHERIC TAIL ENERGITICS FOR VARIOUS LEVEL OF THE MAGNETIC ACTIVITY

YA. I. FELDSTEIN, L. I. Gromova (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, Russia, email: lgromova@izmiran.troitsk.ru) B. V. Rezhenov, G. V. Starkov, V. G. Vorobjev (Polar Geophysical Institute, Apatity, Murmansk region, 184200, Russia, email: vorobjev@pgi.kolasc.net.ru)

luminosity structure allow to suggest physically substantiated method of the plasma regimes boundaries identification (Newell et al.,1996; Feldstein and Galperin,1996).The interrelationship between these high-latitude plasma regimes in the nightside to dawnside sectors and plasma domains of the distant magnetosphere has been demonstrated. DMSP satellites data have been used for statistical investigation of the plasma regimes boundaries dynamics depending on the magnetic activity level. Boundaries determining the polar cap location (b6) and characteristic break of latitudinal variation of the electron energy (b2e) have been used to define the magnetic flux dynamics and to calculate the magnetic energy in the magnetospheric tail during the transition period from the quiet conditions to the very disturbed ones. P.Newell, Y. Feldstein, Y. Galperin, C.-I. Meng, JGR, 101,A5,10737-10748, 1996; Y. Feldstein, Y. Galperin, Cosmic Research,34, N3, 209-227, 1996.

GA3.08/W/22-A6 1210

ENERGETIC IONS FROM THE POLAR SATELLITE AS TRACERS FOR PLASMA SHEET CONDITIONS

P. K. Toivanen, D. N. Baker, W. K. Peterson (LASP, University of Colorado at Boulder, Boulder, CO, USA, Email: petri.toivanen@lasp.colorado.edu) T. I. Pulkkinen (Finnish Meteorological Institute,Helsinki, Finland)

Observations from the POLAR satellite obtained by the Toroidal Imaging Mass-Angle Spegtrograph (TIMAS) and by the MICS sensor of the Charge and Mass Magnetospheric Ion Composition experiment (CAMMICE) frequently show multible peaked distributions in energetic H+ and O+ ions (12--120 keV) in the dusk side magnetosphere. These ions are on open drift paths and thus drift from the tail plasma sheet to the dusk side geostationary region. Our earlier results suggest that, under certain geomagnetic conditions, these observations can be used to determine remotely charactheristics of the plasma sheet over a large portion of the tail. In this study, we mainly address the large-scale electric field, which is responsible for the acceleration of these ions during their drift from the plasma sheet. To trace back the observed distributions, we use an ionospheric electric field model mapped to the plasma sheet together with a modified version of the T89 model in our drift model. These traced-back distributions are then linked to GEOTAIL observations, which show frequently pristine field-aligned O+ beams on energy range up to a few keV originating from the ionosphere. Thus our final aim is to form a coherent picture of O+ flow from the ionosphere to the plasma sheet and of consequent earthward transport and related
acceleration of O+ ions.

GA3.08/W/29-A6 Invited 1400

OBSERVATIONS PERTAINING TO THE LOCATION OF THE SUBSTORM ONSET INSTABILITY

L. A. FRANK, J. B. Sigwarth and W. R. Paterson (All at: Department of Physics and Astronomy, The University of Iowa, Iowa City, IA, USA, email: frank@iowasp.physics.uiowa.edu) S. Kokubun (Solar-

Terrestrial Environment Laboratory, Nagoya University, 3-13 Honohara, Toyokawa, Aichi 442, Japan)

Recent observations of the initially brightened auroral arc at substorm onset provide considerable evidence that the instability is located at geocentric radial distances in the range of about 6 to 12 Re. These findings are based upon unique, high-resolution images from a camera for visible wavelengths on board the Polar spacecraft. The location of the onset instability is particularly important for theoretical analysis and modelling of magnetospheric substorms in that the plasma and magnetic field parameters are significantly different at the above radial distances compared to those for radial distances in the range of 20 to 30 Re which are used for several current theory efforts. Simultaneous measurements of plasmas and magnetic fields at the relevant radial distances in the equatorial magnetotail are used to search for the position of the onset instability. It is found that the onset instability is initially confined to a narrow range of longitudes (local time) and rapidly expands in longitude and to greater radial distances.

GA3.08/E/01-A6 1430

COMPARISON OF AURORAL ARCS OBSERVED WITH POLAR/VIS MEDIUM-RESOLUTION CAMERA AND FINNISH ALL-SKY CAMERAS AND THEIR MAPPING TO THE MAGNETOTAIL

T. I. PULKKINEN, K. Kauristie, and M. T. Syrjasuo (Finnish Meteorological Institute, PO Box 503, FIN-00101 Helsinki, Finland, tel. 358-9-19294654, fax 358-9-19294603,
e-mail: tuija.pulkkinen@fmi.fi) D. N. Baker, N. E. Turner (Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, CO 80309-0590) L. A. Frank and J.B. Sigwarth (Department of Physics and Astronomy, University of Iowa, Iowa City, IA 52242) T. Mukai, Institute of Space and Astronautical Science, Sagamihara, Japan) S. Kokubun (Solar Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Japan) L. Zelenyi (Space Research Institute, Moscow, Russia)

The POLAR/VIS medium-resolution camera can resolve auroral arcs to a scale of a few km. The camera observations show individual arcs embedded within a diffuse band of luminosity, allowing for detailed examination of the auroral breakups and their relation to other substorm onset-associated processes. Observations from the POLAR/VIS medium-resolution camera, Earth camera, Finnish all-sky camera network, and ISTP spacecraft are utilized to examine details of auroral arc breakups and their mapping to the magnetotail during several substorm events in late 1997 and early 1998. In particular, an isolated substorm of about 400-nT intensity occurred on Dec 17, 1997, after almost 20 hours of quiescence. The POLAR/VIS medium resolution camera observed two intensifications in the auroras at 2051 UT and at 2221 UT. The all-sky camera data from Kilpisjarvi showed that auroral activity intensified at 2050 UT, the auroras moved quatorward between 2140 and 2230 UT, after which a strong breakup and poleward motion of auroras followed. Magnetic field modelling techniques are utilized to obtain an accurate mapping between the auroral observations and the magnetotail substorm signatures as observed by GEOTAIL and INTERBALL Tail Probe, both in the nightside magnetotail. The results are used to discuss the processes prior to the global instability onset and their associationto the processes creating auroral breakups.

GA3.08/W/03-A6 1450

THE EXPLOSIVE PHASE OF THE SUBSTORM

John C. SAMSON, R. Rankin, and I. Voronkov (all at Department of Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2J1, email: samson@space.ualberta.ca)

The explosive phase of the substorm, with time scales of 10s of second to minutes, follows the initial brightening of an arc on field lines threading the inner edge of the plasma sheet. Optical data from the Canadian CANOPUS array indicate that the initial brightening is followed within 10s of seconds by enhanced cross tail currents in the inner plasmasheet, and then by dipolarization. Lobe flux reconnection begins within three minutes of the initial arc brightening, indicating an extremely dynamic process with Alfvenic time scales. We argue that the Alfvenic time scales indicate that the explosive phase requires a nonlinear instability. We discuss a hybrid model in which the explosive phase is triggered by shear flow ballooning followed by tearing and reconnection. Ultimately, lobe flux reconnection begins at about 25-30 RE down the magnetotail.

GA3.08/W/19-A6 1520

SHARE RADAR OBSERVATIONS OF INTENSE FLOW BURSTS IN THE MAGNETOTAIL

A. D. M. WALKER and J P S Rash (University of Natal, Durban) K B Baker (The Johns Hopkins University Applied Physics Laboratory) M Pinnock and J R Dudeney (British Antarctic Survey)

Observations are presented of a very unusual event on March 10 1997. At this time, the solar wind conditions were extremely quiet. On the night side the SHARE and Halley radars observed a succession of flow bursts in the ionosphere with velocities exceeding 2 km per s. The poster presents a variety of observations including data from satellites in the solar wind, low altitude satellites passing over the radar field of view, and ground based instrumentation from unmanned ground instruments under the field of view in Antarctica. The event shows some of the characteristics of a substorm, but occurs in the absence of any external driving mechanism. It may be that this is an observation of a fundamental mode of magnetospheric oscillation, uncontaminated by external driving mechanisms.

GA3.08/W/32-A6 Invited 1600

HF RADAR OBSERVATIONS OF IONOSPHERIC CONVECTION IN THE NIGHTSIDE AURORAL ZONE DURING SUBSTORMS

T. K. Yeoman (Department of Physics and Astronomy, University of Leicester, University Road, Leicester, LE1 7RH, U.K.)

High time resolution data from HF radars reveal short-lived convection signatures in the auroral ionosphere during the three phases of the magnetospheric substorm. For example, transient modulations of the electrojet currents during the substorm expansion phase have reported in data from HF radars. The features typically show an interval of suppressed electric field, characterised by large equivalent currents deduced from ground magnetometers, presumably as a consequence of enhanced ionospheric conductivity due to energetic particle precipitation. Following this an enhanced electric field causes a vortical flow. Ground magnetometer data has suggested that the flow vortices propagate azimuthally at up to 6 km s-1, and are typically characterised by equatorward flow enhancements of order 600 m s-1. Recent data from high time resolution HF scans parallel to the L-shell have provided direct measurements of the azimuthal propagation and plasma velocity during such impulsive convection features. The features are not usually accompanied by Pi2 pulsations and in one case study there is some evidence from Geotail spacecraft data of a relationship a dawnward perturbation and dipolarisation of the magnetic field and dawnward plasma flow in the magnetotail, perhaps related to bursty bulk flows. The possible implications of these observations for the substorm process will be discussed.

GA3.08/W/07-A6 1630

CUTLASS HF RADAR OBSERVATIONS OF HIGH LATITUDE AZIMUTHALLY PROPAGATING CONVECTION FEATURES DURING MAGNETOSPHERIC SUBSTORMS

J.A. WILD and T.K. Yeoman (both at Radio & Space Plasma Physics Group, Dept. of Physics and Astronomy, Leicester University, University Road, Leicester, UK, LE1 7RH.
Email: jaw11@ion.le.ac.uk)

Previous observations have identified transient high latitude convection features in the substorm electrojets associated with the expansion phase which were inferred to propagate azimuthally from ground magnetometer data. In addition, during the substorm recovery phase, high time resolution radar modes have been used to study omega bands propagating in an eastward direction. The high time resolution and multi-point nature of the observations leads to a refinement of the previous models of omega band structure. This study combines new data from the CUTLASS radars with observations from the IMAGE, SAMNET, NIPR and Greenland magnetometer networks and the STARE VHF radar in order to look at the zonal flows within the CUTLASS radar field of view. Intervals have been identified in which regions of pulsed flow propagating eastwards are observed directly by the radar and also demonstrate characteristic magnetic behaviour. By directly combining measurements of magnetic field strength and line of sight velocity it is possible to estimate the height integrated ionospheric conductivities at several points within the fields of view of the radars. The continuous nature of the multi-instrumental observations allows the study of the occurrence of azimuthally propagating convection features with respect to substorm phase as well as yielding information regarding the bulk properties and structure of the features themselves.

GA3.08/E/09-A6 1650

THE ELECTRICAL COUPLING OF MAGNETOSPHERIC FLOW VORTEXES AND FLOW CHANNELS TO THE RESISTIVE IONOSPHERE

John W. Bonnell and Joseph E. BOROVSKY (both at Space and Atmospheric Sciences Group, Los Alamos National Laboratory, Los Alamos, NM 87545, USA, email: jborovsky@lanl.gov)

Owing to their polarization electric fields, flows in the magnetosphere drive field-aligned currents that electrically couple to the ionosphere. The details of d.c. current systems driven by flow vortexes in the magnetosphere are examined. It is found that the current systems driven by positive (angular velocity antiparallel to B) and negative (angular velocity parallel to B) vortexes differ greatly. Positive vortexes drive stronger current systems, dissipate more power, and spread across B whereas negative vortexes drive weaker currents, dissipate less power, and do not spread across B.
The signatures above the ionosphere of the two types of vortexes also differ. The details of d.c. current systems driven by flow channels in the magnetosphere are examined. A flow channel in the magnetosphere will exhibit an asymmetry when it couples to the ionosphere; this asymmetric coupling is explored. Extrapolating these studies to flow turbulence in the plasma sheet, predictions are made about the statistics of electric-field divergence at low altitudes and flow vorticity at high altitudes.

GA3.08/W/26-A6 1710

PLASMA SHEET VARIATIONS DURING SUBSTORM ACTIVITY: OBSERVATIONS ON 17TH MAY 1996

J.STOREY, M. Lester (Both at Radio & Space Plasma Physics Group, University of Leicester, Leicester, United Kingdom) T. A. Fritz (Dept. of Astronomy, Boston University, Boston, USA) C. T. Russell (Institute of Geophysics and Planetary Physics / UCLA, Los Angeles, USA) M. Brittnacher (University of Washington Geophysics Program, Seattle, USA) J. B. Blake (The Aerospace Corporation, Los Angeles, USA) J. Scudder (Department of Physics & Astronomy, University of Iowa, Iowa City, USA)

This presentation details the initial results obtained from a study of an interval of substorm activity observed in the high-latitude plasma sheet by the Polar spacecraft, during a pass over the Scandinavian sector on 17th May 1996. The study makes use of the CAMMICE and MFE instruments on board the Polar spacecraft, specifically to investigate any substorm related plasma flows and associated magnetic field variations. Other Polar instruments from which data have been used include two other particle instruments, Hydra and CEPPAD, and the Ultra-Violet Imager (UVI), which provides images of the auroral zone throughout the interval and hence shows ground signatures of the plasma flows observed in situ. Other instrumentation includes the WIND magnetometer and the IMAGE and SAMNET magnetometer chains. These instruments provide background data sets that are used to confirm the presence of substorm activity and give the timing of the onset of any such activity. The particle instruments observePSBL signatures twice during this interval. The first entry into the PSBL is due to a slight re-configuration of the field geometry caused by pseudobreakups occurring at 20:48 and 21:00 UT. The continuing growth phase causes the tail field lines to become more tail-like resulting in the spacecraft exiting the plasma sheet, before the expansion phase onset results in the spacecraft observing CPS ions at 21:45UT.

GA3.08/E/08-A6 Invited 1730

ON THE ROLE OF RESONANCES IN THE TRANSPORT IN THE MAGNETOSPHERE

ENNIO R. SANCHEZ, SRI International, 333 Ravenswood Ave.,Menlo Park, CA 94025

The Sun-Earth connection produces magnetospheric boundaries, cavities, and waveguides where ULF resonances and instabilities can be excited. A combination of simultaneous measurements from high-, low-, and ground-altitude instruments has been used to identify how ULF resonances influence transport in the magnetosphere and onset and evolution of substorms. Intervals were selected for which ISTP spacecraft were appropriately positioned in conjugate positions to ground-based magnetometer and radar chains. Spectral analysis of the observations for the first time establishes a direct relationship between Pc-5 pulsations measured on the ground and the periodicity of dipolarizations and particle injections at geosynchronous altitude, discrete westward electrojet intensifications, plasma and magnetic field oscillations of the plasma sheet and lobes, plasma and magnetic field oscillations in the magnetosheath, and plasma density, convection, and magnetic field pulsations in the plasma sheet. These observations strongly suggest a coupling of resonant cavity modes, which involve energy transfer from compressional oscillations propagating from the outer magnetosphere into the near-Earth closed field lines, with other wave modes in different parts of the magnetosphere. Those modes include waveguide modes originated in the high-latitude open field line regions of the magnetosphere, and waveguide modes in the low-latitude closed field line regions of the magnetosphere encompassed by the low-latitude boundary layers and the plasma sheet. The coupled response of different magnetospheric regions to solar wind

input defines a measure of coherence of the magnetosphere-ionosphere system. The coherence of the system defines a correlation between periodicities in reconnection and bursty plasma transport in the magnetotail and periodicities in magnetic flux buildup and particle injection in the near-Earth region.

THE GLOBAL IONOSPHERIC CONVECTION RESPONSE TO CHANGES IN THE SOLAR WIND AND INTERPLANETARY MAGNETIC FIELD ORIENTATION

AARON RIDLEY (Southwest Research Institute, San Antonio, TX 78228-0510, USA, email: ridley@zed.space.swri.edu)

It has been shown that the ionospheric convection is closely coupled to the interplanetary magnetic field (IMF) orientation and more loosely coupled to the solar wind speed and density. Most studies of the convection have investigated the statistical steady state conditions. Recently, a number of studies have focused on the how the convection changes in response to IMF reorientations. The first studies of this kind showed localized observations of how the convection changed with time. More recently, studies have focused upon how the global convection changes. One result of the global studies is that the global convection pattern is shown to change as a whole, instead of the change in convection spreading slowly over the polar cap. Examples of such simultaneous changes are shown to occur for both IMF orientation changes and sudden changes in the dynamic pressure of the solar wind. We present arguments on the interpretation of the convection data, showing the simultaneous change in convection in the noon, dawn, and dust sectors. We present ground-based magnetometer data to verify these arguments. In addition, we discuss the ramifications of these observations on the dynamics of the magnetosphere-ionosphere system.

GA3.08/E/03-B1 1000

DYNAMICS OF HIGH-LATITUDE IONOSPHERIC CONVECTION AND CURRENT SYSTEM FOLLOWING A SUDDEN SOUTHWARD TURNING OF THE IMF

Nozomu NISHITANI and Tadahiko Ogawa (Solar-Terrestrial Environment Laboratory, Nagoya University, 3-13 Honohara, Toyokawa, Aichi 442-8507, Japan, e-mail: nisitani@stelab.nagoya-u.ac.jp) Natsuo Sato and Hisao Yamagishi (National Institute of Polar Research, 1-9-10 Kaga, Itabashi, Tokyo 173-8515, Japan) Mike Pinnock (British Antarctic Survey, High Cross, Madingley Road, Cambridge CB3 OET, England) Jean-Paul Villain (LPCE/CNRS, 3A Av. de la Recherche Scientifique, 45071 Oeleans Cedex 2, France) George Sofko (Department of Physics & Engineering Physics, University of Saskatchewan, 116 Science Place, Saskatoon, SK., S7N 5E2 Canada)

One example of the global dynamics of ionospheric convection and current system has been studied by using the SuperDARN radar network and high-latitude magnetograms when the IMF changed stepwise from northward to strongly southward. There were two-step changes in the ionospheric flow pattern. The first change of the convection pattern can be characterized by a sudden formation of a large flow vortex in the afternoon sector. This change propagated from the noon sector to the evening sector within 2 to 4 minutes. The second change, which occurred twenty minutes later, can be characterized by a sudden antisunward shift of the flow vortex. The ionospheric current system observed by the high-latitude magnetograms showed gradual formation of the DP2 current system. The formation began simultaneously with the first response of the convection flow and completed a few minutes after the second response. Distortion of the DP2 current system, that is, antisunward shift of the center of the two vortices, occurred simultaneously with the second response of the ionospheric convection pattern. From these observations, we speculate that the first response is associated with the propagation of magnetosonic waves, and that the second response is due to the configuration change of the magnetosphere after the solar wind discontinuity arrived in the magnetotail region.

GA3.08/W/27-B1 Invited 1040

ION AND ELECTRON HEATING IN MAGNETIC RECONNECTION

M. Hoshino (The University of Tokyo, Tokyo, 113-0033 Japan, email: hoshino@geophy.s.u-tokyo.ac.jp)

The origin of hot and dense plasma in the Earth's plasma sheet has been a long- standing problem. Observations have established that the ion temperature is the order of several keV, and the ion temperature in the plasma sheet is always about several times larger than the electron temperature. Many microscopic and macroscopic plasma processes are thought to be involved in the plasma heating: magnetic reconnection plays an important role on energy conversion process from magnetic into kinetic energy, and provides the preferential plasma heating of ions. Current-driven instabilities around the plasma sheet boundary layer are believed to be substantial for the electron heating. Strong turbulence of waves in the plasma sheet is probably important for understanding the hot plasmas as well. These effects are undoubtedly important for various stages of magnetotail evolution associated with magnetic reconnection. We have started to investigate the self-consistent plasma heating and acceleration processes in association with the kinetic magnetic reconnection by using a three-dimensional, electromagnetic, particle-in-cell simulation, in which both the current-driven instabilities and the collisionless reconnection process are described. We have studied where and when ions and electrons gain their energy during reconnection evolution. The results are discussed in terms of the GEOTAIL observations.

GA3.08/E/02-B1 1110

SIGNATURES OF MAGNETOTAIL VARIABILITY IN THE AURORAL ZONE

VAHE PEROOMIAN, Maha Ashour-Abdalla (Both at UCLA-IGPP, Box 951567, Los Angeles, CA 90095-1567, USA, e-mail: vahe@igpp.ucla.edu) Lev M. Zelenyi (Space Research Institute, Academy of Sciences, Moscow, Russia, e-mail: lzelenyi@iki.rssi.ru)

We use a self-consistent, large-scale kinetic model to investigate the formation of the magnetotail and the auroral manifestations of the complicated temporal dynamics that occur there during quiet periods. In our model, the magnetotail's current is calculated by following ion trajectories in a magnetic field that is made up of ion currents calculated at the previous time step. The model takes into account both the local inductive and global dawn-dusk electric fields. We find that the magnetotail is quite variable: magnetic islands are formed, then decay and merge. This process appears to be quasi-periodic, and results from the cycles of loss and replenishment that current-carrying particles undergo in the current sheet; these cycles are themselves caused by the rapid and non-adiabatic energization of ions in the vicinity of the x-lines that form in the model. Ion intertia determines the characteristic time scale for this periodicity, which is on the order of 5 - 10 minutes. The magnitude of the dawn-dusk electric field also influences the time scale. In our model, ion acceleration near the temporally variable location of the x-line stimulates the formation of quasi-periodic, velocity-dispersed ion structures in the ion precipitation profile. Many polar-orbiting spacecraft have observed structures such as these. we will compare our results with these observations.

GA3.08/W/33-B1 1130

WIND OBSERVATIONS OF THE NEAR-EARTH PLASMA SHEET: SOLAR WIND AND GEOMAGNETIC ACTIVITY DEPENDENCE

M. OIEROSET, T. D. Phan, L. Chan, and R. P. Lin (Space Sciences Laboratory, University of California, Berkeley, CA 94720, E-mail: oieroset@ssl.berkeley.edu)

We have studied 20 WIND perigee passes through the plasma sheet earthward of 24 Re. The plasma sheet observations are sorted according to region, interplanetary magnetic field values, solar wind plasma parameters, and Kp values, in an attempt to increase our understanding for the causes of the variations in the plasma sheet plasma parameters. Preliminary results indicate a cold and dense plasma sheet for low Kp values while the plasma sheet gradually becomes heated and less dense with increasing Kp. Our findings are also in agreement with GEOTAIL observations by Terasawa et al. (GRL, 24, 935-938, 1997), showing a cold and dense plasma sheet for northward IMF when the IMF is averaged over several hours prior to the plasma sheet observations. We also survey the interrelationship between the thermal and flow parameters in the plasma sheet in order to investigate the structure and dynamics of the plasma sheet.

GA3.08/E/12-B1 1150

IS THE MHD APPROACH VALID IN THE DISTANT PLASMA SHEET?

Oleg TROSHICHEV (Arctic and Antarctic Research Institute, St.Petersburg, 199397, Russia, email: olegtro@aari.nw.ru); Elizabeth Antonova (Scobeltsin Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email antonova@orearm.msk.ru); Yohsuke Kamide (Solar Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Aichi, 442, Japan, email: kamide@stelab.nagoya-u.ac.jp)

Measurements of the magnetic field and low energy plasma by the GEOTAIL spacecraft were utilized to study correspondence between the plasma velocity and magnetic oscillations in the distant plasma sheet at X = -(79-200) RE. A total of 14 extremely quiet days from available GEOTAIL data in 1993-1994 (12-s averages of the magnetic field and plasma parameters) were chosen for the analysis, identification of the plasma sheet and estimation of the magnetic activity being realized according to Troshichev et al. [JGR, in press]. Case study of behavior of magnetic field and plasma velocity shows that correspondence between the changes in these parameters often is not carried out. The Fourier analysis also sometimes shows striking discrepancy in the frequent spectra for magnetic and plasma parameters when powerful oscillations of plasma velocity (usually VY or/and VZ components) in range 3-8 min occurs against the almost calm magnetic field and vice versa. These results suggest that MHD approach is often violated in the distant plasma sheet even under the extremely quiet conditions.

GA3.08/W/24-B1 1210

OBSERVATION OF PROLONGED, STEADY RECONNECTION IN THE MAGNETOTAIL BY THE GEOTAIL SPACECRAFT

R. T. Mist and C. J. OWEN (Astronomy Unit, Queen Mary and Westfield College, London, UK), T. Mukai (Institute of Space and Astronautical Science, Sagamihara, Japan), S. Kokubun (Solar Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Japan)

It is relatively unusual for conditions in the distant tail to allow a spacecraft to remain in the central plasma sheet continuously for a prolonged period. However, on October 27, 1994, when the Geotail spacecraft was situated in the deep tail (X=-170 RE, Y=20 RE and Z=0 RE), the spacecraft crossed from the north to the south lobe, and spent about 4 hours continuously in the plasma sheet. The magnetic field and plasma moment data throughout this period are consistent with the plasma sheet being formed by quasi-steady reconnection. The level of geomagnetic activity during this period is steady and moderate, with no obvious enhancements due to substorms. We analyse the two-dimensional ion distributions from the LEP instrument during this interval, and study the plasma populations in the north and south lobes, the PSBL and the plasma sheet. We compare these observed distributions with the predictions of reconnection models based on the balance of magnetic field and plasma stresses at the central, cross-tail current sheet. In these models, the plasma sheet population is formed by both heating and acceleration of the inflowing lobe plasma during its interaction with the current sheet. We show that the observed ion distributions are consistent with the expectations of these reconnection models.

THE EARTH'S DYNAMIC MAGNETOTAIL

A. Nishida (Institute of Space and Astronautical Science, Sagamihara, 229-8510, Japan, email: nishida@gtl.isas.ac.jp)

Following the first comprehensive study of the magnetotail conducted with the IMP 1 satellite, Ness [1969] reviewed the latest findings on the physics of the Earth's magnetotail. It is impressive that most of the fundamental concepts were already established in that review. At the end of the paper he listed outstanding problems which future studies should be directed to resolve. In the present paper we shall summarize the advances made in the physics of the magnetotail with reference to the problems he listed, and discuss the remaining issues. Answers to the problems he enumerated as (1) to (6) are given in the following. (1) The formation of the magnetotail is due to magnetic reconnection on the magnetopause. (2) Coherent, well-ordered tail exists at least to the distance of 200 Re and there is no indications of filamentation. (3) The merging across the neutral sheet is impulsive at the near-Earth neutral line. (4) Accelerations both in the magnetotail and in the solar flare are governed by magnetic reconnection. (5) Accelerations occur at the slow-mode shock and in the neutral sheet including the vicinity of the neutral sheet. (6) Electron islands events correspond to plasmoids and plasma-sheet boundary layer. Remaining important issues include (1) mixing of plasma-sheet and magnetosheath plasmas in the LLBL, (2) paucity of the slow-mode shock identification, and (3) trigger of the near-Earth reconnection.

GA3.08/W/16-B1 1430

AURORAL POLEWARD BOUNDARY INTENSIFICATIONS: A FUNDAMENTAL MAGNETOSPHERIC DISTURBANCE COUPLING BURSTY PLASMA SHEET FLOWS TO THE AURORAL IONOSPHERE

L. R. Lyons (Department of Atmospheric Sciences, UCLA, Los Angeles, CA 90095-1565, USA, email: larry@atmos.ucla.edu); G. T. Blanchard (Department of Chemistry & Physics University of Southeastern Louisiana SLU 10878, Hammond, LA 70402-0878, USA); T. Nagai (Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo 152, Japan); T. Yamamoto, T, Mukai, A. Nishida (All at: Institute of Space and Astronautical Science, Sagamihara 229, Japan); J. C. Samson (Department of Physics, University of Alberta, Edmonton, Alberta, T6G 2E9, Canada); S. Kokubun (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa 442, Japan)

Poleward boundary intensifications are nightside geomagnetic disturbances that have an auroral signature that moves equatorward from the poleward boundary of the auroral zone. They occur repetitively, and they appear to be the most intense auroral disturbance at times other than the expansion phase of substorms. They connect to the magnetotail via upward field-aligned currents that are sufficiently intense that a field-aligned potential drop is required. We have used data from nightside conjunctions of the GEOTAIL spacecraft in the magnetotail with the CANOPUS ground-based array in central Canada. During periods with identifiable poleward boundary intensifications, we find that the plasma sheet has considerable structure and bursty flow activity. During periods without such intensifications, the plasma sheet is far more stable with little flows. This is consistent with the intensifications being the result of the mapping to the ionosphere of the electric fields that give rise to bursty flows within the plasma sheet. Two different types of plasma sheet disturbance have been found to be associated with the poleward boundary intensifications. The first is fows that result from Speiser motion of particles in a localized region of thin current sheet. The second, seen preferentially in the near-Earth plasma sheet, consists of energy dispersed ion structures that culminate in bursts of low energy ions and isotropic low-energy electrons. Both are associated with localized regions of enhanced dawn-to-dusk electric fields.

GA3.08/W/23-B1 1450

CHARACTERISTICS OF AURORAL POLEWARD BOUNDARY INTENSIFICATIONS

Eftyhia Zesta (Department of Atmospheric Sciences, UCLA, Los Angeles, CA 90095-1565, USA, email: ezesta@atmos.ucla.edu); Larry R. Lyons (Department of Atmospheric Sciences, UCLA, Los Angeles, CA 90095-1565, USA); John C. Samson (Department of Physics, University of Alberta, Edmonton, Alberta, T6G 2E9, Canada), Erick Donovan (Department of Physics and Astronomy, University of Calgary, Calgary, Alberta, T2N 1N4,Canada)

Poleward Boundary Intensifications (PBIs) of the aurora are a frequently occurring auroral-zone disturbance. They consist of auroral enhancements that move equatorward from near the magnetic separatrix and are associated with ground magnetic disturbances of 20-100 nT and Pi2 pulsations. They are a phenomenon distinct from substorms, occurring both during substorm and non-substorm periods, and are often observed both during enhanced convection intervals and during quiet times. We used meridional scanning photometer data from the CANOPUS stations during the winter of 1996-1997 to identify a number of periods with PBI events. We investigate both the occurrence characteristics and the correlation of PBIs with the IMF direction and magnitude. We find that PBIs are statistically a dusk-to-midnight region phenomenon and are therefore associated with the upward region 1 field-aligned currents. We find that only half of our identified events are associated with substorms. The non-substorm associated PBIs are found to have a clear preference for a radial IMF. However, the radial IMF is a necessary but not sufficient condition for the occurrence of PBI events in the nightside aurora. We also examine all-sky-imager data from the CANOPUS station of Gillam at the time of our PBI events and determine the possible correlation of PBI events, identified in the meridional scanning photometer data, with short-lived, north-south aligned auroral arcs and with equatorward moving east-west aligned auroral arcs.

GA3.08/W/28-B1 1510

LOCAL INTENSIFICATION OF THE TAIL CURRENT AND ASSOCIATED OCCURRENCE OF MAGNETIC RECONNECTION IN THE MAGNETOTAIL

T. MUKAI, Y. Asano, I. Shinohara, and Y. Saito (Institute of Space and Astronautical Science, Yoshinodai, Sagamihara 229-8510, Japan, email: mukai@stp.isas.ac.jp); T. Nagai (Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo 152-8551, Japan, email: nagai@geo.titech.ac.jp)

Recent GEOTAIL observations have clearly demonstrated a crucial role of magnetic reconnection in substorms. There are well-known growth phase signatures in the magnetotail, such as increasing pressure and configuration change to the tail-like magnetic field, representing enhancement of the tail current and thinning of the current sheet. However, these signatures are seen over a wide range of distances down the tail and are not enough to explain a certain location where the reconnection is first initiated. Fortunately we have found a substorm event in which the GEOTAIL spacecraft stayed in the current sheet at a distance of ~17 Re and could clearly observe temporal evolution of the tail current intensification and associated occurrence of magnetic reconnection there. Following the gradual increase in the growth phase, the tail current density increased sharply a few minutes before the onset. The tailward fast flows and increasing plasma temperatures were also observed to start in association with the intensification of the current density. These signatures can be interpreted as the initial occurrence of magnetic reconnection associated with local thinning of the current sheet (because the case is very rare). As time proceeds, the current sheet further thins and the current density is further intensified. This sequence evolves explosively through a few steps in several minutes, expanding the active region.

GA3.08/W/34-B1 Invited 1550

THE HALL TERM EFFECTS IN MAGNETIC RECONNECTION

Dr Masaki Fujimoto Dept. Earth Planet. Sci., Tokyo Inst. Tech

Geotail observations have shown that there are strong field-aligned currents (FACs) that are very likely to be the Hall current generated in magnetotail reconnection. 2D Hall MHD simulations do show that the FACs due to the Hall term are significant and should not be neglected in considering coupling to the ionosphere. These lead us to make 3D Hall MHD simulations of magnetic reconnection to study the three-dimensional structure of the generated FACs. Details of the results, especially in comparison with those obtained by MHD models, will be discussed.

GA3.08/W/11-B1 1620

SIMULATIONS SHOWING GENERATION OF FILAMENTARY FIELD-ALIGNED CURRENTS ABOVE THE AURORAL IONOSPHERE

Daniel W. Swift (Geophysical Institute, University of Alaska, Fairbanks, AK 99775-7320, USA, email: swift@gi.alaska.edu) Yu Lin (Physics Department, 206 Allison Laboratory, Auburn University, Auburn, AL 36849-5311, USA, email: ylin@physics.auburn.edu)

A two-dimensional hybrid code is used to simulate the midnight meridian plane of the magnetosphere. The simulation domain extends from the Earth's ionosphere to 35 Earth radii in the antisunward direction and to 11 Earth radii along the polar axes. The simulation is driven by a dawn-to-dusk electric field imposed at the boundaries. The sequence of events follows those associated with the growth and expansive phases of the substorm. Momentum exchange between the plasma being accelerated Earthward in the neutral sheet and the magnetic field results in a stretching of the magnetic field lines and thinning of the plasma sheet. A pair of field-aligned currents develops connecting the inner edge of the plasma sheet to the auroral ionosphere, with the downward current equatorward of the upward current. The breaking of the inward plasma flow drives these currents. Next follows the apparent dipolarization. "Dipolarization" is carried outward by plasma rebounding off the dipole field. Ion-ion two streaming instabilities are excited behind the expanding dipolarization front. The effect of these instabilities is propagated Earthward along magnetic field lines by shear Alfvén waves. These are seen as field-aligned current filaments above the auroral ionosphere. We take the upward field-aligned current filaments as proxies for auroral arcs.

GA3.08/W/15-B1 1640

STUDY OF THREE-DIMENSIONAL HYBRID SIMULATION OF MAGNETOTAIL RECONNECTION

MASAO NAKAMURA(Solar-Terrestrial Environment Laboratory, Nagoya University, Honohara 3-13, Toyokawa, Aichi 442-8507, Japan, Email: nakamura@stelab.nagoya-u.ac.jp) and Masaki Fujimoto(Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Oookayama 2-12-1, Meguro, Tokyo 152, Japan)

The three-dimensional structure of magnetic reconnection in a thin current sheet (thickness comparable to the relevant ion inertia length), which models the near-Earth tail current sheet just before substorm onsets, are studied by means of 3-D hybrid simulations (ion particle, charge neutralizing massless electron fluid). Magnetic reconnection is initiated by fixing a localized anomalous resistivity in the plasma sheet and generates fast plasma flows in the Earth-tail direction as a result of its explosive growth. On the other hand, the thin plasma sheet is unstable to the tail Kelvin-Helmholtz (K-H) instability, which kinks plasma sheet in the cross-tail plane. For the small resistivity cases, the tail K-H instability is well generated before the explosive growth of reconnection starts. While the kink structure of the plasma sheet modifies the plasma flow, the essential features, such as the dawn-dusk asymmetry of plasma flows and field configuration, still remains unchanged from the large resistivity case where the explosive growth starts before the influence of the tail K-H instability is visible.

GA3.08/E/04-B1 1700

SIGNATURES OF MAGNETOTAIL RECONNECTION DERIVED BY NUMERICAL SIMULATIONS AND VERIFIED IN SPACE

JOERG BUECHNER AND B. Nikutowski (Max-Planck- Institut fuer Aeronomie, Max-Planck-Str. 2, D-37191 Katlenburg-Lindau, Germany)

The true physics behind magnetic reconnection is still an open question. On the other hand large scale topological considerations have shown that reconnection must take place in the Earth's magnetotail. The magnetotail is, therefore, an appropriate site to test reconnection models. We have developed a kinetic model of three-dimensional reconnection and derived its signatures by kinetic plasma simulations. Here we present current results of numerical plasma simulations of specific signatures of collisionless reconnection through thin current sheets. We illustrate some of them in the context of ISTP spacecraft measurements of INTERBALL-1 and GEOTAIL.

GA3.08/W/20-B1 1720

A TAIL CROSSING AT 200 RE--GEOTAIL/HEP-LD OBSERVATION

B.Wilken, Q.G. Zong (both at Max-Planck-Institut fuer Aeronomie, D-37191 Katlenburg-Lindau,Germany, Email: wilken@linmpi.mpg.de) T. Doke (Advanced Research Center for Science and Engineering, Waseda university, Tokyo, Japan) S. Kokubun (Solar-Terrestial Environment laboratory, Nagoya University, Toyokawa, Japan)

In April 1994 Geotail was travelling on a deep tail trajectory. Sustained moderaten geoactivity was driven by the passage of a corotating interaction region (CIR) which started on 3 April and continued until 20 April. On 17 April a CME impinged on the magnetosphere and caused a major magnetic storm. Geotail observed the CME in the dusk magnetosheath/magnetosphere interface at a GSE position (-200,30,-5 Re). Shortly after the CME Geotail started the dusk-to-dawn tail passage. The general level of activity in the magnetotail was found to be very low which corresponded to rather quiet conditions in the geosynchronous orbit and on the ground. However, quasi-periodic low intensity energetic particle bursts embedded in plasmoid-like structures passed Geotail. In the absence of corresponding near-Earth disturbances it is suggested that the regular structures in the deep tail resulted from large amplitude Alfven wave in the solar wind.

GA3.08/E/07-B1 1740

NUMERICAL SIMULATION OF PLASMOID DYNAMICS

B P PANDEY, G.S.Lakhina and M.Roy (Indian Institute of Geomagnetism, Bombay 400 005, India, email: pandey@iig.iigm.res.in, lakhina@iig.iigm.res.in)

The plasmoid dynamics has been studied by a 2-D magnetohydrodynamic simulation code for a magnetotail configuration which takes into account the flaring of the tail. The plasmoid formation and its subsequent motion down the tail is followed for a few hundreds of Alfven time.
Simultaneously, the spatial and temporal evolution of density, pressure, temperature and magnetic field is studied. The results are compared with the Geotail observations.

THE RESPONSE OF THE MAGNETOSPHERE TO AN INTERPLANETARY SHOCK: GLOBAL SIMULATIONS OF THE SEPTEMBER 24, 1998 SUDDEN IMPULSE EVENT

J RAEDER, C T Russell (both at: Institute of Geophysics and Planetary Physics, University of California, 405 Hilgard Ave, Los Angeles, CA 90095, USA, email: jraeder@igpp.ucla.edu)

A very strong interplanetary shock was observed by the Wind spacecraft on September 24, 1998, 2221 UT. The resulting sudden impulse (SI) was observed by several magnetospheric spacecraft, as well as by ground magnetometers. This event gives us a unique opportunity to study the response of the magnetosphere using our global magnetosphere - ionosphere model, and to compare our results in detail with the observations. Besides providing an assessment of the accuracy and robustness of our model for such an event, we will also present a more complete picture of the magnetospheric response as the observations alone could provide. In particular, we will discuss the propagation of the SI initiated waves through the magnetosphere, SI modifications to the current systems, and the causes of the ground magnetic perturbations.

GA3.08/W/04-B1 Poster **0900-02**

TAIL PLASMA FLOWS AND ELECTROJET ACTIVITY

Tsugunobu Nagai (Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo 152-8551, Japan, email: nagai@geo.titech.ac.jp) Tuija I. Pulkkinen (Finnish Meteorological Institute, P.O.Box 503 FIN-00101 Helsinki, Finland, email: tuija.pulkkinen@fmi.fi) Peter Stauning, Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark, email: pst@dmi.dk) Toshifumi Mukai (Institute of Space and Astronautical Science, Sagamihara 229-8510, Japan, email: mukai@gtl.isas.ac.jp) Susumu Kokubun (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa 442-8507, Japan, email: kokubun@stelab.nagoya-u.ac.jp)

The spacecraft Geotail observes tailward/earthward convection plasma flows in the plasma sheet at radial distances of 10-30 Re in association with substorm activity. The ground magnetometer chains in Scandinavia and Greenland monitor electrojet activity, and the central latitude of the westward electrojet can be determined. In this paper, we examine the relationship between tail plasma flows and ground electrojet activity. Tailward plasma flows observed at 20-30 Re are usually associated with westward electrojets at magnetic latitudes of 64-68 degrees, whereas earthward plasma flows observed around 30 Re re often associated with the westward electrojet near 70 degrees. Unusual tailward plasma flows inside 20 Re are related with the westward electrojet near 60 degrees. We present several event studies and statistical results.

GA3.08/E/10-B1 Poster **0900-03**

SUBSTORM ACTIVITY AS A SELF-ORGANIZED CRITICAL PHENOMENON

Vadim M.URITSKY, Mikhail I.Pudovkin (Department of Geophysics, St.Petersburg State University, Petrodvorets, St.Petersburg 198904, Russia, Email: uritsky@snoopy.phys.spbu.ru, pudovkin@snoopy.phys.spbu.ru)

The effect of self-organized criticality (SOC) is proposed as an internal mechanism of generation of 1/f^b -like fluctuations in Earth's magnetosphere. It was suggested that localized in space current instabilities developing in the magnetospheric tail at the initial substorm phase can be considered as the SOC avalanches - dynamic clusters, superposition of which leads to the 1/f^b fluctuations of macroscopic characteristics of the system. Using sandpile model of SOC, numerical investigation of both spatially localized and global disturbances of magnetospheric current layer was carried out. The dependence of model's sensitivity on the accumulated internal energy was shown to be similar to that characterizing natural geomagnetic activity. The power spectrum of sandpile model fluctuations controlled by real solar wind parameters reproduces all distinctive features of the AE fluctuations spectrum, including presence of two frequency ranges with different spectral slopes, that provides an important evidence for our hypothesis. Furthermore, quantitative and qualitative conformity between disturbed dynamics of self-organized critical state of the model and the main phases of real magnetospheric substorm development is demonstrated.
The results obtained suggest that the application of the theory of SOC and cellular automaton technique creates a new promising approach for modelling substorm activity. This approach seems to be adequate for the describing of fractal stochastic features of geomagnetic variations which are difficult to interpret on the base of traditional methods.

ONE-DIMENSIONAL KINETIC MODEL OF THE PLASMA SHEET EVOLUTION DURING A SUBSTORM ACTIVATION

V.I.Domrin and A.P.Kropotkin, Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia

A one-dimensional simulation model is constructed for analysis of the plasma sheet (current sheet, CS) evolution in the near-Earth tail region where an intense CS thinning is known to occur during a substorm activation. Dynamics of the hot plasma in the plasma sheet and of the ambient cold plasma is examined on the kinetic equation basis; a macroparticle code is used for ions to solve the equations while electrons are considered as a massless cold background. Self-consistent electromagnetic fields are calculated as numerical solutions of the Maxwell equations. The plasma sheet evolution takes place under action of an MHD disturbance that is applied on the boundary of the simulation box. That disturbance is assumed to be a consequence of fast tearing process occuring further in the magnetotail.
In the course of the simulated evolution, the electric field of the disturbance penetrates down to the central plane of the CS. That results in acceleration of ions in the CS; accelerated ions then escape CS along the field lines. Eventually the initial CS becomes replaced by an anisotropic one. The current is now carried by initially cold ions which are brought into CS by convection from the tail lobes. Magnetic field "annihilation" is a consequence: electromagnetic energy brought to CS from both sides, is transformed into energy of accelerated ions.

GENERAL ANALYTICAL THEORY OF SELF- CONSISTENT QUASIADIABATIC CURRENT SHEETS

Zelenyi Lev (Space Research Institute, Russian academy of sciences, 117810, Moscow, Russia, Email: lzelenyi@iki.rssi.ru); Sitnov Mikhail and MALOVA HELMI (Skobetsyn Institute of Niclear Physics, 117899, Moscow, Russia, email: stn@dec1.npi.msu.su, mlv@dec1.npi.msu.su)

The basics of unified analytical theory of the structure of self-consistent quasiadiabatic current sheets created by the impinging ion streams are presented. The problem is considered neglecting the jumps of the invariant Iz of nonmagnetized ions. Nonlocal analogue of the Grad-Shafranov equation for the sources of arbitrary anisotropy is obtained and solved numerically. The universal solutions corresponding to the regimes of strong and week anisotropies are investigated. Resulting self-consistent current is a sum of the drift cyclotron current and the magnetization currents flowing in the opposite directions. The maximum thickness of the current sheet is achieved in a case of weak anisotropy and equals to the thermal gyroradius of ions outside the sheet. In a case of strong anisotropy the sheet is compressed to minimal thickness. The effects of real nonadiabaticity are considered when the quasiadiabatic approximation is violated. Jumps of quasiadiabatic invariant Iz result in the gradual suppression of anisotropy and smearing of the current sheet. Influence of electron component creates an additional layer which also effectively broaden the current structure. We also discuss the relevant experimental data from ISEE and modern ISTP spacecraft (Geotail, INTERBALL) about the structure of the current sheets in the distant and near Earth parts of the tail.

EVIDENCES OF UNMAGNETIZED ELECTRON MOTION WITHIN THE PLASMA SHEET AND ITS POSSIBLE CAUSES

Marina STEPANOVA (Universidad de Santiago de Chile, Ecuador 3493, Casilla 307, Santiago, Chile, email: mstepano@lauca.usach.cl), Elizavieta Antonova, Ilya Ovchinnikov, Mickail Teltzov, Elena Vikhreva, (all at Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow 119899, Russia, email: antonova@taspd.npi.msu.su)

We present the results of experimental and theoretical investigation of unmagnetized stochastic motion of elections and plasma mixing within the plasma sheet. Analysis of electron temperature distributions within the plasma sheet has been made using Intercosmos-Bulgaria-1300 polar orbiting satellite. It was shown, that the temperature, which has been obtained taking into consideration the acceleration of precipitating electrons by field-aligned potential drop, is nearly constant in the meridional direction within upward field-aligned current region and their values do not change for different orbits during a quiet geomagnetic time. Analysis of spatial fluctuations of recipitating electron fluxes at a fixed electron energy has shown, that fluctuation spectra of primary electrons have a power dependence and is close to the spectra of electric field fluctuations observed within the plasma sheet. The results of observations are interpreted as the consequence of stochastic plasma sheet particle motion and intensive plasma sheet plasma mixing. The role of different processes in such stochastization is analyzed. For the majority of plasma sheet ions, their Larmor radius can be comparable with the radius of curvature of magnetic field line which can be the source of stochastization. But, in case of electrons such mechanism can be effective only for particles with quite high energy or in the regions of extremely low Bz. Therefore, it is suggested that the main source of observed electron stochastization and one of the powerful source of ion stochastization is their motion in the inhomogeneous electric fields with characteristic scales comparable with particle Larmor radius. Chaotization of particle trajectories may be the part of stochastization process. Particle motion in the homogeneous magnetic field and regular inhomogeneous electric field having sinusoidal distribution in one direction and homogeneous distribution in perpendicular direction is analyzed as an example of a chaotic motion.

APPLICATION OF AN INVERSION METHOD BASED ON MID-LATITUDE MAGNETIC DATA TO ESTIMATIONS OF MEANINGS OF PARAMETERS OF THE GEOMAGNETIC TAIL AND THE IONOSPHERE

Vagina L.I.

On the basis of an inversion method based on mid-latitude magnetic data during the development of 71 substorms we have calculated characteristic temporary and spatial substorm current systems parameters: characteristic times of current increase and decrease, maximal current values, characteristic spatial sizes. The received characteristics were used to find the values of the constants for the homogeneous differential equation of the second order with constant factors. Using the received constants we have made estimations of meanings of parameters of the geomagnetic tail and the ionosphere. The meanings of estimated parameters have appeared within the limits of typical meanings of parameters of a geomagnetic tail and ionosphere, received other methods.

PECULARITY OF GEOMAGNETIC FIELD ON GEOSTATIONARY ORBIT, CONSEQUENCE FOR STATIONARY CONVENTION

KUZNETSOV S.N. (Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, 119899, Moscow, Russia, e-mail: kuznets@srdlan.npi.msu.su)

Analysis of GOES data on geomagnetic field during 1993-94 years shown that in time intervals near equinox we observe stationary increasing of the magnetic field near local midnight.This effect was not observed in solstice intervals. We proposed that this effect is projecting to midnight range of unreally position of field-aling currents. This effect may be connected with assimmetry in precipitation of cosmic ray electrons in magnetic lines of a plasma tail. The range of quasidipolar field near midnight may be foundation of tetha-strap in an aurora.

ON THE KELVIN-HELMHOLTZ HYDROMAGNETIC INSTABILITY

ANZOR GVELESIANI (Institute of Geophysics, Georgian Academy of Sciences, 1, M. Alexidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com)

An analytical magnetohydrodynamic model of tangential discontinuity stability in the Earth's magnetosphere plasma sheath, magnetopause and plasma and neutral sheets is suggested. The general discussion relations for multilayer plasma flows of plane and cylindrical configuration are received. It is shown the role of the plasma compressibility and geometric parameters - thickness and curvature of layers boundaries - on the Kelvin-Helmholtz hydromagnetic instability. The compressibility of plasma results in destabilisation of plasma layers motion. It is found the parameter (product respectively the relations of plasma densities and magnetic fields squares of the neighbouring layers) from the value of each (more or less than 1) defines the effect of the geometry both of tangential discontinuity surface on the cylindrical and plane form of incompressible plasmatic jets.

QUANTITATIVE MODELING 1

GA3.09/E/13-B4 0930

PROPOSED METRICS FOR THE U.S. NATIONAL SPACE WEATHER PROGRAM

R A WOLF (Space Physics and Astronomy Dept., Rice University MS108, P.O. Box 1892, Houston, TX 77251, U.S.A.); T J Fuller-Rowell (NOAA Space Environment Center, 325 Broadway, Boulder, CO 80303, U.S.A.)

The U.S. National Space Weather Program (NSWP) has an overarching goal "to achieve an active, synergistic, interagency system to provide timely, accurate, and reliable space weather warnings, observations, specifications, and forecasts within the next 10 years." Among the critical elements contributing to a successful NSWP is the need to establish metrics against which quantitative goals can be defined and progress can be measured. The definition of space-weather metrics departs significantly from the traditional approach to space science, which places little emphasis on quantifying progress toward the long-term goal of understanding. A report prepared for the U. S. National Science Foundation proposes specific metrics that measure ability to specify and forecast various space-weather parameters. The highest priority physical parameters that must be predicted from ionosphere-thermosphere science are the electron density, neutral mass density, and amplitude of electron density irregularities. The corresponding magnetosphere-ionosphere parameters are the high-latitude ionospheric electric field, auroral electron flux, magnetic indices, and geosynchronous electron fluxes. Among the parameters that solar and interplanetary science must predict are solar-wind bulk properties and the fluxes of solar protons, EUV, and X-rays; times at which disturbances leave the Sun must be predicted, as well as solar-wind transit times.

GA3.09/W/30-B4 0945

MODELLING CORONAL MASS EJECTIONS AND PROMINENCE ERUPTIONS

S. K. ANTIOCHOS (Code 7675, Naval Research Lab, Washington, DC, USA)

The most violent and most energetic manifestations of solar activity are the disruptions of the Sun's magnetic field that give rise to coronal mass ejections (CME) and prominence/filament eruptions. These phenomena are the main drivers of space weather. They are also one of the most interesting of solar phenomena from the viewpoint of basic MHD physics and present a great challenge to MHD theory. In this talk, I will review the major theoretical models for solar magnetic disruptions, and the progress to date on numerical simulations of CMEs/prominence eruptions. In particular, I will focus on the question of the physical requirements, (as predicted by our present understanding), for violent magnetic disruptions on the Sun, and the possibilities for forecasting such events with numerical simulations.

GA3.09/W/08-B4 1010

GLOBAL 3D MHD MODELING OF THE SOLAR CORONA AND SOLAR WIND

Arcadi V. USMANOV (Institute of Physics, University of St.-Petersburg, St.-Petersburg 198904, Russia, e-mail: usmanov@snoopy.phys.spbu.ru)

A self-consistent 3D MHD model of a steady coronal outflow with a flux of WKB Alfven waves in a dipolar magnetic field is developed. The results of simulation demonstrate the formation of a bimodal structure consisting of fast and slow wind. The computed parameters are generally consistent with the data from the Ulysses mission and with parameters typically found at the coronal base. It is shown that two processes determine the meridional distribution of solar wind plasma and magnetic field parameters: (i) the primary meridional relaxation and formation of a flat meridional profile of all the flow and magnetic field parameters (outside the equatorial band) in the region where magnetic forces dominate the thermal and wave gradient forces, and (ii) the secondary meridional redistribution due to the poleward thermal pressure gradient that formed as a result of the primary process. A series of successful simulation runs for the three-dimensional solar wind flow in the axial and tilted dipole magnetic field geometry has been carried out. The results of the 3D simulation are consistent with and further extend those obtained previously with an axisymmetric model.

GA3.09/W/27-B4 1035

MAGNETOHYDRODYNAMIC MODELING OF THE SOLAR CORONA FOR SPACE-WEATHER APPLICATIONS

JON A. LINKER, Zoran Mikic, Roberto Lionello, Pete Riley, Dalton Schnack, and Alfonso Tarditi (Science Applications International Corporation, San Diego, CA 92121)

Solar wind conditions upstream of Earth play a primary role in the initiation of geomagnetic activity. Satellites monitoring solar wind conditions at the L1 point can provide at most a one hour warning of important changes in the solar wind. The prediction of geomagnetic activity days in advance requires the forecasting of solar wind conditions at Earth orbit using remote observations of the Sun. In this talk we will discuss the present status of our magnetohydrodynamic (MHD) computations of the corona and solar wind. We will describe our progress to date in modeling the background solar corona and solar wind, which is essential for predicting the onset of fast solar wind streams at Earth. We will also discuss the elements we believe are necessary for success in modeling CME propagation to 1 A.U. Research supported by NASA and NSF; computations performed at NERSC and SDSC.

GA3.09/W/05-B4 1110

PREDICTING SOLAR WIND SPEEDS

Y.-M. WANG (Code 7672W, Naval Research Laboratory, Washington, DC 20375-5352, USA, E-mail: ywang@yucca.nrl.navy.mil)

Empirical studies have shown that the solar wind speed is inversely correlated with the divergence rate of magnetic flux tubes near the Sun. We discuss how this relationship can be used to predict the solar wind speed at Earth using photospheric magnetograms. We also discuss the implications of the wind speed - expansion factor correlation for the origin of fast and slow wind, with particular emphasis on the relationship between slow wind, open and closed field regions of the corona, and coronal streamers.

GA3.09/E/06-B4 1135

SEMIPHENOMENOLOGICAL MODEL OF FILAMENT-GENERATED SOLAR WIND

K.G.IVANOV and A.F.Harshiladze (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of Russian Academy of Sciences (IZMIRAN), Troitsk, Moscow Region, 142092 Russia, email: Kivanov@izmiran.troitsk.ru)

A semiphenomenological computer model of the solar wind proton number density and velocity variations at the Earth's orbit during special intervals of high solar filament activity was developed. The model allows to compute the proton number density (one hour averaged) long before (up to four days) arrival of solar prominence plasma at the Earth's orbit. The model suitable to the low speed solar wind (for example, the solar wind during the July 1978 event) and to an isolated coronal mass ejection as well (for example, July 10-11, 1996 ISTP event).

GA3.09/E/08-B4 1150

COMPARISONS OF GLOBAL GUMICS-4 RUNS WITH MESOSCALE GROUND-BASED DATA

Pekka JANHUNEN and Kirsti Kauristie (both at Finnish Meteorological Institute, Geophysical Research, POB 503, FIN-00101, Helsinki, Finland, email: Pekka.Janhunen@fmi.fi)

The most recent version of the GUMICS ionosphere-magnetosphere coupling simulation code is part of a flexible general MHD software. The new simulation incorporates automatic grid adaptation, which enables one to study cases with nonzero dipole tilt with no loss in accuracy. Apart from adaptive unstructured grid, GUMICS uses temporal subcycling, which provides additional significant speedup because the Alfv\'en speed is a steeply changing function of position.
To evaluate GUMICS, comparisons with observations are needed. Previous comparisons with older GUMICS versions with global SuperDARN convection patterns showed that higher resolution observations would also be useful. On the other hand, direct comparisons with magnetospheric satellites are plagued by the difficulty of getting a global picture. In this study we apply GUMICS for simulating recent intervals for which solar wind/IMF data and interesting MIRACLE data (a Scandinavian network of all-sky cameras, magnetometers and radars) is available. Within its accuracy limitations, GUMICS predicts the ionospheric conductivities, currents and electric field. Possibilities for intercomparisons with MIRACLE data include comparisons of GUMICS height-integrated Pedersen conductivity patterns with all-sky camera pictures, GUMICS horizontal electric fields with the STARE radar, and comparisons of simulated magnetograms with real ones provided by the by the IMAGE network.

GA3.09/E/03-B4 1215

VALIDATION OF GLOBAL MHD MODELS: GRID CONVERGENCE AND BOUNDARY CONDITIONS

D. L. DEZEEUW, T. I. Gombosi, C. P. T. Groth, and K. G. Powell (The University of Michigan, Ann Arbor, MI, USA , e-mail: darrens@umich.edu)

With advances in computing technology over the last decade, large-scale global models of the space environment have become increasingly sophisticated and complicated. It is crucial to make sure that these codes are validated as much as possible before they are used as analysis and forecasting tools and simulation results are compared with observations. This talk will concentrate on several important aspects of code validation, including grid convergence and the effects of boundary conditions.
Ideally, all MHD simulation results should be independent of the grid on which they are solved, but that is not always the case. A grid convergence study is useful in determining an acceptable level of grid influence in a solution. Grid convergence studies are not often practical to carry out, since most global models are being used at the limit of the available computing resources and significant increases in resolution are not possible. Grid convergence studies for several global magnetospheric configurations will be shown.
Procedures for prescribing boundary conditions can also play a role in the validity and accuracy of global MHD simulations. The type of boundary condition and boundary location (both inner and outer) can lead to differences in simulation results. Several global magnetospheric configurations illustrating these differences will be presented.

QUANTITATIVE MODELING 2

GA3.09/W/12-B4 1400

QUANTITATIVE COMPARISONS BETWEEN GLOBAL MHD SIMULATIONS OF MAGNETOSPHERE AND IN SITU MEASUREMENTS

M. WILTBERGER, C. C. Goodrich, R. E. Lopez, K. Papadopoulos (All at Astronomy Department,University of Maryland, College Park, MD 20742; (301) 405-7936; email: wiltbemj@spp.astro.umd.edu); J G Lyon (Department of Physics and Astronomy, Dartmouth College, Hanover, NH 03755); T. I. Pulkkinen (Finnish Meteorological Institute, P.O.Box 503 FIN-00101 Helsinki)

Spacecraft and ground data combined with multiscale computer models developed by the ISTP are providing a new and coherent picture of the magnetospheric substorms and storms. The Lyon-Fedder-Mobarry (LFM) Global MHD code is dynamically driven by solar wind data provided from upstream satellites and includes coupling between the magnetosphere and ionosphere. The simulation output can be directly compared with the field and flow quantities measured by magnetospheric satellites, ground data from CANOPUS, SUPERDARN, and other ground investigations, as well as images from the POLAR satellite.
We have used the LFM to simulate a variety of events including the storms associated with January 10-11, 1997 and May 1-4, 1998 magnetic cloud passages as well as substorms that occurred on March 9, 1995, May 15, 1996 and Dec 10, 1996. While the number of simulated events is still small, in a statistical sense, they provide us with opportunity to make comparisons between the observations and the simulation under a variety of solar wind conditions. Our results show that the LFM is capable of accurately representing the global magnetospheric state. Direct comparison with spacecraft measurements in the magnetotail is

a particularly challenging task due presence of small scale structures. In order to asses the models accuracy as well as examine both the in situ observations and the results in the larger magnetospheric context we conclude with a series of scientific visualizations that present both the satellite observations and the simulation results for the region near the spacecraft.

GA3.09/W/29-B4 1425

COMPARISONS OF EMPIRICAL MAGNETIC FIELD MODELS, MHD SIMULATIONS, AND ISTP OBSERVATIONS

T I PULKKINEN, (Finnish Meteorological Institute, Helsinki, Finland); M Wiltberger, (University of Maryland, College Park, MD)

Because the magnetospheric research largely depends on a few point measurements from a vast region of space, developing realistic models for the magnetospheric configuration and dynamics is especially important. Empirical models for the magnetospheric magnetic field describe the state of the magnetosphere at a given set of magnetospheric activity parameters, solar wind and IMF parameters. On the other hand, global MHD simulations give a self-consistent description of the temporal evolution of the magnetosphere for a specified solar wind input.
A substorm on Dec 10, 1996, consisted of two onsets, one at 0731 UT and another, larger, at 0800 UT. The early phases of the substorm have been modeled using both empirical models and MHD simulations. Observations indicate that the first onset was localized and did not lead to global reconfiguration. The empirical model results suggest that a thin current sheet was already present during the first onset, and that it persisted throughout the second onset. The MHD simulations do not produce much activity during the first onset, but predict the onset of the second activation within only a few minutes. By comparing the results, the strengths and weaknesses of each of the modeling approaches is discussed.

GA3.09/W/15-B4 1450

WHAT GLOBAL MODELERS NEED TO KNOW ABOUT IONOSPHERE OUTFLOWS

GILES, B. L. (NASA Goddard Space Flight Center, Greenbelt, MD 20771 USA, Email: barbara.giles@gsfc.nasa.gov); D. C. Delcourt (Centre d'Etudes Terrestraire et Planetaire, St. ésMaur-des-Foss, France 94107); D. L. Gallagher (NASA Marshall Space Flight Center, Huntsville, AL 35812 USA); T.E. Moore (NASA Goddard Space Flight Center, Greenbelt, MD 20771 USA); W.K. Peterson (Lockheed Martin Advanced Technology Center, Palo Alto, CA, 94304 USA); G. R. Wilson (Mission Research Corporation, Nashua, NH 03062 USA)

In the 1980's, detectors on S3-3 and Dynamics Explorer observed substantial amounts of ionosphere plasma flowing outward into the magnetosphere. Contemporary observations from Polar, Geotail and ISEE provide evidence that this plasma source substantially contributes to the magnetosphere environment extending at least to the mid-magnetotail region. The exact role of this plasma with regard to magnetosphere dynamics is still highly speculative although the concept enjoys renewed attention within the global modeling community. We present low-energy plasma observations from the POLAR spacecraft to illustrate dependences of the ionosphere source on solar wind and IMF conditions. Emphasis will be given to variations in flux strength, breadth in location, and the global extent of the outflow. Based on these observations, results from previous studies, and particle trajectory code calculations, we will also present initial results of a semi-empirical model of the ionosphere plasma source. Understanding the ionosphere plasma source and its response to solar influences is of significance when seeking to resolve terrestrial versus solar wind participation to the dynamics of the magnetosphere.

GA3.09/E/02-B4 1505

COMPARISON OF THREE QUANTITATIVE MAGNETIC FIELD MODELS OF THE MAGNETOSPHERE

Jean Claude KOSIK (Division Mathematiques, bpi 1214, CNES, 18 Av. E.Belin, 31401 Toulouse Cedex 4, France, email: jean-claude.kosik@cnes.fr)

A quantitative magnetic field model of the magnetosphere has been developped using poloidal vector fields and a NSSDC data base (Kosik, Annales Geophysicae, 1,1999). The main features of this model are briefly presented: ring current region, distant field, magnetopause current system, neutral sheet. The model, tilt and Kp dependent, can be compared to the Tsyganenko 89c model for different Kp and tilt angles. The difference between the total magnetic field and the magnetic field of internal origin, IGRF, is calculated for different Kp values. The corresponding delta B contours which give a clear signature of the ring current region are plotted and compared to the experimental results of Sugiura and Poros. Another comparison is made with the model Tsyganenko96-V1 which depends on the Dst index. Finally the models are compared to a series of magnetic field data and conclusions are drawn.

GA3.09/W/11-B4 1520

INFLUENCE OF THE REGION 1 FIELD-ALIGNED CURRENTS ON DISTURBED MAGNETOSPHERIC STRUCTURE

Igor ALEXEEV (Institute of Nuclear Physics, Moscow State University, Russia, 119899, email: alexeev@dec1.npi.msu.su)

Based on dynamic paraboloid model of the magnetosphere the contribution of the Region 1 field-aligned currents (FAC) to the pressure balance at subsolar point was calculated. The influence of the Region 1 FAC on the equilibrium condition at the inner edge of the tail plasma sheet was studied. The two different aspects of the FAC influence on magnetospheric magnetic field was studied. First, the twist of the magnetic field lines caused by FAC was calculated. Second the displacement of the open field lines bundle to the sunward direction was determined. The FAC control of the magnetospheric structure was investigated.

GA3.09/E/12-B4 1600

MODELLING THE EARTH'S TRAPPED RADIATION BELTS: CURRENT STATUS AND FUTURE DEVELOPMENTS

D. HEYNDERICKX and M. Kruglanski (BIRA/IASB, Brussels, Belgium)

Since their discovery, the Earth's trapped radiation belts have been the subject of several modelling efforts that aim to predict the distribution of the trapped particle population for a given state of the magnetosphere. In general, a trapped radiation belt model uses a coordinate system attached to the geomagnetic field which controls the behaviour of the electron and proton populations. We review the most used geomagnetic coordinate systems and discuss the requirements on the models of the magnetic field on which they are based. Changes in the magnetic field configuration necessitate regular updates of the radiation belt models. Requirements for new models are presented, as well as the data and developments needed to build them.

GA3.09/E/05-B4 1625

RICE CONVECTION MODEL DATA COMPARISONS

T W Garner, R A WOLF, and R W Spiro (Space Physics and Astronomy Dept., Rice University MS108, P.O. Box 1892, Houston, TX 77251, U.S.A.); W J Burke (Air Force Research Labs, Hanscom AFB, MA 01731); N C Maynard (Mission Research Corp., 1 Tara Bd., Nashua, NH 03062, U.S.A.)

An extensive series of Rice Convection Model runs has been carried out for the major magnetic storm of June 4-5, 1991, in an effort to clarify the processes involved in injection of the storm-time ring current. Model predictions are compared with electric fields and kilovolt-particle fluxes measured from CRRES and with ion drifts and precipitating-electron measurements from DMSP. The runs have been successful in reproducing the most basic features of the injection, including deep injection of fresh ions into the inner magnetosphere and the penetration of convection fields into the inner magnetosphere. However, there are quantitative disagreements with regard to many details. The implications of the results for overall understanding of ring-current injection will be assessed.

GA3.09/E/04-B4 1650

NONADIABATIC PARTICLE MOTION NEAR TRAPPING BOUNDARY IN TSYGANENKO T89 MODEL

Prof. S.N.KUZNETSOV and A.Yu.Rybakov (both at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, 119899 Moscow, Russia)

Energetic charged particle motion at trapping boundary region was calculated with using Tsyganenko T89 model. Calculation based on model of particle nonadiabatic motion in dipole field developed at Skobeltsyn Institute of Nuclear Physics. Position of precipitation region of energetic particles was found depending on parameter of adiabatic motion, geomagnetic latitude and geomagnetic local time for different geomagnetic disturbances. Comparison with precipitating and quasi-trapped particle fluxes measured by "CORONAS-I" satellite was performed.

GA3.09/W/20-B4 1705

A MODEL OF THE SPATIAL STRUCTURE OF THE HIGH LATITUDE MAGNETIC PERTURBATIONS (HLMP)

J. A. VALDIVIA (Code 692, NASA/GSFC,Greenbelt, MD 20771; 301-286-3545; e-mail: alejo@roselott.gsfc.nasa.gov) D Vassiliadis (NASA/GSFC/USRA) A J Klimas (NASA/GSFC)

We have generalized the standard nonlinear dynamical approach devised for the AL-VBs coupling [Vassiliadis et al., J. Geophys. Res., 100, 3495, 1995] to construct a two dimensional dynamical model of the spatial structure of the high latitude magnetic perturbations (HLMP). This model is constructed with the help of nonlinear time series techniques from a discrete set of ground magnetometers measurements and WIND data. Different models are constructed for each of the three magnetometer chains (1) Canopus, (2) IMAGE and (3) MM210, which can then be compared with each other. A two dimensional model of the spatial structure of the HLMP is constructed using the fact that as the Earth rotates, the ground magnetometer chain essentially samples the spatial structure of the HLMP repeatedly and for many levels of activity. Therefore, a novel technique is used to reconstruct a full dynamical model, driven by solar wind data from a suitable two dimensional initial condition, of the two dimensional spatial structure of the HLMP and the related equivalent current system (HLCS). This effort is aimed at generating a two dimensional dynamical model of the spatial structure of the high latitude current systems. These models can be used to visualize and to predict the spatial evolution of the current systems as observed by multiple ground stations. Hence, these models could be also useful as a spaceweather forecasting tool.

GA3.09/W/14-B4 1720

HIGH-LATITUDE GROUND GEOMAGNETIC FIELD MODELS WITH A NONLINEAR COUPLING TO THE SOLAR WIND INPUT

D. VASSILIADIS (NASA/GSFC/USRA, at: Code 692, NASA/GSFC, Greenbelt, MD 20771; 301-286-9060; email: vassi@lepgst.gsfc.nasa.gov); J. A. Valdivia, A. J. Klimas, D. N. Baker

Many ground geomagnetic field models are data-based, but most of them are independent of activity, or classify activity according to a geomagnetic index. However it appears possible to represent the dependence of the geomagnetic and current spatial distribution on several distinct processes and parametrize the field models more self-consistently. Clearly such processes are primarily the large-scale convection imposed by the recent solar wind electric field, and, to higher order, internal magnetospheric processes. Here we present a new type of ground geomagnetic field model which is parametrized directly by the solar wind E-field and the internal magnetospheric activity level. The internal activity is represented self-consistently in terms of measurements from four high-latitude magnetometer chains from which a spatial-temporal pattern is constructed. A month-long interval in 1995, which is dominated by high-speed streams and in which WIND monitors the interplanetary conditions during its ascent towards L1, is used as the database for model development ("training"). We extend the techniques used in geomagnetic index prediction / modeling, to represent the geomagnetic state and express it as a superposition of basic geomagnetic patterns. Each pattern is associated with an equivalent current system in a way similar to the method of Sun et al. [JGR A6, 1998]. Starting from an initial geomagnetic state the model is stepped in time by finding similar geomagnetic / solar-wind states among the large number of states stored in the database, and interpolating their dynamics. The field model will be tested for its ability to predict the spatiotemporal development of geomagnetic events while driven by the solar wind input or PC index. The amplitude information obtained from the spatiotemporal predictions will then be compared to that of AL/AU index models.
Similarly to other geomagnetic models (e.g. IZMEM) this model can be coupled to the height-integrated conductivity to estimate ionospheric electrodynamic parameters, such as currents and E-fields, and convection patterns.

GA3.09/E/09-B4 1735

CURRENT CONFIGURATION IN THE HIGH LATITUDE MAGNETOSPHERE AND MAGNETOSPHERE MAGNETIC FIELD MODELING

Elizaveta E ANTONOVA and Natalia Yu. Ganushkina (both at Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia; email: antonova@taspd.npi.msu.su)

Quantitative modeling of the magnetospheric magnetic field require the proper selection of the

inner magnetosphere current systems. Among such systems the inner Earth currents (IGRF field), tail current, inner magnetosphere westward ring current, magnetopause currents and field-aligned currents are ordinarily selected. The analysis of plasma pressure distribution in the magnetosphere and the topology of high latitude magnetosphere show on the existence of one more current system quasi-ring current localized far from equatorial plane near noon. Current lines of this current system have the forms of cut rings. High latitude earthward plasma pressure gradients produce westward currents, anti-earthward plasma pressure gradients produce eastward currents. It is shown that any growth of inner magnetosphere plasma pressure must lead to the appearance of the effective eastward ring current. The role of eastward ring current in the magnetopause motion and near noon field line stretching during substorms is analyzed. The magnetopause pressure balance is discussed.

QUANTITATIVE MODELING 3

GA3.09/E/07-B5 0830

HIGH-LATITUDE CONVECTION PATTERNS: METRICS

Y. KAMIDE (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Aichi-ken 442-8507, Japan, email: kamide@stelab.nagoya-u.ac.jp)

A number of empirical and semi-empirical models for the large-scale distribution of the electric potential, or convection, in the ionosphere have been proposed. These models, which are sorted according to various solar wind conditions, are the result of satellite and radar observations of electric fields, as well as ground-based magnetometer measurements through so-called magnetometer inversion techniques. To evaluate these models in terms of how well they can predict or reproduce the reality, it is important to realize that ionospheric convection patterns consist of two components. One can be predicted reasonably well by proper solar wind parameters, and the other is caused by some "internal" processes in the magnetosphere-ionosphere system. Thus, for a given condition in the solar wind, the response of the convection patterns in the ionosphere can vary to a significant degree.

GA3.09/W/18-B5 0855

RECONSTRUCTION OF HIGH LATITUDE IONOSPHERIC CONVECTION PATTERNS FROM CROSS-POLAR SATELLITE PASSES

Peter ISRAELEVICH and Alexander Ershkovich (Department of Geophysics and Planetary Sciences, Tel Aviv University, Ramat Aviv 69978, Israel, email: peter@jupiter1.tau.ac.il); Vladimir PAPITASHVILI (Space Physics Research Laboratory, University of Michigan, Ann Arbor, MI 48109, USA, email: papita@umich.edu)

In this study we attempt the reconstruction of ionospheric convection patterns over the entire polar region solely from satellite measurements of the electric fields (or ion drifts) made along the cross-polar pass(es). In a simple case, a single cross-polar pass divides the polar cap in two sub-regions; however, additional near-simultaneous passes increase the number of subdivisions and significantly improve the overall calculations. Both horizontal components of the measured vector are required for calculations; the ionospheric electric potential and its normal derivative are set to zero at the equatorial boundary of the polar region. The stream function method is proposed for solving the boundary value problem. The polar ionosphere is taken as a plane with the constant geomagnetic field over the entire polar region; it is supposed that existing field-aligned currents close at altitudes of 100-150 km. Under these assumptions the field vertical derivative equals to zero at the altitudes of several hundred kilometers (e.g., 300-800), and the problem becomes two-dimensional. Assuming also that the two-dimensional ionospheric plasma flow is incompressible, we reduce the magnetohydrodynamic flow to the hydrodynamic one and introduce the stream function strictly related to the ionospheric electrostatic potential in the polar cap. We tested the method using the modeled convection patterns for various IMF conditions and then validated the results reconstructing the patters from the simulated cross-polar passes over both the northern and southern polar caps.

GA3.09/W/25-B5 0910

HIGH LATITUDE IONOSPHERIC CONVECTION MODEL DERIVED FROM DMSP DATA AND PARAMETERIZED BY THE IMF STRENGTH AND DIRECTION

Vladimir PAPITASHVILI (Space Physics Research Laboratory, University of Michigan, Ann Arbor, MI 48109, USA, email: papita@umich.edu); Frederick Rich (Air Force Research Laboratory, Hanscom Air Force Base, Hanscom MA 01731, USA, email: rich@plh.af.mil); Marc Hairston (Center for Space Sciences, University of Texas at Dallas, Richardson, TX 75080, USA, email: hairston@utdallas.edu); Boris BELOV (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, IZMIRAN, Troitsk, Moscow Region, 142092, Russia, email: bbelov@adonis.iasnet.ru)

The ionospheric electrostatic potentials obtained from thermal ion drift measurements made by DMSP satellites in 19931996 are binned by every 1 degree CGM latitude and 0.5 hour MLT over both the northern and southern polar regions. Then the linear regression analysis technique is applied to the IMF data and the DMSP potentials in each bin. However, the available satellite orbits provide lesser coverage over the dayside and nightside sectors of the polar region; some bins have no coverage at all. Recently we re-calibrated electric potentials provided by the IZMIRAN Electrodynamic Model (IZMEM) against xperimental DMSP observations. This allowed us to parameterize the DMSP ionospheric potentials by the IMF strength and direction (e.g., 11.5 kV/nT and 5.0 kV/nT for the southward and northward IMF, respectively). The background" cross-polar potential estimated from DMSP data equals ~33 kV if the IMF is near zero. In this study, we filled the gaps in the DMSP observations over dayside and nightside sectors by the IZMEM potentials and then applied the spherical harmonic analysis to the combined DMSP/IZMEM set of ionospheric potentials for various IMF conditions.

GA3.09/W/06-B5 0925

CORRECTNESS OF COUPLED MODELS OF THE HIGH AND MID-LATITUDE IONOSPHERE

J. J. SOJKA and R. W. Schunk (Center for Atmospheric and Space Sciences, Utah State University, Logan, Utah 84322-4405, Email: fasojka@sojka.cass.usu.edu)

Theoretical formulations of the ionosphere, thermosphere, and magnetosphere are well established. Their numerical solutions in the form of global models, whether stand alone or coupled, are proliferating due to the continued technological breakthroughs, leading to lower costs of computing. The increasing awareness of the adverse effects of space weather through programs such as the US National Space Weather Program (NSWP), is acting to fuel this proliferation. Stumbling along at a somewhat slower pace is the process of evaluating the accuracy, correctness, or even usefulness of such developments. This stage involves the use of "ground truth" observations of the geospace system. However, the acquisition of such data is difficult, and casting it into a mathematically sufficient data base so that it can be used to evaluate models is even more challenging. Experimentally, the complete constraint of ionospheric models is far from achievable. Therefore, we present procedures and initial steps that we are taking to evaluate ionospheric models. The philosophy presented involves emphasizing the evaluation of the inputs as well as the ionospheric outputs. The sensitivity of the system to changes in the inputs is used to determine the relative importance of input knowledge. Both stand alone ionospheric and magnetosphere-ionosphere coupled models will be discussed. The presentation will also demonstrate that most present day models are approaching 100% "correctness", but that they also still have approximately zero skill (usefulness)! The old adage "garbage-in implies garbage-out" is very applicable in todays NSWP environment.

GA3.09/W/03-B5 0950

SPACE WEATHER SPECIFICATION AND FORECAST VERIFICATION

M V CODRESCU, and T J Fuller-Rowell (CIRES-University of Colorado/NOAA - SEL, 325 Broadway, Boulder, CO 80303, USA; e-mail: codrescu@sec.noaa.gov); P Wilkinson (IPS Radio and Space Services, Haymarket, AUSTRALIA)

The increasing use of models for Space Weather specification and forecast and the existence of a variety of competing models with different strengths and weaknesses require continual consideration of validation and verification issues. Consistent approaches based on unified metrics need to be implemented in order to assess progress and to inform potential users about product and service reliability. The evaluation of space weather models is made more difficult by the use of the output of one model as input to another and the sparcity of measurements in the Sun-Earth chain. A number of models have been verified and validated as research tools and are now ready to start verification and validation under operational conditions. We use the Coupled Thermosphere Ionosphere Model (CTIM) to illustrate the verification and validation issues encountered at the Space Environment Center in Boulder, Colorado in the transiton of a research model into operations. We will discuss uncertaincies due to inprecise knowledge of forcings, initial conditions, subgrid scale processes, and uncertain physical or chemical parameters.

GA3.09/W/04-B5 1035

GLOBAL MODELING OF IONOSPHERIC TOTAL ELECTRON CONTENT DURING GEOMAGNETIC STORMS

G. LU (HAO/NCAR, Boulder, CO 80301; 303-497-1554, email: ganglu@ncar.ucar.edu); A. D. Richmond (HAO/NCAR, Boulder, CO 80301); R. G. Roble (HAO/NCAR, Boulder, CO 80301); X. Pi (JPL, Pasadena, CA 91109)

During geomagnetic storms, energy inputs from the magnetosphere can have dramatic effects on the upper atmospheric environment. One such effect is the changes in the ionospheric electron density that can perturb communication and navigation systems. In this paper, we show that, by using realistic time-dependent high-latitude ionospheric convection and auroral precipitation derived from the AMIE procedure, the NCAR TIE-GCM is capable to reproduce many observed features of ionospheric disturbaces in response to the January 1997 geomagnetic storm. In particular, we compare the model simulated ionospheric electron density variations with those observed from the Global Positioning System (GPS) ground-based and low-earth orbiting receivers.

GA3.09/W/19-B5 1100

COMPARISON BETWEEN SUPIM SIMULATIONS, ISR DATA AND GPS TEC MEASUREMENTS

B. MACPHERSON, S. A. Gonzalez, M. P. Sulzer (all at Arecibo Observatory, HC3 Box 53395, Arecibo, 00612, Puerto Rico, U.S.A, Email: bmacpher@naic.edu, sixto@naic.edu, sulzer@naic.edu); G. J. Bailey (The Upper Atmosphere Modeling Group, University of Sheffield, England, Email: g.bailey@sheffield.ac.uk); M. C. Kelley (Cornell University, Email: mikek@anise.ee.cornell.edu); C. Wang (USC, Email: cwng@cams-00.usc.edu); G. hajj and X. Pi (JPL, Email: hajj@cobra.jpl.nasa.gov, xqp@maggie.jpl.nasa.gov)

Because of the effects of the Earth's space environment on the applications of advanced technology, forecasting ionospheric daily variations is a crucial goal of the National Space Weather Program. However, no ionospheric model exists that comes close to the predictive power of meteorological models, due mainly to the relative paucity of ionospheric data and several uncertainties in ionospheric modeling. Therefore, improved ionospheric modeling and a comprehensive ionospheric set of measurements are required to be able to reach the goal of space weather forecasting. Total electron content (TEC, the integrated electron density along theray path) data from the Global Positioning System (GPS) present a potentially powerful tool to monitor the ionosphere due to the continuous data available from hundreds of ground stations. Furthermore, the availability of space-based TEC data from the GPS/MET mission, and several low-Earth orbiters tracking GPS to be launched in the next two-three years, provides a sampling of the ionosphere from a previously unavailable vantage point.
We are currently developing an ionospheric model capable of assimilating GPS TEC measurements that is based on the the Sheffield University Plasmasphere Ionosphere Model (SUPIM). The eventual goal is to be able to nowcast and forecast global ionosphere electron denisties, along with other parameters, using the model and near realtime TEC observations from GPS. We will discuss results obtained by comparing TEC obtained from GPS with TEC deduced from topside ionsphere data taken at the Arecibo Incoherent Scatter Radar facility. These data will also be compared with results from SUPIM. Data from both quiet and disturbed conditions will be discussed.

GA3.09/E/10-B5 1115

AN ASSESSMENT OF MODELS FOR EQUATORIAL PLASMA BUBBLES

JOHN M. RETTERER (Air Force Research Lab., Hanscom AFB, MA, 01731, USA, email: retterer@plh.af.mil)

Equatorial plasma bubbles are the structured depletions of plasma density which develop in the ionosphere after sunset, with which Equatorial Spread-F radio scatter and scintillation are associated. Devising tests for a theoretical model of the equatorial plasma bubbles is a challenge because of their sensitive dependence on the structure of the background plasma and the stochastic nature of the unobservable perturbations from which they grow; it is doubtful whether it will ever be possible to predict the exact location and structure of the bubbles that form on a particular evening, but likepredictions of favorable conditions for thunderstorms on a summer afternoon forecasts of a statistical nature are possible. In

preparation for the development of components of a scintillation forecast model, a review of the assumptions and physics built into current models of the formation of equatorial bubbles was carried out. One of the conclusions was that our understanding of bubble formation is mature enough that it is appropriate to replace the simplified models of the characteristics of the ionospheric plasma with detailed, realistic models. Some of the consequences of this quest for detail will be illustrated with the results of a new simulation code. The results will be shown side-by-side with data from both ground-based observations and satellite flythroughs, inviting at least qualitative comparison. Formidable challenges remain, including the description of the three-dimensional character of the plasma depletions, the development of maller-scale structure, and then a specification of the information needed to characterize the level and nature of the resulting scintillations.Coordinated collection of data of the many aspects of these phenomena willbe required to achieve the level of understanding necessary to combine them to develop an reliable scintillation forecast model.

NEUTRAL DENSITY MODELING AND VALIDATION

Geoff CROWLEY (Southwest Research Institute, San Antonio, TX 78238-5166: email: crowley@picard.space.swri.edu)

Global 3D first-principles models of the thermosphere and ionosphere are at an advanced stage of development and can potentially make important contributions to Space Weather specification and forecasting. The problem has been in showing that these models can routinely improve on the performance of simple empirical models. Neutral densities are of great interest for predicting satellite orbits, and in this paper, we review the state of the art in global modeling of the neutral density, including techniques currently in operational use. Detailed model/data comparisons are presented and the metrics needed to quantify the performance of current and future models are discussed. We address the likely sources of deviations between the models and data, and ask how these might be mitigated. The implications for use of first principles models in real-time Space Weather applications are explored.

GA3.09/W/24-B5 **1205**

STUDY OF ASSESSING CURRENT THERMOSPHERE MODELS WITH NEURAL-NETWORK-BASED THERMOSPHERE MODELS

Jianhua TIAN and Quanfu Fan (both at Center for Space Science and Applied Research, Academia Sinica, 100080, Beijing, China email: jhtian@earth.sepc.ac.cn)

A neural-network-based thermosphere model(NNTM), which has good statistical and generalized capability in modeling total atmospheric density and can provide more data coverage than the current observed data, is used to assessing the accuracy of some current thermosphere models such as MSIS90, MET and CIRA72.
Comparisons are made between the computed values of total atmospheric density between NNTM and other three models. The results show that in the altitude range of 200-400km, MSIS90 is systematically better than MET and CIRA72 in modeling of total density variations under most cases. In 400-600km, MSIS90 is equivalent to MET, while CIRA72 does worse and generates higher total density.

POTENTIAL FIELD APPROXIMATION OF MAGNETIC FIELDS ON THE SUN FROM DAILY MAGNETOGRAMS

Dmitri I. PONYAVIN (Institute of Physics, University of St.Petersburg, 198904, Russia, e-mail: ponyavin@snoopy.phys.spbu.ru)

Daily full-disk magnetograms measured at Stanford were taken separately to infer a large-scale magnetic field configuration in framework of potential field theory. A regularization technique was applied to resolve spherical harmonics from the data covering only visible solar disk. Sets of daily spherical expansion coefficients collected few days later serve as input entries for extrapolating procedure. This procedure was constructed to resolve trends in large-scale magnetic field evolution. Coefficients were than used to predict large-scale magnetic field configurations just near the solar and source surface - the origin of the heliospheric current sheet and solar wind streams. Results of comparison between actual and predicted magnetic fields were presented and discussed.

PREDICTABILITY LIMITS FOR LONG-TERM HELIOSPHERIC PLASMA AND MAGNETIC FIELD VARIATIONS

I.S. VESELOVSKY, A.V. Dmitriev, A.V. Suvorova, M.V. Tarsina, M.O. Riazantseva (Institute of Nuclear Physics, Moscow State University, 119899 Moscow, Russia, Email: veselov@dec1.npi.msu.su)

Solar wind and interplanetary magnetic field are the manifestations of the solar activity that impact on the Earth's magnetosphere most effectively. Correlation functions are calculated for the main average plasma and magnetic field parameters using the data base obtained in 1964-1998 in the heliosphere near the Earth. The flowing time window with a variable width is used for the regression analysis. Characteristic correlation time intervals are found and used for the evaluation of dynamical predictability limits. The role of regular and irregular variations is discussed in attempts of statistical predictions inside and beyond these correlation times under different averaging time intervals and procedures. The prediction of heliospheric parameters by means of Artificial Neural Networks is presented for 1999-2000.

COMPARISON BETWEEN SATELLITE OBSERVATIONS AND RESULTS FROM THE TSYGANENKO AND TOFFOLETTO-HILL MODELS

Pieter B KOTZÉ (Hermanus Magnetic Observatory, P O Box 32, Hermanus 7200, South Africa; e-mail: pkotze@csir.co.za)

Magnetic field measurements obtained from Geotail and other satellites during disturbed periods are compared with calculations from both the Tsyganenko 96 and the Toffoletto-Hill 93 magnetospheric field models. Solar wind particle and magnetic field data from the Wind and IMP8 satellites are used as dynamic input to these models. We investigate disturbances of the Earth's magnetosphere caused by magnetic cloud events resulting in different orientations of the interplanetary magnetic field.The response of the magnetosphere to the passage of the January 10-11, 1997 magnetic cloud event was modelled and compared with data obtained from the Geotail satellite, while using input data from the Wind spacecraft located in an upstream position. Similarly, a magnetic cloud observed by Wind on February 8-9, 1995, located at an upstream distance of 193 Re, resulted in substorm activities being monitored by both the IMP8 and Geotail satellites in different regions of the magnetotail. Modelling results from both the Tsyganenko and Toffoletto-Hill models are compared with observations.

COMBINING THE RICE CONVECTION MODEL WITH MHD

F. R. TOFFOLETTO(1), R. A. Wolf(1), J Birn(2), and M. Hesse(3) (1) Department of Space Physics and Astronomy, MS 108, Rice University, Houston, TX 77251-1892, USA. (email: toffo@rice.edu) (2) MS D466, Group NIS-1, Los Alamos Nat Lab, Los Alamos, NM 87545, USA (email: jbirn@lanl.gov) (3) Electrodynamics Branch, NASA/Goddard Space Flight Center, Greenbelt, MD 20771, USA (email: hesse@gsfc.nasa.gov)

We will describe results from a collaborative effort that is aimed at the development of a self-consistent computational model of a substorm, by coupling the physics of the inner magnetosphere and the ionosphere, as represented by the Rice Convection Model (RCM), and the physics of the tail, as represented by the Los- Alamos/Goddard MHD model of tail dynamics. Another essential element is an equilibrium code that has been developed through a Los-Alamos/Goddard/Rice collaboration. We will present results from the fully merged Tail-MHD/RCM model that test substorm ideas for theoretical consistency. This project evolved as part of the NSF Geospace Environment Modeling (GEM) effort to develop a modular Global Geospace General Circulation Model (GGCM) and consists of a prototypical coupling of a Core Module to a Tail/Substorm Module.

MODELING THE TRAPPING BOUNDARY OF THE RADIATION BELTS AT HIGH AND LOW LATITUDES

Mohamed J. ALOTHMAN and Theodore A. Fritz (both at Center for Space Physics, Boston University, Boston, MA 02215, Email: alothman@bu.edy and fritz@bu.edu)

A model for the High Latitude Isotropic Boundary (HLIB) was introduced by the authors in previous work. This model is based on the ability of particles to bounce between the mirror points while conserving their first and second adiabatic invariants. However, in the region where the magnetic field departs from dipole-like to tail-like in the nightside, the field line radius of curvature becomes comparable to the particle radius of gyration and the first invariant is violated resulting in pitch angle scattering and the generation of the isotropic fluxes seen at low altitudes equatorward of the trapping boundary. Further modeling revealed that particles with intermediate equatorial pitch angles get scattered into the loss cone while those with angles near 90 degrees are almost unaffected by this scattering process. The observations of ISEE 1 and 2 of pitch angle distributions with a depletion around 90 degrees, or what is known as butterfly distributions in different Magnetic Local Times (MLT) support this result. Previous work done on ISEE data, shows that the butterfly distributions are generated by magnetopause shadowing. Further analysis of ISEE observations of the butterfly distributions suggests that the magnetopause can act as both a sink and a source for particles with energy between 24 keV and 2 MeV. Furthermore, modeling the HLIB 30 keV ion fluxes as measured by the NOAA/TIROS as a function of MLT showed a very significant increase in the flux between 3 and 7 am MLT. These observations suggest a population of energetic articles can enter the nightside magnetosphere with a equatorial pitch angle around 90 degrees from one flank of the magnetopause and exit from the other without getting trapped into the radiation belts through scattering. This hypothesis will be examined by the combination of observations from low latitude by ISEE, high latitude from the NOAA/TIROS satellites, and models of the scattering process.

A POLOIDAL VECTOR FIELD MODEL OF THE MAGNETOSPHERE WITH FIELD ALIGNED CURRENTS

Jean Claude KOSIK (Division Mathematiques, bpi 1214, CNES, 18 Av. E.Belin, 31401 Toulouse Cedex 4, France, email: jean-claude.kosik@cnes.fr)

A magnetic field model of the magnetosphere different from the model Kosik99 (Annales geophysicae,1,99) has been developped. This simplifield model has been built using poloidal vector fields only. The magnetic field created by the magnetopause currents is described by one poloidal vector field expressed in cylindrical coordinates. The magnetic field produced by the tail current sheet is described by two poloidal vector fields also expressed in cylindrical coordinates. The curl of these poloidal vector fields can describe the dawn-dusk current flow. The ring current region is described also by a poloidal vector field expressed in spherical coordinates and the generating function adequately describes the depression in the external field. To obtain field aligned currents strictly along the magnetic field lines of the magnetosphere. the J field must be similar to the B field. The J field is also a poloidal vector field and the equations of the J lines are similar to the B field equations. The field aligned current equations can be considered as the degenerate form of the force free equations and the poloidal J field as the curl of a toroidal magnetic field. In our model this toroidal magnetic field is a small perturbation of the poloidal vector field of the magnetosphere and neglected in this first approach.

INTERCOMPARISON OF MATHEMATICAL MODELS OF SOLAR ACTIVITY, INTERPLANETARY MAGNETIC FIELD AND MAGNETIC FIELD ON THE EARTH

Tamara KUZNETSOVA, Lev Tsirulnik and Valery Petrov (all at IZMIRAN, Troitsk, Moscow region, 142092, Russia, email: tvkuz@izmiran.rssi.ru)

A method of nonlinear spectral analysis (called the method of global minimum: MGM) has been used to find periodicities in annual Wolf sunspot numbers (W) during the period 1700-1997. Data on interplanetary magnetic field (IMF) measured in solar wind during space era (1963-1997) are used to find periodicities in IMF. The longest set of magnetic observations on the Earth (D-component at Hartland, 1810-1995) is used for calculation of geomagnetic spectrum. We use MGM advantages: self-consistent selection from a data set of a trend, ability to single out periods which are longer than an input data set The powerest triplet at period T~204 yr. in W testifies to the existence of the slowest non-stationary processes in sunspot formation. Trend in IMF module is described by harmonic at T~198 yr. Our analysis shows that W has the best correlation with IMF module (compared with the other solar wind parameters). These long harmonics in the both spectra show that long-term increase of solar

activity (IMF module) has been finished; decline phase is in progress. Comparative analysis of solar activity and geomagnetic spectra shows that significant spectral peaks of the geomagnetic spectrum are contained in the solar spectrum (periods with error bars coincide: Gleisberg's, Fritz's periods and others). However, harmonics of the solar model that have analog in the geomagnetic spectrum are not the powerest ones. For example, one of the powerest spectral peaks in the solar spectrum at T=11.1 yr. is lower confidence limit in the geomagnetic spectrum. Thus, for supporting of the processes responsible for geomagnetic variations are important defined spectral lines of solar activity spectrum. The common periodicities (their amplitude and phase) in the Sun (W), in the Geospace (IMF module), on the Earth (D-component of the magnetic field) are analyzed

ASSESSMENT OF IONOSPHERIC MODELS: WEATHER SPECIFICATION

D.T. DECKER, J.O. Wise, W.S. Borer (All at Air Force Research Laboratory, Hanscom AFB, MA USA 01731-3010, Email: decker@plh.af.mil) P.H. Doherty (Institute for Scientific Research, Boston College, Chestnut Hill MA USA 02167, Email: doherty@plh.af.mil) R.E. Daniell Jr.(Computational Physics Inc., 240 Bear Hill Rd, Waltham, MA USA 02451, Email: daniell@cpiboston.com)

In recent years there has been work towards using day specific observations and ionospheric models to provide a weather specification of the ionosphere. For example the climatological models IRI, PIM and RIBG are three models that have been used in work of this type. In particular, the U.S. Air Force has developed the Parameterized Real-time Ionospheric Specification Model (PRISM) over the last 10 years. This model uses both ground-based and space-based data available in near real-time to modify the Parameterized Ionospheric Model (PIM) and thus provide a near-real time specification of the ionosphere. While there have been a few validation studies of PRISM, they have been fairly limited in scope and do not provide, as complete and comprehensive validation of PRISM as is practical. In this paper, we discuss the data assimilation capabilities of PRISM and our assessment of its ability to provide improved ionospheric specification. We will particularly focus on the interplay between data coverage, the accuracy of the PIM climatology, the observed spatial and temporal correlations in the ionosphere, and the observed day-to-day variations.

GA3.09/W/02-B4 Poster **0900-09**

ASSESSMENT OF IONOSPHERIC MODELS: THE CLIMATOLOGY

P.H. DOHERTY (Institute for Scientific Research, Boston College, Chestnut Hill, MA USA 02167, Email: doherty@plh.af.mil), D.T. Decker, P.J., Sultan, W.S. Borer (All at Air Force Research Laboratory, Hanscom AFB, MA USA 01731-3010, Email: decker@plh.af.mil), R.E. Daniell Jr. (Computational Physics Inc., 240 Bear Hill Rd, Waltham, MA USA 02451, Email: daniell@cpiboston.com)

The growing focus on space weather has generated interest in quantifying the "state of the art". In part, this requires establishing quantitative metrics and assessing the baseline performance of current models. We are presently involved in a comprehensive effort to assess various ionospheric models, which will contribute to establishing an ionospheric baseline. This effort will eventually involve ionospheric models of various types including empirical, semi-empirical, theoretical, specification, and forecast. For this paper, we focus on several available climatological models: Bent, Chiu, FAIM, IRI, PIM, and RIBG. In order to have a comprehensive approach, we are using a variety of ground-based and satellite-based datasets. These include data from incoherent scatter radar, ground-based ionosondes and digisondes, DMSP in-situ measurements, TOPEX TEC measurements, Faraday rotation TEC measurements, ground-based GPS TEC measurements, and satellite-based TEC measurements. Besides providing a complete picture of what aspects of the models are validated, this work will provide the opportunity to quantify the climatology and weather contained in these datasets. This quantification of the observed ionospheric weather will be useful in establishing goals for future space weather models. In this paper, we will discuss the goals, the methodology, and the results to date of this assessment effort.

GA3.09/W/21-B4 Poster **0900-10**

ON THE DEFINITION OF THE QUIET IONOSPHERE AT MIDDLE LATITUDES DURING THE 21ST SOLAR CYCLE

Anna BELEHAKI and George Moraitis (Institute of Ionospheric and Space Research, National Observatory of Athens) Ioanna Tsagouri (Nuclear and Particle Physics Section, Physics Department, University of Athens)

The dependence of the foF2 critical frequency measured in Rome ionospheric station at local noon on the sunspot number Rz, has been examined during the 21st solar cycle (1976-1986). A clear linear response of the F2 layer critical frequency was found for low level of solar activity (Rz up to 85) while for higher values of Rz the ionospheric response turned to be better fitted by an exponential curve. The quiet values of the foF2 in Rome ionospheric station has been reproduced using the multiple regression method, for low and high level of solar activity. The quantity QoF2 obtained from this model was compared with the monthly median values of the foF2 parameter, for intervals of very quiet magnetospheric activity during various phases of the solar cycle. The results show a much better fit of the QoF2 with the observed values of the foF2 parameter than that we get using the monthly median to define the quiet ionosphere.

GA3.09/W/07-B4 Poster **0900-11**

STATISTICAL CORRELATION BETWEEN THE FOF2 DISTURBANCES AT MIDDLE LATITUDES AND THE GEOMAGNETIC ACTIVITY

Ioanna TSAGOURI (Nuclear and Particle Physics Section, Physics Department, University of Athens) Anna Belehaki and George Moraitis (Institute of Ionospheric and Space Research, National Observatory of Athens) Helen Mavromichalaki (Nuclear and Particle Physics Section, Physics Department, University of Athens)

The correlation between the foF2 middle latitude ionospheric disturbances during several great geomagnetic storms has been investigated aiming the forecasting of the geomagnetic structure during geomagnetic storms. The middle latitude ionospheric disturbances have been estimated using the quantity dfo=100*(foF2-QoF2)/QoF2, where the QoF2 is the quiet value of the foF2 parameter, computed using the method of multiple regression between the observed foF2 parameter at a given ionospheric station at middle latitude and the sunspot number Rz. The quantity dfo was computed using data from a chain of 9 middle latitude stations around the earth for several geomagnetic storms with aa>200, occurred during the 21st solar cycle, between 1976-1986. The correlation coefficient between dfo parameter in each station and various geomagnetic indices (AE,Dst and Kp) was calculated to determine the dependence of the ionospheric middle latitude disturbances on the intensity of magnetic storms, the storm onset sector and the previous energy state of the magnetosphere.

IZMEM MODEL AND GROUND-BASED AND SATELLITES OBSERVATIONS OF THE IONOSPHERIC CONVECTION

L. I. GROMOVA, Ya. I. Feldstein, A. E. Levitin (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, Russia, email: lgromova@izmiran.troitsk.ru)

The space electromagnetic weather model IZMEM has been utilized to define convection at the ionospheric altitude for different directions and intensity of the interplanetary magnetic field (IMF) components. These modeled results have been compared with the convection observed by Akebono, Viking, and Dynamic Explorer satellites. The comparison results have been used for the mutial calibration of both satellite measurements and ground-based SuperDARN observations of the ionospheric convection. The Viking satellite observations allowed to calibrate existing convection models determinating convection dependance on the interplanetary magnetic field for the case of the unstable orientation of the IMF vector.

INVESTIGATION OF BUILDING NEURAL-NETWORK-BASED THERMOSPHER MODELS

Jianhua TIAN and Quanfu Fan (both at Center for Space Science and Applied Research, Academia Sinica, 100080, Beijing, China email: jhtian@earth.sepc.ac.cn)

By using satellite drag density data, the neural- network-based thermosphere models (NNTM) are established to compute the total atmospheric density in the altitude ranges of 200-400km and 400-600km, respectively. Comparisons are made between TMNN and other empirical thermosphere models such as MET, MSIS90 and CIRA72. The results indicate that the overall mean and standard deviations of NNTM are lower than other three models except that MET has a relatively low overall mean deviation in 400-600km. With regard to the distribution of occurrence frequency of the data residuals, NNTM also has a more satisfactory result. In general, with the variation of a specific parameter (F10.7, geomagnetic indices Kp, altitude, latitude, day of year, local solar time etc.), there is a obviously lower value and fluctuation for the mean deviation of NNTM in comparison with that of other models. For the standard deviation, NNTM still has a lower value, however, its curve of standard deviation varying with a specific parameter exhibits a similar shape with the other models. From the results above, it can be seen that NNTM has good statistical and generalized capability in modeling total atmospheric density.

POLAR MAGNETIC FIELD REVERSAL OF THE SUN DURING 1880-1999

Valentine I. MAKAROV (Pulkovo Astronomical Observatory RAS Saint Petersburg, 196140, Russia)

The modern theory of solar activity supposes the generation of the kilogauss magnetic field by the dynamo mechanism at the base of the convection zone. It is generally believed and observations clearly show that the generation and reversal of a poloidal field is the outstanding problem in solar dynamo theories. The special interest are the facts of strong magnetic fields (more than 1500 G) found in polar faculae and connection between strong fluctuation of polar activity and sunspot area in the next sunspot cycle. The non-trivial problem in solar dynamo theories concerns the regeneration of this poloidal field. In this connection we emphasise great importance of H-alpha magnetic charts, as a new method of research of the solar magnetic fields particularly in the period when the magnetic observations of the Sun are not made. Thanks to long-time ground - base and SOHO observations there is the crisis of the modern solar dynamo theory. The old theories did not work and new ones do not exist so far. Two types of large-scale magnetic fields and formation of a zonal magnetic structures of the Sun during 11 cycles, the properties of polarward and equatorward (torsional oscillations) of the magnetic fields in the global magnetic cycle are discussed. Discovery of three-fold magnetic field reversal in 11-yr cycles has been incentive for understanding the nature of the magnetic solar cycle. It are discussed essential conditions for single and three fold magnetic field reversals, dependence of the polarward rate of the sunspot activity and theoretical model for description of the observational data. It is considered the polar drift of the magnetic neutral lines in he current 23-th solar cycle (1995-1999), "queit" and "active" versions of the polar magnetic field reversal. It is shown that polar drift rate of the latitude zones does not exceed 2 m/sec for a low-power activity. In this case the migration time of the latitude zone lasts about a cycle. Using observational data for 11 solar cycles the polar magnetic field reversals during Maunder minimum will be discussed.

GA4.03/L/01-B4 Invited **0905**

THE REFERENCE POINTS OF SOLAR CYCLE

G.V.KUKLIN (Institute of Solar-Terrestrial Physics PO Box 4026, Irkutsk-33, 664033, Russia)

A conception of turning points of cyclic curve of solar cycle was introduced by Chistyakov in 1966. In 1986 Vitinsky, Kuklin and Obridko linked these points with changes of solar activity regimes and renamed them into the reference points. The solar cycle consists of 4 phases: the minimum epoch min, the ascending branch Asc, the maximum epoch Max and the descending branch Des, separated with the reference points t(mA), t(AM), t(MD) and t(Dm). In addition the moments of minimum t(m) and maximum t(M) are the reference points also. For example t(MD) corresponds to the end of polarity reversal in the solar polar caps. Besides mentioned reference points there are preminima, grandfluctuations etc. still more. The reference points

revealed with the help of relative Wolf numbers need to be defined more accurate using other solar activity indices. A list of pretendents to reference and turning points was published by Kuklin in 1992.
Typical changes of regimes of dreen corona emission linked with the reference points were revealed by Badalyan and Kuklin in 1993. Similar peculiarities for indices of the solar global magnetic field were found by Obridko et al. in 1994. In 1998 Kuklin et al. Discovered significant changes of weak correlation coefficients between the solar activity indices and the indices of interplanetary medium and geoelectromagnetic field at the reference points. There are grounds to consider that the reference points determine the organisation structure of the solar cycle and of the solar-terrestrial relationship mechanisms.

DYNAMO PREDICTION FOR SOLAR CYCLE 23 USING POLAR FIELDS

Kenneth SCHATTEN (AI-Solutions, 10001 Derekwood Lane, suite 215,Lanham MD 20706 USA, email:Kschatten@solar.stanford.edu)

Solar activity prediction methods vary widely. They range from examinations of planetary orbits, to Fourier & power series analyses, to artificial intelligence methods e.g. neural nets, to a variety of statistical methods. We concentrate on "precursor methods." These methods were originally developed by Ohl, Gnevyshev, Brown, Obridko, and others. The geomagnetic precursor methods were surprising in that it was not clear why geomagnetic fluctuations could be used to predict solar activity. It was puzzling as to how the Sun could broadcast its future activity levels to the Earth! We now have developed some understanding for how these methods work and have expanded the prediction methods using "solar dynamo precursor" methods. One notably uses a "SODA" index (Solar Dynamo Amplitude), which attempts to measure the trapped magnetic flux inside the Sun, based upon toroidal an poloidal fields. We explain how these methods work, and update a prediction of solar activity for cycle 23. We suggest cycle 23 will be somewhat smaller than cycle 22 based upon these techniques. Estimates suggest a maximum smoothed International Sunspot Number near ~ 130 +/- 30, or a smoothed 2800 MHz radio flux (F10.7) of ~ 180 +/- 30 Hz.

POLAR MAGNETIC FIELD REVERSALS....

Elena E. BENEVOLENSKAYA (Pulkovo Astronomical Observatory, 196140, St. Petersburg, Russia, email: Elena.Benevolenskaya@pobox.spbu.ru)

The polar magnetic field on the Sun changes its sign during the maxima of solar sunspot cycles. It is known that the phenomenon of three-fold reversals of polar magnetic field occurred in solar cycle 20. Other three-fold reversals of the polar magnetic field took place in the southern hemisphere in solar cycles 12 and 14 and in the northern hemisphere alone in solar cycles 16 and 18 (Makarov and Sivaraman, 1989). I present a model of the polar magnetic field reversals. This model is confirmed by the new analysis of magnetograph data of Mount Wilson Observatory and H-alpha charts, which is also presented.

GA4.03/E/05-B4 **1100**

THE EXCITATION OF LINEAR WAVES IN THE POLARITY REVERSAL MAGNETIC FIELD OF THE SUN

A.D. Pataraya (Department of Theoretical Astrophysics, Abastumani Astrophysical Observatory, 2a Kazbegi Ave., Tbilisi, 380060, Georgia); T.A. PATARAYA (Department of physics, Tbilisi State University, 2 Chavchavadze Ave., Tbilisi, 380028, Georgia. E-mail: cipdd@access.sanet.ge

It is known from the alfa and omega dynamo theory, that toroidal and axial components of magnetic field do not change their sign simultaneously. For the dynamo number close to 1 in linear theory the phase difference between them is about pi/2; for the weakly non-linear dynamo waves pi/4. The linear Rossbi and Alfven waves are discussed in the paper during the interval of time of 2 years. During this interval the sign for the components of magnetic field is changing when: 1) the toroidal component of the magnetic field is zero and axial components are Constant; 2) the longitudinal component of the magnetic field is zero and the toroidal component is constant. In the former case the toroidal component of the magnetic field is taken into account with the shear to the longitudinal direction and in the later case is considered longitudinal component of the velocity with the shear to the toroidal direction. The first effect shows that the wave with the large amplitude propagates mainly to the equatorial direction, and wave propagated towards wave lines has smaller amplitude. In the second case the wave with larger amplitude propagates towards wave lines. The mentioned effects well explain the existed observational data.

GA4.03/W/02-B4 **1115**

STRUCTURE AND DYNAMICS OF THE LARGE SCALE SOLAR MAGNETIC FIELD AT A LONG TIME INTERVAL

V.N.OBRIDKO and B.D.Shelting (Izmiran, Troitsk, Moscow Region, 142092, Russia, Email: solter@izmiran.troitsk.ru)

The structure of the large-scale solar magnetic field (LSMF) has been analyzed at a long time interval (1915-1998) and has been compared with the IMF to show good correlation between both data series. The study of the zonal structure (gl0-coefficients) revealed the Hale cycle in variations of the odd coefficients responsible for the symmetry of the hemispheres. Variations of the even coefficients, responsible for the asymmetry of the hemispheres, display much shorter periods of the order of 2-3 years.
The 2- and 4-sector structures were analyzed to reveal the periods equal to 30 and 40 Carrington rotations. It was shown that the rotation period of the magnetic field of the Sun as a whole, as well as of the 2- and 4-sector structures during 1940-1965 was longer than at the beginning and at the end of the Century. Some rotation characteristics were shown to change sharply at the polarity reversals.

SOLAR MAGNETIC FIELD: EXISTENCE OF A PREFERRED LONGITUDE

E.J.SMITH, M.Neugebauer, A.Ruzmaikin, J.Feynman and A.H.Vaughan (Jet Propulsion Laboratory California Institute of Technology, Pasadena CA 91109, USA, email: esmith@jplsp.jpl.nasa.gov)

Eleven year variations are a fundamental aspect of the sun's magnetic field. An important question is whether or not there are aspects of the field that persist in spite of the obvious solar cycle variations. One way such an invariant feature could be manifested is the existence of a "preferred " longitude at which a structure or a series of events are independent of the solar cycle or its phases. During cycle 20, a preferred longitude was, in fact, identified from which fast solar wind originated (Gosling et al., JGR , p.2371, 1977). Motivated by these considerations, we investigated the behavior of the solar wind speed and the radial component of the heliospheric magnetic field over the prior and subsequent cycles using all available spacecraft measurements obtained inside 3 AU. It has been found that a preferred longitude corresponding to a source of fast wind and the m=1 component of the solar magnetic field has persisted over the last 35 years (Neugebauer et al.,1999).The solar rotation period associated with this persistent feature is 27.01 to 27.06 days. Magnetic activity on sun-like stars evident in calcium II H and K emissions also provides evidence of preferred longitudes that persist over several activity cycles in some stars (Vaughan, Science, p.793,1984). These combined observations indicate that this aspect of the sun's magnetic field is not anomalous but may be of fundamental importance in understanding solar -stellar magnetic fields and their generation.

GA4.03/E/01-B4 **1145**

THE MECHANISM OF THE BIENNIAL SOLAR CYCLE.

Elena E. BENEVOLENSKAYA (Pulkovo Astronomical Observatory, 196140, St. Petersburg, Russia, email: Elena.Benevolenskaya@pobox.spbu.ru)

In the frame of the Parker's dynamo theory a model of biennial magnetic cycle on the Sun is presented. This model is based on the idea of two dynamo sources separated in space. The first source which gives rise to Hale's cycle may be located at the lower level of the convection zone, and the second source of the biennial cycle may operate in subsurface regions of the Sun. The model is formulated in terms of two couple systems of non-linear differential equations. It is demonstrated that in the case of weak interaction between the two dynamo sources the basic features of the magnetic cycle such as existence of two component and observed temporal variations of biennial cycle can be reproduced.

GA4.03/W/10-B4 **1200**

THE NORTH-SOUTH ASYMMETRY OF THE SOLAR AND HELIOSPHERIC MAGNTIC FIELD DURING ACTIVITY MINIMA

Silvia BRAVO and Americo Gonzalez-Esparza (Instituto de Geofisica, UNAM, Ciudad Universitaria, Mexico D.F. 04510, email: sbravo@tonatiuh.igeofcu.unam.mx, americo@fis-esp.igeofcu.unam.mx)

Recent in in situ spacecraft observations and the analysis of the galatic cosmics ray intensity at Earth have shown that the heliospheric magnetic field exhibited a north-south asymmetry and that the heliospheric current sheet was inclined with respect to the solar equator during the last sunspot minimum (1996) and problably also during the previous minimum in 1986. In this paper we study the structure of the solar magnetic field at these times to see if this structure can account for the heliospheric asymmetries observed.

GA4.03/W/04-B4 **1215**

ZONAL STRUCTURE AND CYCLIC EVOLUTION OF LARGE-SCALE SOLAR MAGNETIC FIELDS

E.V.IVANOV and VN.Obridko (IZMIRAN, Troitsk, Moscow Region, 142092, Russia, email: solter@izmiran.troitsk.ru)

The structure and evolution of large-scale solar magnetic fields have been analysed for the time interval of 1969-1996 (Carrington rotations 1543-1916). The radial, meridional, and azimuthal components of the magnetic field vector and their absolute values were calculated from the Stanford magnetic maps for every 10 degree interval in the heliolatitude region from 70S up to 70N and were averaged over a Carrington rotation. The auto- and cross-correlation analysis have been applied to study the relationship between the time variations of intensity of the radial and meridional components of the magnetic field and their absolute values at the equator and at higher-latitude regions. A pronounced zonal structure and quasi-biennial variations of the large-scale solar magnetic fields have been revealed. The relationship and differences between the cyclic evolution of large-scale solar magnetic fields in the equatorial (below 50 degrees) and polar (above 50 degrees) heliolatitude zones are discussed.

GA4.03/W/03-B4 **1230**

FORMATION AND STRUCTURE OF PROMINENCES

C. Z. CHENG and G. S. Choe (Princeton Plasma Physics Laboratory, Princeton University, Princeton, NJ 08543)

Based on the 2-1/2D MHD model we have obtained current sheet equilibrium configurations in a quadrupolar field geometry, and we have shown that resistive MHD evolution of these current sheet equilibria can lead to two different prominence field topologies via reconnection processes: one with an X-point and one with an magnetic island hanging in the solar atmosphere. The X-point configuration may occur during solar flares. The field configuration with a magnetic island, where the prominence material residestably, resembles the prominence magnetic field model suggested by Malville. We will illustrate how the Malville type prominence configuration may offer a possibility to understand the 3D prominence chiral structure of barbs by introducing additional localised magnetic poles in the photosphere so that the magnetic island shape can be distorted to form barbs attracted to the magnetic pole locations. We will also discuss possible causes of prominence eruption by considering (1) changes in the magnetic field around the prominence flux tube, (2) rapid growth of instabilities in the prominence flux tube, and (3) drainage of the material downward along the legs.

A SURVEY AND SYNTHESIS OF SOLAR CYCLE PREDICTION TECHNIQUES

David H. HATHAWAY, Robert M. Wilson, and Edwin J. Reichmann (Mail Code ES82, NASA/MSFC, Huntsville, AL 35812 USA, e-mail: david.hathaway@msfc.nasa.gov)

A number of techniques for predicting solar activity on a solar cycle time scale are identified, described, and tested with historical data. Some techniques, e.g. regression and curve-fitting, work well as solar activity approaches maximum and provide a complete description of future activity, while others, e.g. geomagnetic precursors, work well near solar minimum but only provide an estimate of the amplitude of the cycle. A synthesis of different techniques is shown to provide a more accurate and useful forecast of solar cycle activity levels. A combination of two un-correlated geomagnetic precursor techniques provides the most accurate prediction of the amplitude of a solar activity cycle at a time well before activity minimum. A mathematical function dependent upon the time of cycle initiation and the cycle amplitude then describes the

levels of solar activity for the next complete cycle. As the time of cycle maximum approaches better estimates of the cycle amplitude are obtained by fitting previous activity levels to this function. The success of the geomagnetic precursors in predicting future solar activity suggests that solar magnetic phenomena at latitudes above the sunspot activity belts are linked to solar activity which occurs many years later in the lower latitudes.

GA4.03/W/15-B4 Invited 1435

PREDICTION OF SOLAR AND GEOPHYSICAL INDICES...

Jo Ann JOSELYN (NOAA Space Environment Center, Email: jjoselyn@esc.noaa.gov)

Indices of solar and geomagnetic activity exhibit patterns of cycles approximately 11 years in length. Because both solar and geophysical activity can harm technological systems, predictions of solar and geomagnetic activity are desirable for the purpose of long-range planning especially for satellite operations. At the beginning of Cycle 22, a number of thoughtful but disparate predictions for the cycle amplitude were published. The most successful were generally based on precursor, or, solar dynamo concepts. During the recent solar minimum, there have again been a number of papers published predicting the behavior of Cycle 23. Again, the range in the published predictions is large. In 1996, 1997, and again in 1998, a panel of international scientists met to review forecasts of Solar Cycle 23 solar and geomagnetic activity. The panel examined the techniques used and arrived at a consensus for a cycle of smoothed sunspot number amplitude of 160 (between extremes of 130 and 190) reaching maximum near March 2000 (between extremes of June 1999 and January 2001). Besides producing a consensus forecast of the amplitude of the solar cycle, the panel predicted the approximate total number and annual number of geomagnetic disturbances expected during Cycle 23. For both solar and geomagnetic activity, the consensus forecasts are for cycles similar to Cycle 22: large, but familiar. This talk will review the techniques that have been used for cycle predictions, and will compare them with the progress of Cycle 23 through June, 1999.

GA4.03/W/12-B4 Invited 1510

THE SOLAR DYNAMO

L.L.KITCHATINOV (Institute for Solar-Terrestrial Physics, P.O. Box 4026, Irkutsk, 664033, Russia, email: kit@iszf.irk.ru)

The problem of constructing a reasonable solar dynamo model is discussed in relation to the new data on the rotation law supplied by the GONG and SOI-MDI observations. The equatorward activity migration is hardly possible to explain by the standard mechanism of the dynamo wave propagation along the isorotational surfaces. Magnetic field advection by the meridional flow and/or anisotropic turbulent transport are the possible alternatives. The field transport mechanisms would have "enough time" to influence the field dynamics over the activity cycle only if the simulated cycle period is not too short compared with the observed period of about 22 yrs. Dynamo models usually produce (roughly) ten-times shorter cycles. The cycle duration is much sensitive to the top boundary conditions. Implementation of new conditions allowing for a non-free escape of the generated fields from the dynamo region increases the simulated cycle period to its observed value. Multi-periodicities in non-linear dynamos are also discussed in relation to the grand cycles of the solar activity.

GA4.03/L/02-B4 Invited 1615

PERIOD OF SOLAR DYNAMO-CYCLE

Valery N.KRIVODUBSKIJ (Kyiv University Astronomical Observatory Observatorna Street 3Kyiv - 53, UA - 254053, Ukraine)

According to mean magnetic field concept, the action of the helical turbulence (alpha-effect) and radial differential rotation (Omega-effect) play main role in the generation of the solar large-scale magnetic fields (alphaOmega-dynamo). According to Parker (Ap.J. 1955, V. 122, 293) the solution of the dynamo equations, describing the evolution of toroidal and poloidal components of the global magnetic fields, can be treated as the displacement of magnetic dynamo-waves on solar surface. The period T of dynamo-waves is determined by parameters of alpha-effect and radial differential rotation in the solar convective zone (SCZ). Youshimura (Ap.J.S. 1975, V.29, 467) had specified that the direction of dynamo-wave displacement (toward equator or pole) depends on the sign (negative or positive respectively) of the product of alpha-effect and radial gradient of angular velocity. The behaviour of the helical turbulence parameter (alpha-parameter) in the SCZ was investigated. The alpha-effect contributions due to radial gradients of plasma density and of turbulent velocities were taken into account. Our calculations for the SCZ model by Stix (1989) have shown that the azimuthal alpha-parameter, which is the most important for the alphaOmega-dynamo, changes its sign from positive to negative near the zone bottom (in northern hemisphere). So-called magnetic quenching (suppression) of the alpha-effect due to feedback of the global magnetism was researched. It is found that the essential magnetic quenching takes place near the base of the SCZ (quenching-function Psi is equal approximately to 0.4). Using the values of quenched alpha-parameter and radial gradient of angular velocity, obtained from the recent helioseismological researches, we determined the direction of migration and estimated the period T of the dynamo-waves excited by alphaOmega-dynamo in the overshoot layer (z=165-180 Mm) of the SCZ. At the latitudes higher 35 degrees dynamo-wave is directed toward the poles, while at lower latitudes it displaces toward the equator. Calculated period T is about 9 years that is in satisfactory agreement with the observed solar cycle duration. Low-latitude dynamo-wave probably is manifest in the sunspot cycle whereas the wave moving toward the poles is apparently responsible for the polar drift of high-latitude background magnetic fields.

GA4.03/W/14-B4 1630

EXTENSION OF CORONAL MAGNETIC FIELDS TO THE SOLAR WIND STREAMS

N.A.LOTOVA and V.N.Obridko (IZMIRAN, Troitsk, Moscow Region, Russia, email: nlotova@izmiran.troitsk.ru), K.V.Vladimirskii (FIAN, Leninsky Prospekt 53, Moscow, 117924, Russia); V.Rusin (Astronomical Institute, Slovak Academy of Sciences, Tatranska Lomnica 135, 05960, Slovak Republic, Email: vrisun@auriga.ta3.sk)

An investigation of the mechanism the stream structure formation in the solar wind flow has been carried out. Complex analysis of the observational data for magnetic fields at the photosphere level, the white corona views and the geometry of the solar wind transition region was carried out. It has been shown that the structure of the magnetic field close to the Sun's surface is the basic factor determining the solar wind flow structure in the course of all stages of the following acceleration process up to the supersonic streams far from the Sun. A distinct anti-correlation between the magnetic field intensity at the corona level and the distance of the transition region from the Sun is the crucial argument showing the extension of the solar magnetic fields far in the plasma streams.

GA4.03/E/02-B4 1645

MAGNETIC FLUX EMERGENCE AND GEOMAGNETIC ACTIVITY, A CLOSE CORRELATION

Blanca MENDOZA, Alejandro Lara, Dolores Maravilla and Jose Valdes-Galicia, (Instituto de Geofisica UNAM, Ciudad Universitaria, 04510, Mexico D.F. Mexico, email: blanca@tonatiuh.igeofcu.unam.mx)

We analyse data of magnetic flux emergence for solar cycles 21 and 22, Helios 1 interplanetary shocks for cycle 21 and sudden storm commencements (SSC's) for cycles 11 to 22. A dominant variation of 3-years periodicity was found for all three phenomena during cycles 21 and 22. This indicates a correlation and a possible influence of the rate of solar magnetic flux emergence to produce the interplanetary phenomena studied in this work; in particular, the suggested role of coronal mass ejections as a means by which magnetic flux and stresses are taken out of the corona seems to be plausible. When taking cycles 11 to 22 in SSC's, the main periodicity changes to around 4 years.

GA4.03/W/08-B4 1700

GENERATION OF LARGE-SCALE MAGNETIC STRUCTURES AND OSCILLATING GLOBAL MAGNETIC FIELD DUE TO DEFORMATIONAL AND SHEAR INSTABILITY

Evgeniy TIKHOMOLOV and Vladimir Mordvinov (Institute of Solar-Terrestrial Physics, P.O. Box 4026,Irkutsk, 664033 Russia, email: e_tikh@iszf.irk.ru)

We present a model in which interaction between deformational and shear instability gives rise to generation of the global magnetic field oscillating with 22-year period. Instability takes place in high- and mid-latitudes near the interface between convective and radiative zones. At the background of the oscillating global magnetic field the evolution of the large-scale magnetic structures is considered. These structures are generated in low-latitudes by a set of Rossby vortices. Interaction between Rossby vortices brings about rather complicated behaviour of the magnetic fields. Nevertheless, numerical simulations reproduce some peculiarities in the dynamics of the magnetic field in several solar complexes of activity.

POLAR MAGNETIC FIELD REVERSALS IN THE 19TH SOLAR CYCLE

Dmitri I. PONYAVIN (Institute of Physics, University of St.Petersburg, 198904, Russia, e-mail: ponyavin@snoopy.phys.spbu.ru)

H-alpha synoptic charts of large-scale magnetic fields restored by Makarov and Sivaraman have been used to trace a history of magnetic field reversals at the poles of the Sun. A smoothed filtering technique was applied to reveal a large-scale organization and evolution of magnetic fields. It was suggested that actually a single reversal occurred in the Northern Hemisphere during a course of solar cycle 19.

GA4.03/W/01-B4 Poster 1720-02

COMPLEX STRUCTURE OF CYCLIC VARIATIONS OF LARGE-SCALE SOLAR MAGNETIC FIELDS AND SOLAR ACTIVITY

Yu.R.RIVIN (IZMIRAN, 142092, Troitsk, Moscow Region, Russia, email: solter@izmiran.troitsk.ru)

Variations of solar activity with a period of about 11 years, that are usually attributed to the sunspot dynamics, form merely a part of the general dynamics of the large-scale solar magnetic fields [1-2]. They only reflect the dynamics of the quasi-axial dipole alpha-omega-dynamo at the center of the convection zone. This dynamo mechanism generates the magnetic field, changing with a period of about 22 years and is responsible for more than 90% of sunspots. It also plays a key role in the amplitude modulation of the interplanetary magnetic field (IMF) and cosmic rays. Another (quadrupole) source, that is at the bottom of the convection zone, is likely to play an important role in generation of active regions with peculiar sunspots and the sector structure of the general magnetic field of the Sun and IMF, as well as in the field and activity asymmetry between the two solar hemispheres. This source may also have other manifestations. ReferencesRivin Yu.R. Bulletin of the Russian Academy of Sciences. PHYSICS. 1998. V.62. N9. Rivin Yu.R. Astronomy Letters. 1999 (in press).

LONGITUDINAL STRUCTURE OF SOLAR MAGNETIC FIELDS DURING THE TRANSITION FROM CYCLE 22 TO CYCLE 23 INFERRED FROM SOHO MDI DATA

Elena E. BENEVOLENSKAYA (Pulkovo Astronomical Observatory, 196140, St. Petersburg, Russia, email: Elena.Benevolenskaya@pobox.spbu.ru); A. G. Kosovichev (W. W. Hansen Experimental Physics Laboratory, Stanford University, Stanford, CA 94305-4085; email: sasha@quake.stanford.edu); J. T. Hoeksema (W. W. Hansen Experimental Physics Laboratory, Stanford University, Stanford, CA 94305-4085; email: todd@quake.stanford.edu); P. H. Scherrer (W. W. Hansen Experimental Physics Laboratory, Stanford University, Stanford, CA 94305-4085; email: phil@quake.stanford.edu)

We present the results of investigation the latitudinal and longitudinal structure of the solar magnetic field by using full disk SOHO MDI data. It was found that during the transition from cycle 22 to cycle 23 solar activity clustered in fixed longitudinal zones, and that the old magnetic fluxes were replaced by new magnetic fluxes in the same fixed longitudinal regions. The most interesting longitudinal zone was located from 240 deg to 280 deg. From the CR1911 until CR1918, there was a complex of activity of old magnetic fluxes.
This complex of solar activity first emerged in the southern hemisphere and decayed to CR1916. Then, the next old magnetic flux appeared in the same longitudinal zone in the northern hemisphere and existed until CR1919. The same longitudinal zone became active again in CR1923 when a complex of solar activity of new magnetic flux emerged. This longitudinal zone of pronounced activity existed for more than 15 Carrington rotations. Apparently, this zone was the place of reversal of polarity of the toroidal magnetic field during the transition from one cycle to another. We discuss implications of these results for theories of solar cycle.

GA4.03/W/11-B4 Poster **1735-05**

THE AMPLITUDE AND PERIOD OF THE SOLAR CYCLE AS TRACERS OF A NONLINEAR DYNAMO WAVE

Isabella Dmitrieva, Kirill KUZANYAN, and Vladimir Obridko (IZMIRAN, Troitsk, 142092 Moscow region, RUSSIA, email: bella@izmiran.troitsk.ru, email: kuzanyan@dnttm.ru, email: solter@izmiran.troitsk.ru)

Relation of the solar cycle period and its amplitude is a complex problem as there is no direct correlation between these two quantities. Nevertheless, the period of the cycle make an important influence to the Earth's climate, that has been noted by many authors, e.g., Soon et al., 1996. Friis-Christensen and Lassen (1991) revealed the correlation between the cycle length and the Earth's global temperature variation. This problem has been extensively studied but there is no reasonable explanation of such mechanism given yet. The authors make an attempt to analyse the solar indices data with account of recent developments of asymptotic theory of the solar dynamo. The use of the WKB method enables us the estimates of the amplitude and the period of the cycle versus dynamo wave parameters in the framework of the one-dimensional Parker's migratory dynamo (Meunier et al., 1997; Bassom et al., 1998). These estimates link the period T and the amplitude a with dynamo number D and thickness of the generation layer of the solar convective zone h. However, we have not revealed any prominent correlation between the above quantities, which is in agreement with previous authors. Instead, we have noted that the maximum amplitude of the cycle and the temporal derivative of the monthly Wolf numbers at the very beginning of the phase of growth of the cycle have high correlation coefficient of order 0.96.
The hope is that this dependence may be useful for understanding the mechanism of the solar dynamo wave and prediction of the average maximum amplitude of solar cycles.

2D ASYMPTOTIC SOLAR DYNAMO IN THE LIGHT OF INTERNAL ROTATION

G. Belvedere, L. Paterno' (both at Institute of Astronomy, University of Catania, Viale A. Doria, 6, 95125 Catania, Italy; e-mail: gbelvedere@alpha4.ct.astro.it, e-mail: lpaterno@alpha4.ct.astro.it), and Kirill KUZANYAN (IZMIRAN, Solar-Terrestrial Dept., Toitsk, Moscow Region, 142092, Russia, email: kuzanyan@dnttm.ru)

The mean field dynamo equations for a two-dimensional (radius-latitude) alpha-omega model are solved in the leading order of asymptotic expansion by the use of the WKBJ method. The limiting case of short waves (large regeneration rates) is considered. The solution is shown to possess properties of travelling dynamo waves and to obey the so-called Yoshimura theorem. The intrinsic role of the alpha- and omega-factors is discussed. The solution obtained is compared with the one calculated earlier for a one-dimensional model. By using the solar internal differential rotation profile given by a helioseismological inversion, we calculate the location and structure of the different wings of the dynamo wave. Equatorward and poleward branches are found. We compare the solution obtained with available observations of the solar activity cycle.

GA4.03/E/08-B4 Poster **1745-07**

WEAKLY NON-LINEAR DYNAMO WAVES

A.D. PATARAYA (Department of Theoretical Astrophysics, Abastumani, Astrophysical Observatory, 2a Kazbegi Ave., Tbilisi, 380060, Georgia); T.A. PATARAYA (Department of physics, Tbilisi State University, 2 Chavchavadze Ave., Tbilisi, 380028, Georgia. E-mail: cipdd@access.sanet.ge)

Weakly non-linear dynamo waves are investigated with the help of magnetohydrodynamic equations. The solution is given for the amplitude of the weakly non-linear waves and investigated stability for these amplitudes. For alfa omega and alfa in square dynamo waves some conditions of stability are obtained taking into account Coriolis forces in the equation of movement. One of the conditions of stability shows that the wave vector is very close to the normal of the angular velocity of the rotation of Star or Sun.

SPACE-TIME ORDER OF SOLAR LARGE-SCALE MAGNETIC FIELD OVER 40N-40S LATITUDINAL INTERVAL

Lyubov PLYUSNINA (Institute of Solar-Terrestrial Physics, Russian Academy of Sciences, Siberian Branch, P.O. Box 4026, Irkutsk, 664033, Russia, email: lplus@iszf.irk.ru)

Simple technique is suggested to distinguish a trace of long-lived components of large-scale magnetic field (LSMF) with a life time compared or exceeded the solar cycle duration. Its principal variation from those being traditionally used for this purpose is to maintain the 10˚ resolution through the longitude.
The synoptic Ha maps over 1955-1990 are used as input data. The analysis of the LSMF trace over 3.5 solar activity cycles shows the LSMF not to include any other long-lived components except those rotated with the periods of 27 (LSMF27) and 28 (LSMF28) days.
Rather high resolution through the longitude allows one to distinguish the structure and evolutional peculiarities of the LSMF components. On the basis of the study carried out it may be assumed that the LSMF28 originates in every even cycle and dominates next uneven and even cycles. Thus, this component exists over 3 cycles (~33 years) and is most pronounced over 2 last cycles (~22 years). There are two LSMF28 with different phases in even cycles: old and new ones. The LSMF27 is much more fragmented through the longitude and appears to originate again in each new cycle.

FRACTAL PROPERTIES OF LARGE-SCALE MAGNETIC FIELDS ON THE SUN

Irina I. SALAKHUTDINOVA (Institute of Solar-Terrestrial Physics, Russian Academy of Sciences, P.O. Box 4026, Irkutsk, 664033, Russia, email: isalakh@iszf.irk.ru)

It is common knowledge that the magnetic field on the Sun has a cellular, discrete structure. This paper is concerned with fractal properties of the large-scale magnetic field distribution on the Sun. Synoptic maps from the Mt.Wilson, Kitt Peak and Stanford observatories covering the entire observing period from 1959 to 1976, from 1976 to 1985 and from 1976 to 1998, respectively, were used in the study. Method of fractal analyse were applied on a two-dimensional grid. For each Carrington rotation, the following characteristics were calculated: 1) the fractal dimension of the maps; and 2) statistical characteristics of the magnetic field distribution such as the distribution density function, the kurtosis, and asymmetry. It was found that large-scale magnetic fields have a high fractal dimension of about ~2.7 when averaged over all rotations, on scales larger than 20x25˚; on smaller scales, the fractal dimension changes by ~0.3 and becomes equal to ~3.0 averaged over all rotations. The 20x25˚ scale corresponds to the size of active regions. It was also found that the fractal dimension changes from rotation to rotation and shows some time dependence with a period ~30 years, although this period is on the boundary of the time interval of observation. The distribution density function of large-scale magnetic fields on the Sun is characterised by an exponential dependence in this grid. The exponential dependence was also found to change at 20x20˚ scales in this case. The exponent at smaller and larger scales than the indicated one is ~0.4 and ~3.6, respectively. The exponent varies with the time with a period ~11 years. The obtained staistical characteristics show a strong departure from a normal law. Also, these characteristics vary with solar cycle phases. This study has shown that the fractal character of magnetic fields on the Sun manifests itself also in the spatial distribution of large-scale magnetic fields.

PICKUP IONS AS TOOLS FOR PROBING THE COMPOSITION AND PHYSICAL STATE OF THE LOCAL INTERSTELLAR CLOUD

G. GLOECKLER (Department of Physics and IPST, University of Maryland, College Park, MD 20742, USA; e-mail: gg10@umail.umd.edu); L. A. Fisk, N. A. Schwadron and T. H. Zurbuchen (all at Department of Atmospheric, Oceanic and Space Sciences, University of Michigan, Ann Arbor, MI 48109, USA); J. Geiss (International Space Science Institute, Hallerstrasse No. 6, CH-3012 Bern, Switzerland)

Neutral gas and large dust grains from the Local Interstellar Cloud (LIC) surrounding our solar system have easy access to the inner heliosphere. Most interstellar atoms penetrate to roughly 3 AU before they become ionized and are swept away with the solar wind. In situ measurements of pickup ions provide a new powerful tool for deducing important properties of the nearby interstellar medium, including its elemental and isotopic composition, its ionization state and pressure. After the discovery of interstellar pickup helium with the earth-orbiting AMPTE/IRM spacecraft, it was not until Ulysses before most of the other interstellar pickup ions, including the rare Helium-3 isotope, were discovered and studied. We will briefly review some of the latest results of these pioneering studies based on data from the Solar Wind Ion Composition Spectrometer (SWICS) on Ulysses. We will also discuss how measurements in the near future with instruments orders of magnitude more sensitive than those on Ulysses and AMPTE, would address questions on the physical properties and nucleosynthetic status of the present-day galaxy, questions important for understanding the origin of our solar system, the stars, our galaxy, and the nature and destiny of the universe.

GA4.04/W/17-B5 **0900**

ENERGETIC ATOMS OF HELIOSPHERIC ORIGIN

M Hilchenbach(1), KC Hsieh(2) and A Czechowski(3) (1)Max-Planck-Institut fuer Aeronomie, 37191 Lindau, Germany (2)Department of Physics, University of Arizona, Tuscon, AZ 85721 USA (3)Space Research Centre, Polish Academy of Sciences, PL 00716 Warsaw, Poland

Heliospheric energetic hydrogen atoms have been detected at 1 AU by the suprathermal particle sensor CELIAS on SOHO. These energetic neutrals are seen as result of anomalous cosmic ray (ACR) protons transcharging with the local interstellar medium (LISM) in the outer heliosphere. The resulting neutrals then travel on ballistic trajectories, unaffected by the interplanetary magnetic field (IMF), to the inner heliosphere. In the vicinity of the sun, a fraction of these energetic neutral hydrogen is ionised again via photoionisation or collision with the solar wind protons and electrons. We will discuss the implication of this process on the energetic particle quiet time fluxes.

GA4.04/E/06-B5 **0920**

REGARDING THE CORRELATION BETWEEN INTERSTELLAR PICK-UP IONS AND SOLAR WIND PROTONS

Daniel WINTERHALTER (Jet Propulsion Laboratory, California Institute of Technology Pasadena, CA 91109-8099, USA, email: daniel.winterhalter@jpl.nasa.gov) George Gloeckler (University of Maryland College Park, MD 20742-2425, USA) Phillip Isenberg (University of New Hampshire Durham, NH 03824-3525, USA) Edward J. Smith (Jet Propulsion Laboratory, California Institute of Technology Pasadena, CA 91109-8099, USA)

Interstellar hydrogen is primarily ionized by charge exchange with solar wind protons. This directly implies that the pick-up hydrogen density should be linearly correlated with the solar wind proton density. However, it has been reported that this correlation is very poor, probably because of the limited data set used in the previous studies. In this study, we use Ulysses data from 1990 to 1997 with radial coverage ranging from 1 AU to 5 AU, and the heliographic latitude nearly spanning from solar pole to pole. We compare daily averages of the pick-up hydrogen obtained by the SWICS instrument with daily averages of solar wind parameters, primarily the solar wind proton density, obtained by SWOOPS. In addition, measurements by the magnetometer were used to investigate any contribution by the heliospheric magnetic field direction and fluctuation to the solar wind/pickup hydrogen interaction. Preliminarily, we find that the pick-up hydrogen count increases with increasing radial distance as expected. Further, the correlation between solar wind protons and pick-up hydrogen count increases with increasing radial distance, and the correlation decreases at high solar wind speeds (> 740 km/s).

DEPENDENCE OF THE HELIUM PICKUP ION DISTRIBUTION ON THE IMF DIRECTION AND VELOCITIES OF THE SOLAR WIND AND INTERSTELLAR GAS

Y.E. LITVINENKO, E. Moebius (both at Space Science Center, University of New Hampshire, Durham, NH 03824, USA, email: yuri.litvinenko@unh.edu), H. Grunwaldt (Max Planck Institut fur Aeronomie, D-37189 Katlenburg-Lindau, Germany), M. Aellig (Center for Space Research, MIT, Cambridge, MA 02139, USA), P. Bochsler (Physikalisches Institut der Universitat Bern, CD-3012 Bern, Switzerland), D. Hovestadt (Max Planck Institut fur Extraterrestrische Physik, D-85740 Garching, Germany), M. Hilchenbach (Max Planck Institut fur Aeronomie, D-37189 Katlenburg-Lindau, Germany), F.M. Ipavich (Department of Physics and Astronomy, University of Maryland, College Park, MD 20742, USA)

We study variations of the Helium pickup ion distribution with the IMF direction and the solar wind and interstellar gas velocities. The pickup Helium data provided by the CELIAS CTOF sensor onboard SOHO are combined with the solar wind data from CELIAS MTOF Proton Monitor and the interplanetary magnetic field data from WIND convectively extrapolated to the SOHO position. We confirm an earlier finding that the pickup Helium flux density in the antisunward direction decreases significantly when the interplanetary magnetic field is parallel to the solar wind velocity. This is most likely due to incomplete pitch angle scattering from the sunward hemisphere in phase space. A new effect identified in the data is a shift of the pickup ion velocity cut-off to values significantly exceeding twice the solar wind speed. The shift is observed by SOHO on the upwind side, with the effect being more pronounced for lower solar wind speeds, whereas no shift was observed by AMPTE SULEICA on the downwind side. The inclusion of the local interstellar gas velocity into the model distribution leads to agreement with observations. Therefore the velocity cut-off depends not only on the solar wind speed but also on the neutral Helium inflow speed and the position of a spacecraft. We study this variation and suggest using it as a diagnostics of the inflow.

GA4.04/E/02-B5 Invited 1020

SOURCES AND ACCELERATION OF ENERGETIC PARTICLES IN THE HELIOSPHERE

B. KLECKER, A.T. Bogdanov (both at Max-Planck-Institut fuer extraterrestrische Physik, Garching, D-85740, Germany, Email: bek@mpe.mpg.de)

Measurements of energetic particles are now available from a fleet of spacecraft in the inner and outer heliosphere, covering energies from keV to GeV, elements from H to Fe, and radial distances from 1 to ~ 70 AU. These measurements provide new insight into the sources of these particles and the acceleration processes involved. Recent measurements with advanced instrumentation of high sensitivity onboard Ulysses, SAMPEX, Geotail, WIND, SOHO and ACE led to the discovery of interstellar and interplanetary sources of pickup ions, of multiply charged Anomalous Cosmic Rays (ACRs) and of new ACR elements not observed previously. The pickup ions, together with solar wind ions, are the seed population for acceleration processes acting e.g. at interplanetary shocks, at corotating interaction regions, and at the solar wind termination shock. In this paper we review the recent measurements of pickup ions and ACRs, discuss the questions of pre-acceleration in the inner heliosphere and of injection efficiencies of pickup and solar wind ions, summarize the implications of the ACR ionic charge measurements for acceleration and loss processes, and discuss open questions.

GA4.04/W/03-B5 1050

A NEW SEED POPULATION FOR ENERGETIC PARTICLES IN THE HELIOSPHERE

N. A. SCHWADRON, L. A. Fisk, G. Gloeckler*, and T. H. Zurbuchen (all at Department of Atmospheric, Oceanic, and Space Sciences, University of Michigan, Ann Arbor, MI, USA, 48109-2143, email: nathanas@umich.edu, lafisk@umich.edu, gg10@umail.umd.edu, thomasz@engin.umich.edu); J. Geiss (International Space Science Institute, Bern, Switzerland CH-3012, email: geiss@issi.unibe.ch) *G. Gloeckler also at Department of Physics and ISTP, University of Maryland, College Park, Maryland, USA, 20742.

A new source of pickup ions has been discovered, the "inner source". The composition is similar to that of the solar wind which suggests the most plausible production mechanism involves the absorption and re-emission of solar wind ions from interplanetary dust grains. Inner source pickup ions may also be a significant seed population for accelerated particles in co-rotating interaction regions (CIRs). Accelerated inner source ions may therefore influence the composition of CIR-accelerated particles which is known to differ from that of interstellar pickup ions. Our present observational knowledge of inner source composition will be discussed and implications for accelerated particles in the heliosphere and the anomalous component will be explored.

GA4.04/W/13-B5 1110

ENERGETIC SOLAR PROTONS FROM DIFFERENT SOURCES

L.I. MIROSHNICHENKO (1), R. Pèrez Enrìquez (2), and B. Mendoza (Instituto de Geofisica UNAM, Mèxico, D. F., 04510, MEXICO; (1) Permanent address: IZMIRAN, Troitsk, Moscow Region, 142092, RUSSIA; (2) Campus UNAM, Juriquilla, Querétaro

As it is widely accepted now, a significant fraction of the solar energetic particles (SEPs) observed at 1 AU after major solar flares are actually accelerated at a CME-driven shock. Besides, in the emerging new paradigm for SEP acceleration in different sources at or near the Sun, the existence of two types of flares - impulsive and gradual ones - is recognized. Within this concept, it is temptable to separate also SEPs into two groups - interacting and escaping ones, - and to derive their "source spectra" by observational data on different solar emissions (gamma rays, neutrons, protons, etc.). By different techniques, those spectra have been restored for 80 solar proton events (SPE) of 1949-1991. In this paper, all available data on the source spectra of solar cosmic rays (SCR) are summarised and revised. The data are presented in the form of the Catalogue of the source spectra. Then, we separate them depending on the source type and interplanetary conditions of SEP propagation, taking into account existing uncertainties in the derived power-law spectral indexes. It is shown, in particular, that the spectrum indexes in some events (February 23, 1956; January 28, 1967; May 07, 1978; February 16, 1984; June 15, 1991 and others) do not correlate with each other at different energy thresholds (>10 MeV and >500 MeV). Moreover, the source spectra reveal a spectral steepening for high energies, such a peculiarity may be characteristic of large events (e.g., of February 23, 1956 one). It should be emphasized the great importance of the Catalogue data as an initial information for the development of a comprehensive quantitative theory of particle acceleration at the Sun. The theory should explain the spectrum form in the entire range of observed SCR energies (rigidities), from >1 MeV (43.5 MV) to >20 GeV (20.9 GV for protons), by a single model or, at least, by a single scenario, taking into account a possibility of multiple particle acceleration.

GA4.04/W/02-B5 1130

NEW OBSERVATIONS OF THE TRANSPORT OF ENERGETIC PARTICLES FROM IMPULSIVE SOLAR FLARES

J. E. MAZUR (The Aerospace Corporation, 2350 E. El Segundo Blvd., El Segundo, CA, 90245-4691, USA, email: joseph.mazur@aero.org); G. M. Mason and J. R. Dwyer (both at Department of Physics, University of Maryland, College Park, MD 20742, USA, email: mason@sampx3.umd.edu, dwyer@umstep.umd.edu); J. Giacalone (Department of Planetary Sciences, University of Arizona, 1629 E. University Blvd., Tuscon, AZ 857721-0092, USA, email: giacalon@lpl.arizona.edu)

Interplanetary particle events from impulsive solar flares are enriched in Ne-Fe and in the 3He isotope compared to the solar wind; they also show little scattering in the interplanetary medium. Whereas the details of higher intensity shock-associated particle events depend on the observer's changing connection to a propagating shock, the impulsive events probe the transport in the interplanetary medium from a more localized source at the sun to 1 AU. We have used instrumentation on board the NASA Advanced Composition Explorer (ACE) spacecraft, launched in late 1997, to measure the ionic composition and temporal profiles of dozens of impulsive flares with high sensitivity. These new measurements show that subtle changes in the interplanetary magnetic field can greatly affect the observed event profiles, sometimes disconnecting the observer from one event while another nearly simultaneous particle injection continues unaffected. We will report on these new findings from ACE and their interpretation using a numerical simulation of charged particle transport in a meandering interplanetary magnetic field.

GA4.04/W/18-B5 1150

ENERGY SPECTRA AND ABUNDANCES VARIATIONS OBSERVED BY ACE DURING THE AUGUST 1998 SOLAR ENERGETIC PARTICLE EVENT

G.C. HO (Applied Physics Laboratory, Johns Hopkins University, Laurel, MD 20723-6099, USA, Email: george.ho@jhuapl.edu); R.B. Decker; R.E. Gold; S. M. Krimigis (all at Applied Physics Laboratory, Johns Hopkins University, Laurel, MD 20723-6099, USA, Email: robert.decker@jhuapl.edu); G.M. Mason; J.R. Dwyer (Department of Physics, University of Maryland, College Park, MD 20742, USA, Email: mason@sampx2.umd.edu); and J.E. Mazur (Aerospace Corporation, El Segundo, CA 90245-4617, USA, Email: joseph.mazur@aero.org)

As we approach the maximum of solar cycle 23, Solar Energetic Particle (SEP) events are occurring with increasing frequency. In contrast to the previous solar maximum, however, in this cycle we have an array of highly sensitive instruments onboard various spacecraft within the heliosphere to observe SEP events. Hence, we are able to study individual SEP over much boarder energy ranges and resolve more ion species than ever before. In this talk, we will present results using the Ultra Low Energy Spectrometer (ULEIS) onboard the ACE spacecraft for an SEP event. On August 24, 1998 a X10/3B flare was reported at N35E09 and its associated Type II radio burst was also seen on WIND. One and a half-days later, an interplanetary shock was observed on ACE. The shock produced large enhancements of particles up to few MeV per nucleon. We will discuss the elemental abundance ratios of C, N, O, Ne, Mg, Si, and Fe both as a function of time and energy from few tens of keV to a few MeV per nucleon. The energy spectra of these ions will be compared with current acceleration models.

GA4.04/E/01-B5 1210

WIND OBSERVATIONS OF ENERGETIC PROTON EVENTS AT TRANSIENT INTERPLANETARY SHOCKS

M. MAKSIMOVIC(1), D. Lario(1), T.R. Sanderson(1), D. Berdichevsky(2) and A. Szabo(2) (1) Space Science Department of ESA/ESTEC, PO Box 299, 2200 AG Noordwijk, The Netherlands (2)NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA

Between December 1994 and May 1997 the WIND spacecraft observed ~30 transient interplanetary shocks. We analyze the relation between the properties of these interplanetary shocks (local shock speed, Alfven Mach number, magnetic compression ratio, angle between the normal to the shock and the upstream magnetic field direction) and the energetic proton intensities observed around the shock passage. We compute the energy spectra and the three-dimensional anisotropies of protons in the energy range 20 keV - 10 MeV observed by the solid state detector of the WIND/3DP instrument. We investigate the correlation between shock strengths and proton fluxes as well as the behaviour of the proton anisotropies and spectra around the shock.

ENERGETICS PARTICLES IN THE HELIOSPHERE: LOCAL AND INTERSTELLAR SOURCES, SOURCES CYCLE DEPENDENCE AND 3D STRUCTURE-2

GA4.04/W/06-B5 Invited 1400

TRANSPORT OF ENERGETIC PARTICLES IN HELIOGRAPHIC LATITUDE BY DIRECT MAGNETIC CONNECTION: EVOLUTION DURING THE SOLAR CYCLE.

L. A. FISK, T. H. Zurbuchen, and N. A. Schwadron, (Department of Atmospheric, Oceanic, and Space Sciences University of Michigan)

One of the important results from the Ulysses mission has been the apparent ease with which energetic particles propagate in heliographic latitude. Particles that are accelerated in Co-Rotating Interaction Regions (CIRs) at low latitudes are seen at the highest heliographic latitudes; low latitude CIRs affect the modulation of galactic cosmic rays at high latitudes. These observations have led to new models for the heliospheric magnetic field in which field lines acquire a systematic polar component, and thus can provide for direct magnetic connection from low to high latitudes. The mechanisms for creating these polar components are straightforward at solar minimum, but less obvious as solar activity increases and the well-developed polar coronal hole pattern breaks down. In this paper the new models for the heliospheric magnetic field are reviewed and the likely evolution of the mechanisms which create the systematic polar component of the field during the solar cycle are discussed.

GA4.04/W/07-B5 1430

COMPARISON OF EISCAT IPS RADIAL AND MERIDIONAL SOLAR WIND VELOCITY MEASUREMENTS WITH MEASUREMENTS MADE BY ULYSSES.

MORAN PJ, Breen AR, Fallows RA, Williams PJS. (Physics Department, UWA, Penglais Hill, Aberystwyth, Ceredigion. SY23 3BZ)

Observations of interplanetary scintillation (IPS) made using EISCAT allow accurate solar wind velocity measurements to be made at all heliographic latitudes, whilst extended observations enable the large-scale direction of the solar wind flow to be determined. The IPS results show the high latitude wind to be similar in velocity to measurements made by ULYSSES and the data also regularly show there to be a small but significant non-radial component of around 1

or 2 degrees, generally in the meridional direction from the pole to the equator. A comparison of both velocity measurements along a streamline, and large scale non-radial flow are made between the EISCAT and ULYSSES datasets.

GA4.04/W/15-B5 1450

SHOCK EVOLUTION AND THEIR RELATION TO ENERGETIC PARTICLES IN THE OUTER HELIOSPHERE

J. D. RICHARDSON, A. J. Lazarus, K. I. Paularena (M.I.T., Center for Space Research, 37-655, Cambridge, MA, USA, 02139); R. Decker (Johns Hopkins Applied Physics Lab., Laurel, MD); and F. McDonald (IPST, University of Maryland, MD)

Shocks in the solar wind are important for initial energization of pickup ions in the solar wind. As the solar wind propagates outward, the frequency of shocks and their strength decrease. The timing of energetic particle increases is no longer as closely related to the passage of shocks. We discuss the evolution of shocks observed by Voyager from 1 to 58 AU and their relationship to energetic particle increases.

GA4.04/E/03-B5 1510

THE TERMINATION SHOCK: 1979 - 1995

Y. C. WHANG and J. Y. Lu (both at Department of Mechanical Engineering, Catholic University of America, Washington, D. C., email: whang@cua.edu) L F. Burlaga (NASA Goddard Space Flight Center, Greenbelt, Maryland)

We study the varying location, jump condition, and shock speed of the termination shock from 1979 through 1995 taking into account the effects of pickup protons. Pickup protons and neutral hydrogen are calculated using a hot hydrogen model. Plasma and magnetic field data from Voyagers over a 17-year period from 1978 through 1994 are used as input to carry out this study. The full MHD equations are integrated to extrapolate input data from the Voyager trajectory to the upstream of the termination shock. The flow condition across the shock is required to satisfy the jump equations formulated in the moving shock frame of reference, and the solar wind flow immediately downstream of the shock is required to satisfy the condition of constant reverse Riemann invariant. The postshock temperature of pickup protons is calculated using recently obtained empirical formula of Whang and Burlaga.

GA4.04/W/05-B5 Invited 1530

THE PHYSICS OF THE TRANSPORT OF GALACTIC ANDANOMALOUS COSMIC RAYS IN THE HELIOSPHERE

J. R. JOKIPII and J. Kota, (University of Arizona, Tucson, AZ, 85721 USA Email: Jokipii@lpl.arizona.edu)

Observations of cosmic rays, magnetic fields and plasmas from a variety of spacecraft over the past several years, and associated modelling efforts, have led to a reasonably-complete picture of the quiet heliosphere. Models and computer simulations can account for the major observed features of cosmic rays and their interactions. This will be illustrated by showing the results of simulations and their physical interpretation. The major remaining problem appears to be the precise modes of latitudinal transport of energetic particles.

As we approach the next solar maximum, it is expected that the nature of the heliosphere, and hence its interactions with cosmic rays, will change dramatically. Progress in understanding and modelling these changes will also be discussed.

GA4.04/W/14-B5 Invited 1620

SPATIAL AND TEMPORAL VARIATIONS OF ANOMALOUS COSMIC RAYS IN THE HELIOSPHERE

R. A. LESKE, A. C. Cummings, R. A. Mewaldt, and E. C. Stone (Space Radiation Laboratory, Mail Code 220-47, California Institute of Technology, Pasadena, CA 91125 USA, email: ral@srl.caltech.edu); E. R. Christian (NASA/Goddard Space Flight Center, Code 661, Greenbelt, MD 20771 USA)

Anomalous cosmic rays (ACRs) provide a sensitive probe of the access of cosmic rays to the inner heliosphere, varying in intensity by more than two orders of magnitude during the course of the solar cycle. Their distribution in the heliosphere, specifically their radial and latitudinal intensity gradients, as well as the variation of these gradients with the magnetic polarity of the solar cycle, provide important constraints on theories of the transport of these particles from their acceleration site at the solar wind termination shock. We review measurements of the ACR intensities and spectra as determined in the outer heliosphere by the Pioneer and Voyager spacecraft, at high latitudes by Ulysses, and at 1 AU by SAMPEX, ACE, and other spacecraft, and compare these measurements to models of the modulation and transport of ACRs. We also discuss new information becoming available from the ACE spacecraft. With its outstanding statistical accuracy, ACE data can provide a detailed record of ACR intensity and spectral changes on short time scales during the approach to solar maximum, and with its excellent mass resolution, the spectra of individual ACR isotopes may be monitored.

GA4.04/W/04-B5 1650

SOLAR CYCLE EFFECTS ON THE SPECTRUM OF ACR OXYGEN

D.C. HAMILTON, M.E. Hill, and G. Gloeckler (all at Department of Physics, University of Maryland, College Park, MD, 20742, USA, Email: douglas.c.hamilton@umail.umd.edu); R.B. Decker and S.M. Krimigis (both at Johns Hopkins Applied Physics Laboratory, Laurel, MD)

The Voyager 1/2 LECP instruments have measured the anomalous cosmic ray oxygen spectrum (0.3 - 40 MeV/nuc), mostly in the outer heliosphere, during the two solar cycles since the spacecraft were launched in 1977. Large temporal and spatial variations in intensity have been observed, particularly in the low energy portion of the spectrum. At Voyager 1, the peak ACR oxygen flux was observed at a nearly constant energy of 1.3 MeV/nucleon during the years 1993 to 1998 as V1 travelled from 53 AU to 71 AU. The flux at that energy increased by a factor of about 80 from 1992 to 1998, largely as a result of declining modulation during the approach to solar minimum. In fact the ACR flux at V1 and V2 continued to increase in 1997 and 1998 after the nominal minimum of the 11-year solar activity cycle in 1996. In addition, a comparison of the ACR oxygen spectra at Voyager 1 and Voyager 2 has revealed effects resulting from the 22-year solar magnetic cycle. In the 1997 solar minimum, the flux was higher at V1 than at V2, indicative of less modulation at V1, which was 16 AU farther from the sun. However, during the previous solar minimum in 1987, the ACR oxygen flux was higher at V2 than at V1 even though V1 was about 8 AU farther from the sun. The difference in the data from the two solar minima is apparently explained by the 1990 polarity reversal of the solar magnetic field. Predicted ACR drift patterns in 1987 produce maximum ACR fluxes near the heliographic equator while those in 1997 produce low fluxes near the equator. V2 was near the equator in 1987 while V1 was at 31° latitude, and the large negative latitudinal gradient dominated the positive radial gradient. In 1997 both gradients would lead to a larger flux at V1. We will discuss these and other solar cycle variations in the ACR oxygen spectrum.

COMPOSITION OF ANOMALOUS COSMIC RAYS

A. C. CUMMINGS, C. D. Steenberg, and E. C. Stone (all at Caltech, Mail Code 220-47, Pasadena, CA, USA 91125, email: ace@srl.caltech.edu)

Anomalous cosmic rays (ACRs) originate as interstellar neutral gas which enters the heliosphere, becomes ionized, and then is accelerated at the solar wind termination shock, currently thought to lie within approximately 90 AU from the Sun. The composition of ACRs is important to questions concerning the injection and acceleration process at the solar wind termination shock, as well as to questions about the composition and ionization state of the gas in the local interstellar medium. We present a study of the composition of ACRs using energy spectra acquired during the current solar minimum period with instruments on the Voyager spacecraft. We use a full-drift model to describe the propagation of these particles in the heliosphere. We will compare the results with previous determinations and discuss the implications of the findings. This work was supported by NASA under contract NAS7-918.

SPECTRAL AND COMPOSITION CHARACTERISTICS OF ENERGETIC IONS UPSTREAM OF THE EARTH'S BOW SHOCK

M. I. DESAI, J. R. Dwyer, and G. M. Mason (Dept. Of Physics, University of Maryland, College Park, MD 20742); J. E. Mazur (Aerospace Corp., Los Angeles, CA 90009). T. T. von Rosenvinge, and R. P. Lepping (NASA/GSFC, Greenbelt, MD 20771)

Since the launch of the WIND spacecraft in November 1994 until the middle of 1998, the SupraThermal Energetic Particle (STEP) telescope has detected well over a thousand short-duration (lasting typically from a few minutes up to a few hours) ion intensity enhancements originating from the vicinity of the Earth's bow shock. We present here for the first time a detailed statistical analysis of the differential energy spectra of ion species such as H, He, CNO, NeS, and Fe in the 30 keV/nucleon up to a few MeV/nucleon energy range associated with such events. We also survey the abundances of heavy ions such as C, Ne, and Fe relative to O observed during the events. We discuss the implications of the above results for the traditional models that have been proposed to account for the origin and acceleration of these upstream ions.

ANISOTROPY AND SCATTERING MEAN FREE PATH OF INTERSTELLAR PICK-UP IONS

Z. Nemeth and G. ERDOS (both at KFKI Research Insitute for Particle and Nuclear Physics, 1525 Budapest P.O. Box 49, Hungary, Email: erdos@rmki.kfki.hu), A. Balogh (The Blackett Laboratory, Imperial College, London SW7 2BZ, UK, email: a.balogh@ic.ac.uk)

Pitch angle distributions of interstellar pick-up ions at high heliographic latitude have been studied in connection with the scattering mean free path of the particles. Based on high time resolution Ulysses magnetic field measurements, we have determined the pitch angle of pick-up ions at the moment of ionization. We have found that the long time average of the source anisotropy of the pick-up ions is not a ring distribution, due to large deviations of the magnetic field from Parker spiral. We have solved the transport equation of pick-up ions including an anisotropic source term consistent with magnetic field measurements, and we have estimated the value of the scattering mean free path which results in particle distribution matching Ulysses observations. Our conclusion is that the scattering mean free path of pick-up ions is significantly smaller than reported earlier.

LOW ENERGY PROTONS AS A PROBE OF INTERPLANETARY ENVIRONMENT PERTURBATIONS

M.F. Bakhareva, A.V. DMITRIEV, I.S. Veselovsky, and M.A. Zeldovich (Institute of Nuclear Physics, Moscow State University, 119899, Moscow, Russia, email: dalex@srdlan.npi.msu.su)

The main aspects of the relationship between the fluxes of low energy (about 1 MeV) protons and interplanetary medium conditions are discussed in the paper using observational data for more than 100 events in 1972-1994 and theoretical arguments. The effective acceleration (stochastic and magnetic pumping) of the protons at the interplanetary shocks defines the background level and strong variations of particle fluxes. Solar cycle variations of background proton fluxes are associated with acceleration and propagation conditions in the heliosphere. The strong enhancements of the low energy proton fluxes are produced by corotating and CME shocks. These enhancements forestall the perturbations up to tens hours. This property of the low energy proton fluxes permits to consider these particles as a probe of the interplanetary perturbations. Methods of a short-term prediction based on this property are presented and discussed.

STATISTICS OF PROTON EVENTS MEASURED ON HIGH-ALTITUDE SATELLITE GRANAT IN 1990-1995

Eugene A. Chuchkov, Elena E. Grigorenko, Sergey I. Ermakov, Nickolay N. Kontor, German P. Lyubimov, Nickolay N. PAVLOV, Vladimir I. Tulupov, and Boris Ya. Scherbovsky (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: nnpavlov@taspd.npi.msu.su).

We measured fluxes of protons of 1 MeV through tens MeV energy on the GRANAT in 1990-1995. The satellite's orbit is as high as 200 000 km in its initial apogee. Our instrument has two blocks of sensors continuously directed sunward and opposite respectively. Common time resolution is 20 minutes and 2 minutes - for few channels only. A period of the mission falls on the time of high solar activity and many solar events have been recorded in our data collection. This paper presents some results of the statistical analysis performed for the acquired data. In the analysis we try to identify every individual enhancement in proton-flux intensity. For each enhancement, such characteristics as amplitude, duration, fluence, and some others are picked up for the available energy channels. Where is possible and reasonable, the overlapped enhancements are decomposed to the superposition of elementary profiles that could be bound to the individual solar events. Involving of different energy channels allows us to estimate energy spectrum of propagating protons for each event and, further, to assess total energy of accelerated particles for a particular solar flare. All mentioned parameters are gathered into statistical distributions. A dependence of various characteristics of those distributions on the phase of a solar cycle is also studied.

PARTICLE DIFFUSION IN A GAS OF NON-LINEAR MHD STRUCTURES: AN INELASTIC BILLARD MODEL

B. LEFEBVRE and V. Krasnoselskikh (LPCE/CNRS, 3A av. De la Recherche Scientifique, F-45071, Orleans, France. Email: lefebvre@cnrs-orleans.fr)

Diffusion and acceleration of particles by "coherent structures" in large-scale plasma turbulence is studied. Our model is inspired from the Lorentz gas, but with inelastic collisions. Its statistical properties such as diffusion, Lyapunov exponents, entropy are studied. The applications we have in mind are:
a) diffusion and acceleration in the quasi-parallel shock region
b) particle heating in the solar corona where multiple reconnection sites may occur.

GA4.04/W/11-B5 Poster **0830-05**

TWO-COMPONENT STRUCTURE AND BI-DIRECTIONAL ANISOTROPY OF RELATIVISTIC PROTON IN THE SEPTEMBER 29, 1989 EVENT

E.V. VASHENYUK (1) and L.I. Miroshnichenko (2) (1) Polar Geophysical Institute, Apatity, 184200, RUSSIA; (2) Instituto de Geofisica UNAM, Mèxico, D. F., 04510, MEXICO; Permanent address: IZMIRAN, Troitsk, Moscow Region, 142092, RUSSIA

Ground Level Enhancement (GLE) of September 29, 1989 was remarkable, in particular, by strong variations of the energy spectrum and anisotropy direction of relativistic solar cosmic rays (SCR). Although a CME-driven shock has been proposed as the most plausible mechanism to account for the behaviour of relativistic protons during all the event, no generally accepted explanation exists at present. We try to explain these peculiarities relying upon a concept of two SCR components. The first, hard prompt component (PC) was suggested to originate from impulsive behind-the-limb flare, its anisotropy being directed outwards the Sun. The source of the second, soft delayed component (DC) presumably occupied a wide area (as large as a CME), however, it had a pronounced bidirectional anisotropy. It means that the IMF during the GLE might have a shape of giant loop with its both ends rooted into the Sun. Some observational data indicate that such a structure was built-up before the event, due to intensive eruptive activity behind the solar limb. It is argued that the DC acceleration, ejection and propagation have been operating behind the CME-driven shock.

THE DIMENSION OF MODULATION REGION IN THE HELIOSPHERE AND HIGH RIGIDITY COSMIC RAY-SOLAR ACTIVITY HYSTERESIS PHENOMENON

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated toTel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; email: lid@physics.technion.ac.il); Irina Dorman (Institute of History of Science and Technology, Russian Academy of Science, Staropansky 1/5, Moscow 103012, RUSSIA); N. Iucci and M. Parisi (Terza Universita di Roma, Dipartimento di Fisica "E. Amaldi", Via della Vasca Navale 84, 00146 Rome, Italy); G. Villoresi (IFSI/CNR-Frascati c/o Terza Universita di Roma, Dipartimento di Fisica "E. Amaldi", Via della Vasca Navale 84, 00146 Rome, Italy)

On the basis of cosmic ray (CR) neutron monitor and muon telescope data as well as solar activity (SA) data for 5 solar cycles the CR-SA hysteresis phenomenon is investigated. Obtained results show that by high rigidity CR particles it can be determined only the effective dimension of modulation region in the Heliosphere (in dependence of particle rigidity) but not the distance from the Sun to the terminal shock wave. This effective dimension of modulation region decreased with CR rigidity increasing. High rigidity CR particles don't feel the situation out of modulation region up to the terminal shock wave but its global time variation contains an important information on the CR diffusion coefficient distribution in the inner Heliosphere and connection with SA.

HYSTERESIS PHENOMENON IN LONG-TERM COSMIC RAY-SOLAR ACTIVITY CONNECTION AND COSMIC RAY MODULATION IN THE LAST 250 YEARS

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; email: lid@physics.technion.ac.il); Irina Dorman (Institute of History of Science and Technology, Russian Academy of Science, Staropansky 1/5, Moscow 103012, RUSSIA); N. Iucci and M. Parisi (Terza Universita di Roma, Dipartimento di Fisica "E. Amaldi", Via della Vasca Navale 84, 00146 Rome, Italy); G. Villoresi (IFSI/CNR-Frascati c/o Terza Universita di Roma, Dipartimento di Fisica "E. Amaldi", Via della Vasca Navale 84, 00146 Rome, Italy)

On the basis of cosmic ray (CR) neutron monitor, muon telescope, and ionization chamber data, as well as solar activity (SA) data for the last 6 solar cycles, the hysteresis phenomenon in the connection between CR and SA is investigated. On the basis of low rigidity CR data we determine the average (for solar cycle) dimension of the Heliosphere and CR propagation parameters. The results, obtained separately for odd and even solar cycles, are compared and discussed in the frame of CR convection-diffusion propagation model, by taking into account drift effects. Then, on the basis of data for 1965-1998 we determine the expected change of CR propagation parameters and position of terminal shock wave during these solar cycles. We tested the obtained results by using CR and SA monthly data for 1953-1965. Then, by using the available SA data in the past (including the period of Maunder SA minimum), we obtain information on the time variations of solar wind properties and CR modulation versus particle rigidity for the last 250 years.

THE 27-DAY VARIATION OF COSMIC RAYS IN CONNECTION WITH INHOMOGENEOUS DISTRIBUTION OF SOLAR ACTIVITY AND WITH THE POSITION OF INTERPLANETARY NEUTRAL CURRENT SHEET

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; E-mail: lid@physics.technion.ac.il), J.F. Valdes-Galicia (Instituto de Geofisica UNAM, 04510 Mexico D.F., MEXICO)

Based on daily data of the cosmic ray neutron intensity detected at Deep River we determined the amplitude and phase of cosmic ray 27-day variation for each solar rotation for periods during the ascending (1976-1978, 1986-1988) and descending (1982-1984, 1991-1993) phases of solar cycles 21 and 22. We compare the obtained results with the 27-day variation of solar activity and with the evolution of the interplanetary neutral current sheet tilt-angle. The conclusion of our research is that 27-day cosmic ray variation is caused by at least two mechanisms. The first is rotated inhomogeneous modulation, and the second is caused by the rotation of the inclined interplanetary neutral current sheet and existing of transverse cosmic ray gradients connected with the sheet (which leads to cosmic ray 27-day variation with amplitude to be approximately proportional to the tilt-angle).

COSMIC RAY HYSTERESIS EFFECTS IN DEPENDENCE OF PARTICLE RIGIDITY AND DIMENSIONS OF EFFECTIVE MODULATION REGION

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; email: lid@physics.technion.ac.il); Irina Dorman (Institute of History of Science and Technology, Russian Academy of Science, Staropansky 1/5, Moscow 103012, RUSSIA); N. Iucci and M. Parisi (Terza Universita di Roma, Dipartimento di Fisica "E. Amaldi", Via della Vasca Navale 84, 00146 Rome, Italy); G. Villoresi (IFSI/CNR-Frascati c/o Terza Universita di Roma, Dipartimento di Fisica "E. Amaldi", Via della Vasca Navale 84, 00146 Rome, Italy)

Our studies of the neutron component data have made possible to find the hysteresis character of the relationships between the variations in solar activity and in cosmic ray intensity. This effect arises from the delay of the interplanetary processes (responsible for cosmic ray modulation) with respect to the initiating solar processes which correspond to some effective velocity of solar wind and shock waves propagation. We extended these investigations with taking into account data of cosmic ray observations by ionization chambers, muon telescopes and neutron monitors and supermonitors on the stations with different cut-off rigidity as well as data of cosmic ray measurements in stratosphere and on space probes. Obtained results on hysteresis effects for about 4 solar cycles we analyze in the frame of theory of cosmic ray nonlinear modulation and determine the dimension of effective modulation region in dependence from particle rigidity.

GAMMA-RAY PRODUCTION IN THE HELIOSPHERE BY GALACTIC AND SOLAR COSMIC RAYS

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; email: lid@physics.technion.ac.il),

The interaction of cosmic ray particles (protons, nucleus and electrons) with matter determines main processes of high-energy gamma ray generation: through neutral pion decay and bremsstrahlung emissivity. From other side, the intensity of these processes depends from the space-time distribution of matter as well as from the space-time distribution of cosmic ray energy spectrum and contents. By solving self-consistent spherical-symmetric problem for the Heliosphere (with taking into account energetic particle pressure influence on solar wind plasma propagation and energetic particle kinetic stream instability influence on the small-scale magnetic structure of plasma) we determine galactic cosmic ray modulation in the interplanetary space in dependence from the level of solar activity, from the radial distance and from the particle energy as well as plasma density space-time distribution. On the basis of these results we calculate approximately an expected gamma-ray emissivity of the Heliosphere from galactic cosmic rays in dependence of direction of view for inside and outside observers. Then we determine approximately expected gamma-ray emissivity of Heliosphere from solar cosmic rays for great solar energetic particle events.

COSMIC RAY ANISOTROPIES IN THE HELIOSPHERE

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Currenr address: P.O.Box 2217, Qazrin 12900, ISRAEL; E-mail: lid@physics.technion.ac.il)

Cosmic ray anisotropy is one of main characteristics of galactic cosmic rays. The observed cosmic ray anisotropy in the interplanetary space consists mainly from two parts with different origin and different dependences from particle rigidity and from interplanetary magnetic field (IMF). One part is produced by cosmic ray convection-diffusion processes and does not depend from the direction of IMF; the other part is produced by cosmic ray drift processes and strongly depends from the direction of IMF. Both parts are connected with cosmic ray gradients and parameters of cosmic ray propagation in the space. This review paper reflects research of 3-dimensional, North- South and ecliptic cosmic ray anisotropies in the Heliosphere, on determination by cosmic ray anisotropy data transport parameters of cosmic ray propagation and distribution of cosmic ray density gradients in the interplanetary space.

ADDITIONAL CHARGED PARTICLE PROPAGATION IN SPACE PLASMA WITH TWO TYPES OF SCATTERS: APPLICATIONS TO THE HELIOSPHERE

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; E-mail: lid@physics.technion.ac.il); V. Shogenov (Kabardino-Balkar State University, Nalchik, Russia).

We determine the transport parameters for cosmic ray propagation in the Heliosphere in the frame of model [1]. In this model first type of scatterers are magnetic inhomogeneities frozen in solar wind (as a background plasma) moved with some velocity w. These scatterers are characterized by transport path W(R), where R is the rigidity of charged particles. The second type of scatterers are magnetic clouds, high speed streams, shock waves (considered only as scatterers) moved with some average velocity u and characterized by transport path U(R). From the collisional Boltzmann equation we derive the diffusion approximation and then determine diffusion tensor and effective convection speed which will be characterize cosmic ray propagation and modulation in in the Heliosphere (the additional cosmic ray acceleration we consider in [2]).

THE EVENT OF 24 MAY 1990 AND THE PROBLEM OF SOLAR NEUTRON PROPAGATION THROUGH THE EARTH'S ATMOSPHERE: DOES THE "REFRACTION" EFFECT EXIST

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; E-mail: lid@physics.technion.ac.il); V. Shogenov (Kabardino-Balkar State University, Nalchik, Russia).

To obtain absolute values of solar neutron intensity changing in dependence of altitude and zenith angle of the Sun we recalculate all available experimental data with taking into account the type of detector as well as the change of galactic cosmic ray intensity in dependence of altitude and cut-off rigidity (by using analytical approximation for neutron component coupling function). After this procedure the attenuation length of solar neutrons in the assumption of straight-ahead transport from the Sun through the atmosphere reduces from unreasonable great value of 208 g/sq.cm to 149 g/sq.cm. The obtained value still contradicts with data on neutron cross-sections. Then we take into account the "refraction" effect in solar neutron propagation through the atmosphere according to our calculations and the attenuation length reduces to about 110 g/sq.cm) in accordance with neutron cross-section data.

SIMULATION OF SOLAR NEUTRON SCATTERING AND ATTENUATION IN THE ATMOSPHERE FOR DIFFERENT INITIAL ZENITH ANGLES

LEV DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, Israel; email: lid@physics.technion.ac.il), I.V. Dorman (Institute of History of Science and Technology RAN, Staropansky 1/5, Moscow 103012, Russia) J.F. Valdes-Galicia (Instituto de Geofisica, UNAM, Mexico)

We test the usually used suggestion that solar neutron propagation through the atmosphere for some initial zenith angle T of the Sun will be the same as for vertical direction, but for the depth h/cosT. Our simulation of multi-scattering of neutrons on small angles with attenuation for different initial zenith angles shows that this suggestion is not correct. The main cause of this is the bigger attenuation of neutrons scattered to the bigger zenith angles which grows asymmetry in the neutron angle distribution. Media zenith angle of solar neutrons decreases during its propagation through the atmosphere.

GA4.04/L/13-B5 Poster **1400-08**

DRIFT ANISOTROPY AND TRANSVERSE GRADIENTS OF COSMIC RAYS IN THE INTERPLANETARY SPACE ACCORDING TO GROUND AND UNDERGROUND OBSERVATIONS FOR ABOUT 25 YEARS

LEV I. DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; email: lid@physics.technion.ac.il), H. Ahluwalia (Dep. of Physics and Astronomy, University of New Mexico, Albuquerque, USA)

We used 25 years data of underground muon telescopes and ground based neutron supermonitors as well as data of solar wind speed and interplanetary magnetic field (IMF) parameters (mainly for 1965-1990). We separated all data for AWAY and TOWARD directions of IMF in three zones: NORTH (effective heliolatitude of the Earth +6 degrees), EQUATORIAL (effective heliolatitude 0 degrees) and SOUTH (effective heliolatitude –6 degrees). We take into account that cosmic ray convection-diffusion anisotropy not depend from the direction of IMF and drift anisotropy changes the sign with the changing of the IMF direction. We separate these two types of cosmic ray anisotropies and determine the dependence of cosmic ray drift anisotropy from particle rigidity as well as transverse gradient in the interval from +6 degrees to -6 degrees.

GA4.04/L/14-B5 Poster **1400-09**

COSMIC RAY CONVECTION-DIFFUSION ANISOTROPY IN THE INTERPLANETARY SPACE ACCORDING TO GROUND AND UNDERGROUND OBSERVATIONS

LEV I. DORMAN (IZMIRAN, Technion and Israel Cosmic Ray Center, affiliated to Tel Aviv University; Current address: P.O.Box 2217, Qazrin 12900, ISRAEL; email: lid@physics.technion.ac.il), H. Ahluwalia (Dep. of Physics and Astronomy, University of New Mexico, Albuquerque, USA)

To determine the clean cosmic ray convection-diffusion anisotropy we used 25 years data of underground muon telescopes and ground based neutron supermonitors as well as space apparatus data of solar wind speed and interplanetary magnetic field (IMF) parameters (mainly for 1965-1990). We separate all data for AWAY and TOWARD directions of IMF in the three zones of the Earth's heliolatitude: NORTH, EQUATORIAL and SOUTH. Since the cosmic ray convection-diffusion anisotropy does not depend from the direction of IMF, but drift anisotropy change the sign with the changing of the IMF direction we excluded the drift anisotropy from observation data and in the first time obtained information on the clean cosmic ray convection-diffusion anisotropy in the interplanetary space in dependence of particle energy in the interval from few GeV to about 300 GeV and in dependence on heliolatitude. We discuss obtained results in the frame of modern theory of cosmic ray anisotropy formation in the Heliosphere.

SOLAR WIND INTERACTIONS WITH MAGNETOSPHERES: A TUTORIAL UPDATE ON PHENOMENOLOGY AND PHYSICS

C. T. RUSSELL (Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095-1567, USA, email: ctrussell@igpp.ucla.edu)

The size of a planetary magnetosphere is determined by the balance between the solar wind dynamic pressure and the magnetic and plasma pressure exerted by the planetary magnetosphere. The shape of the magnetosphere is additionally affected by the drag of the solar wind on the obstacle. Increasingly it is found that this drag is predominantly associated with reconnection. It is not yet well understood what controls the rate of reconnection of the interplanetary magnetic field (IMF) to that of the Earth but the ionosphere is believed to be important. If so, then investigation of the magnetosphere of Mercury is a high priority because its weak ionosphere provides an important contrast to Earth's. In fact Luhmann and co-workers have proposed that Mercury does not have substorms but rather the magnetosphere is immediately responsive to the solar wind. The ISTP program is making significant in roads in understanding both the coupling of the ionosphere and the magnetosphere and the magnetosphere with the solar wind. Current systems, through potential drops and wave particle interactions, heat ions that escape into the magnetosphere while the energy for this process is provided by the solar wind. The solar wind entry into the polar cusp differs from northward to southward IMF populating dayside field lines and the nightside field lines relative to the bifurcation field line in these two situations. The motion of the cusp in local time for different By polarities provides unambiguous evidence for motion of the reconnection site on the magnetopause. Jupiter provides an important contrast to the terrestrial magnetosphere. The Mach number of the solar wind has increased substantially by 5.2 AU, changing the conditions for IMF reconnection with the planetary magnetic field. Io supplies much mass, perhaps one ton per second to the magnetosphere. This mass is spun up by the corotational electric field enforced by the ionosphere and a magnetodisk is formed. Radial outward and convection transports the ions to the tail where reconnection separates them from the planetary magnetic field and the emptied closed field lines convect back into the magnetosphere. It is possible that in contrast to the terrestrial magnetosphere, jovian magnetospheric activity is internally, not externally driven.

STRUCTURES IN THE CORONA, THE SOLAR WIND, AND THE LARGE-SCALE HELIOSPHERE: NEW RESULTS FROM RECENT ACTIVITY MINIMUM

Rainer SCHWENN (Max-Planck-Institut fuer Aeronomie, D 37191 Katlenburg-Lindau, Germany, Email: schwenn@linmpi.mpg.de)

The space missions SOHO and Ulysses were lucky to be fully operational during the recent solar activity minimum in 1996. They encountered the sun in exactly the same magnetic configuration as did Skylab and Helios one full Hale cycle ago. Then, many basic features of the 3D heliosphere were discovered. This time, we observed in much more detail, how closely the magnetic topology of the corona is associated with the solar wind stream structure. The boundaries separating fast coronal hole flow from slow solar wind confined to the equatorial streamer belt can be traced all the way down to the sun. For the first time, the slow wind was made visible, and its acceleration profiles was measured. Its release mechanism remains under debate. The fast wind was found to be accelerated much closer to the sun. It reaches its final speed inside 10 Rs. Evidence for strong ion cyclotron heating was also found.

GA4.06/W/06–B1 Invited **1040**

AN UPDATE ON UNDERSTANDING THE CORONA

Ruth ESSER (Harvard Smithsonian Center for Astrophysics, 60 Garden Street, Cambridge MA 02138, USA, email: resser@cfa.harvard.edu)

Observations from the Solar Heliospheric Observatory and from ground based instruments carried out over the past few years have led to results that demand a revision of the physical picture of the inner corona. These results, particularly the ones concerning particle temperatures and flow speeds, have initiated new investigations of possible heating mechanisms operating in the inner corona. The picture of the coronal plasma that emerges from these new observations, as well as recently suggested heating mechanisms will be discussed. The consequences of the new observations and heating mechanisms for solar wind modelling will be addressed. Different approaches to solarwind modelling will be compared.

CORONAL MASS EJECTIONS NEAR THE SUN AND IN THE SOLAR WIND: PRESENT UNDERSTANDING

J. T. GOSLING (Los Alamos National Laboratory, Los Alamos NM 87545, USA, email: jgosling@lanl.gov)

Coronal mass ejections, or CMEs, play a fundamental role in the long-term evolution of the solar corona and are the prime source of transient (as opposed to corotating) solar wind disturbances and large, non-recurrent geomagnetic storms. Recent years have witnessed a virtual explosion of CME-related studies. This interest and emphasis arise both because of an increased awareness of the importance of these events to solar-terrestrial physics and because of superb new observations available from SOHO, YOHKOH, WIND, ACE, and Ulysses. This paper attempts to provide an overview of present understanding of CMEs in both their solar and heliospheric contexts, with emphasis on results from the last ~5 years.

ION COMPOSITION AND SOURCES IN THE HELIOSPHERE

P. BOCHSLER (Physikalisches Institut, University of Bern, Sidlerstrasse 5 CH 3012 Bern Switzerland Email: Peter.Bochsler@soho.unibe.ch)

Most charged particles in the heliosphere originate either from the solar wind or from interstellar neutrals penetrating deep into the innermost parts of the solar system where they are converted into 'pick-up ions' either by charge exchange with solar particles or by photoionisation, to be swept out again, together with the magnetized solar wind plasma. Minor sources in the heliosphere are cometary dust, and cometary and planetary atmospheres. Each source has its specific features, i.e. velocity distributions, and ionic, elemental, and isotopic abundance pattern. Compositional information of the charged heliospheric medium is often used to identify and disentangle contributions from different sources. On the other hand, compositional data provide valuable information about the sources themselves.
This review will concentrate on results from the Ulysses-, WIND-, SOHO- and ACE-missions.

GA4.06/W/05-B1 **1440**

OVERVIEW OF FIRST RESULTS FROM THE ADVANCED COMPOSITION EXPLORER

E. C. STONE (Space Radiation Laboratory, Mail Code 220-47, California Institute of Technology, Pasadena, CA 91125 USA, email: ecs@srl.caltech.edu)

The Advanced Composition Explorer (ACE) is providing high resolution observations of the elemental and isotopic composition of ions and energetic particles of solar, local interstellar, and galactic origin. Studies of these three samples of matter will address the origin of the elements and their subsequent processing, the formation of the corona and the acceleration of the solar wind, and energetic particle acceleration and transport. Six high resolution spectrometers cover an energy interval ranging from the solar wind to galactic cosmic rays with collecting powers 10 to 1000 times greater than previously available. Three other instruments that monitor the interplanetary environment also provide real time data to the NOAA alert system for impending geomagnetic storms. Launched on August 25, 1997, ACE arrived at the L1 libration point 1.5 million kilometers upwind of Earth in December 1997 to begin a mission extending at least five years to the next maximum in solar activity. This talk will provide an overview of some of the first results from ACE, including high time-resolution measurements of the composition of the solar wind and coronal mass ejections, studies of the ionic charge-state and isotopic composition of the first solar particle events of cycle 23, and high-resolution measurements of the isotopic composition of anomalous and galactic cosmic rays.

THE 3-D HELIOSPHERE: HOW ULYSSES HAS CHANGED OUR VIEW

R. J. FORSYTH (The Blackett Laboratory, Imperial College, London SW7 2BZ, UK, email: r.forsyth@ic.ac.uk)

The Ulysses mission, with its aims of establishing how heliospheric phenomena depend on latitude, and to make the first observations of the polar regions of the heliosphere, has now been underway for more than 8 years. The mission is providing a unique data set covering, among others, the solar wind, the heliospheric magnetic field, energetic particles and cosmic rays. The polar orbit of the spacecraft about the Sun brought Ulysses into the high latitude regions of the heliosphere during 1994 and 1995 during a time when solar activity was decreasing and approaching minimum, allowing these phenomena to be studied in perhaps their simplest states. This review focuses on the contributions that Ulysses has made so far to our knowledge of the 3-D heliosphere, both confirming accepted theory, and throwing up new unexpected results. Ulysses is now well on its way to returning to high latitudes in 2000 and 2001. Some of the open questions that Ulysses will address at this time of solar maximum when the structure of the heliosphere is expected to be much more complex will be briefly discussed.

AN UPDATE ON GALILEO RESULTS ON JUPITER'S MAGNETOSPHERE

N. KRUPP (Max-Planck-Institut für Aeronomie, D- 37191 Katlenburg-Lindau, Germany, email: krupp@linmpi.mpg.de)

A new era of outer planets exploration began when the Galileo spacecraft reached Jupiter in December 1995. Galileo is up to now performing in-situ measurements in the Jovian magnetosphere as the first orbiting spacecraft of an outer planet. Measurements along the elliptic orbits cover nearly all local times and distances between 6 and 142 Jovian radii (RJ). In this report the Galileo results on Jupiter's magnetosphere based on energetic particle measurements of the Energetic Particles Detector (EPD) will be summarized in context to results of other instruments onboard Galileo. They will be compared to the perspective derived from the previous flyby missions. Three-dimensional particle anisotropies in the Jovian magnetosphere show that a dawn-dusk asymmetry exists with larger anisotropy amplitudes in the dawn than in the dusk sector at comparable distances. Also larger radial/field-aligned anisotropies in the dusk magnetosphere are found. Particle flow in the corotation direction are observed in the Jovian magnetotail at distances of 142 RJ. These results require a modification of earlier models of the global flow pattern. Another result of Galileo is the evidence for large-scale dynamic processes within the Jovian magnetotail changing the energetic particle intensities and the slope of energy-time spectra periodically. Strong particle bursts occurring in the predawn sector at distances of 100 RJ and over 100 energy-time dispersed particle signatures in the inner magnetosphere document substorm- or storm-like processes in the Jovian magnetosphere. Energetic particle results onboard Galileo also contribute to the study of the interaction between the Jovian magnetosphere and the Galilean satellites. At Io electron beams along the Io flux tube have been discovered, and at Ganymede the ion sputtering rate could be determined. One of the main results of Galileo so far is the discovery of Ganymede's magnetosphere within the Jovian magnetosphere. Important properties of Ganymede's magnetosphere were derived from changes in the flow direction and magnitude of energetic ions and their loss-cone distributions could be used to determine the surface magnetic field of Ganymede.

SOLAR SOURCE REGIONS OF CORONAL MASS EJECTIONS

S.P. PLUNKETT (1), B.J. Thompson (2), O.C. St. Cyr(3), R.A. Howard (4) (1) Universities Space Research Association, Naval Research Laboratory, Washington, DC 20375, USA. (2) NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA. (3) Computational Physics Inc., NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA. (4) Naval Research Laboratory, Washington, DC 20375, USA.

It is generally accepted that coronal mass ejections (CMEs) are the major solar drivers of many space weather phenomena, including large, non-recurrent geomagnetic storms and solar energetic particle events. High-quality synoptic observations of the solar corona, as carried out by the EIT and LASCO experiments on SOHO, provide near real-time imaging of CMEs, and can be used to help predict the occurrence of geomagnetic disturbances several days in advance. Extreme-ultraviolet images of the low corona and solar disk, as recorded by EIT, reveal a complex web of CME signatures. These observations, together with visible light observations of the outer corona by LASCO, have provided new insights into the origin and initiation of CMEs, and their subsequent evolution as they propagate outwards into the interplanetary medium. In this paper, we use these observations to address the following questions. What types of quiescent solar structures are most likely to produce a CME? How do the manifestations of CME activity near the solar surface relate to the observed properties of CMEs at larger distances from the Sun? Finally, can our improved understanding of CME origins improve our ability to identify potentially geo-effective solar events?

MAGNETIC CLOUD INTERACTION WITH THE SOLAR WIND AND THE RELATION TO MAGNETIC STORMS

Alisson DAL LAGO, Walter D. Gonzalez, Alicia L. Clua de Gonzalez and Luis E. A. Vieira (National Institute for Space Research, INPE, CP 515, Sao Jose dos Campos 12201-970, Sao Paulo, Brazil, e-mail: dallago@dge.inpe.br)

Magnetic clouds are interplanetary structures with a large rotation in the magnetic field direction, an enhanced field strength (typically >10 nT), a low proton temperature and plasma beta parameter, and a radial extent which takes about 24h to cross the spacecraft, near 1 AU. If the speed of the cloud is larger than the upstream slow solar wind plus the magnetosonic wave's phase velocity, a fast shock wave will form in front of the cloud. Using some previously reported magnetic cloud events we study the role of the static (thermal plus magnetic) pressure in the enhancement of the magnetic field strength inside the cloud, as it interacts with

the sheath region of the fast ejecta. The interaction between these clouds and other streams is also addressed. This reinforces the relation of this type of fast ejecta to intense magnetic storms. We observe that some slow non-shock magnetic clouds can also lead to intense storms if they are compressed by another high-speed stream.

GA4.08/W/19-B3 0930

EXPANSION AND DECELERATION OF ICMES

T. MULLIGAN and C. T. Russell (Institute of Geophysics and Planetary Physics and the Department of Earth and Space Sciences, University of California Los Angeles, USA, e-mail: tamitha@igpp.ucla.edu)

In order to predict the geomagnetic consequences of an ICME seen in advance of striking the Earth we must understand how it is evolving as it propagates. Observations of ICMEs show unambiguous evidence for expansion in their magnetic profiles. The rate of expansion can be deduced together with the size and orientation of the ICME for rope-like structures. The velocities of ICMEs can be measured twice by a single spacecraft. The velocity of the driven shock can first be estimated by the density comparison and then the velocity of the leading edge of the ICME can be measured. Sometimes the velocity of the trailing edge of the ICME provides a third measurement. These velocities can be used to estimate the deceleration or acceleration of ICMEs if expansion of the ICME is taken into account. We apply this formalism to a set of ICMEs observed by Pioneer Venus including those associated with specific CME events observed in quadrature with coronographs.

GA4.08/W/10-B3 Invited 1030

THE INTERPLANETARY ORIGIN OF INTENSE AND SUPERINTENSE GEOMAGNETIC STORMS AND OF INTENSE AND FREQUENT SUBSTORMS

W. D. GONZALEZ, A. L. Clua de Gonzalez, A. dal Lago and L. E. Vieira (National Institute for Space Research, INPE, CP 515, Sao Jose dos Campos 12201-970, Sao Paulo, Brazil, e-mail: gonzalez@dge.inpe.br)

Around solar maximum, two interplanetary structures are important for the development of storms, involving an intense and long duration Bs component of the IMF: the sheath region behind the forward shock of a fast CME, and the CME ejecta itself. Frequently, these structures lead to the development of intense storms with a two-step growth in their main phases. These structures also lead sometimes to the development of very intense storms, especially when an additional streams involved. The second stream can compress the primary cloud, bringing with it additional Bs structures. Thus, at times very intense storms are associated with three or more Bs structures. We also discuss evidence that magnetic clouds with very intense core magnetic fields tend to have large velocities, thus implying large amplitude interplanetary electric fields that can drive very intense storms.
During solar minimum, high field regions called Corotating Interaction Regions (CIRs) are created by the interaction of fast streams (emanating from coronal holes) with low speed streams associated with the heliospheric current sheath . However, because the Bs component is typically highly fluctuating within the CIRs, the related storms have weaker strengths, although intense substorms can develop.Frequently, high speed streams are accompanied by long-duration and large-amplitude Alfvenic fluctuations, with their Bs component causing intermittent reconnection. The intense, continuous and long duration auroral activity associated with these fluctuations is called High-Intensity Long Duration and Continuous Auroral Activity (HILDCAAs).

GA4.08/E/17-B3 1105

REPLY OF THE GEOMAGNETIC FIELD TO THE SOLAR WIND VARIATION DURING STORM TIME

Maria Andrea VAN ZELE and Otto Schneider (both at Geofisica, Dto. de Ciencias Geologicas, Ciudad Universitaria, 1428 Buenos Aires, Argentina)

The dependence of the geomagnetic variation due to the symmetrical equatorial ring current during a storm is calculated from the Dst indices and the ram pressure of the solar wind. The dynamical process of the ring evolution is expressed by a linear differential equation; the non homogeneous part can be expressed with good agreement by a linear combination between the dawn-dusk component of a delayed interplanetary electric field Ey(IMF) and its derive Ey'(IMF). The model is tested on the basis of solar parameters recorded each 5 minutes, and magnetograms, for the first months of 1979. The characteristic time T (decay) is calculated for periods when Bz(IMF)0 (homogeneous equation). The term of the non homogeneous part depending of Ey(IMF) acts as a rectifier; if Bz(IMF)>0 the magnetosphere is a closed system and the plasmasphere allows the quick entry of particles or eject them if Ey is varying, as the AE indices show. The delay between the arrival of the solar wind at the magnetospheric nose and their influence on the ring is of some 60 minutes; while the factor accompanying Ey(IMF) is the same for the studied storms, the factor multiplying Ey'(IMF) varies slightly.

Wednesday 28 July PM

GA4.08/E/07-B3 Invited 1300

ENERGETICS AND TOPOLOGY OF THE MAGNETOSPHERE DURING GEOMAGNETIC STORMS

D.N. BAKER (Laboratory for Atmospheric and Space Physics, University of Colorado, Cam-pus Box 590, Boulder, Colorado, 80309-0590, USA, email: baker@lynx.colorado.edu)

Major geomagnetic storms represent a powerful extraction of energy from the solar wind flow and subsequent dissipation of that energy in many different forms. Ring current injection and decay, ionospheric Joule heating, particle precipitation into the atmosphere, and several other physical processes are exhibited rather clearly in large storm events. The modern-day constellation of operating spacecraft gives an unprecedented opportunity to study magnetic storm processes and energetics. This paper focuses on recent coronal mass ejection (CME) events that have been well-observed near the sun. These disturbances are followed from the sun to their arrival in near-Earth space. The reconfiguration of the magnetosphere under the driving influence of CME/magnetic clouds is examined and the energetics of various forms of input and output are assessed. It is concluded that a good understanding can be obtained of magnetospheric configuration changes and energy flow using space-based and ground-based observations.

GA4.08/W/05-B3 1335

FACTORS AFFECTING THE INTENSITY OF THE STORM-TIME RING CURRENT

M. F. THOMSEN (Space and Atmospheric Sciences, Los Alamos National Laboratory, Los Alamos, NM 87545, USA, Email: mthomsen@lanl.gov), J. P. Smith (University of Texas, Austin, TX), J. E. Borovsky (Los Alamos National Laboratory, Los Alamos, NM; Email: jborovsky@lanl.gov), and M. R. Collier (Goddard Space Flight Center, Greenbelt, MD)

The relationship between the strength of the storm-time ring current and several potential source-strength parameters is explored for a number of geomagnetic storms that have occurred over the last few years. A good correlation is found between the maximum value of abs(Dst*) (Dst* =Dst corrected for magnetopause currents) in each storm and the plasma-sheet density observed at geosynchronous orbit during the 12 hours preceding the storm maximum. A similar comparison of abs(Dst*) with interplanetary parameters shows that abs(Dst*) is significantly and independently correlated with the eastward interplanetary electric field and the solar-wind density, with optimal time lags of less than one hour and five hours, respectively. A consistent picture emerges from these results in which the solar wind feeds the near-earth plasma sheet on a time scale of about 5 hours, and that enhanced magnetospheric convection caused by an increased eastward interplanetary electric field leads directly to the injection of this source population into the ring current region.

GA4.08/W/02-B3 1400

A STUDY OF TWO-STEP MAIN PHASE MAGNETIC STORMS

L. E. VIEIRA, W. D. Gonzalez, A. L. Clua de Gonzalez and A. Dal Lago (National Institute for Space research, INPE, CP 515, Sao Jose dos Campos 12201-970, Sao Paulo, Brazil, e-mail: eduardo@dge.inpe.br)

It has been recently shown that a substantial fraction of intense geomagnetic storms have their main phases with a two-step development, that is, before the ring current has decayed significantly to the prestorm level, a new major particle injection occurs, leading to a further development of the ring current, and making Dst decrease a second time. Also, most of the interplanetary structures that cause these storms have been observed to be magnetic clouds, in which the two-step main phase response corresponds to the two Bs (southward Bz component of the IMF) structures encountered in the sheath region ahead of the cloud and in the cloud itself. In this work we divide the clouds in two groups, concerning the rotation in the Bz component of the cloud. Thus, we investigate the difference in the geomagnetic response (peak Dst value) to the two types of clouds, one with a south-north (SN) rotation and the other with a north-south (NS) rotation. We expect a different response in peak Dst, because in the SN case the Bs field of the cloud comes much closer in time to the Bs field of the sheath region, than in the NS case.

GA4.08/E/16-B3 Invited 1425

INTERPLANETARY AND MAGNETOSPHERIC ELECTRIC FIELDS DURING GEOMAGNETIC STORMS: WHAT IS MORE IMPORTANT, STEADY STATE FIELDS OR FLUCTUATING FIELDS?

Y. KAMIDE (Solar-Terrestrial Environment Laboratory, Nagoya University, Toyokawa, Aichi-ken 442-8507, Japan, email: kamide@stelab.nagoya-u.ac.jp)

Most of the Dst variance during intense geomagnetic storms can be reproduced by changes in large-scale electric fields in the solar wind. A continuous controversy exists, however, as to whether the successive occurrence of substorms, i.e., magnetospheric electric fields, plays a direct role in the energization of storm-time ring current particles. This talk proposes that, during magnetic storms, the quasi-steady component of the interplanetary electric fields is important in enhancing the ring current, while changes in the solar wind electric fields are responsible for initiating magnetospheric substorms. Thus, in a Gedanken experiment, if we were to control the solar wind, generating purely steady southward IMF (interplanetary magnetic field), we would be able to create a geomagnetic storm during which no substorms occur.

GA4.08/W/15-B3 1530

INTERBALL MULTI-SATELLITE OBSERVATIONS OF MAGNETOSPHERIC RESPONSE TO MAGNETIC CLOUDS

Yu. I. YERMOLAEV, G. N. Zastenker, N. L. Borodkova, R. A. Kovrazhkin, N. S. Nikolaeva, M. N. Nozdrachev, S. P. Savin, L. M. Zelenyi (Space Research Institute, Moscow 117810, Russia, Email: yermol@afed.iki.rssi.ru); Z. Nemecek, J. Safrankova (Charles University, Praga, Czech Republic); J.-A. Sauvaud (CESR/CNES, Toulouse, France)

Several results of statistical studies related to the interaction of interplanetary magnetic clouds with the Earth's magnetosphere as observed on the INTERBALL satellites during 1995-1998 are presented. Magnetosphere response to the clouds is usually the same as its response to the similar changes of solar wind and IMF parameters and the main cause of very strong magnetospheric disturbances is high pressure pulses on leading and trailing edges of clouds. Interactions of clouds with the magnetosphere results in its compression and deformation, large scale motions of the magnetic tail and initiations of stroms and substorms. Several important consequences of these processes are (1) observations of magnetospheric regions and boundaries much closer to the Earth than on average; (2) increases of density and temperature in outer regions of magnetosphere; (3) multiple crossings of geomagnetic tail boundaries presumably due to tail flapping, and (4) bursty fluxes of high energy ions and electrons in the auroral region and polar cap.The work was supported in part by INTAS grant 96-2346.

GA 4.08/E/22-B3 1555

ROLE OF HELICON MODES IN THE INJECTION OF OXYGEN IONS IN THE RING CURRENT

G. S LAKHINA (Indian Institute of Geomagnetism, Colaba, Mumbai-400 005, India, email: lakhina@iig.iigm.res.in)

The presence of an ionospheric-origin anisotropic oxygen ion beam can excite a helicon mode instability in the near-Earth plasma sheet region. The helicon mode instability could be excited under the conditions when the usual long wavelength fire-hose modes are stable. The modes are are likely to attain saturation as the typical e-folding time of the instability is about a few minutes in the near-Earth plasma sheet region. Therefore, the instability could significantly affect substorm dynamics and lead to enhanced ionosphere-magnetosphere coupling. Low-frequency turbulence produced by these modes could scatter electrons trapped in the inner central plasma sheet region and help excite the ion tearing modes, leading to substorm onset.

As a result the oxygen ions would be injected towards the Earth's nightside magnetosphere. Repeated injection by this process would lead to enhanced oxygen ions in the storm-time ring current.

GA4.08/W/11-B3 1620

THE GEOTAIL ORBIT MAY 12 TO 17, 1997 – AN OUTSTANDING EXAMPLE FOR SOLAR-TERRESTIAL INTERACTION

B. WILKEN, Q.G. Zong (Max-Planck-Institut fuer Aeronomie,D-37191 Katlenburg-Lindau, Germany, email: wilken@linmpi.mpg.de); T. Doke (Advanced Research Center for Science and Engineering, Waseda university, Tokyo, Japan); T. A. Fritz (Boston University, Boston, USA); M. Grand (Space Science Division, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, England); S.Livi, U. Mall (Max-Planck-Institut fuer Aeronomie,D-37191 Katlenburg-Lindau, Germany)

In the interval of interest the elliptical 8 x 30 Re Geotail orbit had a apogee in the undisturbed solar wind at about 1500 LT. On the outbound path, the spacecraft crossed the magnetopause at 0900 LT and bowshock 1030 LT. The interplanetary loop of the trajectory (outside the bow shock) started early 13 May and continued until the beginning of May 16 when Geotail passed the bow shock on the inbound leg at a local time position of 1800 LT. The inbound magnetopause crossing occurred at 1930 LT.Throughout the interplanetary segament Geotail observed the arrival of flare particles on April 12, the appearence of a CME on 15-16 May which appears to be intimately connected with a CIR. In addition, an energetic oxygen event was observed when Geotail appoached the dusk magnetopause. This paper provides a global perspective of this interest interval.

GA4.08/E/01-B3 1645

PROBLEMS OF IONOSPHERIC F-LAYER STORMS

Henry RISHBETH (Department of Physics and Astronomy, University of Southampton, Southampton SO17 1BJ, UK, email: hr@phys.soton.ac.uk)

The effects of geomagnetic activity on the ionospheric F-layer are complex and difficult to understand in detail. The most striking changes are the large decreases of F-layer electron density during large magnetic storms. The well-catalogued "initial-phase" and "main-phase" effects in F-layer storms are well on the way to being understood, it being widely accepted that changes of neutral air composition play a big part in at least the "main-phase" changes of electron density. Many intriguing problems remain, however, for example how storm effects depend on solar activity, to what extent they might be predictable, and the response of the F-layer to low levels of magnetic activity that cannot be classified as well-defined"storms".

GA4.08/W/18-B4 Invited 0830

MAGNETOSPHERE-IONOSPHERE COUPLING: HOW DO OXYGEN IONS GET INTO THE STORM-TIME RING CURRENT AND WHY IS THERE A DELAY?

HARLAN E. SPENCE (Boston University Center for Space Physics, 725 Commonwealth Avenue, Boston, MA 02215, email: spence@bu.edu), J. L. Roeder and J. F. Fennell (The Aerospace Corporation, P.O. Box 92957, Los Angeles, CA 90009), R. Friedel (Los Alamos National Lab, Mail Stop D-436, Los Alamos, NM 87545), T. A. Fritz (BU), and M. Grande (Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire, OX11, OQX, England)

During geomagnetic storms, the composition of magnetospheric ring current ions can change dramatically. The main phase of a storm is accompanied by the appearance of heavy ions, most notably oxygen. The heavy ions during storms can often contribute significantly to the total energy density of the hot magnetospheric ion population. At times it can be the predominant component of the total plasma pressure. Therefore, it plays an important dynamical role in the physical development of magnetic storms. In this presentation, we shall review the latest observations of heavy ions in the magnetosphere from data collected by the NASA/USAF CRRES satellite and most recently by the CAMMICE experiment on the NASA/POLAR satellite. We shall compare the heavy ion composition as a function of magnetic storm strength and prior activity history. One critical parameter, the time delay between magnetic storm onset and the arrival of energetic heavy ions into the ring current will be explored. Finally we shall assess the role of the ionosphere as a source for magnetospheric, energetic heavy ions and the physical mechanisms for ion transport.

GA4.08/W/13-B4 0905

ENERGETIC OXYGEN EVENTS IN THEMAGNETOSHEATH CAUSED BY GEOACTIVITY

Grand (Space Science Division, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon,England) S.Livi, U. Mall (Max-Planck-Institut fuer Aeronomie, D-37191 Katlenburg-Lindau, Germany), D. J. Williams (The Johns Hopkings University, Johns Hopkins Roade, maryland, USA)

On 26 January 1994, two energetic oxygen ion bursts were observed in the dayside magnetosheath when the spacecraft was located at (4.3, 16.3, 0.7) R_e. The oxygen enhancements peaked at energies of about 260 keV. The commencement of the two impusive flux increases at 1405 and 1440 UT are delayed by about 15 minutes elative to the onset of two substorm injections at 1349 and 1422 UT. On 10 January 1997, the impact of a CME led to a moderate storm (Dst=-84 nT). Thoughtout the early phase of the storm Geotail was skimming the afternoon magnetopause and observed energetic oxygen intensities persisting for 150 min. The angular distributions of these ions are rather anisotropic. The oxygen events are characterised by strong impulsive increases in the flux whereas energetic protons and helium ions were essentially absent. These observations suggest that heavier energetic ions can leak out of the dayside magnetosphere into the magnetosheath during magnetospheric activity.

GA4.08/W/03-B4 Invited 0930

DEVELOPMENTS, POSSIBLE INTERACTIONS, AND DECAY OF THE MAGNETOSPHERIC RING CURRENT AND THE MAGNETOTAIL CURRENTS

J.U. KOZYRA, C.R. Clauer, T.I. Gombosi, M.W. Liemohn, J. Lande, D.L. DeZeeuw, C.P.T. Groth, K.G. Powell (University of Michigan, Ann Arbor, Michigan 48109-2143 USA, email: jukozyra@engin.umich.edu)

The Dst-index, corrected for the effects of magnetopause currents, has commonly been used to track the development and decay of the ring current during magnetic storms. In-situ observations of energetic ring current ions imply that the Dst index may not always monitor changes solely in the ring current but may reflect important contributions from other current systems. Recent studies examining the relationship between the symmetric ring current, the partial ring current, and the magnetotail current, and their relative contributions to the Dst-index, are reviewed. To examine the possible advantages of more complete local time magnetic field information, a drift-loss model of the ring current is used to calculate the local-time-dependent depression in the surface magnetic field due solely to the ring current during its development and decay. These model-generated magnetic field signatures are compared to observations from a longitudinal chain of 18-20 mid-latitude magnetometers. Contributions from various current systems are identified in the magnetometer data on the basis of characteristic spatial and temporal signatures. A local-time-averaged magnetic field depression is derived from this data and compared to the modelled and observed Dst-indices. Finally, an investigation of the magnetic signature at the Earth's surface of the partial ring current and tail currents, and their strength relative to the ring current contribution, is made using the BATS-R-US global MHD model. Since there are some events in which the velocity (V) and the number density (N) values in the cloud change substantially with respect to those in the nearby structures, we address the role of the dynamic pressure (1/2NmV^2) in the overall pressure distribution.

GA4.08/W/14-B4 1035

PROPOSAL OF A SET OF DST-AFFILIATED INDICES FOR IMPROVEMENT OF MAGNETIC STORM INTENSITY REPRESENTATION

Masahisa SUGIURA (Research Institute of Science and Technology, Tokai University, Tokyo 151-0063, Japan, email: sugiura@jspan.kugi.kyoto-u.ac.jp) Toyohisa Kamei (Graduate School of Science, Kyoto University, Kyoto 606-8512, Japan, email: toyo@kugi.kyoto-u.ac.jp)

In the recent years, considerable attention has been paid to the relationship between solar wind parameters and magnetic storms and/or substorms. The relationship between magnetic storms and substorms still remains to be an unsettled problem. In the studies of these subjects and also in the investigations of various disturbance phenomena, the Dst and AE indices are frequently used as numerical parameters representing the intensities of magnetic storms and substorms, respectively. However, by definition, the Dst index expresses only the axially symmetric component in the Fourier expansion of the low latitude disturbance magnetic field on the earth's surface with respect to local time. In the development phase to the maximum phase of magnetic storms, especially in intense magnetic storms, higher harmonic components are generally not negligible. A proposal is made to make a set of parameters affiliated with the conventional Dst index available to the scientific community to improve magnetic storm representation for the studies on various aspects of magnetic storms. Using the proposed parameters, a statistical and case investigation of axially asymmetric magnetic storm fields is made, giving attention to the phases of the higher harmonics. Relations to other disturbance phenomena are also discussed in the context of this set of parameters.

GA4.08/W/09-B4 1105

THE GEOTAIL AND RING CURRENT DYNAMICS UNDER DISTURBED CONDITIONS

V.V. KALEGAEV (Institute of Nuclear Physics, Moscow State University, 119899 Moscow, Russia)

The magnetospheric magnetic field is highly time-dependent and may undergo rapid changes (magnetospheric substorms and geomagnetic storms). These are events during which the most interesting magnetospheric physics phenomena (auroras, precipitations at high latitudes, acceleration of particle beams in the geotail etc.) occur. The dynamics of magnetospheric large-scale current systems was studied for the case of magnetic storm on 23-27 November 1986 using the dynamic paraboloid model and data of on-ground and satellite measurements.
A set of "submodels" calculating the magnetospheric current systems response to the changes in solar wind conditions was developed. The magnetic field variations at the Earth's surface as well as on the geostationary orbit are calculated and compared with the Dst and GOES 6 measurements respectively. Comparison of independently obtained magnetopause currents, ring current and geotail currents contributions into Dst shows that they are about one order.
The energy stored in geotail is calculated in terms of paraboloid model. It correlates strongly with the energy flow in the magnetosphere generated by solar wind - magnetosphere dynamo. The total energy of ring current particles is calculated using data of AMPTE/CCE measurements. It was shown that this energy increases when auroral activity diminishes. During substorm activity energy stored in the magnetotail transports mainly to the auroral ionosphere.

F-REGION RESPONSE TO GEOMAGNETIC DISTURBANCES

A.D. DANILOV (Institute of Applied Geophysics, Rostokinskaya 9, Moscow 129 128, Russia)

The F2-region response to geomagnetic disturbances usually called an ionospheric storm is a rather complicated event. It consists of so called positive and negative phases, which have very complicated spatial and temporal behaviour. During the recent decade there was a significant progress in understanding of this behaviour. The principal features of the positive and negative phase distribution and variations have been explained on the basis of the principal concept: during a geomagnetic disturbance there is an input of energy into the polar ionosphere, which changes thermospheric parameters, such as composition, temperature and circulation.
Composition changes directly influence the electron concentration in the F2 region. The circulation spreads out the heated gas to lower latitudes. The conflict between the storm-induced circulation and regular one determines spatial distribution of the negative and positive phases in various seasons. There are still problems unsolved. The most acute ones are: the appearance of positive phases before the beginning of a geomagnetic disturbance, occurrence of strong negative phases at the equator, the role of vibrationally excited nitrogen in forming the negative hase, the relation of positive phases to the dayside cusp.

GA4.08/E/06-B4 1335

A REVIEW OF THE EFFECTS OF GEOMAGNETIC STORMS ON THE HIGH AND MID-LATITUDE THERMOSPHERE AND IONOSPHERE

DAVID REES (CASS, Utah State Univ. Utah State University, Logan, UT 84322-4405, USA). Email: walnut1@easynet.co.uk,)

During geomagnetic storms, the interaction of the solar wind with the magnetosphere generates a large and highly variable, inflow of energy and momentum through the combination of intense Joule and particle heating, and through momentum coupling from the rapidly-motion of ionospheric plasma to the neutral gas via ion drag. At times of very large geomagnetic disturbances, the auroral oval expands equatorward, sometimes penetrating to 45o magnetic latitude, or even lower. The large and complex disturbances generated within

the high-latitude thermosphere may be seen as large increases of temperature, density, major changes of neutral composition, while very rapid wind flows and large amplitude waves are also generated which may subsequently propagate creating truly global effects. Gross disturbances of the global ionosphere usually accompany these thermospheric disturbances. The ionosphere not only reacts to changes thermospheric density, composition and flows, but also to changes of ionisation sources and processes directly exciting ions and electrons. Observations describing the nature and scale of disturbances of the thermosphere and ionosphere during geomagnetic storms will be evaluated, using appropriate numerical simulations by global coupled models, highlighting the distinct roles of nergetic, dynamical and chemical coupling between the thermosphere and ionosphere.

GA4.08/E/05-B4 1400

HEIGHT PROFILE OF THE EFFECT OF GEOMAGNETIC STORMS BETWEEN THE IONOSPHERE MAXIMUM AND THE TROPOSPHERE

Jan LASTOVICKA (Institute of Atmospheric Physics, Bocni II, 141 31 Prague 4, Czech Republic, email: jla@ufa.cas.cz); Alexei D. Danilov (Institute of Applied Geophysics, Rostokinskaya str. 9, 129226 Moscow, Russia, email: hciag@sunny.aha.ru)

A geomagnetic storm is a complex process. Its various features act at different heights. In the F2 region, the mid-latitude effect is basically an ionospheric response to storm-induced changes in the neutral atmosphere, which are primarily a consequence of a strong Joule heating of the auroral thermosphere. At lower heights, the role of ionization and photochemistry processes increases due to shorter electron lifetime. At the base of the F1 region (h ~ 160-170 km), the storm effect is almost absent. Further down, the most pronounced feature is the filling in the valley between E and F regions. At E-region maximum a complex action of several factors results in a slight decrease of foE, even though below and above the electron density increases. Further down, in the lower ionosphere, a large increase of electron density is observed as a consequence of a very large increase of particle precipitation. In the neutral upper middle atmosphere, the effects of enhanced particle precipitation weaken with decreasing altitude and become insignificant and/or absent in the stratosphere. The effect of geomagnetic storms re-appears in the lower atmosphere, but as an effect of different morphology and origin. The most promising mechanism seems to be at present Tinsley's hypothesis of "electrofreezing". Thus, we find three height regions of distinctly different processes: (1) F2-region, where the ionospheric effect is basically a response to storm-time changes of the neutral thermosphere, (2) the lower ionosphere and upper middle atmosphere, where the effects are caused by storm-related precipitation of energetic particles, (3) the lower atmosphere, where the effect is possibly related to changes in galactic cosmic rays and atmospheric electricity.

GA4.08/P/02-B4 1425

IONOSPHERIC STORM EFFECTS AT MILLSTONE HILL DURING THE GEOMAGNETIC STORMS OF 5-14 JUNE 1991: COMPARISON OF THE IZMIRAN MODEL RESULTS AND DATA

A V PAVLOV (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russia Academy of Science, Troitsk, Moscow Region, 142092, Russia)

This study compares measurements of the ionospheric F region at Millstone Hill during the severe geomagnetic disturbances of 5-14 June 1991 with results from the IZMIRAN time-dependent mathematical model of the Earth's ionosphere and plasmasphere. The inclusion of the measured exospheric temperature in the MSIS-86 model and the atomic oxygen correction factors improves the agreement between the modelled and measured NmF2 and electron temperatures. Anomalously low values of the F-peak altitude seen as a "G condition" on ionograms and observed on June 5, 10, and 13 exist in the ionosphere due to wind-induced plasma drift velocities, when a poleward wind forces O+ ions to lower altitudes where the increased recombination rate decreases [O+] and increases [NO+] and [02+]. The increases in the O+(4S) + N2 loss rate due to vibrationally excited N2(v) and 02(v) lead to the decreases in the daytime F2 peak electron density up to a factor of 2 and 1.4 respectively. The difference between the non-Boltzmann and Boltzmann distribution assumptions of 02(v) and between ion and neutral temperature can lead to an increase up to about 7% or a decrease up to about 8% of the calculated NmF2 and to changes of the electron temperature up to 3OO K as a result of an increase or a decrease of the loss rate of O+(4S) ions and the electron cooling rate. The IZMIRAN model uses the new cooling rate of thermal electrons by electron impact excitation of fine structure levels of atomic oxygen based on the revised excited cross sections (Bell et al., Monthly Notices of the Royal Astronomical Society, 293, L83-L87, 1998). It is found for the first time that this cooling rate is not one of the dominant electron cooling processes in the F region of the ionosphere.

GA4.08/E/03-B4 1520

F1 LAYER AT GEOMAGNETICALLY DISTURBED TIME AT LOW SOLAR ACTIVITY AS MEASURED AT PRUHONICE STATION

D. BURESOVA (Institute of Atmospheric Physics, Bocni II, 141 31 Prague Czech Republic, e-mail: buresd@ufa.cas.cz)

This paper attempts to demonstrate the changes of the F1layer main parameter and structure during geomagnetic storms. To analyse F1 region behaviour we have selected ten periods of rather strong geomagnetic activity (5<Kp<8) with similar course and with at least three 91quiet91 days before the event for different seasons from 1994 - 1996. The electron density profiles for these periods, derived from all available hourly ionograms from Pruhonice station (50B0N, 15B0E) were analysed to investigate electron density variability of the F1 layer.
Seasonal differences and a diurnal asymmetry of the effects in the F1 layer are presented. The storm negative influence in NmF2 appears to be much stronger in the morning than in the afternoon hours, mainly for spring, geomagnetically disturbed time. We haven92t found a significant effect of geomagnetic storm in electron density in the F1 region in spring while there is a substantial effect in autumn at 180 and 190 km heights. We have compared our results with these obtained from ionograms from some other European ionospheric stations. In general, the F1 layer appears to be much more stable during geomagnetic storms than the F2 layer.

GA4.08/W/01-B4 Invited 1545

GEOMAGNETIC FIELD MODELLING FOR MAGNETIC STORMS AND ITS COMPARISON WITH OBSERVATIONS

Igor. ALEXEEV (Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: alexeev@dec1.npi.msu.su); Yasha Feldstein (Institute of Terrestrial Magnetism, Ionosphere, and Radio Wave Propagation of the Russian Academy of Science, Troitsk, 142092 , Russia, email: gromova@izmiran.rssi.ru)

The main topics which will be discussed: a) the development of the dynamic paraboloid magnetospheric model; b) the usage of this model for calculation of contributions of Chapman-Ferraro current, the ring current, and currents in the tail plasma sheet to the ground magnetic field variations during magnetic storms; and c) investigation of auroral electrojets dynamics, behavior of boundaries of plasma precipitation and usage the paraboloid magnetic field model for revelation of the interrelationship between geomagnetic phenomena at low altitudes and large-scale magnetospheric plasma structure. Key parameters of the model, ground state of the magnetosphere and its energy were determined. Input model parameters were determined by the solar wind velocity and density, IMF strength and direction, tail lobe magnetic flux value of F , and total energy of ring current particles. The characteristic boundaries of the auroral particle precipitation, determined based on DMSP particle measurements, were used to calculate a value of F . The influence of the field-aligned, tail and ring currents on the magnetospheric magnetic field structure was studied. It was found that the polar cap area is strongly controlled by the tail current. The paraboloid model was used for mapping the electrojet center and boundaries into the magnetosphere, and the study of the relationship between electrojets and magnetospheric plasma domains during magnetic storms. Analysis of magnetic field variations during magnetic storms shows that the contribution of the ring current, tail current and magnetopause currents to the Dst variation are roughly equal.

GA4.08/W/16-B4 1610

TEMPORAL AND SPATIAL DEVELOPMENT OF THE RING CURRENT DURING MAGNETIC STORMS INFERRED FROM GROUND MAGNETIC DATA

C. R. CLAUER, J. Lande, J. U. Kozyra, M. Liemohn (Space Physics Research Laboratory, University of Michigan, Ann Arbor, MI 48109-2143, USA, email: rclauer@umich.edu)

The Dst-index is traditionally utilized to characterise the development and decay of the ring current during magnetic storms. This index, however, has many shortcomings, which have been discussed by a number of authors in recent meetings and papers. For example, the tail current, partial ring current, and magnetopause boundary currents all make contributions to the disturbance field which do not necessarily cancel, nor which are adequately corrected for in creating Dst. In addition, the ring current development and decay processes are not symmetrically distributed and do not necessarily produce a symmetric ring current. Thus, it is important to undertake the analysis of the low latitude storm-time magnetic disturbance field in both high temporal and spatial resolution. Using data from a longitudinal chain of 18 to 20 midle atitude magnetic observatories, we investigate the world-wide disturbance field during several magnetic storms. We find both symmetric and asymmetric development and decay of the magnetic disturbance field. Comparisons with theory are obtained by comparison with results obtained using the Ring current Atmospheric interaction Model to compute and track the local time dependent depression of the surface magnetic field through the same events.

INFLUENCE OF SHOCK-INDUCED IONOSPHERIC CONDUCTIVITY ENHANCEMENTS ON STORM MAIN PHASE INTENSITIES

B. TSURUTANI, X.-Y. Zhou, J.K. Arballo, and D. Winterhalter, (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, 91109, email: btsurutani@jplsp.jpl.nasa.gov) T. Araki (Kyoto University, Dept of Geophysics, Kyoto 606, Japan); H. Yang (National Institute of Polar Research, Tokyo, Japan); G. Rostoker (University of Alberta, Edmonton, Alberta, Canada T6G 2J1); T. J. Hughes (Canadian Space Agency, PO BOX 7275, Vanier, ON. Canada K1L 8E3) R. P. Lepping and D. Berdichevsky (Goddard SFC, Code 695.0, Greenbelt, MD 20771) W. D. Gonzalez (INPE - CAIXA Postal 515, 12200 Sao Jose Dos Campos, Sao Paulo, Brazil)

Interplanetary shocks lead to SIs and SSCs (SIs with following magnetic storm main phases). It is well known that the IMF BS within the interplanetary sheaths and magnetic clouds lead to strong magnetic reconnection and the main phases of magnetic storms. However, the shocks themselves can cause enhanced dayside aurora and nightside pseudobreakups (PBs) and substorm expansion phases. Interplanetary shocks compress the outer magnetosphere, lead to adiabatic compression of pre-existing magnetospheric plasma, and loss of particles to the ionosphere by the loss cone instability. The particle loss is associated with the auroral light intensification and also enhanced ionospheric conductivity.
The latter effect, enhanced ionospheric conductivity, may influence the intensity of the magnetic storm main phase, which follows. We examine the WIND 1997 interplanetary shocks to study dayside aurora, nightside PBs and substorms. We will comment on the ionospheric effects on later storm main phase intensities using specific examples.

RELATIONSHIP BETWEEN THE SOLAR SOURCES OF INTERPLANETARY PLASMA STREAMS AND TYPES OF LONG AURORAL DISTURBANCES

M.G.GELBERG, S.Z.Kershengolz, S.V.Sharaeva (Institute of Cosmophysical Research and Aeronomy, 31 Lenin Ave., 677891 Yakutsk, Russia, email: lae@sci.yakutia.ru)

The influence of four solar sources: suddenly disappearing filaments (SDF), coronal holes (CH), heliospheric current sheet (HCS) and solar flares (sf) on the development of four types of long (>10 h) auroral disturbances (HILDCAA) for 51 events are investigated. At the analysis the classifications of interacting streams of interplanetary plasma (by K.G. Ivanov) and HILDCAA (by the authors) are used.
It is shown that SDF streams creates the second type HILDCAA, for CH and HCS stream classes the first type HILDCAA predominate, sf-streams causes the third type HILDCAA. It is found that in interacting of interplanetary plasma streams from a few solar sources, the total intermixing of streams near the Earth's orbit did not occur. It is found that if SDF stream interacted with the streams from other solar sources, then in auroral zone the second type HILDCAA was developed. Sf-streams probably are less dominated in the streams of mixed classes.
The fourth type of HILDCAA coinciding with the stationary convection periods is observed only one time, 16.08.78, when the Earth crossed the SDF+CH streams, but the probability of its appearance is about 0,25. Its absence in the considered events testifies to the non-completeness of classification of interplanetary plasma streams and their solar sources by K.G. Ivanov.

GA4.08/E/11-B3 Poster 0900-02

DISTRIBUTION OF HILDCAA OF DIFFERENT TYPES FROM SEASON TO SEASON AND IN A SOLAR ACTIVITY CYCLE

M.G. GELBERG, S.Z. Kershengolz, S.V. Sharaeva (Institute of Cosmophysical Research and Aeronomy,31 Lenin Ave., 677891 Yakutsk, Russia, email: lae@sci.yakutia.ru)

A possibility to classify the long auroral disturbances (HILDCAA) into four types by using

minute values of auroral indices has been shown. The variations of HILDCAA appearance frequency of each type from season to season and in a solar activity cycle are investigated on data of auroral indices for the period of 1978-1993. It is found that a probability of appearance of the first type HILDCAA has two maxima in spring and in autumn, and minima- in summer and in winter. The distribution of the appearance frequency of the fourth type HILDCAA has a wide maximum in the period from April to August, and for the remaining months of an year it is equal to 1/4 of maximum one. In seasonal distributions for the second and third types a clear minimum in June and growth of the probability of HILDCAA appearance to the winter months are found.
The analysis of distribution of the appearance probability of different type disturbances of HILDCAA in a solar activity cycle shown that appearance frequency of the first and fourth types was maximum in years of maximum solar activity, and for the second and third types- at the minimum solar activity.

PERIODICITIES IN GEOMAGNETIC STORMS AND SOLAR ACTIVITY CYCLE

Probhas RAYCHAUDHURI (Department of Applied Mathematics, Calcutta University, Calcutta 700 009, India email: prc@cucc.ernet.in)

Geomagnetic storms are large disturbances in the Earth's magnetosphere, often sustaining for several days or more. During the period of geomagnetic storms, the magnetic field measured at the surface of the Earth perturbed by strong electric field flowing within both the magnetosphere and ionosphere, the aurora brightness and extends to low magnetic latitudes, and intense fluxes of charged particles are generated within the magnetosphere. Periodicities in geomagnetic storms are of very much interest to us because of their adverse effects on radio communications, satellite systems and power grid etc. In this paper we have studied 173 geomagnetic storms data which are related with the Forbush decreases (FD for the years 1976-1986 and have found that geomagnetic storms data exhibit periods around 1.5, 2.38, 4.81 and 7.56 years at 99% confidence level (CL). We have studied also FD with solar flare data and major solar proton events (SPE) data (E>10 MeV) for the years 1976-1986 and have found that FD, solar flare data exhibit periods around 0.95, 2.4 and 4.75 years at 99% CL, while SPE data exhibit periods around 2.6 and 5.0 years at 95% CL. We expect also that coronal mass ejections(CMEs) have the same periodic behaviour as SPE data, geomagnetic storms data etc. are associated with CMEs. Common periodicity around 2.5 years of solar neutrino data, sunspot number data, FD data, major solar proton events data, geomagnetic storms data etc. suggest that they behave similarly and may have a common origin.

THE ENERGY INPUT TO THE AURORAL REGION DURING TWO TYPES OF GEOMAGNETIC STORMS

L.P.SHADRINA and V.G.Vasilieva (Institute of Cosmophysical Research and Aeronomy SB RAS, 31 Lenin ave., Yakutsk, 677891, Russia email: l.p.shadrina@sci.yakutia.ru)

The geomagnetic storms for the period from 1973 to 1986 was examined. It is shown, that during two types of storms, differs by the numerical parameter b = (DDst / SAE), the energy input to the auroral region has an essential distinctions. During first type storms (with b > 0.02) the energy enters to the auroral activity by impulsive processes. This display both in auroral oval dynamics and in auroral indices behaviour. Second type of storms (with b < 0.01) accompanies by gradual energy input to the auroral zone. It is proposed, that the cause of this difference is a high values of interplanetary magnetic field variability sH during first type of geomagnetic storms.

THE DISTRIBUTION OF ENERGETIC OXYGEN EVENTS IN THE MAGNETOSHEATH

Q.G. ZONG, B. Wilken (Max-Planck-Institut fuer Aeronomie, D-37191 Katlenburg-Lindau, Germany Email: zong@linmpi.mpg.de)

GEOTAIL observations with the HEP-LD spectrometer in the dayside magnetosheath between Jan. 1996 and Dec. 1997 have been examined with respect to the occurrence of bursty oxygen events. The oxygen observed in these events has an energy from 140 to 4000 keV, the origin is thought to be terrestrial. Without exception the bursts are observed in association strong geomagnetic activity (magetic storms or substorms). The occurrence frequency of oxygen burst events exhibits a strong dawn-dusk (GSE Y axis) symmetry. All oxygen events have been detected in the duskside magnetosheath. Since these oxygen ion events in the magnetosheath are strongly related to magnetic storms, it is thus suggested that the oxygen ions may escape from the ring current via a dayside reconnection or leakage process.

STORM-SUBSTORM RELATIONSHIP: THE "MAIN" SUBSTORM

Lyudmila V. TVERSKAYA (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: tverskaya@taspd.npi.msu.su)

Development of the concept of the "main" substorm has a long history. It has started in 70-s as far as was shown the shift of the west electrojet to L~3 at the main phase of a strong magnetic storm. All published cases of direct observations of the ring current asymmetry were analysed. To the day, just one case has been registered on a time scale compared with substorm duration (~1 hour). As appears, in that case the night-day asymmetry of the main-phase ring current measured near the equatorial plane has a sign opposite to that calculated from the low-latitude magnetic stations' data. This effect was explained as a result of distortion of Dst-variation by the strong polar electrojets and it was observed in several storms. Last year a substorm that is characterised by the lowest latitude position of the auroral electrojets during the main phase of a storm has been called the "main" substorm. As is shown for many storms, electrojets reach their lowest latitude position some hours before |Dst| reaches its maximum. Various approaches to the study of an empirical dependence of the west electrojet position (Lwj) on Dst amplitude are compared. The formula that well describes this dependence in whole range of the storm Dst amplitudes (50 - 600 nT) is: |Dst|=27500/(Lwj)**4.
Contribution of "main" and other substorms to the formation of the storm ring current is discussed.

INTERPLANETARY AND GEOMAGNETIC PRECURSORS OF FORTHCOMING GEOMAGNETIC STORMS

K.G.IVANOV, E.P.Romashets, and V.G.Petrov (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of Russian Academy of Sciences (IZMIRAN); Troitsk, Moscow Region, 142092 Russia, email: romash@izmiran.rssi.ru)

Three phase dynamics of the interplanetary and geomagnetic disturbances is usual during the Earth's voyage through the coronal streamer belt. As a rule, a broad region just ahead of a forward interplanetary shock wave is responsible for the first (growth) phases of such disturbances (heliospheric substorms).
These regions and their geomagnetic effects may be considered as precursors of forthcoming more intensive disturbances. The MHD structure of typical interplanetary precursors (January 4-5 and May 14, 1997 ISTP events) and their geomagnetic effects will be considered.

LOW-FREQUENCY OSCILLATIONS BEFORE RECURRENT HIGH-SPEED FLOWS - THE POSSIBLE FORERUNNERS OF MAGNETIC STORMS.

Olga KHABAROVA (Department of Solar-Terrestrial Physics, The Institute of Terrestrial Magnetism, Ionosphere and Radiowaves Propagation, Russia 142092, Moscow region, Troitsk;
email: MARY.L@izmiran.troitsk.ru)

Steady long-period (from minutes till hours) oscillations of solar wind components before high-speed flows are considered. The conditions of their origin and consequent effect on the magnetic field of the Earth are discussed. 10 high-speed with most precisely exhibited such oscillations are chosen. Is found out, that the oscillations of various periods have a various nature, in the main they appear due to large-scale instabilities. The most low-frequency oscillations are registered in region of orbit of the Earth before recurrent high-speed flows from coronal holes. The calculations show, that they are evoked by gradient instabilities of solar wind plasma near high-speed flow. For the half of selected flows there are data about practically simultaneous registration of magnetic field of the Earth oscillations of close frequencies (range Pc6). Thus, it is possible to assume, that considered long-period oscillation can excite the oscillations of geomagnetic field and to be forerunners of magnetic storms.

MAGNETIC STORM EFFECTS ON EQUATORIAL ELECTROJET CURRENT

R.G.RASTOGI, (Department of Physics, Gujarat University and Physical Research Laboratory, Ahmedabad 380 009 India, email: parvs@prl.ernet.in

It has been shown that every one of the aspects of a magnetic storm i.e. storm sudden commencement (SSC), storm time variation (Dst), and disturbance daily variation (SD) in all the three D, H and Z components of the geomagnetic field at low latitudes has a characteristic special signatures of the equatorial electrojet. Distinct longitudinal inequalities in these storm effects are identified with some non-dipole characteristics of the earths magnetic field. The preliminary negative impulse in SSC(H) at equatorial latitudes are shown to be related to the IMF changes during the impact of solar plasma with the earths magnetosphere.

MAGNETIC DISTURBANCE EFFECTS ON DECLINATION AT LOW AND MIDDLE LATITUDES

RASTOGI, R.G. and M.E.James (Department of Physics, Gujarat University, Ahmedabad 380 009, India Winch, D.E., School of Mathematics and University of Sydney, Sydney NSW Australia)

The Eastward component (Y) at geomagnetic field at low and middle latitudes are studied for storm time and disturbance daily variations. Storm time (Dst) variations in Y are shown to faithfully follow the corresponding variations of Dst variations of H field at equatorial and low latitudes. Significant longitudinal effects are isolated in the disturbance effects in Y field. Quantitave explanations are given for the observed effects at different longitudes around the earth. It is concluded that the disturbance ring current cannot be considered as axially symmetric for explaining the observed storm time effects on ground magnetic fields.

FIELD -ALIGNED CURRENTS AS SEEN BY THE POLAR AND INTERBALL -2 DURING 11 JANUARY 1997 EVENT

A.Z. BOCHEV 1, Guan Le 2 , V.G. Petrov 3 , D.L. Danov 1 , Y.I. Feldstein 3, P.T. Newell 4 1 Solar - Terrestrial Influences Laboratory, BAS, Sofia, Bulgaria 2 Institute of Geophysics and Planetary Physics, Los Angeles, USA 3 Institute of Earth's Magnetism and Radiowave Propagation (IZMIRAN), Moscow, Russia 4 Applied Physics Laboratory, The John Hopkins University, Laurel, USA

In this talk field-aligned currents (FAC) in the north auroral magnetosphere during the CME geomagnetic storm on January 11,1997 are examined by using data mainly from magnetic field experiments on board of INTERBALL -2 and POLAR satellites. During the event from 0300 to 0600 UT, the spacecrafts crossed the dusk side from low to high latitudes in the altitudinal range 12000 to 40000 km. FAC structures were identified for sure on both magnetograms. The measurements permitted to monitor two unusual FAC systems separated from each other. The equatorward system was a remarcable demonstration of intense oscillating fields during steady Bz IMF >>0, immediately after the end of the most dramatic compression of the magnetosphere. In contrast the poleward system appeared as irregular structures probably controled by a strong unsteady By IMF. Correlations with double -theta aurora are discussed also.

MAGNETIC EFFECT OF REGION 1 FIELD-ALIGNED CURRENTS IN A COURSE OF MAGNETIC SUBSTORM

Elena BELENKAYA (Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, Email: Elena@dec1.npi.msu.su)

In a course of magnetic substorm, dynamics of the Region 1 field-aligned currents generated by the solar wind is considered. Based on a simple spherical model, magnetic field of the field-aligned currents is calculated everywhere up to on-ground level. During magnetic storm the polar cap boundary significantly shifts equatorward together with zones where Region 1 field-aligned currents flow into and out of the ionosphere. The magnitude of the Region 1 field-aligned currents increases in a course of substorm. As a consequence, magnetic effect of the Region 1 currents significantly depends on a phase of substorm, and have a maximum in a main phase.

THE DYNAMICS OF INTERACTION BETWEEN MAGNETIZED SOLAR WIND FLOW AND THE EARTH--MAGNETOSPHERE SYSTEM

N.A. BARKHATOV (Nizhniy Novgorod State Pedagogical University, 1, Ulyanova str., Nizhniy Novgorod 603005, Russia, email: nikolay@barkh.sci-nnov.ru); N.S. Belliustin (Radiophysical Research Institute, 25, Bolshaya Pecherskaya str., Nizhniy Novgorod, 603600, Russia, email: nick@nbell.sci-nnov.ru); A.E. Levitin (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, 142092, Russia, email: lgromova@izmiran.troitsk.ru)

One-dimensional calculating medium for space-time dynamics simulation of interaction between the Solar wind magnetised flow and magnetosphere-Earth system is constructed. Possibility of elementary modelling of quasi-stationary structure like bow shock wave, arising at collision of space plasma flow with Earth magnetic field is investigated. Non-stationary transitional processes, induced by density and velocity inhomogeneities in a solar wind flow are analysed by means of calculating program. It is shown, that the calculating system allows to obtain theoretical graphics of possible magnetic field variations on Earth surface at various inhomogeneities' characteristics for comparisons by the measurements. Thus the numerical calculations allow to adjust a relationship between sharply varying conditions in the Solar wind (concentrations, velocities, components of interplanetary magnetic field) and amplitude and scale of impulse (including SI), registered on the Earth surface. Obtained forms of magnetic field variations can be used for co-interpretation of Earth and Satellite measurements on magnetic field and other medium parameters.

EXTERNAL MULTIDIMENSIONAL CLUSTER CLASSIFICATION OF GEOMAGNETOSPHERIC STORMS

Joseph KOVALEVSKY and Elena Kovalevskaya (Institute of Terrestrial Magnetism? Ionosphere and Radiowave Propagation RAS IZMIRAN 142092 Troitsk, Moscow Region, Russia, email: jkoval@izmiran.rssi.ru)

The external multidimensional cluster classification of 31 geomagnetospheric storms (GMS) by support processes is presented for the purpose of setting of comparatively homogeneous groups (clusters) of such events with rather alike in support processes and inner structures. Every GMS is characterized by inner structure, consisting of 32 measuring and derivate physical processes. The discussion is restricted to the case of four-dimensional classification. These GMS are analyzed from the point of view of the type and scale similarity of four support processes (Bz- and By- components of IMF, Dst- and AE- indices) of their physical core. The core is composed of storm initial and main phases and quick part of recovery phase. It is clearing up what of the greatest importance is for GMS external classification: the scale of changes of support processes or their character independent on the scale. It is demonstrated that for GMS cores two classifications are effective both according to inner processes similarity and according to inner processes correlativity. Two common clusters (with respect to both type and scale similarity) and two specific groups (for type and scale similarity) have been obtained. Obtained clusters and groups are characterized by different variants of inner structure, and hence by different variants of core physical development. Particular emphasis has been placed on the interplanetary- magnetospheric couplings analysis of three intense (Dst-124 #-149 nT) GMS of the scale similarity group. These storms have different complex internal physical structure development of which are impossible to represent by single known interplanetary parameter (say, Bz, Ey, or e).

AN INVESTIGATION OF INTENSE GEOMAGNETOSPHERIC STORMS USING SEQUENTIAL-CLUSTER ANALYSIS

Joseph KOVALEVSKY and Elena Kovalevskaya, Institute of Terrestrial Magnetism, Ionosphere and Radiowave Propagation, RAS, IZMIRAN, 142092, Troitsk, Moscow Region, Russia, e-mail: jkoval@izmiran.rssi.ru;

Intense geomagnetospheric storms (GMS) can be thought of as the complex system physical phenomena or as pattern recognition objects. For solution of part of unsolved GMS physical problems we invoke to adequate approach: to pattern recognition methods, including the sequentional and cluster analysis. The effectiveness of sequentional-cluster analysis of empirical and theoretical data is demonstrated on example of two GMS (27.08 and 28.09, 1978). The distinctive feature of these two GMS is that they have nearly equal minimal , mean value and dispersion of Dst -field and of IMF Bz - component, but rather different athimuthal interplanetary electric field (Ey), and Akasofu (e) and Murayama (FM) parameters. The GMS are characterized by interconnected set of 29 plasma processes of which 13 are initial and 16 are 'derivative' processes derived for physical interpretation of phenomenon. The 'geoeffective' parameters search, the most important processes relationships revealing and consideration of processes dynamic on the base of dendrite structure analysis are done. It is shown that none of the known theoretical 'geoeffective' parameters cannot provide an equally adequate interpretation of phases peculiarities of the whole Dst - processes. It has been revealed an important role of IMF Bx- and By- component and protone temperature T in the development of studied GMS. The Dst-AE couplings was weak.

THE OERSTED GEOMAGNETIC SATELLITE MISSION. INSTRUMENTATION AND DATA HANDLING. PRESENTATION OF INITIAL RESULTS

T. NEUBERT (1), P. Stauning (1), E. Friis-Christensen (2), F. Primdahl (2,3), J. Jxrgensen (3), I. Laursen (3), T. Risbo (4), and N. Olsen (2) 1. Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark. Fax: +45 3915 7460. E-mail: neubert@dmi.dk 2. Danish Space Research Institute, DK-2100 Copenhagen, Denmark 3. Dep. Automat., Danish Technical University, DK-2800 Lyngby, Denmark 4. University of Copenhagen, DK-2100 Copenhagen, Denmark

The Xrsted satellite is equipped with instrumentation for high-precision measurements of the Earth's magnetic field. The satellite, furthermore, carries instruments for detection of the high-energy charged-particle radiation environment and for remote sensing of the upper atmosphere. The Xrsted satellite is launched into a near-earth polar orbit in January 1999. The orbit has an inclination of 96 degrees and a height varying between 620 and 850 km. The initial orbit plane is at 15-03 hours local time. At a nodal drift of 0.77 degrees/day the satellite will achieve a noon-midnight orbit in the middle of its planned 14 months mission. The principal aim of the satellite is to accomplish an accurate mapping of the Earth's magnetic field arising from internal sources and the detection of current systems in space. Prime focus will be on high-latitude field-aligned current systems and energetic particle radiation and their coupling to ionospheric convection and polar radiowave absorption features. The presentation will briefly outline the instrumentation of the Xrsted satellite and describe the data handling procedures. The main emphasis will be on the presentation of initial results of the measurements from the satellite and correlated high-latitude ground-based observations.

GA5.08/E/02-B1 Invited **0920**

OERSTED INTERNAL FIELD SCIENCE AND INITIAL FIELD MODELS

Nils OLSEN (Danish Space Research Institute, Juliane Maries Vej 30, DK-2100 Copenhagen, e-mail: nio@dsri.dk), Robert A. Langel (Goddard Space Flight Center (Emeritus), Greenbelt/MD, 20707, USA), Torben Risbo (Geophysical Department, Copenhagen University, Juliane Maries Vej 30, DK-2100 Copenhagen) and Terence J. Sabaka (Hughes STX Corp., Lanham/MD, 20706, USA)

The main objective of the high-precision geomagnetic satellite mission Oersted (launched in January 1999) is to measure the Earth's magnetic field with an accuracy of better than 2 nT. We will present first results about the Oersted internal field research, and especially on the main field modeLling effort.

GA5.08/W/06-B1 **0945**

COMPARISONS OF MAGNETIC FIELDS MEASURED BY ØRSTED SATELLITE WITH MODELED HIGH-LATITUDE FIELD-ALIGNED CURRENT SYSTEMS

Vladimir PAPITASHVILI*, Freddy Christiansen, Torsten Neubert, Ole Rasmussen, and Peter Stauning (Danish Meteorological Institute, Lyngbyvej 100, DK-2100, Copenhagen, Denmark, email vp@dmi.dk; *also at SPRL, University of Michigan); Lidia Dremukhina and Anatoly Levitin (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, Russia, email: lgromova@izmiran.troitsk.ru)

An automated technique based on derivation of field-aligned current distributions for various IMF conditions from the IZMIRAN Electrodynamic Model (IZMEM, http://www.sprl.umich.edu/MIST) is developed and utilised for calculations of the magnetic field disturbances along the Ørsted satellite orbit. The "modelled" satellite magnetograms are compared with Ørsted observations to determine possible contributions to these measurements from the varying 3-D magnetosphere-ionosphere current systems. This allows better interpretation of satellite magnetograms over polar latitudes for case studies, as well as the construction of a new model of field-aligned currents from the Ørsted data. The presentation will focus on detailed comparisons of newly obtained field-aligned current distributions with the Iijima-Potemra Region 1/Region 2 system as well as with the cusp DPY currents for various IMF conditions. These new results and the automated technique could also be utilised for correction of satellite observations from the external field contribution over polar latitudes to better fit the data for the main geomagnetic field modelling.

GA5.08/W/02-B1 **1005**

PRELIMINARY RESULTS FROM THE DANISH SATELLITE OERSTED, A REPORT FROM THE IPGP GROUP

YVES COHEN, Gauthier Hulot, Mioara Mandea Alexandrescu, Pascale Ultré-Guérard, Benoit Langlais, Christophe Vernin, Jean-Louis Le Mouel (Institut de Physique du Globe de Paris, 4 Place Jussieu, 75252 Paris Cedex 05, France, email: cohen, ghulot, mioara, ultre, langlais, vernin, lemouel@ipgp.jussieu.fr)

The Danish magnetic satellite Oersted was to be launched on January 16, 1999 at 10:39:52 UTC, from Vandenberg Air Force Base inCalifornia, justa few hours after the final deadline for submitting the present abstract. It is therefore not yet clear what the status of the mission will be by the time of the meeting. IPGP being involved through CNES (French Space Agency) in the commissioning of the Overhauser magnetometer, our team nevertheless intends to report on at least some preliminary results concerning the intensity data acquired with this instrument. It is otherwise hoped that in the mean time, more complete data sets, acquired by both the OVH intensity magnetometer and the CSC vectorial magnetometer during the first few months of the flight, will also have been made available to the international community involved in the Oersted program. IPGP being part of this community (through two proposals, "Modelling the Earth's main magnetic field and characterising the equatorial electro-jet through its magnetic effects measured from space", "The variations of the field of internal origin: characterisation and interpretation"), we will hopefully report on our first preliminary results. These will mainly concern main field and secular variation modelling for the beginning of 1999, based on both Oersteddata and ground measurements. Tentative comparisons with models derived from the MAGSAT 1980 mission will also be discussed. Outline of our proposals will otherwise be recalled.

GA5.08/W/05-B1 1055

MODELING OF MAGNETIC FIELDS FROM HIGH-LATITUDE CURRENT SYSTEMS ALONG MAGNETIC SURVEY SATELLITE ORBITS

L. A. DREMUKHINA, Ya. I. Feldstein, A. E. Levitin (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, Russia, email: lgromova@izmiran.troitsk.ru); V. O. Papitashvili (Space Physics Research Laboratory, University of Michigan, Ann Arbor, MI 48109, USA, email: papita@umich.edu)

The IZMIRAN Electro-dynamic Model (IZMEM, http://www.sprl.umich.edu/MIST) is utilised to define the distribution of high-latitude field-aligned currents over both the Northern and Southern polar regions dependent on the interplanetary magnetic field (IMF) strength and direction. Then the magnetic field disturbances caused by these currents are calculated along the magnetic survey satellite orbit from the Biot-Savart's law for various IMF conditions. The magnetograms obtained by MAGSAT in 1979-1980 are modeled to show capabilities of the proposed technique. Calculations of the magnetic field contributions from field-aligned currents along the orbits can be performed in both the geographic co-ordinates and the "corrected geomagnetic latitude - magnetic local time" co-ordinates. The obtained modelling results are in good agreement with experimental observations in defining the high-latitude, field-aligned current spatial distribution. However, the offset produced by subtraction of the main magnetic field model (e.g., DGRF-1980) from satellite data causes some discrepancies; more studies are required in fitting the model with data and tuning the technique. Some applications of the proposed technique to the forthcoming magnetic satellite surveys (e.g., Oersted, CHAMP, etc.) are discussed.

GA5.08/W/09-B1 1115

EFFECT OF THE EQUATORIAL ELECTROJET ON INTERNAL MAGNETIC FIELD MODELS COMPUTED FROM SATELLITE DATA PASCALE

ULTRE-GUERARD and Yves Cohen (Institut de Physique du Globe de Paris, 4 Place Jussieu, 75252 Paris Cedex 05, France, email: ultre, cohen@ipgp.jussieu.fr)

At the beginning of the eighties, 20 years before the Oersted project, Magsat, the first satellite devoted to vectorial measurements of the total Earth magnetic field, has shown how such a dense and homogeneous satellite data set could improve magnetic field models. However, internal field models computed with satellite data include the ionospheric contributions since the horizontal ionospheric currents are located under the satellite orbit. This was a central issue with Magsat data as its orbit was sun-synchroneous at 6h and 18h, i.e., local times with significant ionospheric activity. In this study, we focus our attention on the equatorial electrojet current and quantify the error on main magnetic field and also crustal models due to this equatorial current. In doing so, residuals on each component of the magnetic field are computed by substracting main field models to the data and then averaged in 2 x 2 degree bins. These residuals are then fitted using a current sheet model and the result is referred to as the equatorial electrojet reference model (EERM), estimated at the Magsat altitude. This EERM is then inverted in a Spherical Harmonic Analysis up to degree and order 13. The computed model (EECM) is shown to have significant contribution on main field models and to have the same order of magnitude as the Earth field around degree 13. The EE contribution is also shown to be significant at the CMB. It is now usual to reduce the effect of the horizontal ionospheric current by using simultaneously observatory and space data. In order to test this method we use a synthetic EE current and compute the corresponding synthetic values at Magsat location as well as for about 100 observatories. A new model is then computed extracting the magnetic potential associated to the EE current in order to quantify the improvement on the main field model.

GA5.08/W/12-B1 Invited 1135

INVERTING VECTOR MAGSAT DATA FOR THE CRUSTAL POWER SPECTRUM

David LOWE (1), R L Parker (1), C G Constable (1), M E Puricker (2) (1) Cecil H and Ida M (Green Institute of Geophysics and Planetary Physics, Scripps Institute of Oceanography, University of California at San Diego, La Jolla, CA 92093-0225, USA) (2) Geodynamics Branch and Raytheon, ITSS, Goddard Space Flight Center. MD 20771, USA)

A model of the crustal Mauersberger-Lowes spectrum (Rl) is essential in producing detailed core field models - Rygaard-Hjalsted et. al. (1997) demonstrated relationships between Rl and the component covariance matrices used in core field inversions. The crustal field is isolated from MAGSAT dawn and dusk data by subtracting the Comprehensive Model (under development at GSFC by Sabaka, Langel, Olsen and Richmond) to account for sources in the ionosphere, magnetosphere and core. The passes are restricted to +/-50¡ dipole latitude because the Comprehensive Model does not reproduce high latitude features (field aligned currents) particularly well. A high quality subset of this data has been compiled by visually inspecting the crustal residuals for features (gaps, tears) that, in addition to being non-geomagnetic in origin, would contaminate spectral estimates. The power spectral density (PSD) of each flight local component along each "good" great circle path (GCP) is robustly estimated using multitapers. Following O'Brien (1996), the PSDs are then inverted for a smooth Rl, at wavelengths down to 800km (l=50). The same techniques will be applied to higher accuracy vector data from ¯RSTED (when available). Resolution limits for crustal field models can be set at the signal-to-noise transition in the spectral domain. This wave-number (kres) varies from pass to pass. It is possible to subdivide these GCPs into continental and oceanic and investigate whether these regions' different compositions and formation processes translate into different kres and Rl.

GA5.08/E/07-B1 1330

MAGNETIC SUSCEPTIBILITY CONTRASTS OF THE LITHOSPHERE

J. DYMENT (CNRS UMR "Domaines Océaniques", Institut Universitaire Européen de la Mer, Université de Bretagne Occidentale, Plouzané, France; email: jerome@univ-brest.fr); J. Arkani-Hamed (Earth and Planetary Sciences, McGill University, Montreal, Canada)

Because they mix the fundamentally different physics of the induced and remanent magnetization in the lithosphere, satellite magnetic anomalies are often difficult to interpret in terms of geology. We determine the induced magnetic anomalies of the Earth by removing a model of the magnetic anomalies due to the remanent magnetization of the oceanic lithosphere from the observed satellite anomalies. For consistency with the observed data, the remanent magnetic anomalies are filtered following the processing scheme applied to the Magsat data to remove the external and core field components. The resulting induced magnetic anomalies are inverted to bulk magnetic susceptibility contrasts. The new bulk susceptibility contrast map display relatively simple figures in the oceans, with the exception of the large and north-south trending anomalies removed by the initial processing of the satellite data. Normal oceanic crust shows a uniformly low bulk susceptibility, whereas oceanic plateaus exhibit higher bulk susceptibilities related to their thicker crust.
Subduction zones display higher bulk susceptibilities due to the magnetization of the colder subducted slabs. Passive margins present a consistent signature, with a higher bulk susceptibility over the continents, a lower one over the oceans, and a representative bulk susceptibility contrast of about 0.65 to 0.70 SI km across the ocean-continent boundary. Variations of the bulk susceptibility contrast across the ocean-continent boundary depends on the nature of the continental lithosphere and the type of continental margin.

GA5.08/W/08-B1 Invited 1350

RECOGNITION OF LITHOSPHERIC REMANENT MAGNETIZATION IN THE SOUTH ATLANTIC FROM SATELLITE

M PURUCKER (Geodynamics Branch, Goddard Space Flt Ct, Greenbelt, MD 20771 USA, email: purucker@geomag.gsfc.nasa.gov); J Dyment and N Grammatica (Universite de Bretagne Occidentale, Plouzane, France, email: jerome@catamaran-gw.univ-brest.fr)

In order to enhance our knowledge of the oceanic lithosphere, especially in poorly studied areas like the South Atlantic, we have compared Magsat observations with a new model of the remanent magnetization of the world's oceans developed by Dyment and Arkani-Hamed. The South Atlantic region is characterised by high levels of external magnetic fields and a north-south magnetic grain, both of which pose problems for the polar-orbiting Magsat magnetic field satellite. The Magsat observations that we use are those of Cain et al (JGG, 1990), who solved simultaneously for both core and lithospheric fields up to degree and order 49. A comparison between model and observations permits recognition, for the first time from satellite, of 1) the Cretaceous quiet zones, 2) the period of more rapid field change in the early Tertiary, and 3) the enhanced signal over the spreading ridge. The observations also show other, previously recognised features of the satellite field in the South Atlantic, including Walvis ridge and the Cretaceous quiet zone north of the South Sandwich islands. The observations of Cain et al appear to be superior to the observations of Arkani-Hamed et al in recovering north-south trending signals. However, the Arkani-Hamed et al observations appear to be superior in recovering east-west trending signals. The greater amplitude in the Cain et al observations confirm the results of Dyment and Arkani-Hamed that deeper oceanic sources are required and that the basaltic layer is inadequate to produce the observed signal.

GA5.08/W/10–B1 1415

USING QUALITY SATELLITE MAGNETIC DATA IN MODELS OF THE MAIN GEOMAGNETIC FIELD

Alan THOMSON (Global Seismology and Geomagnetism Group, British Geological Survey, West Mains Road, Edinburgh, EH9 3LA, Scotland. e-mail: a.thomson@bgs.ac.uk)

The Oersted satellite mission should provide a magnetic data-set of comparable quality to that of Magsat. In this paper we examine the characteristics of models of the core-generated field based, at least in part, on such satellite data (possibly using early Oersted data, if available). Comparisons will be made with main-field models derived solely from ground-based measurements.

POSTER VIEWING 1435

FINE TUNING GLOBAL FIELD MODELS BASED ON SATELLITE MAGNETIC OBSERVATIONS

Joseph CAIN and D Mozzoni (Geophysical Fluid Dynamics Institute, Florida State University, Tallahassee, Florida 32306-4360, USA)

In past analyses of the data from projects such as Vanguard 3, Cosmos49, POGO and Magsat, it was clear that in all instances the separation of sources has not been carried out completely. The integration of the vertical component of Magsat data to obtain internal spherical harmonic coefficients to degree 65 (M07AV6) resulted in a curious double hump in the residual diagrams, with no obvious relation to a separation of the data in local time or any other parameter that could be envisioned. Although the model differed only slightly from those derived later using all components and least squares adjustment so as to produce a near Gaussian error distribution, the difficulty remained a mystery without satisfactory explanation. In the least squares adjustments of all the components to produce such models as M102189 a prior "reduction" was made of each component by fitting residual curves separately for the dawn and dusk portions of the orbits with polynomials. This reduction significantly reduced the overall residuals of fit to the data, but left unanswered the nature of the variations. Attempts to statistically evaluate the nature of the residuals by season and altitude or other geophysical parameters, also produced no obvious pattern. Lastly, determinations of the variational field from surface magnetic observatories for each 24 hour period and computation of the estimated field at satellite altitude on the assumption of E-layer horizontal electrical current sheets could not be related to residual patterns in the Magsat data. The generally accurate internal field models that resulted in spite of such uncertainties was due to the fact that the internal field is mostly vertical, and the vertical current components have no effect on the scalar potential. During the dawn and dusk periods of Magsat data there were enough intervals where the imbedded horizontal currents were small that their effects were equally negligible in the resulting models. Likewise, for POGO, the large volume of data allowed a selection of the quietest intervals during early morning hours when such currents were very low. Even so, the fact that POGO models could achieve residual distributions near 1 nT, whereas even with many more terms, the best Magsat models were in the range of 5-10 nT implied the need for better reductions. These issues are discussed and evaluated for the more recent data from Ørsted and Astrid-2 projects.

GA5.08/E/01-B1 1605

BACKUS EFFECT AND PERPENDICULAR ERRORS IN HARMONIC MODELS OF REAL VS. SYNTHETIC DATA

C.V. VOORHIES, J. Santana and T. Sabaka (Geodynamics Branch, Code 921, NASA's Goddard Space Flight Center, Greenbelt, MD 20771 USA; email: voorhies@geomag. gsfc.nasa.gov)

Measurements of geomagnetic scalar intensity on a thin spherical shell alone are not enough to separate internal from external source fields; moreover, such scalar data are not enough for accurate modelling of the vector field from internal sources because of un-modelled fields and small data errors. Spherical harmonic models of the geomagnetic potential fitted to scalar data alone therefore suffer from well-understood Backus effect and perpendicular errors. Curiously, errors in some models of simulated 'data' are very much less than those in models of real data. We analyse select Magsat vector and scalar measurements separately to illustrate Backus

effect and perpendicular errors in models of real scalar data. By using a model to synthesise 'data' at the observation points, and by adding various types of 'noise', we illustrate such errors in models of synthetic 'data'. Perpendicular errors prove quite sensitive to the maximum degree in the spherical harmonic expansion of the potential field model fitted to the scalar data. Small errors in models of synthetic 'data' are found to be an artefact of matched truncation levels. For example, consider scalar synthetic 'data' computed from a degree 14 model. A degree 14 model fitted to such synthetic 'data' yields negligible error, but amplifies 4 nT (rms) added noise into a 60 nT error (rmss); however, a degree 12 model fitted to the noisy 'data' suffers a 492 nT error (rmss through degree 12). Geomagnetic measurements remain unaware of model truncation, so the small errors indicated by some simulations cannot be realised in practice. Errors in models fitted to scalar data alone approach 1,000 nT (rmss) and several thousand Nt (maximum).

THE INTERMEDIATE ANOMALIES AT THE TERRITORY OF RUSSIA AND SURROUNDING AREA

Valentina I. KOLESOVA, Victor I. Pochtarev and Maria A. Effendieva (St.-Petersburg filial, Institute of Terrestrial Magnetism, Ionosphere and Radiowave Propagation, Muchnoy per.2, box 188, 191023,St.-Petersburg, Russia, email: kmp@telecom.lek.ru)

For the first, the intermediate anomalies were detected by V.I.Pochtarev at the territory of USSR using the generalized airborne magnetic data in 1965. Later M.A.Vasiliyeva carried out the new generalisation of the relative airborne magnetic data with the help of the total force data measured at base net. The space spectral analysis of the obtained chart gave the opportunity to detect the long-wave components having the periods 200-350, 500-700 and 1100-1300 km. The first two components are the more intensive at the Russian and East Siberian Platforms, they reached 700 nT; the intensity of the third component everywhere is equal 150-200 nT. It was shown, that the regions having the large particularities in the lithosphere of the ancient shields and platforms near the Moho's boundary are marked by the stationary 200-350 km magnetic and gravitational components. The zones of the high seismic velocities placed under Moho's boundary are detected by 500-700 km magnetic and gravitational anomalies. The chart of the intermediate anomalies was compiled at the base of M.A.Vasiliyeva's total force map. The detected space spectral characteristics were taking into account. The obtained intermediate anomalies were interpreted with the help of the original author's method at the base of the magnetic, gravitational and seismic data. All intermediate anomalies are placed in the regions of the ancient shields and platforms with the high thickness of the Earth's crust. The same intermediate anomalies are detected in the POGO magnetic data.

GA5.08/E/05-B1 Poster **1400-02**

PECULIARITIES OF A SUBSTORM DEVELOPMENT WITH THE SHARP BEGINNING OF AN EXPANSION PHASE

R.N.BOROYEV (Institute of Cosmophysical Research and Aeronomy,31 Lenin Ave., 677891 Yakutsk, Russia, email: lae@sci.yakutia.ru)

On AE-indices the sub-storms with the sharp beginning of an expansion phase have been selected. A moment of expansion and the longitude localisation of the sub-storm center was determined as on ae and on data of ground magnetovariation stations. By using data satellite measurements of the geomagnetic field in the geostationary orbit a study of the magnetosheric current system in period of such sub-storms has been carried out. In all considered events the satellites the GEOS-5 and GEOS-6 were either in the midnight or morning sector. It is found that before the expansion phase onset for the sub-storms with a sudden beginning the field-aligned currents are not observed in-like the sub-storms with a gradual beginning of the expansion phase [1]. It is apparently explained by the narrow longitudinal localisation of a sub-storm center before the expansion phase onset as compared with a distance between the satellites.

PROFILES OF THE MAGNETIC ANOMALIES ON THE NEAR SURFACE, STRATOSPHERICAL AND SATELLITE ALTITUDES

Yu. P. Tsvetkov, N. M. ROTANOVA, and V. I. Odintsov, Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Russian Academy of Sciences. IZMIRAN, Troitsk, Moscow Region, 142092, Russia. email: golovkov@izmiran.rssi.ru

Profiles of the anomaly crustal field to the extent of 6000 km having one and the same route have been constructed. Crustal fields on the near-surface altitudes were obtained from a map of magnetic anomalies of territory USSR (1974), on the satellite and on the stratospherical altitudes data of the MAGSAT and of the balloon surveys were used. The spectral analysis and comparison of amplitude-frequent characteristics for each of profiles were done. As the standard for the comparison the results of spectral analyses of the balloon surveys were chosen. The present researches have shown: firstly, the agreement (except for two sites of ~200 km) of the balloon and near-surface profiles, high identity of the profile spectra in range of wavelengths of 200-2200 km, and also reliable correlation of the crustal fields on satellite and stratospheric altitudes in frequency domain of 500-3000 km, secondly, the agreement of the spatial distribution of spectral harmonics of investigated profiles upto wavelengths of ~2000 km.
Conclusion is made, data of the balloon surveys may be used for an estimation of accuracy of the regional maps.

GA5.08/W/11-B1 Poster **1400-04**

SPATIAL-TEMPORAL AND SPECTRAL ANALYSIS OF THE GEOMAGNETIC DATA FROM MAGSAT NINA

Nina Rotanova, Vadim Golovkov, Andrei Kharitonov (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Russian Academy of Sciences.IZMIRAN, Troitsk, Moscow Region, 142092, Russia, email: golovkov@izmiran.rssi.ru)

The method of natural orthogonal components (NOC) was applied to the satellite data from MAGSAT. It was used to solve the following satellite survey problems: - revelation and extraction of the spurious data; - separation of the residual field obtained after removing of the main field from observed ones, on parts originated by the crustal magnetisation and the ionospheric current systems. A conclusion is made that the technique of NOC analysis allows to find a solution of the above-mentioned tasks and should be included into the scheme of the satellite data processing to prepare both the vector and scalar magnetic anomaly maps. Spectral analysis was applied to the geomagnetic field data from MAGSAT. Spectra were computed by the maximum entropy method. It is shown that a set of three spectral peaks within about 500 km, 1000 km and 3000 km are singled out on the satellite altitudes, connected with anomaly fields. Reality of the obtained spectral peaks is confirmed by results of the spectral analysis of the gravity field. The spectral estimations of the anomaly field were used for determination of the depths of the magnetic sources.

CRUSTAL MAGNETIC ANOMALIES FROM SATELLITE: THEIR RELATIONSHIPS WITH LITHOSPHERE

Sergei D. ODINTSOV (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow reg., 142092, Russia, Email: odintsov@izmiran.rssi.ru)

The simple method ("SIMP") of construction maps of the anomaly magnetic field for middle latitudeis by using the Magsat satellite data is suggested. Anomaly maps were constructed by SIMP for a series of regions (for territory of Western and Eastern Europe, of the Pakistan and of the most part of territory of Russia). The comparison of such maps was made with other maps received by the classical method. The comparison showed some disagreements between these maps for same regions. The careful analysis of our maps (the comparison with near-surface, airborne and balloon's surveys) showed the some advantage over received maps by classical method. Using the interpolated data of anomalies we created models of anomalies by the method of Spherical Cap Harmonic Analysis. These models are compared with the ones of gravitational anomaly maps. Also anomalies maps were directly compared with tectonic and geologic maps. The results obtained in the present study are discussed.

HOW DOWNWARD FIELD CONTINUATION CAN CONTRIBUTE TO MAGNETIC FIELD ANALYSIS AND INTERPRETATION

Wigor A. WEBERS, (GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany)

The well-known spherical harmonic analysis (SHA) as adequate global internal magnetic field model is an infinite power series expansion from the mathematical point of view. Consequently, ground-based and satellite altitude SHA field models show different convergence quality that reflects different physical contents of the SHA terms of both field data sets. The practical calculations use finite SHA partial sums truncated at a definite index. The downward field continuation procedure WIGCONT uses the invariant characteristic of functional behaviour of the contributions of the SHA terms, i.e. of the functional system of the SHA expansion to the volume of a parallelepiped in a mathematical functional space as regularising criterion. Applying this procedure enables to evaluate the physical content of the satellite SHA model in comparison to the simultaneous ground-based one. This relates to the spatial characteristics of the SHA terms and to its different time structure when the behaviour of the SHA field models in time is investigated. Moreover, when the downward continued satellite altitude SHA model is referred to the simultaneous ground-based one and compared with model calculations then the different contributions of the external field to both data sets can be studied.

MONITORING THE EQUATORIAL ELECTROJET ACTIVITY USING GROUND STATIONS DURING THE OERSTED MISSION

YVES COHEN, (IPGP, Observatoire de St Maur, 4 avenue Neptune, 94107 St Maur des Fossés, France, email: cohen@ipgp.jussieu.fr); Vafi Doumouya , (Univ. Côte d'Ivoire, FAST Dépt de Physique, 22 BP 582 Abidjan 22, Côte d'Ivoire, email: doumouv@syfed.ci.refer.org); Pascale Ultré-Guérard, (IPGP, 4 place Jussieu, 75252 PARIS Cedex 05, France, email: ultre@ipgp.jussieu.fr); and Jacques Vassal, IRD, 32 avenue H. Varagnat, 93143 Bondy Cedex, France, email: jacques.vassal@bondy.orstom.fr

The Equatorial Electrojet is an ionospheric current that regularly flows along the geomagnetic equator. Its amplitude is a combination of diurnal and seasonal variations. Its magnetic activity can be measured by any magnetic station around the geomagnetic equator. It is also measured by any low altitude polar orbiting satellite. It has been shown that the large-scale magnetic field created by this current affect the description of both crustal and main magnetic fields deduced from polar orbiting satellite measurements.
In order to reduce this effect, an independent estimate of this current based on ground stations is necessary. A chain of 3 ground magnetic stations was installed perpendicularly to the geomagnetic equator, just before the launching of the Oersted satellite. These data will be collected during the whole mission, and will be used to remove the effect of this current from the satellite profiles. We propose here a method that can be used to isolate the Equatorial Electrojet effect from satellite data.

400 YEARS OF GEOMAGNETIC FIELD CHARTING AND MODELLING

David R BARRACLOUGH (British Geological Survey, Murchison House, West Mains Road, Edinburgh EH9 3LA, UK)

William Gilbert's assertion, in 1600, that the Earth is a great magnet can be regarded as presenting the first model of the geomagnetic field. Edmond Halley's Atlantic and World Charts of about 100 years later were the first magnetic charts to be published - and were also the first charts to use contour lines. The development of geomagnetic field models during the 400 years since Gilbert and of geomagnetic charts in the 300 years since Halley will be described. Emphasis will be on global models and charts, and on mathematical models. The close relationship between charts and mathematical models will be explored.

GA6.02/E/09-B1 1420

FORTY OR FOUR CENTURIES REMOTE PAST HISTORY AND SUPERSTITION SCIENCE

Luiz M.Barreto (Observatorio Nacional. Rua General Bruce, 586. 20921-400, Rio de Janeiro, RJ. Brasil e-mail: barreto@on.br)

In spite of its prominent place in the History of Science, for a long time Geomagnetism was a kind of myth. A "South-Directing Chart" in China (2634 b.C.) is the oldest notice, but the first quotation about the compass use was made by Shen Kua (1088 b.C.), also in China. The first European reference to a compass was made in 1190 a.D.by Nekham and it is probable that Marco Polo's descriptions about the Chinese Technology could be the reason for European curiosity. There are no clear written documents about that natural phenomena. The period of forty centuries could be called the "Prehistoric Geomagnetism". The important role of the compass for the Great Navigation success was not a source of scientific activities. There were two reasons for this : to mantain the nautical techniques in secret, and the mystic Middle Age thinking. The birth of Galileo's Scientific Method was the greatest scientific historical landmark, and it had provoked in Geomagnetism a bright spot, the publication of Gilbert's "De Magnete" (1600). It could be considered as the first ever published scientific book. Hundred years later, Halley presented his Magnetic Atlantic Charts. The "Prehistoric Period"had finished. However, the real meaning of the Geomagnetic Field was not established, since only the value of two angles, a mere qualitative concept, had been achieved. In 1832, Gauss created his measuring instruments and methods, to describe completely the vector "Geomagnetic Field". The Science of Geomagnetism was born.

REMARKS ON LIFE AND WORK OF -JULIUS BARTELS

Hannelore and KARL-HEINZ BERNHARDT (Platz der Vereinten Nationen 3, D-10249 Berlin, Germany)

J. Bartels (1899-1964), who was president of IAGA (1954-57) and, later, vice-president of IUGG (1957-63), worked at the beginning of his academic career at the university of Berlin and at the forestry college of Eberswalde from 1927 to 1944. Bartels' activities during this period of his life as well as his relation to the Prussian Academy of Sciences are characterized based on archival records. Also most of his significant contributions to mathematical statistics in meteorology and geophysics, which are considered in some details as an important part of his versatile lifework, have been written in this time.

Following the doctor thesis (Göttingen, 1923), Bartels started in the fields of statistics with the study of cyclic variations of meteorological and geomagnetic parameters which are superimposed by strong non-cyclic components. The application of the synchronization method in this connection required to eliminate carefully the selection or curvature effect, which had often been misinterpreted formerly. Further, Bartels improved the methods of periodogram analysis and the statistical testing of their results on the basis of the contemporary theory of probability. Special attention was paid by him to problems of statistical testing in case of auto-correlated data as connected with the phenomena of persistence and quasi-persistence in meteorological and geophysical time series. Finally, he introduced special Monte Carlo like methods, as the shaking test, to test the signficance and the reliability of phenomena observed in time series. His rigorous criticism and the numerous remarks to avoid misleading conclusions from incorrect statistical data interpretation should be considered as exemplary also nowadays.

EARLY HISTORY OF GEOMAGNETIC RESEARCH IN INDIA

R.G.RASTOGI, (Department of Physics, Gujarat University and Physical Research Laboratory, Ahmedabad 380 009 India, e-mail: parvs@prl.ernet.in)

India has a long standing of geomagnetic research since as early as 1792 when regular magnetic observations were started at Madras. Later Simla, Madras and Trivandrum formed part of the global network of observatories organised by Gottingen Magnetic Union in 1835. The development of geomagnetic and ionospheric observatories in India are discussed with thirteen geomagnetic observatories operating today between the latitudes of electrojet center and Sq focus. On the scientific research side, the publications by Prof.J.A. Broun (1874) "Observations of magnetic declination made at Trivandrum and Augustia Malley" and by N.A.F. Moos (1910) "Magnetic observations made at the Government Observatory Bombay for the period 1846 to 1905" forms the classical momumental works on Geomagnetism. Some of pioneering research on solar, lunar and storm time variations of the magnetic field at low latitudes are described.

GA6.02/W/01-B1 1520

DECLINATION AND LONGITUDE: FRENCH THEORY AND OBSERVATION IN THE EARLY 17TH'S CENTURY

Pascale ULTRE-GUERARD and Mioara Mandea Alexandrescu (Institut de Physique du Globe de Paris, 4 Place Jussieu, 75252 Paris Cedex 05, France, email: ultre, mioara@ipgp.jussieu.fr)

Using archive materials held in libraries at Paris and Dieppe, we pay tribute to some of our French ancestors who made notable advances in both the theoretical and observational development of geomagnetism during the early 17th century. About two years after "De Magnete", a French cartographer, Guillaume de Nautonnier, published his monumental ``Mecométrie de l'eymant cest a dire la manière de mesurer les longitudes par le moyen de l'eymant''. Nautonnier claimed, by considering observed values of declination, that all magnetic meridians converge in a regular fashion to the magnetic poles, one located near Greenland and the other near Georges V land. This would lead to a method of determining longitude at sea, which was perhaps the most important scientific problem at the time. In 1611, Didier Dounot's ``Confutation'' showed that the values of declination do not support Nautonnier's hypothesis. The subsequent debate on this subject during the first half of XVIIth century proved to be extremely important in the development of geomagnetism.
Another important French contribution at that time was by Jean Guérard, a hydrographer, described by Fournier, as: "one of the most precise observer he had ever known, who wanted to have the most exact magnetic compass...". In one the Captain Guérard's maps the declination of the magnetic compass is indicated in order to show navigators where the compass is more or less declining (1631). This map is centered on the Atlantic Ocean and predates Edmond Halley's well-known chart of declination in the Atlantic by 70 years. However, the declination values are plotted in 17 distinct locations, and so the chart cannot really be compared with Halley's isogonic representation of declination. The declination values measured by Guérard are presented and compared with an existing historical model.

WILLIAM GILBERT AND "THE MAGNET" A VISIONARY WORK

A. OROZCO (Instituto de Geofisica, Ciudad Universitaria, 04510, Mexico, D.F., Mexico; email: adolfo@tonatiuh.igeofcu.unam.mx;)

In 1600 The Magnet by William Gilbert came out from the press. This book is considered as the beginning of the scientific studies about geomagnetism. This masterpiece of work was not only a complete study about the known facts about the magnetic needle, compasses, magnetic materials, and properties of the magnetic stone, but also it contains a very imaginative and clever set of theories and hypothesis about the origin, characteristics and evolution of the magnetic field of the earth.At a distance of 400 years it is very interesting and enlightening to study the visionary proposals of Gilbert, his life, the support he received from the Royal Authorities and the impact of this scientific work. The aim of this paper is to present only some outlines of the work and the impact of the book of Gilbert with the idea to promote a more complete and insightful work on the history of geomagnetism along this four centuries.

GA6.02/E/04-B1 Invited 1610

GEOMAGNETISM AND FUNDAMENTAL SCIENCE

Giovanni P. GREGORI (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy; e-mail: gregori@atmos.ifa.rm.cnr.it)

The history of geomagnetism can be conceived from different viewpoints, such as e.g. dealing (1) with the discovery of the time- and space-morphology of the field, or (2) with the ideas about its prime cause, or (3) with instruments, or (4) with the h euristic potential of the geomagnetic record for studying Earth's history, etc. The present contribution is mainly concerned with the impact of geomagnetism on fundamental science, and the related feedback. The early investigations by Descartes culminated with Gilbert's De Magnete, while Kepler attempted at explaining the planetary orbits by means of the magnetic force, until Newton formulated the law of universal gravitation (thus starting the still surviving dichotomy between gravitation and e.m.-weak forces). In 1820 Ampere discovered the magnetic effects of an electric current, while Gauss was developing potential theory up to a stage of excellence, and he did not afford in setting order into electrodynamics, a target that was later achieved by Maxwe l l. The interaction between geomagnetism and fundamental physics later implied on one side the unsuccessful search for the generation of the magnetic field by rotating an electrically neutral object. On the other hand, two basic aspects are as yet inadequ a tely exploited. (1) The approximation of steady flow of a plasma is inadequate, and there is need for applying, rather, the Hamilton/Jacobi (instead of Newton/Maxwell's) formulation e.g. for explaining the magnetosphere, its substorms and storms, etc. or for investigating the average skin depth of penetration of a time varying external field into an approximately spherical heterogeneous Earth. (2) The interaction between the gravitational (tidal) force and the dynamo is a basic process that appears like l y to be an ubiquitous feature in the universe, suited also for explaining planetary and lunar magnetic fields. The events in history of science, concerned with the viewpoint here considered, seem to be still in progress.

GA6.02/E/07-B1 1630

J.J. NERVANDER AND HELSINKI GEOMAGNETIC OBSERVATORY (1838-1912)

H. NEVANLINNA (Finnish Meteorological Institute, P.O.Box 503, FI-00101 Helsinki, Finland, email: heikki.nevanlinna@fmi.fi)

J.J. Nervander (1805-1848), Physics Professor at Helsinki University, was the first geomagnetician in Finland. He introduced electromagnetism and geomagnetism to Finnish scientific community in the 1820's and 1830's. Nervander designed one of the first galvanometers applying Örsted's invention of electric and magnetic interaction. He was the central figure in establishing a full-scale geomagnetic observatory in Helsinki in 1838. Under Nervander's ambitious leadership the observatory routines and instrumentations were on high international level. Magnetic and meteorological observations started in 1844. Nervander's premature death interrupted the data treatment and publication of observation material. However, observations were continued after him almost 70 years. The observation frequency was 6 times per hour (H, D and Z) untill 1857, and one hour after that. At the Finnish Meteorological Institute, the successor of Nervander's magnetic observatory, all magnetic observations made at the observatory have been transformed into electronic form. There are altogether 1,000,000 observations of H and D which form a rather homogeneous and continuous series of of magnetic field observations 1844-1910. The quality of Z data is poor. Using H and D we have derived local geomagnetic activity indices K and Ak. The correlation between Helsinki activity indices with global aa-index since 1868 is good: on monthly basis the correlation coefficient is 0.95 and even on daily level 0.8. Helsinki activity index series can be thus used for analyzing magnetic activity for two solar cycles 1844-1868 from which time not much other magnetic data is available.

GA6.02/E/06-B1 1645

TANAKADATE'S STUDY ON VERTICAL CURRENTS

HARUYO YOSHIDA (Graduate School of Science, Department of Physics (history of science), Hokkaido University, Kita-10, Nishi-8, Kita-Ku, Sapporo, 060, Japan, e-mail: hyoshida@hps.sci.hokudai.ac.jp)

Vertical currents are assumed as an interesting topic in history of geomagnetic study. However, little attention has been paid to the early development of this study which Tanakadate(1856-1952), Japanese physicist, was actively engaged in. A hypothesis of vertical currents was proposed by Schmidt in 1895. He claimed that a small part of geomagnetic force was caused by electric currents traversing the earth's surface and had no corresponding potential. This led to a heated controversy between two groups over the existence of vertical currents. One group(Schmidt, Bauer) drew a conclusion from the magnetic state of the earth as a whole that vertical currents did exist. The other (Rucker, Carlheim-Gyllenskiold, van Rijckervorsel, and Liznar) got the negative results based on minute and accurate magnetic surveys on their own countries. Tanakadate, a man of deep insight into this difficult problem, joined neither of the groups and approached it from an independent point of view. Successfully accomplishing a magnetic survey of Japan(1893-96) as complete as those of European countries, he improved the method employed by the latter group and deduced a detailed distribution of vertical currents in Japan. Current distributions for Austria and the UK were also

calculated in order to compare them with that for Japan. By drawing lines ofequal vertical currents, Tanakadate found that these calculations for different countries gave a line of no current running through the middle of each country, while magnetic distributions display different patterns. Tanakadate thus doubted rather the effectiveness of the method to examine the existence of currents than the reality of the hypothetical currents as some predecessors had done.

GA6.02/E/10-B1 1700

A CENTURY OF GEOMAGNETIC OBSERVING IN NEW ZEALAND

Don MCKNIGHT (Institute of Geological & Nuclear Sciences, PO Box 30-368, Lower Hutt, New Zealand, email: d.mcknight@gns.cri.nz)

1999 marks the centenary of New Zealand's geomagnetic observing programme. It was in February 1899 that the first comprehensive survey of the magnetic field in New Zealand and its outlying islands commenced, and in November 1901 that continuous recording of the field commenced in Christchurch. At the time this was only the fourth permanent observatory in the Southern Hemisphere.
The first magnetic observations were made in New Zealand in 1642 by Abel Tasman.
Further observations were made over the next 250 years by Cook, Stokes, Drury and numerous other navigators and surveyors. It was the practical need for reliable geomagnetic information together with the scientific need for more data from the Southern Hemisphere that led to the establishment of the observatory programme in 1899. The observatory opened in time to provide calibration facilities for Scott's first Antarctic expedition, and went on to host numerous other Antarctic expeditions and survey vessels.
The Christchurch observatory was forced to vacate its site in a city park due to the installation of an electric tram system in 1905. The new site at Amberley, 40 km to the north, eventually became disturbed as well and in 1978 the observatory was shifted again, this time 40 km to the southwest to its present site in the Eyrewell Forest. During its near-century of continuous operation the observatory has gone through a number of upgrades, the most recent being a change to digital instrumentation in 1990.
Eyrewell observatory serves as the reference station for repeat station survey work in the New Zealand region and is a member of INTERMAGNET. Examination of its history reveals lessons concerning the siting and value of such a facility, and also the importance of the prompt measurement and publication of results.

ONE HUNDRED YEARS OF GEOMAGNETIC MEASUREMENTS AT THE LA PLATA ASTRONOMICA OBSERVATORY AND MAGNETIC SATATIONS

Julio Cesar GIANIBELLI and Iris Rosalia (Cabassi, Observatorio Astropnomico De La Plata Paso Del Bosque email: jcg@fcaglp.fcaglp.unlp.edu.ar, rosy@fcaglp.fcaglp.unlp.edu.ar)

When the Astronomical Observatory at La Plata, Argentina, was created in 1882, a pavilion was building for magnetic observations. The first observations were carried-out in 1889. The development of investigations, surveys and instalations of two permanent magnetic observatories (Las Acacias and Trelew) was carried out to the present. An historical review of the geomagnetism evolution and the present state of the discipline in Argentina, are present.

GA6.02/E/11-B1 1730

JOHANN VON LAMONT - FIRST YEARS OF GEOMAGNETIC RESEARCH IN MUNICH, 1836 - 1845

Martin BEBLO and Heinrich Soffel (both at Geophysical Observatory Fuerstenfeldbruck, University of Munich, Ludwigshoehe 8, D-82256 Fuerstenfeldbruck, Germany,
Email: magnetic@fur.observatory.uni-muenchen.de).

Johann von Lamont started with sporadic geomagnetic observations in Munich in 1836. Since 6 o'clock in the morning on August 1st, 1840, he run regular observations with variometers built by Gauss and Meyerstein in Goettingen. In May and June 1841 Lamont replaced the Gauss variometers (suspended magnets with a weight of 25 lb - 11.4 kg) by instruments of his own design using very small and light magnets. These instruments improved significantly accuracy and sensitivity of geomagnetic measurements and made geomagnetic surveys possible. Some years later Lamont developed his travel thodolite and distributed 45 instruments of this type for scientific work worldwide. His instruments became international standard for geomagnetic instruments for more than 50 years.

GA6.02/W/04-B1 1745

EDMOND HALLEY'S VOYAGES IN THE "PARAMORE" (1698-1700) AND THE FIRST ISOGONIC CHART OF THE EARTH'S MAGNETIC FIELD

Toby D G CLARK (British Geological Survey, West Mains Rd., Edinburgh, EH9 3LA, Scotland, UK; e-mail: t.clark@bgs.ac.uk)

As well as marking the 400th anniversary of Gilbert's "de Magnete", it is also 300 years since the astronomer Edmond Halley was given command of the "Paramore" which he sailed around the Atlantic recording measurements of magnetic declination. His motivation was a combination of his wish to collect data to improve his theory of the Earth's magnetic field,published in 1692, and his interest in improving navigation methods. His two voyages, made in the years 1698-1700, were not without adventure, and on his return he compiled a chart of magnetic declination, which is reputed to be the first on which contour lines were used to depict a physical quantity. Halley's measurements remain an important dataset for modern geophysicists studying the secular variation of the geomagnetic field over the last few centuries. In this paper we will outline Halley's theory of the Earth's magnetic field, examine his voyages with reference to the log of the "Paramore", and finally compare the 17th century voyages with a modern expedition being planned to commemorate this anniversary.

THE INTERNATIONAL TERRESTRIAL REFERENCE SYSTEM AND ITS ROLE INTO A GLOBAL EARTH OBSERVATION SYSTEM

Claude BOUCHER, Zuheir Altamimi and Patrick Sillard (all at IGN/ENSG/LAREG, 6-8 Avenue Blaise Pascal, 77455 Marne-la-Vallee, France, email: boucher@ensg.ign.fr)

A terrestrial reference system is a key element of an integrated Earth observation system. This paper reviews the basic concepts and illustrates this fact with several examples: links with GPS and IGS, geophysical and oceanographic applications. Then a short summary of what is currently done by the International Earth Rotation Service, including new developments on time series and reference solutions presented. A focus on the ITRF2000 program is given in this paper.

G6/W/05-B1 0850

CORE: CONTINUOUS, HIGH ACCURACY EARTH ORIENTATION MEASUREMENTS FOR THE NEW MILLENNIUM

NANCY R. VANDENBERG and C. C. Thomas (both at NVI, Inc./Goddard Space Flight Center, Greenbelt, MD 20771 USA, Email: nrv@gemini.gsfc.nasa.gov), J. Bosworth, B. Chao, T. Clark, C. Ma (all at NASA/GSFC, Laboratory for Terrestrial Physics, Greenbelt, MD 20771 USA)

The international geodetic VLBI community will inaugurate during 1999 a new phase of the program called CORE: Continuous Observations of the Rotation of the Earth. The capabilities of the new Mark IV correlators, available as of mid-1999, will enable greater sensitivity, more frequent observing sessions and improved system throughput.
The CORE program, begun in 1996 with the CONT96 campaign, has gradually increased the number of observing sessions per week. As of early 1999 the average is 2.5 24-hour sessions per week (including the NEOS sessions). This will expand to 3.5 sessions per week in the second half of 1999, with the goal being continuous sessions by 2001.
More than 20 global VLBI stations are participating in geodetic data acquisition sessions in 1999. These sessions will add nearly 300,000 individual observations to the geodetic VLBI data base. Accuracy goals for each 24-hour session are 3.5 _sec for UT1 and 100 milli-arcsec for pole position.
The CORE program's scientific goals are focused on the needs of Earth system science in the new millennium, concentrating on areas that include the solid Earth core (libration, core modes, free core nutation), variations in sub-daily and long-term ocean tides, and episodic signals (earthquakes, geomagnetic jerks). These science areas can be effectively addressed with the high accuracy, continuous Earth orientation measurements provided by the CORE data.

G6/E/03-B1 0910

EARTH SCALE BELOW A PART PER BILLION FROM SATELLITE LASER RANGING

D. E. SMITH and R. Kolenkiewicz (Laboratory for Terrestrial Physics, NASA GSFC Code 920, Greenbelt, MD 20771, USA, e-mail: dsmith@tharsis.gsfc.nasa.gov) P. J. Dunn and M. H. Torrence (Raytheon Corp., 7701 Greenbelt Rd., Greenbelt, MD 20770, USA)

Since the LAGEOS I satellite was launched in 1976, the systematic instrument error of the best satellite laser ranging observatories has been steadily reduced to the current level of only a few millimeters. Advances in overall system accuracy, in conjunction with improved satellite, Earth, orbit perturbation and relativity modeling, now allows us to determine the value of the geocentric gravitational coefficient (GM) to less than a part per billion (ppb). This precision has been confirmed by observations of the LAGEOS II satellite, and is supported by results from Starlette, albeit at a lower level of precision. When we consider observations from other geodetic satellites orbiting at a variety of altitudes and carrying somewhat more complex retro-reflector arrays, we obtain consistent measures of scale, which however must be based upon empirically determined, satellite-dependent detector characteristics. We will present the most recent estimate of GM, which lies within the two ppb uncertainty of the current standard, but differs from it by more than the error of the new estimate. Both the current standard and our recommended value fall comfortably within the ten ppb uncertainty of that determined from the most accurate alternative: from lunar laser ranging observations. The precision of the estimate of GM from satellite laser ranging has improved by an order of magnitude in each of the last two decades, and we will discuss projected advances which will result in further refinements in this measure of Earth scale.

G6/C/G5/W/06-B1 0930

LONG-TERM STABILITY OF ALTIMETRIC DATA WITH APPLICATIONS TO MEAN SEA-LEVEL CHANGE

P MOORE, M D Reynolds and P Sterlini Aston Geodesy Group,Division of Civil Engineering, Aston University, Birmingham, B4 7ET, UK, email: moorep@aston.ac.uk.

The oceanographic community has access to near 14 years of altimetric data ranging from GEOSAT in 1985-1989 to the current TOPEX/Poseidon and ERS-2 missions. For sea-level rise studies careful validation is required to avoid contamination of the results by spurious non-oceanographic effects. In this study we first utilise in situ tide gauge data to monitor stability of the TOPEX/Poseidon data base. This series is then linked to both ERS satellites by dual satellite crossovers. The analysis is then extended to incorporate GEOSAT ERM data through tide gauge enhanced dual satellite crossovers with TOPEX. Results of the stability analysis are utilised to extract global mean sea-level change over the period 1986-1999.

GEODETIC MODEL TECTONIC PLATE MOTIONS

Mikhail PRILEPIN (United Institute of Physics of the Earth, B.Gruzinskaya Str., 10, 123810 Moscow, Russia, email: prilepin@uipe-ras.scgis.ru) Vladimir Shevchenko(United Institute of Physics of the Earth, B.Gruzinskaya Str., 10, 123810 Moscow, Russia)

Geodetic data for velocity movements of the main tectonic plates are one of the most valuable contributions of geodesy to Earth science in the last 15 years. These data verify in general the results obtained by geology, paleomagnetism and seismology and make the fact of tectonic plate movements much more convinsing. The good agreement on average of the rates for global plates in different time scales - quasi-real time for geodetic rates and 3 millions years for geology-geophysical rates - shows that the evolutional transformation of upper geospheres of the Earth are going at rate at the level 10-9 R, where R - radius of the Earth. This can also serve as evidence that there was no extantion of the Earth for at least the last three millions years. In report the analysis and evaluation of the data for rate movements obtained by SLR, VLBI and GPS are carried out and the geodetic model of annuel rates for main plate together with an averaged interplate deformation feature is developed, taking into account the data from regional projects in California, Caribbean Sea, South America, Mediterranean Sea, Caucasus, Tian-Shan, Himalay, Tibet, Japan and Kurily-Kamchatka.
Using the geodetic model the, boundaries of some small plates are specified, the real rates of subduction and collision of some plates are determined. Significant differences in the rates between NUVEL-1 and geodetic data in some places and the problem of stability in time of the global geodetic reference frames are discussed.

HIGH-RESOLUTION GRAVITY FIELD MODELING

G6/C/G3/E/43-B1 1100

GFZ-1 IMPACTS ON GLOBAL GRAVITY FIELD SOLUTIONS

BODE, A., König, R., Massmann, F.-H., Raimondo, J.-C., Reigber, C., Schwintzer, P.

Nearly three years of GFZ-1 data are evaluated for use in global gravity field satellite-only solutions. GFZ-1 is the lowest geodetic mission ever flown for the pure purpose of gravity field recovery. GFZ-1 provides at its altitude a so far unknown piece of knowledge of the gravity field at high degrees and orders. It is therefore also a good test object for precise orbit determination in view of the upcoming missions CHAMP and GRACE. As GFZ-1 data are of type SLR, the known uneven distribution of the data in time and space limits the use for gravity field recovery. The problems of assimilating GFZ-1 data into gravity field solutions and the benefits are discussed.

IMPROVEMENTS IN GLOBAL GRAVITY FIELD MODELS FOR OCEAN CIRCULATION STUDIES

D. P. CHAMBERS, M. C. Kim, S. Poole, J. C. Ries, and B. D. Tapley (University of Texas at Austin, Center for Space Research, R1000, Austin, TX, 78712, USA, Email: chambers@csr.utexas.edu)

Current global marine geoid models based on satellite tracking data are inadequate for resolving the long-wavelength ocean circulation to better than 5 cm/sec, especially in the tropics. Studies have been conducted to improve geoid models by combining information from ocean general circulation models with satellite altimetry data to determine the marine geoid signal. The solutions also include satellite tracking data and surface gravity measurements. The data have been combined with various wieghts, and the effect of relative data weighting on the solution is discussed. The result of the study is a new high resolution gravity field that improves the determination of the general ocean circulation from satellite altimetry while maintaining comparable satellite orbits with older models.

G6/C/G3/E/09-B1 1140

ON THE MODELING OF LONG WAVELENGTH SYSTEMATIC ERRORS IN SURFACE GRAVIMETRIC DATA

Nikolaos K. PAVLIS (Raytheon ITSS Corporation, 7701 Greenbelt Rd., Greenbelt, MD 20770, USA, email: npavlis@geodesy2.gsfc.nasa.gov)

Long wavelength systematic errors in (near) global gravity anomaly data bases have been identified as a major limitation of these data for several years now. The specific origin of these systematic errors is not clearly understood, although several possible causes have been identified [Heck, 1990]. To minimize their effects, down weighting (sometimes rather arbitrary) of surface gravimetry, and elimination of its very long wavelength contribution is employed in current global geopotential solutions. Pavlis [1998] proposed an alternative approach for the treatment of these effects, whereby one attempts to separate the long wavelength systematic errors (in the form of low degree surface spherical harmonic models), from the valid gravitational signal present in the data. He demonstrated that this could be done in a combination solution environment where satellite tracking information and surface gravimetric data are simultaneously adjusted.
On the basis of the preliminary results mentioned above, further analyses will be reported here. These aim specifically to address the question of highest degree up to which the separation between systematic errors and gravitational signal can be accomplished reliably, given the currently available satellite tracking and surface gravimetric data. The feature applicability of this technique, in anticipation of various geopotential mapping missions (e.g., CHAMP, GRACE and GOCE) will also be addressed. In addition, the identification of the specific cause(s) for the observed systematic errors in the gravimetric data will be attempted.

G6/C/G3/E/23-B1 1200

INVESTIGATION OF DIFFERENT METHODS FOR THE COMBINATION OF GRAVITY AND GPS/LEVELLING DATA

Heiner DENKER 1 (email: denker@ife.uni-hannover.de) Johannes Ihde 2 (email: ihde@leipzig.ifag.de) Uwe Schirmer 2 (email: schirmer@leipzig.ifag.de) Wolfgang Torge 2
(email: torge@ife.uni-hannover.de) Hans-Georg Wenzel 1 (email: wenzel@ife.uni-hannover.de) 1 (Institut fuer Erdmessung, Uni Hannover, Schneiderberg 50, D-30167 Hannover), Germany 2 (Bundesamt fuer Kartographie und Geodaesie, Aussenstelle Leipzig, Karl-Rothe-Strasse 10-14, D-04105 Leipzig, Germany)

Two different methods for the combined computation of the quasigeoid are compared in a test area in Germany. Both methods are based on the remove-restore technique and use the global geopotential model EGM96, point gravity data with a spacing of a few km, a digital terrain model and GPS/levelling control points (with a spacing of about 25 km).
In method I the global model is combined first with the gravity and terrain data using the least squares spectral combination technique with integral formulas. The resulting height anomalies are given in a 1.0' x 1.5' grid. Then a smooth corrector surface is developed from the GPS/levelling data by least squares collocation, including a signal and a trend component.
The second method is based on a common adjustment of the EGM96 reduced gravity and height anomaly observations using point masses and appropriate weight relations. The point masses are arranged at a depth of 10 km, 30 km and 200 km, and in hilly areas also at a depth of 5 km.
Both techniques are compared from the methodological and numerical point of view. The results are discussed and show an agreement at the cm level.

G6/W/01-B1 1220

WORLD GEODETIC DATUM 2000

ERIK W. GRAFAREND and Alireza Azmoudeh-Ardalan, (Geodetic Institute, Stuttgart University Geschwister-Scholl-Str. 24D D-70174 Stuttgart, Germany Tel: +49+711+1213390 Fax: +49 711 121 3285, email: grafarend@gis.uni-stuttgart.de)

Based on current best estimates of fundamental geodetic parameters, i.e., (Grafarend and Ardalan, Journal of Geodesy 71 (1997) 673-679), GM (Ries et al., Geophys. Res. Letters 19 (1992) 529-531), (Lemoine et al., GRAGEOMAR 1996, International Association of Geodesy Symposia 117, (1996) 461-469) and the form parameters of a Somigliana-Pizetti level ellipsoid, namely the semi-major axis a and semi-minor axis b (or equivalently the linear eccentricity) are computed. There are six parameters namely the four fundamental geodetic parameters and the two form parameters {a, b} or which determine the ellipsoidal reference gravity field of Somigliana-Pizetti type constraint to two non-linear condition equations. Their iterative solution leads to best estimates , for the tide-free geoid of reference and for the zero-frequency tide geoid of reference. The best estimates of the form parameters of a Somigliana-Pizetti level ellipsoid, {a, b}, differ significantly by -0.398m, -0.454m, respectively, from the data of the Geodetic Reference System 1980.

SATELLITE POSITIONING FOR HIGH-PRECISION APPLICATIONS

G6/C/G1/E/32-B1 1400

COMPUTATION OF PRECISE GLONASS ORBITS FOR IGEX

Daniel INEICHEN, Markus Rothacher, Tim Springer, and Gerhard Beutler (Astronomical Institute, University of Berne, Sidlerstrasse 5, CH-3012 Berne, Switzerland,
email: daniel.ineichen@aiub.unibe.ch)

On October 19, 1998, the beginning of the International GLONASS Experiment (IGEX), the Center for Orbit Determination in Europe (CODE) has started to compute precise orbits for all active GLONASS satellites. The duration of the campaign was initially arranged for three months, but was prolonged for at least three additional months. One of the main reasons for this extension was the launch of three new GLONASS satellites at the end of the year 1998.
The processing of the IGEX network is done on a routine basis at CODE and precise ephemerides are made available through the global IGEX data centers. The improved GLONASS orbits are referred to the International Terrestrial Reference System (ITRF96) and to GPS system time. They are therefore fully compatible with GPS orbits and allow a combined processing of both satellite systems. All GLONASS satellites are equipped with a laser reflector array and the SLR ground network is tracking most of the GLONASS satellites. First comparisons of the GLONASS orbits computed by CODE with the SLR measurements show that the orbit accuracy is in the order of 20cm. The experiences made with the processing of the IGEX network and the benefits of improved GLONASS orbits for regional network processing will be the main topics of the presentation.

G6/C/G1/L/16-B1 1420

IMPACT OF A THIRD NAVIGATIONAL FREQUENCY ON GPS AND GNSS-2 AMBIGUITY RESOLUTION

P.J.G TEUNISSEN, N.F. Jonkman, P. Joosten, D. Odijk (department of Mathematical Geodesy and Positioning, Faculty of Civil Engineering and Geosciences, Delft University of Technology, Thijsseweg 11, 2629 JA Delft, The Netherlands, email: p.j.g.teunissen@geo.tudelft.nl)

Wide ranging design studies are currently conducted for both the Global Positioning System (GPS) as well as the European second generation Global Navigation Satellite System (GNSS-2). Although the studies are carried out within different frameworks - for the GPS within the framework of modernizing the current systems' architecture, for the GNSS-2 within the framework of overall system design - some of the options under consideration are the same. Amongst these is the implementation of a third navigational frequency in order to enhance ambiguity resolution performance for real-time high-precision position determination. In this contribution the ambiguity resolution performance will be compared and analyzed for some of the triple frequency scenarios discussed in the literature, i.e. a third civil GPS frequency, the GPS C/A code split spectrum or dual signal scenario and a GNSS-2 triple frequency set-up. The merit of each of these scenarios will be judged by means of ambiguity resolution success rates, being the probability of estimating ambiguities at their correct integer values. The success rates are evaluated for the basic single-epoch geometry-free observation model using both the bootstrapped as well as the integer least squares estimator. In addition, the optimal choice for the parametrization of the ambiguities will also be identified.

G6/W/04-B1 1440

FOUR-DIMENSIONAL GEODESY: TIME DEPENDENT INVERSION FOR EARTHQUAKE AND VOLCANIC SOURCES

Paul SEGALL (Geophysics Department, Stanford University, Stanford CA, 94305
email: segall@stanford.edu)

The past five years has witnessed a tremendous expansion in the number of permanent Global Positioning System (GPS) receivers. There are now GPS networks in Japan, California, and Hawaii that provide crustal deformation data that are dense in both space and time. These data, combined with tilt and borehole strain measurements, can be used to invert for spatial and temporal variations in fault slip and magma chamber dilation. Previously, space-time inversions had been hampered by poor signal to noise in the data, contaminating non-tectonic motions near the instrument (benchmark wobble), and our lack of knowledge of the temporal character of aseismic motions. The recently introduced Network Inversion Filter (Segall and Matthews, J.G.R., 1997) yields estimates of quasi- static fault slip as a function of space and time using data from dense continuous geodetic networks. The NIF employs time domain, Kalman filtering, and allows for non-parametric descriptions of slip velocity, local benchmark motion, and measurement error. A state-space model for the full geodetic network is adopted, so that all data from a given epoch are analyzed together. This allows the filter to distinguish between non-steady fault slip and local surficial effects like benchmark wobble. We have used the Network Inversion Filter to analyze the time- dependence of post-seismic slip following the 1989 Loma Prieta earthquake, to image rift-zone deformation opening and aseismic fault slip following the January 30, 1997 eruption at Kilauea volcano, Hawaii, and to image a propagating dike off the Izu Peninsula in Japan. In situations where the geometry of the causative geologic structures is unknown it is advantageous to use filtering techniques to image the strain-rate fields in space and time.

SOUTHERN CALIFORNIA CRUSTAL DEFORMATION AND ITS TECTONIC IMPLICATIONS

Zheng-Kang SHEN and David D. Jackson (both at Department of Earth & Space Sciences, UCLA, Los Angeles, CA 90095-1567, USA; email: zshen@ess.ucla.edu)

The Crustal Deformation Working Group of the Southern California Earthquake Center has recently released its Southern California Crustal Deformation Velocity Map 2.0 (http://www.scecdc.scec.org/group_e/release.v2. We analyzed the geodetic data used in the release and derived station velocities before and after the 1992 Landers earthquake. Significant velocity changes were found for sites located within about 60 km of the earthquake epicenter. The average strain rate in the region increased from ~0.10 to ~0.30 micro-radian/yr. We also estimated fault slip rates in southern California using the pre-Landers geodetic velocities and elastic dislocation theory. We used a modified fault model, defined by the California Department of Mine and Geology (USGS Open-file Report 96-706) and derived mainly from geological information, to lay out the fault geometry. We adopted the CDMG fault slip rates and uncertainties as a priori data to constrain the least-squares inversion of geodetic data for fault slip rates. Generally the geodetic and geologic estimates are quite consistent, except for a few places. For example, the geodetic rates are significantly lower than the geologic rates along the Mojave, San Bernardino, and Coachella Valley sections of the San Andreas, but the other way round at the Brawley seismic zone and the Imperial fault. These discrepancies suggest that the current fault slip rate beneath the locking depth along the San Andreas is lower than its long-term average. This may reflect the fact that the San Andreas has experienced no large earthquake since 1857, and the fault has passed the time period of rapid post-seismic deformation and entered one of slow deformation. On the other hand, the Landers and Imperial faults are still being affected by post-seismic deformation caused by the 1992 Landers and the 1940 and 1971 Imperial Valley earthquakes respectively. A second inversion of the geodetic velocities derived from the post-Landers data reveals a substantial reduction of the fault slip rate along the Mojave section of the San Andreas and a significant increase of the fault slip rate along the San Bernardino section of the San Andreas respectively. These results suggest a decrease of the earthquake probability along the Mojave section and an increase of the probability along the San Bernardino section of the San Andreas, independently conforming previous estimates obtained by analyzing Coulomb stress change along faults caused by the Landers earthquake.

G6/C/G1/L/24-B1 1520

A CONTINUOUSLY OPERATING GPS-BASED VOLCANO DEFORMATION MONITORING IN INDONESIA: CHALLENGES AND PRELIMINARY RESULTS

Chris RIZOS, Shaowei Han, Craig Roberts & Xiujiao Han (at School of Geomatic Engineering The University of New South Wales, Sydney, Australia, email: c.rizos@unsw.edu.au, s.han@unsw.edu.au, z2183871@student.unsw.edu.au, xj.han@unsw.edu.au) Hasanuddin Abidin (at Department of Geodetic Engineering, Institute of Technology Bandung Bandung, Indonesia, email: hzabidin@indo.net.id) R. Sukyhar (at Vulcanological Survey of Indonesia, Bandung, Indonesia)

In the past decade or so there has been increasing interest in the use of permanent, continuously operated GPS networks, and a small number of continuous networks have been deployed in the USA, Japan, Canada and several other developed countries for large scale crustal motion studies. However, only in Japan has it been possible to establish a country-wide continuous GPS network to support seismic research, and ultimately contribute to hazard mitigation through the implementation of an earthquake warning system. Even with such a dense network of high quality dual-frequency GPS receivers as established by Japan's Geographical Survey Institute, the station separation is of the order of 20km or more. There are, however, applications of GPS deformation systems which require receiver densities of the order of just a few kilometres. Furthermore, the high cost of such GPS systems means that most countries cannot possibly afford to establish such systems. Applications of dense permanent GPS arrays include monitoring of volcano flanks, micro-faults, ground subsidence due to underground mining or fluid extraction, slope stability, and even engineering structures such as dams, bridges, etc. This paper describes the design of an automatic GPS-based volcano deformation system that is being deployed by the authors on an Indonesian volcano in early 1999. The basis of the design is the use of a number of low-cost GPS receivers across the area of interest, each costing less than US$2000 each. The critical technical problems that had to be overcome, and preliminary results obtained to date, will be described.

G6/C/G1/W/19-B1 1540

GPS DATA COLLECTION STRATEGIES FOR THE QUASI-CONTINUOUS MONITORING OF DEFORMATION IN REGIONS OF HIGH SEISMIC RISK

MIKAEL LILJE (Geodetic Research Division, National Land Survey, 801 82 Gavle, Sweden,
email: mikael.lilje@lm.se).Paul Cross and Paul Cruddace (both at Department Geomatic Engineering, University College London, WC1E 6BT, London, UK, email: paul.cross@ge.ucl.ac.uk, paul.cruddace@ge.ucl.ac.uk).

The research described in this paper is part of the EC funded project GPS Seismic Hazard in Greece (SING), one of the objectives of which is to optimize GPS data collection strategies for the monitoring of the crustal strain. As part of this work the concept of a quasi-continuous approach has been developed in which small numbers of receivers are moved from station to station when they (and logistical support) are available. In this way large numbers of stations can be monitored in a flexible way without the need for dense arrays of permanently located receivers and without the need to plan campaigns involving large groups of people and the associated complex logistics. The practical implementation of a quasi-continuous procedure involves the establishment of temporary base stations whilst other receivers are moved in the local regions. The efficiency is then a function of the time spent on each station and the distance between the stations, and this paper specifically addresses these issues. The particular observation system that we describe consistes of two permanent observing receivers at ITRF sites within Greece, a limited number semi-permanent stations and a small number of mobile GPS receivers moving from point to point in a quasi-continuous manner. Data collected during part of the 1998 SING fieldwork in Greece has been processed using a variety of subsets of the data available to answer the specific questions raised and detailed conclusions are drawn which lead to practical guidelines for optimum observation strategies to be used for future data collection within the SING project.

ADVANCES IN THEORY AND NUMERICAL TECHNIQUES

G6/W/07-B1 1620

THE MACCULLAGH REPRESENTATION OF THE TIME-VARYING GRAVITY FIELD

GRAFAREND, E.W. (Geodetic Institute, Stuttgart University Geschwister-Scholl-Str. 24D D-70174 Stuttgart, Germany Tel: +49+711+1213390 Fax: +49 711 121 3285,
email: grafarend@gis.uni-stuttgart.de; Engels, J.; Varga, P.

The Cartesian moments of the mass density of a gravitating body and the spherical coefficients of its external gravity field are related in a peculiar way. In particular the products of inertia can be expressed by the gravitational coefficients (MacCullagh-formulae). Here we focus on the small variations of the Cartesian moments due to tidal displacement, loading displacement, displacements generated by incremental centrifugal forces or transverse surface stresses, respectively. Accepting the Love-Shida-hypotheses, which are valid in spherical approximation, the mass conservation law allows a representation of the incremental mass density by the respective excitation function. A representation of an arbitrary Cartesian monome is always possible by sums of solid spherical harmonics multiplied by powers of the radius. Introducing these representations into the definition of the Cartesian moments we arrive at an extension of the MacCullagh formulae. In particular, for excitation functions with a vanishing harmonic coefficient of degree zero also the (diagonal) incremental moments of inertia can be represented by the excitation coefficients. An application of these relations consists in model computations of the length of day, which depends on the polar moment of inertia of the earth.

G6/C/G4/L/01-B1 1640

DIRECT METHODS IN PHYSICAL GEODESY

Petr HOLOTA (Research Institute of Geodesy, Topography and Cartography, 250 66 Zdiby 98, Praha-vychod, Czech Republic, email: gope@asu.cas.cz)

In this paper an approach is applied to the recovery of the gravity potential from boundary data that can be ranged under non-classical methods in the solution of boundary value problems. Two interpretations are shown with a particular view to the nature of Stokes', Molodensky's and other boundary value problems in physical geodesy. First the approach is discussed in terms of calculus of variations and the determination of the disturbing potential is treated as a minimization problem for a quadratic functional. The role of the respective Euler's conditions is explained. Then an interpretation based an Lax-Milgram's lemma is demonstrated that exhibits a broader flexibility. The paper contains a discussion concerning bilinear forms that define the problems under consideration and treats also the related functional-analytic aspects. Subsequently, an interpretation of the solution in terms of various function bases is approached with the particular view to the construction of the respective Galerkin's system. Finally, appropriate estimates of the accuracy are discussed.

G6/C/G4/E/04-B1 1700

WAVELETS AND COLLOCATION: AN INTERESTING SIMILARITY

Christopher KOTSAKIS (Dept. of Geomatics Engineering, University of Calgary, 2500 University Drive N.W., Calgary, Alberta, Canada T2N 1N4 email:ckotsaki@ucalgary.ca)

A rigorous theoretical connection between the statistical (non-stochastic) collocation principle and the multiresolution(MR)/wavelet framework of signal approximation is made in this paper. The rapid developments in MR and wavelet theory over the past few years have provided very efficient tools for spectral studies of irregular gravity field signals, which are often, however, thought as competitive with the already applied concepts and techniques in gravity field modeling. It is the aim of this paper to demonstrate that the wavelet formalism indeed lies at the very core of the mathematical foundations of Physical Geodesy and it fits perfectly into the concept of the statistical approximation of the gravity field. In particular, it will be shown how the use of the minimum mean square error criterion always gives rise to a MR Analysis Approximation in the Hilbert space L2(R), under some very mild constraints on the behavior of the (deterministic) covariance function of the unknown field. In this way, the so-called stationarity restriction problem in operational gravity field modeling becomes just a 'pseudo-problem'. Some other practical issues, such as the selection of data referencing models for spectral analysis purposes, as well as other computational and modelling considerations, are also explained and finally some conclusions are given at the end of the paper.

G6/C/G4/W/18-B1 1720

COORDINATE SYSTEMS IN FOUR-DIMENSIONAL SPACE-TIME GEODESY

Volker SCHWARZE (Uni of Stuggart, Dept of Geodetic Science, Geschwister Scholl-Strass, Stuggart, 70174, Germany, Email: schwarze@gis.uni.de)

In mathematical geodesy coordinate systems of spatially isotropic type or parallel type are pretty well known in the two-dimensional case. These concepts can also be applied to define four-dimensional space-time coordinate systems. It can also be shown that the concept of holonomity and the construction of appropriate coordinate systems are closely related.
Numerical examples demonstrating the application in geodesy are widely discussed.

G6/C/G3/E/35-B1 1740

RECOVERING THE GLOBAL GRAVITY FIELD FROM SATELLITE MEASUREMENTS OF THE FULL GRAVITY GRADIENT

Margarita PETROVSKAYA (Main Astronomical Observatory of Russian Academy of Sciences, Pulkovskoe Shosse 65, Pulkovo, St. Petersburg, 196140, Russia, email: petrovsk@gao.spb.ru) Janusz Zielinski (Polish Space Research Center, Barticka 18A, 00-716, Warsaw, Poland,
email: jbz@cbk.waw.pl)

Earlier, main aspects of the spaceborne boundary value (BV) problem were discussed for the most optimal case, when the global Earth potential is approximated from the full magnitude G of the gravity gradient. The expression for G was derived which depends on both the second and first order partial derivatives of the disturbing potential. In the present paper the unique BV equation G(obs)=G(Cnm) is compiled where G(Cnm) is the spherical harmonic series, depending on the unknown potential coefficients Cnm, and the observable Gobs is expressed in terms of the local orbital coordinates. This equation is solved with respect to Cnm in form of a simple quadrature formula. By means of simultaneous exclusion of the first order potential derivatives from both sides of the BV equation, its reduced version is derived and the corresponding solution for the potential coefficients is found which depends only on the components of the gravity gradient tensor. The above BV relation is also transformed to the form which is appropriate for applying the least squares procedure in simultaneous processing of satellite and surface observations.

SEAMLESS GRAVITY-DEVELOPMENT IN SATELLITE AND AIRBOURNE GRAVIMETRY

G6/C/G2/E/12 1100

DIRECT AND LOCAL COMPARISON BETWEEN DIFFERENT SATELLITE MISSIONS FOR THE GRAVITY FIELD ON THE FLIGHT

Alberta Albertella, Federica MIGLIACCIO and Fernando Sanso' (all at Politecnico di Milano, Dip. IIAR, Sez. Rilevamento, Piazza Leonardo da Vinci 32, 20133 Milano, Italy,
e-mail: fsanso@ipmtf4.topo.polimi.it)

Many different satellite missions are in project at this moment to estimate the global gravity field of the earth and its time variations. The principles of measurement are basically three, namely the measurement of accurate orbit anomalies and of non-gravitational forces acting on the satellite; the measurement of the differential orbit anomalies and of their time variations along the line of sight of two twin satellites; the measurement of the gradiometric tensor. In all three cases it is interesting to be able to compare the observations of one and the same mission at different times at points close in space, as well as observations from different missions approximately on the same area. This in fact can produce an on the flight calibration or cross-calibration procedure. To reach this goal an interesting procedure is to try to "localize" the observations so that the problem is reduced to the comparison of different functionals of T in the same zone of space. The equations for this purpose are analyzed and a few simulations are performed.

G6/C/G3/W/08-B2 1120

SIMULATION OF GOCE ORBIT DETERMINATION AND GRAVITY FIELD RECOVERY

J. Van Den IJSSEL, R. Koop and P. Visser (Delft Institute for Earth-Oriented Space Research, Delft, The Netherlands, email: jose.vandenijssel@lr.tudelft.nl) A. Selig, P. Hoyng and M. Smit (SRON, Utrecht, The Netherlands) N. Sneeuw, J. Mueller and R. Rummel (IAPG, Muenchen, Germany)

The Gravity field and steady-state Ocean Circulation Explorer (GOCE) is one of 4 ESA candidate missions in the Earth Explorer Mission program. Its main mission objective is a high-resolution, high-accuracy and homogeneous determination of the static Earth's global gravity field. To this aim GOCE will be equipped with a gradiometer providing Satellite Gravity Gradiometry (SGG) measurements, a GPS/GLONASS (GRAS) receiver providing Satellite-to-Satellite Tracking (STT) measurements and a Drag Free Control (DFC) to compensate non-conservative forces. The gravity field recovery of the GOCE mission will be based on both SST and SGG measurements. The gradiometer is particularly sensitive to the medium and high frequency gravity field information and the GRAS receiver will be used for the long and medium wavelengths. In the framework of the preparations for this mission and parallel to the phase A development a simulator facility is being developed. The main purpose of this simulator is to show how all system aspects of the satellite affect both the SGG and SST measurement accuracy and hence the final achievable gravity field recovery accuracy. To this end orbit recovery simulations are conducted to determine realistic values for the achievable orbit accuracy in the presence of error sources like e.g. measurement noise, dynamic modeling errors for the gravity and tides model and tropospheric correction errors. Furthermore, software is developed for the least-squares estimation of geopotential coefficients from SGG and SST data from GOCE. The procedure is based on an iterative, semi-analytical approach with a block-diagonal normal matrix. Recent progress in the development of the simulator will be shown.

Within the European AGMASCO project (Airborne Geoid Mapping System forCoastal

Oceanography), cooperations with user groups from Oceanography, Geology and Geodesy have been arisen. The airplane based gravimetry/altimetry system provides a rapid surveying procedure which is specially employed in not easily available marine and land areas (e.g. coastal/shelf areas, polar regions). In Geodesy, it serves for the improvement and refinement of already existing geoids and of future satellite-only models. The availability of precise regional geoids allow the monitoring of the dynamic sea-surface topography by satellite altimetry. For applications in geology and geotechnics, gravimetry is a pre-surveying method for exploration of energy resources. Exemplary the AGMASCO products such as gravity anomalies, sea-surface heights and improved regional geoids (Skagerrak/1996, Fram Strait/1997, Azores/1997) will be discussed. The accuracies correspond to the state-of-the-art of airborne gravimetry/altimetry.

A COMPARISON OF STABLE PLATFORM AND STRAPDOWN AIRBORNE GRAVITY

C.L. Glennie, K.P. Schwarz, A.M. BRUTON (Department of Geomatics Engineering, The University of Calgary, 2500 University Drive N.W. Calgary, Alberta, Canada T2N 1N4 R). Forsberg, A.V. Olesen, K.R. Keller, (KMS, National Survey and Cadastre, Rentemestervej 8, DK-2400 Copenhagen NV, Denmark)

To date, most operational airborne gravity results have been obtained using damped two-axes stable platform gravimeter systems such as the LaCoste and Romberg (LCR) S-model marine gravimeter. However, successful flight tests have also been flown using a strapdown inertial navigation system (INS), showing accuracy comparable to that obtained with the LCR gravimeter.
In June of 1998 three flight tests were undertaken which tested the LCR gravimeter and a strapdown INS gravity system side by side. To our knowledge this was the first time such a comparison flight was undertaken. The flights occurred in Disko Bay, off the west coast of Greenland. Several of the flight lines were flown along existing shipborne gravity profiles to allow for an independent source of comparison of the results.
This paper will present the results and analysis of these flight tests. The measurement method and error models for both the stable platform and strapdown INS gravity systems will be presented and contrasted. An inter-comparison of gravity estimates from both systems will be given, along with a comparison of the individual estimates with existing shipborne gravity profiles. The platform gravimeter and strapdown system have very different error behaviour, and therefore, combining the two estimates could give an overall increase in the performance and stability of airborne gravity

CALIBRATION/VALIDATION METHODS FOR GRACE

Christopher JEKELI (Department of Civil and Environmental Engineering and Geodetic Science, Ohio State University, 2070 Neil Ave., Columbus, OH 433210, USA, e-mail: jekeli.1@osu.edu).

The upcoming GRACE (Gravity Recovery and Climate Experiment) satellite mission is expected to map Earth's global gravitational field with unprecedented accuracy, especially at the long wavelengths. The measurements are line-of-sight range rates between two co-orbiting, low-altitude satellites that can be transformed into geopotential differences. One method to attempt the calibration and validation of GRACE data is to compare the long-wavelength field constructed from these data to a long-wavelength field obtained from terrestrial measurements. To achieve useful validation, the terrestrial standard must be based on extremely accurate data that are globally distributed. Moreover, if the terrestrial data distribution is not uniform and sufficiently dense, their long-wavelength constituents are difficult to ascertain. On the other hand, however, since in situ geopotential differences are derived from GRACE data, calibration and validation can be conducted at the local level. That is, using very accurate local terrestrial gravity fields that are upward continued to satellite altitude, one can calibrate GRACE data without requiring the construction of a global field. This paper compares the different calibration schemes, from the theoretical view (downward versus upward continuation, frequency versus space domain), the practical view (types of terrestrial data bases; e.g., global absolute gravity nets versus local, high-accuracy geoids and other models), and the science view (gravity mapping, as well as temporal changes).

THE CHALLENGE OF KINEMATIC POSITIONING AND ATTITUDE DETERMINATION

G6/W/06-B2 1400

THE MUTUAL IMPACT OF MODERN KINEMATIC METHODS AND AIRBORNE GEOSCIENCES

Alain GEIGER, Marc Cocard, Maurizio Scaramuzza, Hans-Gert Kahle and Etienne Favey (Institute of Geodesy and Geodynamics, Swiss Federal Institute of Technology, ETH-Hoenggerberg, CH-8093 Zurich, Switzerland, email: geiger@geod.ethz.ch)

Satellite methods open new fields of expertise for geodetic sciences. Especially kinematic methods are of growing interest for a large variety of applications. Airborne surveying in geo-sciences call for precise trajectography. Examples are aero-photogrammetry, Laser scanning for terrain elevation determination or airborne geophysics (gravimetry, magnetics). To document these developments, projects are presented which show the mutual impact of kinematic applications and geodesy. An integrated Laser-Profiler system, including DGPS and attitude sensors, was implemented on an aircraft to determine profiles of sea surface heights, and to monitor glacial fluctuations at the decimeter-level. On the fly ambiguity resolution algorithms were developed to constrain the position of the aircraft below the 10-cm level. Extensive campaigns were carried out in the Ionian and Aegean Seas. This area includes one of the steepest gradients of the geoid coincident with the Hellenic subduction zone.
The satellite geodetic methods can also be used to verify and validate new procedures in civil aviation. Geodetic methods may even be integrated into operational systems (blunder detection or RAIM algorithms, on the fly carrier phase solutions). An example is given of a project for analyzing and testing the feasibility of GPS-aided approaches for civil aviation in the Swiss Alps. During several test flights and dedicated ground missions various problems, such as satellite visibility, multipathing, GPS signal interference and the influence of the topography on the navigation and the GPS system were addressed. The tests showed the potential of satellite based systems for approaches, in particular for use in rugged terrain.

ABSOLUTE KINEMATIC GPS POSITIONING

Jay Kwon, Christopher JEKELI, and Shin-Can Han (all at Department of Civil and Environmental Engineering and Geodetic Science, Ohio State University, 2070 Neil Ave., Columbus, OH 433210, USA, e-mail: jekeli.1@osu.edu).

The Global Positioning System (GPS) has proved invaluable for precise positioning of moving-base platforms, such as aerial photogrammetric systems and ocean buoys that are used to study ocean circulation and sea level changes. To achieve sub-decimeter accuracy in position requires differential data processing with respect to a fixed base station in order to cancel the large GPS satellite clock errors (due primarily to Selective Availability). However, differential GPS methods introduce some additional errors, such as higher noise and unmodeled tropospheric delay differences for longer baselines (> 100 km). Also without a direct data link between the two receivers, these methods restrict the amount of data processing that can be done on board the moving platform. We have developed a method to estimate the GPS satellite clock errors to an accuracy as good as ±0.3 ns (±10 cm) and arbitrary resolution using OSU's GPS orbit determination software. With these estimates it is possible to conduct accurate absolute positioning of any moving base, unfettered by base station support requirements. This paper presents the clock estimation results and discusses applications to remote kinematic positioning.

G6/E/06-B2 1440

A GPS/INS/IMAGING SYSTEM FOR KINEMATIC MAPPING IN FULLY DIGITAL MODE

Mohamed M.R. Mostafa (Department of Geomatics Engineering, The University of Calgary, 2500 University Dr. N.W., Calgary, Alberta, Canada T2N 1N4, E-mail: mmrmosta@acs.ucalgary.ca); Klaus-Peter SCHWARZ (Department of Geomatics Engineering, The University of Calgary, 2500 University Dr. N.W., Calgary, Alberta, Canada T2N 1N4, E-mail: schwarz@ensu.ucalgary.ca)

This paper describes the development and testing of a fully digital multi-sensor system for aerial image capture and georeferencing for applications in remote sensing, mapping, and GIS. This system has been developed at The University of Calgary. The main objective of developing such a system is to acquire and georeference digital imagery in remote areas where ground control is neither available nor needed. The system incorporates a navigation grade strapdown Inertial Navigation System, GPS receivers, and two high resolution digital cameras. The two digital cameras capture strips of overlapping nadir and oblique images. They are configured in such a way as to overcome the geometric limitation of their small format size. Image exposure time and INS digital records are time-tagged in real time by the GPS. The INS/GPS-derived trajectory allows for the determination of the six independent parameters describing the motion of the carrier aircraft. Those trajectory parameters are directly related to the problem of exterior orientation. During postprocessing, image exterior orientation information is extracted from the INS/GPS-derived trajectory. This approach eliminates the need for ground control to provide 3D position of objects that appear in the field of view of the system imaging component. Test flights were conducted over the campus of The University of Calgary. In this paper, the multi-sensor system configuration and calibration is briefly reviewed and results of the test flights are discussed in some detail. First results indicate that major applications of such a system in the future are in mapping of utility lines, roads, pipelines (at mapping scales of 1:1000 and smaller), and the generation of digital elevation models for engineering applications.

G6/C/G3/E/11-B2 1500

GPS BASED ATTITUDE AND POSITION DETERMINATION FOR AIRBORNE REMOTE SENSING

Kevin SHERIDAN and Paul Cross (both at Department of Geomatic Engineering, University College London, Gower Street, London WC1E 6BT, UK, email: sheridan@ge.ucl.ac.uk and pcross@ge.ucl.ac.uk)

The design and testing of a GPS based position and attitude determination system for the direct georeferencing of airborne imagery is discussed. By combining dual frequency, high data rate GPS receivers with a relatively simple gyroscopic attitude and heading reference system, position and orientation data can be collected at a rate which matches that of a typical airborne scanner, with an accuracy adequate for georeferencing any imaged features.
Data collected in two flight trials in October 1998 have been processed using software developed at University College London and the University of Newcastle Upon Tyne, to determine a best estimate of the aircraft trajectory. The software employs single epoch ambiguity resolution, a modified double differencing algorithm for direct determination of attitude parameters, and a Kalman filter for data integration. The performance of this system is compared to that of a commercially available GPS multi-antenna attitude determination unit (Ashtech ADU2). Position and attitude are also calibrated using classical photogrammetric techniques with ground control.
Details of the computation methods are presented, and results are shown with an analysis of the possible applications.

ADAPTIVE KALMAN FILTERING FOR INS/GPS/GLONASS INTEGRATION

Jinling WANG, Mike Stewart and (Maria Tsakiri School of Spatial Sciences Curtin University of Technology GPO Box, U1987, Perth, WA 6845 Australia Email: Wang@vesta.curtin.edu.au)

Inertial Navigation System (INS) and satellite based positioning systems (GPS and GLONASS) are widely used autonomous positioning and attitude determination techniques. Either system has its own features. In the GPS/GLONASS systems, carrier phase measurements are superior in accuracy as long as integer carrier phase ambiguities are correctly resolved and no cycle-slips occur. The NS provides self-contained and high-rate accurate measurements within short time periods. However, systematic errors in the INS measurements may grow over time without bounds. Integration of GPS/GLONASS and INS can overcome shortcomings of each system. For integrated INS/GPS/GLONASS positioning, the high accuracy of INS measurements over short time periods is useful for cycle-slip correction and ambiguity resolution, whereas the precise carrier phase measurements are ideally suitable for continuous INS calibration.
Tightly-coupled INS/GPS/GLONASS integration is commonly implemented using a Kalman filter combining disparate raw measurements from INS and GPS/GLONASS sensors. Reliable Kalman filtering results, however, are highly dependent on the correct definition of stochastic models used in the filtering process. Stochastic modeling for INS and GPS/GLONASS measurements is not trivial, however. In this paper, a newly developed adaptive Kalman filtering algorithm is employed to estimate stochastic model for the measurements. Testing results from some experiments will be presented.

PRECISION ENGINEERING-NEW CONCEPTS AND SYSTEMS

G6/L/01-B2 1620

GEOTECHNICAL EXPLORATION - WIDER FIELDS OF ACTIVITY FOR GEODESISTS AND GEOPHYSICISTS

Ewald BRUECKL (Institute of Geodesy and Geophysics,Vienna University of Technology, A-1040 Wien, Gusshausstrasse 27-29, Austria, email: ebrueckl@luna.tuwien.ac.at)

In April 1998 the Symposium on Geodesy for Geotechnical and Structural Engineering was held in Eisenstadt, Austria, by the IAG, SC4. During one working session, titled "Geotechnical Exploration Strategy", experts from the fields of geotechnical exploration gave a view over tasks, methodology, results, and significance of geotechnical exploration based on a multidisciplinary approach combining the individual geoscientific methods. The geodetic community has a traditional position within geotechnical exploration, however, it turns out geodesists are rarely included into the planning and decision making team and new fields of activities are not occupied by geodesists adequately to their knowledge and expertise.
Based on an operational model of a multidisciplinary exploration team a strategy is drafted to improve the situation described above. Essential impulses could come from the universities by combining a universal education in Geodesy with a good geophysical training. This can diversify the methodes to be offered and improve the ability to develop geoscientific models. The construction and maintenance of databases including visualization and data exchange, as well as the global optimization of complex systems is fundamental to geodetic and geophysical work and additional geoscientific applications of these techniques should be emphasized. Further, a basic understanding of Geology and related geosciences is important to promote the integration into a geotechnical exploration team.

G6/L/02-B2 1640

BUILDING STRUCTURES AS KINEMATIC SYSTEMS

Rainer FLESCH (Civil Engineering Research Unit _FPZ P Arsenal, Faradaygasse 3, A-1030 Vienna, email: flesch@arsenal.ac.at); Dr.-Ing. Heribert Kahmen, (University of Technology Vienna, Institute of Geodesy and Geophysics, Dept. of Applied and Engineering Geodesy, Gusshausstrasse 27 - 29/E128/3, A-1040 Vienna, email: Heribert.Kahmen@tuwien.ac.at)

At the end of the 20th century, builders all around the world are pushing the limit in their quest for structural height and length. The competition for building bigger and taller is as old as civilization. Opening a new area in building the first skyscrapers began rising in Chicago and New York toward the end of the nineteenth century. Meanwhile, a new group of tall structures enters the picture: radio and TV broadcasting masts, towers, and industrial chimneys. The worlds` tallest structure is the KTHI TV mast (629 m) in Fargo, USA. At the same time the span lengths of bridges are increasing. In the near future main spans of more than 2000 m will be possible.
For safety inspection of civil engineering structures dynamic methods have to be developed. The described method is a combination of dynamic insitu testing and Finite Element Modelling.
For testing of the models a great variety of geodetic measurement systems and other sensor systemsis available. It will be shown, how different types of sensor systems can be used for the different inspection tasks.

G6/C/G1/E/55-B2 1700

MONITORING THE HEIGHT DEFLECTIONS OF THE HUMBER BRIDGE BY GPS AND GLONASS

Gethin ROBERTS, Vidal Ashkenazi and Alan Dodson (IESSG, University of Nottingham, Nottingham, NG7 2RD, UK, Email: gethin.roberts@nottingham.ac.uk)

This presentation details trials recently conducted by the IESSG whereby kinematic GPS and the Russian equivalent to GPS, Global'naya Navigatsionnaya Sputnikovaya Sistema (GLONASS), were used to monitor the deflection of the Humber Bridge, UK, under a loading of 160 tons, moved across the bridge by five articulated lorries. The trial consisted of placing four dual frequency GPS receivers and a GPS/GLONASS receiver on the bridge deck, a dual frequency GPS receiver upon one of the lorries and reference receivers placed on land. The data, gathered at 5 Hz, was then processed in an On the Fly manner resulting in a precision of the order of a few millimetres. Finite element modelling of such structures can take advantage of similar trials and results. The results were compared to a Finite Element Model by the Department of Mechanical Engineering at the University of Brunel, UK, and showed remarkable comparisons. Further trials were conducted in order to assess the use of single frequency carrier phase GPS receivers to position strategic locations upon the bridge at a rate of 10Hz. These trials demonstrated that a fast data capture rate would enable such GPS positioning to be used to monitor the deflection of smaller structures with a higher rate of movement.

G6/L/03-B2 1720

MOBILE MULTI-SENSOR SYSTEMS: THE NEW TREND IN MAPPING AND GIS APPLICATIONS

Naser EL-SHEIMY (Assistant Professor, Department of Geomatics Engineering, The University of Calgary, 2500 University Dr., N.W., Calgary, Alberta, Canada, Tel: (403) 220 7587, Fax: (403) 284 1980, E-mail: naser@ensu.ucalgary.ca)

Multi-sensor systems have become an emerging trend in mapping and GIS applications because they allow a task-oriented implementation of geodetic concepts at the measurement level. Examples of such systems can be found in airborne remote sensing, airborne laser scanning and mobile mapping from vans and trains. All of them have in common that the sensors necessary to solve a specific problem are mounted on a common platform. By synchronizing the data streams accurately, the solution of a specific problem is possible by using data from one integrated measurement process only. The post-mission integration of results from a number of disjointed measurements processes and the unavoidable errors inherent in this process are avoided. This results in greater conceptual clarity, task-oriented system design and data flow optimization, and also offers in most cases the potential for real-time solutions, which are becoming more important in many applications.
The presentation will cover both, the concept of multi-sensor integration and implementation aspects. Based on experience with a number of different systems, features common to most systems will be identified and a unified model for multi-sensor integration will be formulated. Suitable observables for these models will be assessed, and factors affecting system performance will be discussed. All major features will be illustrated by examples. Finally, data-flow optimization and the potential for automation of the data acquisition and feature extraction process will be reviewed with a view to future systems.

G6/L/04-B2 1740

TRAFFIC GUIDANCE AND CONTROL -TECHNOLOGICAL CHALLENGES FOR GEODESY AND GEOMATICS

Wolfgang MOHLENBRINK (Institute for Applications of Geodesy to Engineering), University of Stuttgart, Geschwister-Scholl-Str. 24D, D-70174 Stuttgart, Germany
Email: wolfgang.moehlenbrink@iagb.uni-stuttgart.de)

Land vehicle navigation units for mono- and multimodal traffic systems based on digital rail and road maps are seen as booming markets for future geo-information services. Especially car navigation systems based on standardized digital road maps provide key technology for traffic guidance and control. The emerging border crossing market require standardized metric and topological reference systems. Due to the changing professional cernel competences of geodesists - the classical scenario of expertise in accuracy for local, regional and global geometric networks will be changed to the picture of an information service provider for accurate complete up-to-date and in time available information with precise geometical attributes. Therefore a special working group _Traffic Guidance and Control with members of industry, traffic authorities and IAG-experts with the following tasks: development of topological information structures for intermodal traffic guidance systems definition of information quality requirements for traffic information services research work on information and data quality procedures for safety relevant traffic systems operations has been proposed and founded at SC 4(IAG) at Eisenstadt, Austria, hold on April 20-22, 1998.
These technological challenges could be a future market for all members of IAG.
