Doug FINLAYSON (Australian Geodynamics Cooperative Research Centre (AGCRC), Australian Geological Survey Organisation, Canberra, Australia, email: dfinlays@agso.gov.au); Dick Glen (AGCRC, Geological Survey of New South Wales, St. Leonards, NSW 2065, Australia, email: glenr@minerals.nsw.gov.au); Russell Korsch, David Johnstone (AGCRC, Australian Geological Survey Organisation, Canberra, Australia, email: rkorsch@agso.gov.au, djohnsto@agso.gov.au)

The Lachlan Transverse Zone (LTZ) is a newly recognised major yet subtle WNW-trending structure that cuts across the meridional to NNW regional grain of the Neoproterozoic to Mesozoic Tasmanides of South eastern Australia. The LTZ represents the reactivated extension of the southern edge of a WNW trending weak zone that cuts through the Australian continent. The western part of the LTZ separates the Thomson Orogen to the north and Delamerian Orogen to the south. Further east in the Lachlan Orogen, the LTZ has been recently identified as a corridor of repeated faulting and folding since the Early Silurian. The LTZ also controls the localisation of crustal and mantle-derived melts, including Late Ordovician high K (shoshonitic) monzonites and related volcanics that contain major gold and copper deposits in central New South Wales.
In the eastern belt of the Lachlan Orogen, velocity models derived from a 1997 wide-angle seismic profile and reflection profiling across the LTZ have identified significant sub-surface features within the upper and middle crust. These are interpreted to be associated with the Ordovician Macquarie Arc in the north and contrast with features under the Ordonvician turbidites and Early Devonian granites to the south. They are inferred to be expressions of the LTZ and related structures in the middle and lower crusts and indicate the lithospheric nature of its character.

EFFECTS OF SOLAR PROTON EVENTS ON THE MIDDLE ATMOSPHERE

CHARLES H. JACKMAN (Code 916, NASA Goddard Space Flight Center, Greenbelt, Maryland, 20771, U.S.A., email: jackman@assess.gsfc.nasa.gov) Eric L. Fleming (Steven Myers and Associates Corporation, Vienna, Virginia, 22180, U.S.A., email: fleming@kahuna.gsfc.nasa.gov)

Solar proton events (SPEs) can result in increases in both HOx (H, OH, HO2) and NOx (N, NO, NO2) constituents in the polar middle atmosphere. Decreases in mesospheric and upper stratospheric ozone caused by HOx constituents produced by SPEs have been observed during several events, however, ozone levels generally recover within a few hours after the end of these events because of the short lifetime of the HOx species. The NOx species feed into the more inclusive odd nitrogen family, NOy (N, NO, NO2, NO3, N2O5, HNO3, HNO4, ClONO2), over a period of hours to weeks. In low sun and lower altitude conditions, the NOy family lasts several months or more in the stratosphere causing prolonged ozone changes over these longer periods. Observations of mesospheric winds during and after SPEs have also indicated some variations as a result of these atmospheric perturbations. An overview of the influence of SPEs on the polar neutral middle atmosphere will be presented in this paper.

JSA45/E/07-B4 **0945**

THE LATITUDE EXTENT OF SOLAR PROTON FLUX FROM THE POLAR REGIONS DURING QUIESCENT AND DISTURBED GEOMAGNETIC CONDITIONS

M.A. SHEA and D.F. Smart (Air Force Research Laboratory, VSBS, 29 Randolph Road, Hanscom AFB, Bedford, MA 01731-3010, U.S.A., email: shea@plh.af.mil)

The extent of most solar proton events is limited to the region of the polar cap above a corrected magnetic latitude of 60 degrees (i.e. quiescent magnetic field L values greater than ~4). Approximately 15 percent of the proton events each solar cycle contain protons with energies in excess of 500 MeV which make transient contributions to mid latitude regions. However, during magnetic activity, the polar cap expands equatorward. The combination of a fast interplanetary shock and enhanced geomagnetic activity is the condition for very large solar proton fluence with a distribution of the flux to surprisingly low latitudes. For example, during the October 1989 solar proton event and major geomagnetic disturbance we compute there was a significant flux of protons down to a geographic latitude of ~37 degrees. The cutoff boundaries are surprisingly sharp in the energy range of 30 to several hundred MeV.

SOLAR WIND AND ENERGETIC ELECTRON PRECIPITATION VARIATIONS: EFFECTS ON THE MIDDLE ATMOSPHERE

LINWOOD B. CALLIS (Atmospheric Sciences Division, NASA Langley Research Center, Hampton, VA 23681-0001, e-mail: lbc@jaguar.larc.nasa.gov)

A solar-atmospheric coupling by electrons (SOLACE) precipitating into the atmosphere which affects global ozonehas been reported. This coupling, and the findings required for the confirmation of this coupling, are described. Observations of the solar wind, precipitating electron fluxes, nitric oxide in the thermosphere and mesosphere, and nitrogen dioxide measurements in the lower mesosphere and upper stratosphere confirm the existence of this solar-terrestrial coupling mechanism which is shown to be important to the odd nitrogen budget of the lower thermosphere and the mesosphere. Two-dimensional chemical transport simulations from 1979 through 1987 including a typical trace gas scenario, UV flux variations, and the effects of energetic electron precipitation (EEP) have been carried out to assess the importance of these effects on stratospheric ozone and odd nitrogen. Results indicate that the effects of EEP on ozone extend to the middle latitudes and are comparable to those due to solar UV variations but have significantly different latitudinal distributions of the ozone depletions. Satellite observations of trace species throughout the stratosphere and published three- dimensional tracer simulations, provide evidence for the dispersion to lower latitudes of the odd nitrogen formed by the electrons in the mesosphere and descending into the stratosphere during the late fall, winter, and early spring. The implications of these findings are discussed.

THE INFLUENCE OF AURORAL AND PHOTOELECTRONS ON ODD-NITROGEN, ODD-HYDROGEN AND OZONE IN THE MIDDLE ATMOSPHERE

Guy P. Brasseur and Rashid Koshravi (both at the National Center for Atmospheric Research, Boulder, Colorado, 80303, USA, email: brasseur@ucar.edu)

SOCRATES, a two-dimensional model of the atmosphere extending from the surface to 120 km altitude has been used to assess the response of the mesosphere and stratosphere to the preciptation of auroral and photoelectrons. This response will be compared to the impact of solar variability on the middle atmosphere, and to the perturbations caused by the release in the atmosphere of anthropogenic chemical compounds.

JSA45/E/10-B4 1125

MAGNETOSPHERE-THERMOSPHERE COUPLING: COMPARISON OF MEASUREMENTS OF ELECTRON FLUXES IN THE MAGNETOSPHERE AND NITRIC OXIDE IN THE THERMOSPHERE

D.N. BAKER, C.A. Barth, and S.C. Solomon (Laboratory for Atmospheric and Space Physics, University of Colorado, Campus Box 590, Boulder, Colorado, 80309-0590, USA, e-mail: baker@lynx.colorado.edu); S.M. Bailey (CES, Hampton University, Hampton, VA 23668); S.G. Kanekal (Goddard Space Flight Center, Greenbelt, MD 20771); G.M. Mason (University of Maryland, College Park, MD 20742)

Simultaneous measurements have been made of electrons in several energy ranges (>25keV, >0.4MeV, >1 MeV, 2-6 MeV) with the SAMPEX spacecraft and of nitric oxide density in the lower thermosphere by the SNOE spacecraft for the period March 11, 1998 to December 31, 1998. Comparison of the observations show that during periods of geomagnetic storms, the electron fluxes increase and move to lower L-shells. In response, the nitric oxide density in the auroral region increases and the auroral boundary moves equatorward. These coordinated meas-urements help to clarify an important solar-terrestrial coupling process.

JSA45/W/13-B4 1145

THE DEPENDENCE OF JOULE HEATING ON THE SOLAR WIND-MAGNETOSPHERE COUPLING FUNCTION DURING MAGNETIC STORMS

Ms HUIXIN LIU

By using EISCAT data, Joule heating rates in the auroral ionosphere during different storm events are calculated. The correspondent solar wind-magnetosphere coupling functions,epsilon, are derived from IMP8 and WIND satelllite data. Through cross-correlation analysis certain relationship is found between the auroral ionospheric Joule heating rate and epsilon. And its dependences on solar cycle, season, geomagnetic activities are also presented.

THE EFFECTS OF THE VARIABLE SOLAR WIND ON THE GLOBAL ELECTRIC CIRCUIT

Brian A. TINSLEY, (University of Texas at Dallas, Richardson, TX 75083-0688 USA, e-mail: Tinsley@UTDallas.edu).

The global electric circuit links the troposphere, middle atmosphere, and ionosphere, and the distribution of current density in any one region responds to changes in properties of any of the others. We review models of the global circuit, and of effects on the latitude distribution of ionosphere-earth current density Jz, due to:
(1) Changes in the cosmic ray energy spectrum and flux
(2) Solar proton events
(3) Changes in polar cap ionospheric potential
(4) Changes in relativistic electron precipitation (REP) from the magnetosphere. The changes in conductivity in the stratosphere induced by REP and associated Bremsstrahlung X rays can extend down to 35 km. If the stratosphere has been pre-conditioned to a sufficiently low value of conductivity by H2SO4 aerosols and vapor from volcanic injections then the modulation of this conductivity by REP can modulate the vertical column impedance sufficiently to modulate Jz. Observational data on all four modulations of the latitude distribution of Jz are sparse and noisy, but consistent with theory. Given that such changes can affect cloud microphysics (as discussed in my paper in JSA16), correlations of atmospheric temperature and dynamics with Jz and with solar activity can be explained.

JSA45/W/11-B4 1430

VARIABILITY OF COSMIC RAY FLUXES TO THE EARTH ATMOSPHERE AND CLIMATE CHANGE

Joan Feynman and Alexander RUZMAIKIN (Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Dr., Pasadena, CA 91109, USA, email: aruzmaikin@jplsp.jpl.nasa.gov)

High energy cosmic rays may influence the formation of clouds, and thus can have an impact on weather and climate. Cosmic rays in the solar wind are incident on the magnetosphere boundary and are then transmitted through the magnetosphere and atmosphere to reach the upper troposphere. The flux to the troposphere will depend both on the intensity and spectrum of the cosmic rays at the outer boundary of the magnetosphere (magnetopause) and on the configuration of the magnetosphere through which they propagate. Both the incident flux and the magnetospheric transmission have changed systematically during this century due to systematic changes in the solar wind. We show that, early in the century the region of the troposphere open to cosmic ray precipitation was usually confined to a relatively small high-latitude region. As the century progressed there was a systematic increase in the size of this region by over 7 degrees. We suggest that these changes contributed to climate change during the last 100 years.

JSA45/W/18-B4 1450

INFLUENCE OF FORBUSH DECREASE OF GALACTIC COSMIC RAYS ON ATMOSPHERIC CHARACTERISTICS IN ANTARCTICA

Larisa Egorova, Valery Vovk and Oleg TROSHICHEV (all at Arctic and Antarctic Research Institute, St.Petersburg, 199397, Russia, email: olegtro@aari.nw.ru)

Relationship between variations of the galactic cosmic rays (GCR) and behavior of atmospheric pressure, temperature and wind speed observed in the region of Antarctic plateau (Vostok station), has been studied for solar cycle 1981-1991. 52 events of Forbush decrease in GCR observed in winter seasons when the solar radiation above Vostok station is absent have been chosen for analysis. It is shown that Forbush decreases affect the temperature profiles at altitudes 0-20 km, the temperature being increased up to maximum (20%) in the near-ground layer (0-3 km). There is a stable correlation between energetic (1-10 GeV) proton flows and variations in tropospheric and near-ground atmospheric pressures, the time delay (0-5 days) being depended on type of solar flare and course of the pressure change before the solar flare. The Ground Level Event in the solar protons led to 2-3 % growth in the atmospheric pressure at altitudes 0-15 km, whereas Forbush decrease produce a 2-8 % reduction in the pressure, the extent of pressure variations at altitudes 10-15 km being much more than that in the near-ground layer. In case of powerful Forbush decreases (20 events) the pressure reduction started simultaneously with decrease in GCR or one day later. In case of less power Forbush decreases the time delay is more, the maximum delay (up to 6 days) being observed when GCR variations occur against the background of the pressure growth. The temperature and pressure differences give rise to changes in a direction of winds observed above Vostok in connection with Forbush decreases. Results of investigation imply that connection between the above mentioned processes is explained by changing of the atmospheric transparency owing to formation of ice particles and small atmospheric components.

JSA45/E/16-B4 1510

ENERGETIC ELECTRONS AND THEIR EFFECTS ON STRATOSPHERIC AND MESOSPHERIC OZONE IN MAY 1992 AND BEYOND

W. Dean PESNELL (Nomad Research, Inc., Bowie, MD 20716, USA,
email: pesnell@NomadResearch.com) Richard A. Goldberg (NASA Goddard Space Flight Center, Laboratory for Extraterrestrial Physics, Code 690, Greenbelt, MD 20771, USA,
email: goldberg@nssdca.gsfc.nasa.gov) David L. Chenette and Edward E. Gaines (both at Research and Development Division, Lockheed Martin, Palo Alto, CA 94304, USA, email: chenette@spasci.com, gaines@spasci.com) Charles H. Jackman (NASA Goddard Space Flight Center, Laboratory for Atmospheres, Code 916, Greenbelt, MD 20771, USA, email: jackman@assess.gsfc.nasa.gov)

The increased fluxes of precipitating energetic electrons (E > 1 MeV) during highly relativistic electron events (HREs) produce ion concentrations in the upper stratosphere and lower mesosphere that exceed the background concentrations. Coupled ion-neutral chemistry models predict that this increased ionization should drive HOx reactions and deplete mesospheric ozone by up to 30%. As HREs are more intense and more frequent during solar minimum than maximum, it was also predicted that mesospheric ozone would show long-term effects as a result of these events. To calibrate the effect HREs have on mesospheric ozone, we have studied the May 1992 HRE with several instruments on the UARS. Electron fluxes measured with HEPS give the duration and spatial coverage of the HRE. Ozone data from MLS, CLAES, and HRDI were examined for the chemical signature of the HRE, ozone depletions within the magnetic L-shell limits of 3 < L < 4.
Using the multiple viewing angles of HRDI, we compare mesospheric ozone at similar local solar times before, during, and after the HRE. This removes some of the ambiguity caused by progressive sampling of the diurnal cycle over a yaw cycle of the satellite. Our analysis shows that between altitudes of 55-75 km the ozone mixing ratio is not affected by the particles at the signal-to-noise level of the data. Extrapolating our results to solar timescales requires allowing for the seasonal dependence of water vapor, as well as the occurrence rate, geographic coverage and duration of HREs. Detecting a long-term trend in the ozone driven by precipitating electrons appears to require a substantial increase in the signal-to-noise ratio of the satellite measurements.

JSA45/W/19-B4 1550

THE SOLAR WIND INFLUENCE ON THE THERMAL REGIME OF THE MIDDLE ATMOSPHERE AT DIFFERENT LATITUDES

Ludmila MAKAROVA and Alexander Shirochkov (both at Arctic and Antarctic Research Institute, St.-Petersburg, 199397 Russia,.e-mail: shirmak@aari.nw.ru)

The reliable evidences are presented which demonstrate that the energetic balance of the middle atmosphere must include energy of the solar wind that under definite conditions can play important role in determination of the middle atmosphere thermal regime. The experimental data used for this study include results of the rocket and baloon measurements performed by the Russian scientists for many years at various polar and midlatitudinal observatories. The measured atmospheric parameters were compared with the concurrent values of the solar wind density (n) and its dynamic pressure (Psw=m n V2, where m- proton mass, n and V - the solar wind density and velocity, respectively). The solar wind parameters determine value of subsolar distance between the Earth's magnetosphere magneopause and the Earth. The latter parameter seems to be the universal geophysical index directly proportional to the amount of the solar wind energy transferred into the near - Earth space including the atmosphere. This study reveal a high degree of correlation between the solar wind dynamic pressure and/or the magnetopause position and the following atmospheric processes:a) variability of the thermal regime of the middle atmosphere, b) occurrence of the sudden stratospheric warmings, c) violation of the regular regime of circulation in the middle atmosphere, d) ozone density at definite stratospheric altitudes, e) temperature gradient in the tropopause. These connections are more evident in winter (when UV radiation is weak) and under Eastern QBO orientation. It is noteworthy that the influence of the solar wind on the atmospheric processes has a global scale. A probable physical mechanism responsible for these processes is a version of the global electric circuit with the magnetopause as the external element of this circuit.

JSA45/W/12-B4 1620

LONG-TERM EFFECTS OF THE VARIABILITY OF SOLAR UV RADIATION ON THE ION CHEMISTRY OF THE MIDDLE ATMOSPHERE

Thomas Ulich1, Esa Turunen1, Pekka Verronen2, Erkki Kyrölä2 1Sodankylä Geophysical Observatory, FIN-99600 Sodankylä, Finland; 2Finnish Meteorological Institute, Geophysical Research, P.O.Box 503, FIN-00101, Helsinki, Finland

The solar UV radiation is the main ionising factor in the day-time upper mesosphere during quiet geophysical conditions. The UV radiation varies with the solar activity cycle. This variation is much stronger than the variability of the total solar irradiance or the variability of visible light. We use the detailed 55-ion Sodankylä Ion Chemistry (SIC) model in order to study the effects of changing UV input to the atmosphere. Using available UV data and models as input in the calculation of the ionisation balance, we compare the model results both with long-term data sets from ground based instruments, and with available satellite data.

JSA45/E/02-B4 Invited 1640

GEOMAGNETIC STORM IMPACT ON ATMOSPHERIC OZONE LAYER

Jan LASTOVICKA (Institute of Atmospheric Physics, Bocni II, 141 31 Prague 4, Czech Republic, email: jla@ufa.cas.cz)

A brief review of effects of strong geomagnetic storms on total ozone content, targeted to effects observed near the latitudinal circle of 50oN, shows that at these latitudes geomagnetic-storm related changes in total ozone can very probably be attributed to storm-related changes in atmospheric circulation. Both ground-based and TOMS data are used. Significant effects of geomagnetic storms on otal ozone have been observed only in winter and for strong storms, Ap > 40 or better 60, and only under very specific conditions - high solar activity and the east phase of QBO. This means that it s rather rare effects, as shown by an analysis of data over 1963-1995. The observed effects consist in redistribution of ozone, not in ozone production or loss, which again point out to their dyn origin. They are developed best in the European/North-Eastern Atlantic and East Siberian/Aleutian sectors and invisible in latitudinal average values. In European sector, the effect consists in a significant increase of total ozone with and just after the storm. Overall, the effect at 50oN appears as substantial diminishing of longitudinal variation along this latitudinal circle. The effect of geomagnetic storms is pronounced at 50oN, absent at 40oN (too low latitude), and it does not occur in a systematic manner also along the 60oN latitudinal circle.
No detectable effects of geomagnetic storms on laminae (narrow layers of substantially enhanced ozone concentration) in ozone profiles are found in data from several analyzed ozonesounding stations, even though laminae are generally sensitive to various influences. The effects of geomagnetic storms in circulation in the European/North-Eastern Atlantic area do not support meridional circulation and, therefore, contrary to total ozone no increase in laminae is observed.

JSA45/L/01-B4 Invited 1710

EFFECTS OF SOLAR CYCLE ULTRAVIOLET VARIATIONS ON OZONE

Lon Hood (Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721, USA, email: lon@lpl.arizona.edu)

At wavelengths where photo dissociation of molecular oxygen is important in the upper stratosphere, solar spectral irradiance changes from solar minimum to maximum are substantial ($\sim$ 6\% at 205 nm). Current two-dimensional chemical/dynamical models predict corresponding changes in ozone of several per cent with maximum amplitude in the middle stratosphere (3--5 mb). However, observations based on satellite measurements since 1979 indicate a solar cycle variation of ozone with maximum amplitude of 4--6\% in the upper stratosphere (1--2 mb). The observed solar cycle ozone change approaches zero in the middle stratosphere (4--10 mb) and then increases again in the lower stratosphere. The most probable explanation for the disagreement between observations and models is transport effects on ozone or other species (e.g., methane) that are not included in 2-D models.
In addition to the upper stratospheric ozone variation, a change in total ozone from solar minimum to maximum is observed with global mean amplitude of 1.5--2.0\%. According to SBUV-SBUV/2 data, most (about 85\%) of this variation occurs in the lower stratosphere (altitudes $<$ 28 km) where 2-D models predict only a small photochemical ozone response. The observed lower stratospheric ozone variation therefore appears to be driven by circulation changes between solar minimum and maximum. These circulation changes are probably associated with the observed quasi-decadal oscillation originally reported by K. Labitzke and H. van Loon. Recent work by S. Chandra and co-workers indicates evidence for changes in tropospheric ozone in the tropics that are out of phase with stratospheric ozone changes on a time scale of a solar cycle. This would imply that the lower stratospheric ozone variation is somewhat larger than previously estimated.

JSA45/E/01-B4 1740

11-Y SOLAR MODULATION OF THE INFLUENCE OF THE EQUATORIAL QBO ON TOTAL OZONE AND STRATOSPHERIC CIRCULATION OVER NORTHERN EUROPE

Boris SOUKHAREV (Department of Climatology, St.Petersburg State University, 10 linia, 33, 199178, St.Petersburg, Russia, email: boris@seb.usr.pu.ru)

The monthly mean data of total ozone over Northern Europe and indices of stratospheric circulation at 30 hPa (Cne) over the region for the months from January to March for the period 1957-1996 are used in order to show that the 11-y solar cycle can be a modulator of the remote influence of the equatorial QBO on the interannual variability of ozone and stratospheric dynamics over polar region. Method of the running correlation between the total ozone (and indices Cne) and the equatorial stratospheric zonal wind demonstrates clear modulation of an 11-y solar signal for February and March. The curves of the running correlations show that a sign of correlation between the equatorial stratospheric zonal wind and the studied parameters changes in dependence on solar activity.
Special statistical procedure has been used for the demodulation of an 11-year solar signal from the time-series of ozone and indices Cne. The obtained solar signal which is in phase with the solar cycle, is most clear for February and March. Using the same procedure, an attempt to retrieve the February - March time-series of total ozone and Cne from the data of equatorial zonal wind and 10,7 cm solar radio flux has been made. Correlation coefficients between the retrieved and initial ozone and Cne data for February are about r = 0,80 in the periods of solar extrema. Thus, the resent study shows that the most part of the interannual variability of total ozone and stratospheric dynamics over Northern Europe in February - March can be expressed as a product of interaction between the 11-y solar cycle and the equatorial QBO.

JSA45/E/04-B5 Invited 0830

ARE THERE SOLAR SIGNALS FROM THE MIDDLE ATMOSPHERE IN THE POLAR ICE?

Gisela A. M. DRESCHHOFF (Space Technology Center, University of Kansas, Lawrence, KS 66045, USA) M.A. Shea and D.F. Smart (both at Space Effects Division, Geophysics Directorate/PL, Hanscom AFB, Bedford, MA 01731, USA) K.G. McCracken (Jellore Technologies, Mittagong, NSW, Australia)

Ultra-high resolution measurements of nitrate concentrations in snow and ice from both polar regions revealed the superposition of a number of components such as seasonal variations and longer-term trends. Part of this signal has been interpreted as having been produced in the auroral zone by ionization and modulated by the solar activity cycle. In addition, the fine structure of the nitrate signal reveals the stratospheric ionization effects of large solar proton events such as the solar flare of 1972, which produce distinct pulses of nitrate anomalies that are recognizable over wide areas of the Antarctic and the central Greenland ice sheets. For this reason, local and regional meteorological influences have been effectively eliminated. The resence of such nitrate anomalies retained in the stratigraphy of the continental ice sheets, remains a challenge for model calculations and the parameterization used to represent the chemical and dynamical processes operating at the high magnetic latitudes.
This paper presents a discussion of indirect observations of energetic particle injections into the polar atmosphere, including the frequency of impulsive nitrate events, a quantitative estimate of nitrate production by solar protons, a comparison with the cosmic ray record, and the occurrence of large solar proton events during the time interval 1576-1990.

JSA45/W/10-B5 0900

SOLAR CYCLE DEPENDENCE OF MIDLATITUDE MESOPAUSE REGION WINDS AND WAVES

Christoph JACOBI and Martin Lange (Institute for Meteorology, University of Leipzig, Germany, email: jacobi@rz.uni-leipzig.de)

Long-term measurements of mesopause region winds performed at Collm, Germany, show a 11-year solar cycle dependence of the of the zonal prevailing wind, so that during solar maximum the spring and summer easterlies in the upper mesosphere are stronger than during solar minimum. The measurements are presented in comparison with model results. The changes of the mean circulation influences the conditions for the excitation of the 2-day wave, so that during solar maximum the quasi 2-day wave is stronger than during solar minimum.

JSA45/L/02-B5 Invited 0920

AN ADJOINT METHOD OF CALCULATION OF ENERGETIC SOLAR-PARTICLE-EVENT EFFECTS ON THE EARTH'S ATMOSPHERE

K. O'Brien (Northern Arizona University, Flagstaff, AZ 86011 USA), Herbert H. Sauer (CIRES, University of Colorado, Boulder, CO 80303, USA; NOAA Space Environment Center, Boulder, CO 80303, USA)

High energy solar particles, produced in association with solar flares and coronal mass ejections, occasionally bombard the earth's atmosphere, resulting in radiation intensities additional to the already-present cosmic-ray dose rates. Access of these particles to the earth's vicinity during times of geomagnetic disturbance are not adaquately described by using static geomagnetic field models. These soalr fluxes are also often distributed non-uniformly in space, so that fluxes measured by satellites obtained at great distances from the earth and which sample large volumes of space around the earth cannot be used to predict fluxes locally at the earth's surface. We present here a method which uses the ground-level neutron monitor counting rates as adjoint sources of the flux in the atmosphere immediately above them to obtain solar-particle dose rates as a function of position over the earth's surface. We have applied this approach to the large September 29-30, 1989 event (GLE 42) to obtain the magnitude and distribution of the dose rates from an atypically large event. This approach could easily be adapted to the calculation of other atmospheric quantities of interest, such as ionization and energetic primary and secondary particle fluxes.

JSA45/W/16-B5 0950

THE ROLE OF PLANETARY WAVE PROPAGATION IN COUPLING THE MIDDLE AND UPPER ATMOSPHERES THROUGH A SOLAR CYCLE

Neil ARNOLD and Terry Robinson (both at the Department of Physics and Astronomy, Leicester, LE1 7RH, UK, email: nfa1@ion.le.ac.uk)

A new three-dimensional model of the middle and upper atmosphere between ~10-350km has been constructed to study the dynamical coupling between the two regions. In addition to more sophisticated radiative transfer calculations in the thermosphere and a better representation of ion drag, a three-dimensional diabatic heating scheme was adopted in the middle atmosphere for the first time. Previously reported results using a simplified upper atmosphere had indicated that there could be significant coupling in the winter hemisphere, especially during warming events, that varied according to solar flux levels. These simulations have been repeated under a range of different initial and boundary conditions using the improved version of the model and the preliminary results compared. Possible implications for the climate of the middle atmosphere will be discussed.

JSA45/E/09-B5 1010

OZONE RESPONSE AFTER SOLAR PROTON EVENTS IN 1997-1998

Alexei KRIVOLUTSKY, Alexsand Kuminov, Alexandr Repnev (all at Central Aerological Observatory, Pervomayskaya Str.3, Dolgoprudny 141700, Moscow Region, Russia,
email: alkriv@mycomp.netclub.ru) Nina Perejaslova and Margarita Nazarova (both Institute of Applied Geophysics, Moscow, Russia)

Solar Proton Events (SPEs) in 1997 and 1998 as a cause of chemical species perturbations in the middle atmosphere has been investigated using numerical photochemical model and energy spectrum of the solar proton fluxes measured by Russian satellite system "Meteor" which has polar orbits with usual inclination about 80-82 degrees.SPE which was in November 1997 was the first event after the solar minimum looked like the manifestation of a new solar cycle growth.Model calculations has been accompained by UARS data analysis (MLS instrument) at high latitudes of the Southern Hemisphere during November 1997 at 20-80 km range of altitudes. Energy differencial spectrum of solar protons was used to calculate a correspondent ionization rates in the middle atmosphere after SPEs. This ionization in accordance to the theory leads to the NOX and HOX production and disturbs neutral chemical

system of the atmosphere including ozone.
Model calculations has shown short-term negative ozone response in the mesosphere(with increased HOX content) and long-term response in the stratosphere accompained by increased NOX content.

JSA45/E/11-B5 1030

EFFECTS OF TIME VARIABLE SOLAR RADIATION ON THE MIDDLE ATMOSPHERE DYNAMICS

FAHRUTDINOVA A.N., Guryanov V.V., Berdunov N.V., Zaitcev A.V., Fedorov D.V. (Kazan State University, Kazan 42008, Russia, email: Antonina.Fahrutdinova@ksu.ru)

The investigation of effects of time variations of solar radiation in dynamics of middle atmosphere have been conducted by long series of measurements, made by radiometeor method within the height interval 80-110 km at Kazan University radiostation (56 N, 49 E) during the period 1986-1995 and by the time series of Katz indexes in Atlantic-European sector at latitude zone 50-70 N for the period 1977-1990. The correlation coefficients of interannual variations of solar radiation and the following dynamics parameters: mean annual values, amplitudes of annual and semiannual oscillations of zonal wind within the height interval 80-110 km, and also mean annual values, amplitudes of annual and semiannual oscillations of Katz indexes at 6 levels within the height interval 0-30 km. It has been found that the level of connection and the sign of correlation are changing depending on the interval of heights of middle atmosphere and the dynamic parameters.

THE GLOBAL ATMOSPHERIC-ELECTRICAL CIRCUIT, MESOSPHERIC ELECTRICAL PHENOMENA, AND PARTICLE PRECIPITATION - VOLCANOES LIKE LIGHTNING RODS

C. Bellecci (II Universita di Roma, Tor Vergata, Roma, Italy); C. Bianchi, G. de Franceschi, G. di Stefano, G. Romeo, C. Scotto, Q. Taccetti, and B. Zolesi (ING, Roma, Italy); G. M. Crisci (UNICAL, Arcavacata di Rende, Cosenza, Italy); G. P. Gregori (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy; e-mail: gregori@atmos.ifa.rm.cnr.it); I . Marson (Universita di Trieste, Italy); and G. Paparo (IDAC-CNR, Roma, Italy)

The interpretation appears difficult of several phenomena, such as e.g. the positive charge of the ionosphere, domes of light, noctilucent clouds, elves, sprites, blue rays, lightnings within volcanic plumes, earthquake lights, geo-e.m. earthquake precur s ors (within either ground, or the ionosphere, or airglow), limb-scanning of the step-like airglow discontinuities and their relation with the South-American anomaly, etc. All such items envisage that some relevant bias forbids a satisfactory assessment of the global atmospheric-electrical circuit. Perhaps, one related key-aspect is concerned with the total Coulomb charge of the precipitating particles over the atmosphere. In fact, until the late '60's they were generally believed to be strictly neutral. Later on, the spectroscopic evidence by polar auroras showed that proton auroras are observed within one large sector of the sky of a given station, while electron auroras are displayed in the remaining part of the sky. Hence, the supposed Coulomb neutral i ty is achieved only when integrating over a large area. The concern remains about the eventual deviation in time of Coulomb neutrality, and on the time range needed for average neutrality (either seconds, or solar cycle, or else). How could such a feature be observed? Has it ever been discussed? An experiment on the volcanic island of Stromboli is supposed to investigate the electrical relations between volcanic explosions, their Coulomb charge, lightnings, and related ionospheric disturbances. Similar unknown effects could exist over anomalous geothermal areas, etc. High time-resolution ionosondes ought to be collected.

JSA45/E/05-B5 Invited 1110-02

HF DOPPLER OBSERVATIONS OF LOWER IONOSPHERE IN SOLAR PROTON EVENTS

Takumi ICHINOSE, Nobuyuki Nakai and Tatehisa Ohta (Department of Electronics, Doshisha University, Kyotanabe, Kyoto 610-0321, Japan, email: tichinos@mail.doshisha.ac.jp) Toru Ogawa (Nagareda, Kamitakano, Kyoto 606-0037, Japan, email: pxi03720@nifty.ne.jp)

Effects of the high-energy solar protons on the lower ionosphere at low magnetic latitude have been observed by the HF Doppler technique. The 5, 8 and10 MHz standard frequency signals have been received with a horizontal distance of 390 km. The magnetic latitude of the reflection point is about 25 degrees. We analyzed this phenomenon in the last ten years and found its characteristics as follows,
(1) Classes of the solar X-ray flares are between M4 and X1. Because, smaller ones have not enough numbers of emitted particles and larger ones ionize lower E-region to generate fadeouts of the ionospheric propagation. (2) Mean velocity of the particles is larger than ten thousand km/s and it takes only a few hours from the Sun to the Earth. Because, it is necessary to have such high velocity to enter into the lower ionosphere at low-latitude.(3) These events started as a sharp positive pulse of the Doppler shifts that almost coincides with the beginning of the solar proton events observed by the GOES satellites. This pulse was followed by the medium scale TID's. These facts show that the solar protons ionize directly the low-latitude atmosphere, and cause the ionospheric disturbances.

VARIATIONS IN THE INTERPLANETARY MAGNETIC FIELD SECTOR STRUCTURE AND QUASI 2-DAY WIND IN THE MIDDLE ATMOSPHERE AT ALTITUDES 80–105 KM

B.L.Kashcheyev, B.V.Kalchenko Kharkov (State Technical University of Radioelectronics)

The paper gives the description of basic results of joint measurments of drift of meteoric trails conducted in course of coordinated programme.The observations were made at different points of Earth during 1968-98 .The statistic of measurments is big. In the series of meteor trails observations in the equatorial zone (2 N,45 E) carried out in 1968-1970 in the meridional direction the 2-days periodicity drift amplitude predominated in 49,6% of cases, the diurnal periodicity amplitude predominated in 36,7% of cases and in semidiurnal periodicity amplitude predominated in 13,7% of cases. In the zonal direction these number were 26,0;46,5 and 27,5 respectively. The conection of interplanetary magnetic field sector structure variations with quasi 2-day wind in the middle atmosphere at altitudes 80-105 km is discused . The methods of data processing are discussed as well.

THE SIGNAL OF SOLAR/GEOMAGNETIC VARIABILITY IN THE TOTAL OZONE

A.Yu.Belinskaya,Ed.KAZIMIROVSKY,G.K.Matafonov (Institute of Solar-Terrestrial Physics, Russian Academy of Sciences, P.O.Box 4026, 664033, Irkutsk, Russia, email:edkaz@iszf.irk.ru)

The East-Siberian region is the area of special interest for the total ozone content (TOC) variations due to climatic features and record low ozone values during some spring/winter periods.We beleive that some part of TOC variability is closely connected with solar variability,solar wind,solar proton events,geomagnetic storms etc.We have tested the possible TOC response on the above mentioned external forcing ,first of all for East Siberia and then for some different longitudes along midlatitude circles (database from TOMS,Nimbus-7,USA).We have demonstrated the possible response of TOC depending on solar cycle phases, QBO phases and longitude.We support the hypothesis of redistribution of ozone due to changes in the circulation pattern under external (solar/geomagnetic) forcing.

EFFECT OF SOLAR VARIABILITY ON THE ELECTRON DENSITY SMALL SCALED SPECTRA IN THE MIDDLE ATMOSPHERE

Olga G. KHUTOROVA, Guerman M. Teptin (both radioastronomy dep., Physics fac., Kazan State University, 18, Kremlevskaya st., Kazan, Russia, 420008, e-mail: olga@erae.kazan.ru)

The model of electron density small scaled spectra depended on parameters of the middle atmosphere and the lower ionosphere was carried out. The empirical dependence of these parameters on the solar variability is used.
The 27-day numerical variance of the electron density spectra are obtained for different heights (80-100 km).

UNUSUAL CHANGES OF SOLAR DIURNAL VARIATIONS OF INTENSITY OF COSMIC RAY NEUTRON AND MESON COMPONENTS

Marina Despotashvili, Nugzar NACHKEBIA, Luli Shatashvili (Cosmic Ray Department, Institute of Geophysics, Georgian Academy of Sciences, !, Aleksidze st., Tbilisi 380093, Georgia, e-mail: nugzar@geophy.acnet.ge; nachkebia@yahoo.com)

The abnormal cases solar diurnal anisotropy of intensity of Cosmic Ray (CR) neutron and mezon components for 1976-1986 are considered. There were used, corrected for a barometric effect, hourly data of neutron monitors of stations Kiel and Tokyo, and meson data of surface station of Nagoya. After removal century trend there were calculated Furie-coefficients of the appropriate harmonics for each station. The cases, when value of amplitude solar diurnal anisotropy A>2A1 (A1 is annual value) at least in three cases among the four following days by the data of any considered stations of CR, were studied. 28 cases of abnormal increase of solar diurnal anisotropy of CR intensity are revealed. From the observed events of abnormal increase of solar diurnal anisotropy ~ 40% of cases are unusual - with growing effective rigidity of primary particles amplitude of anisotropy does not decrease, but sometimes it is even increased. Approximately 90 % of these cases are connected with sector structure of the interplanetary magnetic field. The appropriate interpretation is given.

JSA45/W/17-B5 Poster 1110-07

INFLUENCE OF SOLAR COSMIC RAYS HIGH ENEFRGY PROTON FLUXES ON THE OZONE DEPLETION DURING ANTARCTIC OZONE HOLE PERIOD

Valery Uljev,Igor Moskvin,Alexander SHIROCHCOV,Ludmila Makarova (all at Arctic and Antarctic Research Institute,Saint-Petersburg, 199397,Russia, e-mail: shirmak@aari.nw.ru)

A two-dimensional chemistry-transport model of polar stratosphere coupled with a model of the calculation of the ionization rate due to the solar cosmic ray (SCR) fluxes is used for study of influence of SCR proton flux of high energy (> 200 MeV) on the ozone content at 15 - 20 km inside antarctic polar cap during august - october period. Two model experiments were performed: model flux was introduced into chemically quiet stratosphere and into chemically disturbed stratosphere simulating antarctic ozone hole. The model flux is that of 4 August 1972 SPE (15 UT) with the flux intensity at the energy >200 MeV multiplied by 1 - 20 times. In the first experiment no remarkable variation of ozone content was revealed at 15 - 20 km. In the second experiment it was revealed that the model SCR proton flux increases the ozone hole depletion by 5 - 80% . Therefore one can conclude that the impulsive SCR proton flux of high energy and intensity (e.g. during GLE) may decrease ozone content at 15 - 20 km only in chemically disturbed conditions caused in the low stratosphere by polar stratospheric clouds.

JSA45/E/06-B5 Poster 1110-08

THE INFLUENCE OF THE 11-Y SOLAR CYCLE ON THE INTERANNUAL VARIABILITY OF TOTAL OZONE OVER NORTHERN EUROPE IN WINTERTIME.

Boris SOUKHAREV (Department of Climatology, St.Petersburg State University, 10 linia, 33, 199178, St.Petersburg, Russia, email: boris@seb.usr.pu.ru)

Based on the monthly mean data of total ozone from December till March for the period 1957-1996 for the eight stations of Northern Europe the influence of the 11-y solar cycle on the interannual variability of ozone over the region is investigated. Correlation between the monthly means of total ozone over the studied region and the values of 10,7 cm solar radio flux does not show evident relationship. However, the same analysis conducted on the condition that the data are grouped according to the westerly (W) and easterly (E) phases of the equatorial stratospheric quasi-biennial oscillation (QBO) shows clear positive correlation during the W phase and negative one during the E phase of the QBO. The highest connections are revealed for February (r = 0,71 and r = -0,63 for the W and E QBO phases respectively). It is found that the solar/ozone correlations are much stronger in the periods of solar extrema (peaks and hollows of 11-year solar cycle) than in the periods of transition between solar extremes. Correlation coefficients for February during the periods of solar extrema are r = 0,77 (-0,72) in the W (E) phases while during the transitional periods the coefficients are r = -0,58 (-0,28) in the W (E) phases. The differences E-W between themonthly means of ozone over the region during the E and W QBO phases are about E-W = -30 DU, E-W = 61 DU and E-W = 20 DU during the periods of solar maximum, minimum and transition respectively.
Possible physical reasons of the variation of the ozone/QBO relationship on the 11-y solar cycle time scale are discussed.

A SIMPLE EMPIRICAL MODEL FOR GLOBAL DAMAGE UV-B IRRADIANCE

Vasilyev V.I. (Institute of Experimental Meteorology SPA Typhoon, World Ozone Station 307, 249020 Obninsk, Kaluga Region, Lenin St. 82, Russia, email: iemvasilyev@netscape.net) Tikhonov V.N. (Russian Institute of Agricultural Radiology and Agroecology, 249020 Obninsk, Kaluga Region, Kiev highway 1, Russia, email: tikhon@obninsk.com) Brick N.V. (Biological Department Moskow State Lomonosov University, 119899 Moscow, Russia)

This paper presents first results on the possibility of the short-term forecasting and modelling of the global damage UV-B irradiance (DUV) reaching the ground. The simple mathematical model relating DUV irradiance with solar zenith angle (Za) has been built. The modelled data are based on the experimental measurements performed by Brewer #044 Mark II spectrophotometer at Obninsk (Russia, 55.12 N, 36.6 E) during 1997. Each UV-B global spectrum sampled by Brewer was integrated in the range 290-325 nm by standard DUV routine and compared with the corresponding output of the model which uses the following empirical relation: DUV = exp{A[cos(Za)]^(1/C)+B}It was found out that most experimental data obtained at the clear sky or direct sun expositions, being plotted in co-ordinates ln(DUV) vs.[cos(Za)^(1/C)], often form one or two straight lines for each observed day: morning and/or afternoon fits. The best fits were obtained for C=2.5 ... 3 and statistical analysis indicates that the total amount of ozone has surprisingly little effect on the fitting coefficients A and B. But sum of them, that is ln(DUV) for Za=0, depends on ozone layer thickness with the correlation coefficient being about -0.8. The obtained results may be useful for inter- and extrapolation, filtering and smoothing of experimental data, in procedures for the short-term UV Index forecasting: a few early morning measurements at Za about 80-85 degrees can predict all daily values of DUV with very good sccuracy - for the clear sky conditions.

MODELING THE EFFECTS OF SOLAR PROTON EVENTS ON MIDDLE ATMOSPHERE

Pekka VERRONEN and Erkki Kyrölä (Both at Finnish Meteorological Institute, Geophysical Research, P.O. Box 503, FIN-00101 Helsinki, Finland; email: pekka.verronen@fmi.fi) Esa Turunen and Thomas Ulich (Both at Sodankylä Geophysical Observatory, Tähteläntie 112, FIN-99600 Sodankylä, Finland; email: esa@sgo.fi)

The ionization by solar UV-radiation and energetic particle precipitation causes variation in upper atmosphere constituent concentrations. Ionization and chemical reactions lead to a production of odd nitrogen in the mesosphere, which in turn affects the ozone balance. Under polar night conditions the nitric oxides are long lived and may be carried down into the lower atmosphere, where they can participate in destruction of stratospheric ozone.
Three European satellite missions, Envisat-1, Ørsted, and Odin, will be launched in next two years. Together with the EISCAT incoherent scatter radars and a network of other ground measurements they will provide a so far unique possibility to address this scientific problem in the auroral region.
In order to establish the magnitude of the effects of proton events on middle atmosphere we have added relevant neutral chemistry into the SIC-model and modeled some proton events using a variety of available measurement data.
We will present our project, the latest development of our model, and the preliminary modeling studies.

SOLAR ULTRAVIOLET IRRADIANCE VARIATIONS FROM UARS SOLSTICE

Thomas N. WOODS, Gary J. Rottman, Giuliana de Toma, Julius London, (all at Laboratory for Atmospheric and Space Physics, University of Colorado, 1234 Innovation Dr., Boulder, CO 80303, USA; e-mail: tom.woods@lasp.colorado.edu), and Dick White (High Altitude Observatory, National Center for Atmospheric Research, PO Box 3000, Boulder, CO 80307, USA)

The SOLar Stellar Irradiance Comparison Experiment (SOLSTICE) on the Upper Atmosphere Research Satellite (UARS) has been making daily measurements of the solar ultraviolet (UV) irradiance since October 1991. The standard SOLSTICE solar UV irradiance data product covers the 119 to 420 nm range in 1 nm intervals. The solar UV radiation at the shorter wavelengths is deposited in Earth's middle atmosphere; whereas, the solar radiation at the longer UV wavelengths is deposited in the lower atmosphere and much reaches the surface for wavelengths above 320 nm. The solar UV radiation is a important source of energy for the middle atmosphere as well as the driver for the photochemistry in the middle atmosphere. The understanding of the variability of the solar UV irradiance is thus critical to fully understand the variability seen in the middle atmosphere. The variability of the solar UV irradiance is on all time scales with the 27-day solar rotation period and the 22-year solar magnetic cycle being the dominant variability seen in the SOLSTICE data. The longer wavelengths, above 260 nm, show the least amount of variability, 1% or less over the solar cycle. The shorter wavelengths show the most variability, as much as a factor of 2 for some of the solar far UV lines.

THE QUANTIFICATION OF MELT PROPERTIES WITHIN A MAGMA RESERVOIR

Dr. Mark A.J. TAYLOR (Bullard Laboratories, University of Cambridge, email: taylor@esc.cam.ac.uk)

The quantification of melt properties within a magma reservoir is extremely important in predicting and monitoring of volcanic eruptions. The comparatively low rigidity of magma chambers beneath volcanoes and mid-ocean ridges results in a low-velocity zone. Seismic tomography can provide us information about the wave velocities, and also attenuation and anisotropy of these regions. Here we use effective medium theory to relate this information to, and place subsequent constraints on, the material properties and composition of such magmatic bodies. Using a combination of the self consistent scheme [Hill, J. Mech. Phys. Solids, 1965, and Budiansky, J. Mech. Phys. Solid, 1965] and differential effective medium theory [Boucher, Rev. Metall., 1976 and McLaughlin, Int. J. Eng. Sci., 1977] in a similar way to Mainprice [Tectonophys, 1997] we examine the effect of introducing inclusions of melt into a solid matrix on the elastic constants (and hence shear and compressional velocities), attenuation, and anisotropy of the resulting medium. We consider both a homogeneous distribution of spherical inclusions and either aligned or randomly oriented elliptical inclusions. The effect of assuming an isotropic or anisotropic background matrix material is also considered. From this we are able to place some bound on the melt fraction and possible microstructure of magma chambers that is consistent with parameters from seismic inversions. In particular we hope to apply this technique to the data from the 1996 and 1997 land and sea reflection surveys at Mount Vesuvius [Gasparini, EOS, 1998].

P-WAVES TELESEISMIC VELOCITY TOMOGRAPHY OF THE HOGGAR SWELL (CENTRAL SAHARA, ALGERIA)

Abdelhakim AYADI (Dept. E.S.S./C.R.A.A.G., BP 63 Bouzaréah 16340 Algiers, Algeria, email: ess1@ist.cerist.dz); Catherine Dorbath (E.O.S.T., 5, Rue René Descartes, F-67084 strasbourg Cédex, France e-mail: cath@mapu.u-strasbg.fr); Alain Lesquer (Centre de Geologie et de Geophysique, Université Montpellier II, e-mail: lesquer@dr13.cnrs.fr); Mourad Bezzeghoud (Deopt. de Fisica, Universidad de Evora, Apartado 94, 7001, Evora, Portugal, email: mourad@uevora.pt)

The Hoggar region is known as one of the important swell in the African continent. Its altitude is ranging from 500m to 2908m at Tahat hill (Atakior). The Hoggar massif and other uplifts (Air, Tibesti, Eghei, Darfur, Cameroon mount) form a system of domal uplifts with semilar scale, morphology and volcanic activity (Lesquer et al., 1988). The knowledge of the structure beneath the Hoggar swell will enable us to understand the origin of the formation of this massif. In order to get an image of the lithosphere in the region we have performed a teleseismic field experiment. This later has been fixed for 3-months, where 33 short-period seismic stations have been installed along a 700-km long NNW-SSE profile crossing the central Hoggar and extend to the In-salah Sahara basin. This P-wave teleseismic tomography, is the only one made on midplate swell in Africa. No similar studies have been found in the literature on the African swells, in order to compare the results especially the nearest one as Air or Tibesti. The high quality of the data recorded during this experiment, enable us to perform a velocity inversion. From various observations compiled with the tomographic results, we can say that the Hoggar swell appears to have an altered lithosphere characterised by a low density, which make the swell in isostatic equilibrium. This low-density body seems to be elongated in the EW direction. The NS structures identified by previous studies seems to have an influence on the distribution of the velocity perturbations. The 4.50° NS megafault and the In Ouzal fault system appeared as a predominant structure in the lithosphere. Northward, the heat flow anomaly in the Sahara basin, could have a mantle origin.

THREE DIMENSIONAL STRUCTURE OF BANDAI VOLCANO, NORTH-EASTERN JAPAN, DERIVED FROM ARTIFICIAL SOURCE EXPERIMENT

H. HAMAGUCHI, S. Ueki, S. Tanaka, T. Yamawaki (all at Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, email: tanaka@aob.geophys.tohoku.ac.jp); Research Group for Seismic Exploration of Bandai Volcano

Ten universities in Japan and Japan Meteorological Agency jointly performed a seismic exploration with active sources in Bandai volcano to reveal three dimensional structure in October 1997. We installed 292 seismic stations with a short-period seismometer and a portable data logger in and around the volcano over the area of 20 x 15 km2. Spaces among stations are about 500 m on the volcano, and about 1 km around the volcano. Eight artificial sources were exploded with dynamite of which charge sizes were 100-250 kg. We have obtained successfully about 2300 travel times of the first motion from the experiment. The travel time data is inverted to obtain three dimensional structure of the volcano. We used the damped least squares for inversion and the pseudo-bending method for the ray trace originally programmed by Zhao et al. (1992). A grid size for inversion is 0.02_i (nearly 2 km) for horizontal directions and 500 m for a vertical direction. An initial model is two-layered model with laterally varying thickness of the upper layer inferred from the time-term method. The r.m.s. travel time residual is reduced from 0.23 s at the initial model to 0.13 s at the final one. We performed a resolution test with checkerboard-pattern and find that the final model has a good resolution up to 2 km depth from the ground surface. The most characteristic feature of the internal structure of the volcano is extremely high velocity regions (velocity perturbation greater than 20 %) beneath the volcano. This indicates that the basement of the volcano is elevated. The secondary characteristic feature is an extremely low velocity region (velocity perturbation more than 20 %) under the eastern flank of the volcano. The low velocity region is found just under the crater of the volcano and is close to seismic absorption region discovered in a previous fan-shooting experiment by Ueki et al. (1990).

MONITORING VOLCANOES AND GEOTHERMAL SYSTEMS WITH SEISMIC TOMOGRAPHY.

B.R. JULIAN (U.S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025, U.S.A., Email: julian@usgs.gov); G.R. Foulger (Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, U.K., Email: g.r.foulger@durham.ac.uk)

Local-earthquake tomography has recently found negative Vp/Vs anomalies at several geothermal systems and volcanoes. At the Hengill-Grensdalur volcanic complex in southwest Iceland, which hosts a mixed-phase hydrothermal system, the shallow parts of the Vp/Vs anomaly underlie areas of surface hot springs, and the deeper parts converge spatially to a small region that is probably a heat source. The Geysers, in northern California, a "dry" steam reservoir, is marked by a strong (~9%) Vp/Vs anomaly that is becoming detectably stronger as steam is extracted for power generation. At Mammoth Mountain, in eastern California, a Vp/Vs anomaly occurs in an area that has experienced massive carbon dioxide emissions since about 1990. All these anomalies can be understood quantitatively using the theory of elasticity of fluid-saturated porous media. The Hengill-Grensdalur anomaly is somewhat too strong to be the effect of variations in only the pore-fluid compressibility, and requires in addition variations in the elasticity of the rock matrix, caused perhaps by hydrothermal alteration. Measurements on core samples from. The Geysers show an unusual increase in the rigidity modulus upon drying (the spaghetti effect), which accounts for much of the observed anomaly. Carbon dioxide is highly compressible even at low temperatures, and carbon dioxide flooding of petroleum reservoirs has been known to change seismic-wave speeds by as much as 10%. Thus a carbon dioxide body might plausibly cause the anomaly at Mammoth Mountain, although knowledge about structure there is currently inadequate to confirm this conjecture.

MONITORING RESERVOIR DEPLETION AT THE GEYSERS GEOTHERMAL AREA, CALIFORNIA, USING SEISMIC TOMOGRAPHY

G.R. FOULGER (Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, U.K., email: g.r.foulger@durham.ac.uk); B.R. Julian (U.S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025, U.S.A., email: julian@usgs.gov); R.C. GUNASEKERA (Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, U.K., email: r.c.gunasekera@durham.ac.uk)

Two decades of industrial extraction of steam from The Geysers geothermal reservoir in northern California has caused substantial environmental changes there. These changes include the induction of continuous, small-magnitude earthquakes at a high rate and altering the seismic-wave speeds in the reservoir. The area is continuously monitored by a network of 22 seismic stations operated by the UNOCAL Corporation, whose kind release of the data we gratefully acknowledge. This is an ideal experimental setup for monitoring industrially induced changes in Earth structure using repeated local-earthquake tomography. We conducted tomographic inversions, using the method of Thurber and Eberhart-Phillips, for data from 1991 and 1994. The exploited steam reservoir is associated with a strong (~9%) negative Vp/Vs anomaly, which can be explained as the effect of compressible vapour-phase pore fluid and of drying out of the rock matrix as water flashed to steam during progressive reservoir depletion. Between 1991 and 1994, the magnitude of the Vp/Vs anomaly increased to about 13%, which is consistent with continued pressure reduction and flashing of pore water to steam. These results demonstrate that Vp/Vs tomography is potentially valuable for monitoring geothermal reservoir exploitation and environmental change. This work is continuing with inversions of data from 1993, 1996 and 1998.

JSS46/W/05-B4 Invited 1150

HIGH-RESOLUTION TOMOGRAPHY OF KILAUEA CALDERA HAWAII

P.B. DAWSON, B.A. Chouet (U.S. Geological Survey, 345 Middlefield Rd. MS910, Menlo Park, CA 94025, email: dawson@usgs.gov)

A high-resolution velocity model (0.5-km resolution) of the Kilauea caldera region is obtained by tomographic inversion of both first arrival times and S-wave arrival times. Data are from the permanent Hawaiian Volcano Observatory seismic network, a ten-station broadband seismic network, and a temporary array consisting of two concentric rings of stations with diameters of 2 and 4 km centered on the caldera. Between January 8 and February 9, 1996 all three arrays were operating with a total of 300 seismic components being recorded. A total of 4580 first arrivals and 2558 S-wave arrivals from 207 earthquakes were used in the inversion to obtain both the P-wave and Vp/Vs velocity structure of the caldera. Relatively low P-wave velocities are observed within the first km in the center of and along the southern boundary of the caldera, and near the Kilauea Iki Crater. High P-wave velocities are observed in the northeast and southern portions of the caldera and are attributed to ponded, cooled flows. Below this structure a low-velocity volume is imaged beneath the southern caldera and upper-east rift. The velocity contrast between this zone and the surrounding structure is about 10%. This feature persists to a depth of 3 km below sea level. The ratio Vp/Vs beneath the caldera block roughly mimics the P-wave structure and is anonymously high, with values over 2 to depths of 2 km below sea level. The primary difference between the two models is that the Vp/Vs model shows two distinct zones of high Vp/Vs. Below 2 km below sea level Vp/Vs decreases to more normal values near 1.8. The corresponding Poisson ratio is 0.33 in the upper 3 km and 0.25 below 2 km below sea level. The high value of the Poisson ratio in the upper 3 km is consistent with a hot volume which may contain a small fraction of melt. The large-scale features of the velocity structure imaged by high resolution tomography are consistent with results obtained from an earlier larger-scale (2 km resolution) tomographic image of Kilauea Volcano based on HVO network data.

JSS46/W/12-B4 1210

IMAGING GAS BENEATH AN ACTIVE VOLCANO USING SEISMIC TOMOGRAPHY

G.R. FOULGER (Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, U.K., Email: g.r.foulger@durham.ac.uk); B.R. Julian, A.M. Pitt and D.P. Hill (All at U. S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025, U.S.A., Email: julian@usgs.gov)

Mammoth Mountain is a volcanic peak on the SW caldera rim of Long Valley, a large, active, silicic volcano in eastern California. It is the site of frequent earthquake swarms, long-period earthquakes and massive surface venting of volcanic carbon dioxide gas, which has killed extensive areas of forest. Local-earthquake tomography using data from 15 temporary stations deployed in 1989 reveals a substantial low-Vp/Vs anomaly in the upper three kilometers whose margins correspond closely to the area of carbon dioxide emission. A network of 14 seismometers was deployed in the area for 3 months in summer 1997, supplementing the 7 permanent stations operated by the U.S. Geological Survey, to gather data to repeat the tomographic inversion and constrain possible changes in the 8-year interim period. These experiments form part of the ongoing Long Valley monitoring project of the U.S. Geological Survey. An excellent set of earthquakes was recorded. Preliminary results of the repeat tomography will be presented.

JSS46/W/01-B4 1230

P-WAVE ANISOTROPY, STRESS, AND CRACK DISTRIBUTION AT COSO GEOTHERMAL FIELD, CALIFORNIA

Jonathan M. LEES, Huatao Wu (Dept of Geology and Geophysics, Yale University, New Haven, CT, 06511 email: lees@love.geology.yale.edu)

A new inversion method for P-wave anisotropy [Wu and Lees, GJI, 1999], has been applied to high-precision, microseismic travel-time data collected at Coso geothermal region, California. Direction-dependent P-wave velocity, and thus its perturbation, are represented by a symmetric positive definite matrix A instead of a scalar. The resulting anisotropy distribution is used to estimate variations in crack density, stress distribution and permeability within the producing geothermal field.
A circular dome-like structure is observed at the southwestern part of the geothermal region southwest of Sugarloaf Mountain. Regional deviatoric stress distribution is determined through a linear stress-bulk modulus relation and deviatoric stress is estimated to be 3 -- 6 MPa at geothermal production depths (1 -- 2 km), assuming 20% anisotropy is stress related. The stress field is compressional NNE-SSW and dilational WNW-ESE, coinciding with a previous, independent study using earthquake focal mechanisms. Following a theory on flat, elliptic cracks, residual crack density estimated from P anisotropy is ~0.0078, assuming crack aspect ratios >> 1:60 (i.e. not sufficiently linear) and is ~0.041 when crack aspect ratios are close to 1:60. Residual crack orientation distribution is related to velocity anisotropy. Based on the anisotropic part of crack density distribution function, the anisotropic part of permeability distribution may be calculated by a statistical approach via simple parallel fluid flow along cracks.

JSS46/E/04-B4 1400

FIRST ARRIVAL TIME TOMOGRAPHY OF MT.VESUVIUS VOLCANO FROM ACTIVE SEISMICS

Aldo ZOLLO, Andre Herrero, Raffaella De Matteis (Dipartimento di Scienze Fisiche, Universit di Napoli "Federico II); Claudio Chiarabba, Raffaele Di Stefano, Giovanni B.Cimini (ING, Rome); Roberto De Franco, Giancarlo BIELLA, Grazia Caielli, Rosaria TONDI (IRRS, Milan); Jean Virieux, Antony Lomax, Raffaella Montelli (CNRS-UMR GeoAzur, Nice)

Seismic recordings of 17 on land shots from 1994 and 1996 experiments have been used to retrieve the shallow (down to 4-5 km) P wave velocity structure of Mt. Vesuvius. Sources and receivers were deployed along about 30-km long conjugate profiles, crossing the top of the volcano. The recording array was composed by 140 three-component digital, short period seismographs. 250 Kg to 800 Kg of seismic gel was used for each shot. The first arrival time picking vs. distance has been performed using different data pre-processing procedures and representation by reduced travel time curves and NMO correction. The data inversion has been performed using either T(X) and Tau(p) curves and are based on arrival and delay time tomography approaches. In particular, different methods for travel time computations in laterally heterogeneous media are applied based on the exact and approximate ray tracing codes or wavefront tracing techniques like the eikonal method. For the solution of the inverse problem we used both the linearized pertubative approach, which need a well constrained initial model, or a fully non linear global optimization method. A quantitative comparison of the different images of the shallow crustal structure underneath Mt.Vesuvius obtained by applying the various techniques will be shown.

JSS46/E/03-B4 1420

TOMO VES: AN INTEGRATED SEISMIC PROJECT FOR INVESTIGATING THE STRUCTURE OF MT. VESUVIUS

Paolo GASPARINI (Dipartimento di Scienze Fisiche, Universita' di Napoli, Italy); Uli Achauer (EOST, Strasbourg, France); Claudio Chiarabba (Ist.Naz.Geofisica, Rome,Italy); Roberto De Franco (Ist.Ric.Rischio Sismico, CNR, Milan, Italy); Giuseppe De Natale (Osservatorio Vesuviano, Naples, Italy); Michel Dietrich (LGIT, Universite' J.Fourier, Grenoble, France); Mario Mango Furnari (Ist. Cibernetica, CNR, Naples, Italy); Dominique Gibert (CNRS-Universite de Rennes, Rennes, France); Eduard Kissling (ETH, Zurich, Switzerland); Roberto Scarpa (Dipartimento di Fisica, Universita' dell'Aquila, Italy); Satish Singh (Dept. Earth Sciences, Bullard Lab. University of Cambridge, UK); Jean Virieux (CNRS, UMR GeoAzur, Nice, France); Aldo Zollo (Dipartimento di Scienze Fisiche, Universita' di Napoli, Italy)

TomoVes project aims at reconstructing the detailed models of Mt. Vesuvius structure using seismic wave velocity and attenuation. It is mainly a controlled source experiment using on-land and offshore energy sources recorded both on land and by OBS. These data are integrated with a selected earthquake set. This project is a reflection/refraction experiment which wants to use the whole information retrievable in the complete incidence angle range (from near vertical to wide angle). Due to the high population density around and on the volcano it has not been possible to design an optimal 3-D acquisition geometry. Therefore to gain 3-D information each shot was recorded both in line and fun receiver configuration. The on-land experiment was integrated by a reflection experiment using about 2000 eight 16-liters aigun shots in the bay of Naples, recorded at few selected sites on-land, mirroring the volcano down to the Moho. Processing and interpretation of these data constitute a EEC supported project involving 12 working teams from France, Italy, Switzerland and UK. The general strategy of data interpretation is to proceed gradually from 1-D to 2-D/3-D models and from shallow to deep. The velocity and attenuation structure of the volcano will be obtained by ad hoc integrated seismic processing tools which are developed and adapted to image the complex volcanic environment in non conventional acquisition geometries. Further products of the project will be the implementation of a seismic, gravity and aereomagnetic data-base for Mt.Vesuvius and a set of methods to be applied for seismic imaging of volcanic complexes.

JSS46/L/01 1440

SHALLOW VELOCITY MODEL FOR MT. VESUVIUS VOLCANO, ITALY, FROM ARRAY MEASUREMENTS OF SEISMIC NOISE".

R. SCARPA

The use of dense seismic arrays on volcanoes is useful to infer from noise measurements the shallow velocity structure. In the present work resultsobtained using data from short-period arrays during three experiments carried out in different places on the Vesuvius Volcano are compared. Correlation method was applied on 120-400 seconds time-windows of the noise recorded during all the experiments, allowing to get the shallow velocity structure, up to 500 meters, beneath the investigated sites on volcano. The first two experiments are part of a research project aimed to the high resolution seismic tomography of Mt. Vesuvius using explosive sources. During the first experiment executed in 1994 on the summit crater, the array consisted of two groups of short period geophones, 4.5 Hz natural frequency, formed by 16 and 25 vertical components (plus two horizontal components), distributed along an arc shape. The second experiment was performed in 1996 at about 100 meters a.s.l., on the SE flank of volcano. The 63 channels-array, with circular geometry and an aperture of 200 meters, was equipped with 21 three-component sensors, 4.5 Hz natural frequency. The last experiment was executed in 1998 at about 600 meters a.s.l. on the SW flank of volcano, deploying a seismic array of two three-component and eighteen vertical short period (4.5 Hz extended to 1 Hz) stations, with an aperture of approximately 600 meters, for a seven months operation. The correlation method allowed to define the dispersive characteristics of surface waves composing the noise, from which velocity models of the sub-surface structure were inferred for each investigated site. Results seem to confirm lower seismic velocities beneath the crater compared to those obtained at lower flanks on volcano.

JSS46/W/02-B4 1500

JOINT INTERPRETATION OF GRAVITY AND SEISMIC TOMOGRAPHY DATA FOR MT. VESUVIUS

Ulrich ACHAUER (EOST, UMR CNRS-ULP 7516, Strasbourg, France, email: ulrich.achauer@eost.u-strasbg.fr); Giovanna Berrino, Paolo Capuano, Guiseppe De Natale (all at Observatorio Vesuviano, Naples, Italy); Claudio Chiarabba (ING Rome, Italy); Anne Deschamps (Geosciences AZUR, Nice, France); Paolo Gasparini (Dep. of Geophysics and Volcanology, University of Naples, Italy)

In the framework of the EEC project "Internal structure of Mt. Vesuvius through 3D high resolution seismic tomography (Tomoves)", which focuses on the delineation of the structural

setting of Mt. Vesuvius volcano, a joint analysis of gravity and seismic data has been performed. The investigated area covers all the Campanian plain and the Gulf of Naples in order to be able to well-define as well deeper structures. All the available gravity data around Vesuvius and the Campanian area have been quality checked and re-analyzed together with new gravity data collected offshore and along selected profiles in the Vesuvian area. All this data constitute a new gravity database of about 18,000 measurements. The seismic database consists of data collected during the 1994 and 1996 Vesuvius tomography experiments, by teleseismic and regional arrival times. An newly developed joint-inversion program, including 3D-ray tracing and an adaptive grid scheme, is currently being updated in the framework of this project to be used not only for transmission tomography, but for "refraction" type tomography as well. We have opted for a ray-tracer type like in Zhao's inversion program. We perform an analysis on the velocity-density relationship to be used in the joint inversion algorithms, therefore a preliminary modeling of gravity data has been performed. The main goal of this work is to define the morphology of the Moho discontinuity in the Vesuvian area and the shallower main structures or discontinuities like the volcanic sedimentary boundary.

JSS46/W/11-B4 1540

EARTHQUAKE DATA BASE FOR SOMMA-VESUVIUS TOMOGRAPHY

Giuseppe DE NATALE (Osservatorio Vesuviano, V.Manzoni, 249,80123 Napoli, Italy, email: pino@osve.unina.it); Claudio Chiarabba (ING V.di Vigna Murata,605, Roma, Italy, email: doggydog@nettuno.ingrm.it); Anne Deschamps (UMR Geo-Azur CNRS/UNSA Rue A. Einstein, 250, F06560, Valbonne, France, email: deschamp@faille.unice.fr); Edi Kissling (Institute of Geophys., ETH Zurich, CH8093, Switzerland, email: kiss@tomo.ifg.ethz.ch)

In the framework of the TOMOVES Project for Somma -Vesuvius tomography, some field experiments have been performed, aimed to build a data base of local earthquake data. 6 portable digital stations were added to the monitoring networks of OV, five from ETH (Zurich) and 1 broad-band from ING (Roma). The complete network in the period May-August 1996 consisted of 20 stations, located within 15 Km from Vesuvius crater. Several hundreds microearthquakes(ML from 0.2 to 3.2) have been recorded in this period. In addition, during the active experiment some stations from CNRS (Nice) put on active seismic profiles have continuously recorded micro-earthquakes. The coincidence of the active and passive experiment periods with an intense seismic activity allowed to collect a very good earthquake data set. This work presents the data and projects to integrate active and passive data in a high-resolution joint tomography.

JSS46/W/10-B4 1600

IMAGING OF THE JEMEZ VOLCANIC FIELD USING KIRCHHOFF MIGRATION OF TELESEISMIC WAVEFIELDS

Claudia Maria APREA, Steven Hildebrand, Michael Fehler, Lee Steck, W. Scott Baldridge, Peter Roberts (all at Earth and Environmental Sciences Division, MS D443, Los Alamos National Laboratory, Los Alamos NM 87545, USA, email: fehler@lanl.gov)

A novel application of a seismic imaging method usually used to search for oil and gas was used to construct an image of the seismic reflectivity of the subsurface of the Jemez Volcanic Field (JVF) in Northern New Mexico, USA. Volcanism began in the JVF about 13 Ma. The region underwent major caldera-forming eruptions at about 1 Ma and a resurgent dome formed. The most recent eruption was about 50-60 Ka. Several geophysical studies have been undertaken to characterize the subsurface of the JVF, the most recent one being a tomographic study using teleseisms as sources. There is clear evidence for the existence of a low velocity zone at mid crustal depths (5-12 km) beneath the region. In an attempt to augment information obtained from the tomography study, we initiated a study of the teleseismic waveforms using a Kirchhoff migration approach. Migration provides an image of the subsurface reflectivity, which is sensitive to strong velocity and density contrasts. We used waveforms recorded on an array of 50 seismometers spread throughout the region. To separate the direct arrival from phases converted at subsurface discontinuities, we used an imaging condition for waves that were first reflected from the Earth's surface. The method provides a remarkably clear image of the subsurface of the JVF. We can clearly see reflections from the base of caldera, the top and bottom of the low velocity zone, and several mid and deep-crustal and/or upper mantle reflectors. Changes in polarity of the reflections provide convincing evidence of the validity of the image and aid in its interpretation.

JSS46/L/01-B4 1620

WIDE-ANGLE SEISMIC PROFILING ACROSS THE RABAUL VOLCANO: A FRAMEWORK FOR TOMOGRAPHIC IMAGING OF CALDERA ARCHITECTURE

Doug FINLAYSON (Australian Geological Survey Organisation, Canberra, Australia email: dfinlays@agso.gov.au); Oli Gudmundsson (Australian National University, Canberra, Australia, email: oli@rses.anu.edu.au); Wally Johnson (Australian Geological Survey Organisation, Canberra, Australia, email: wjohnson@agso.gov.au); Ima Itikarai (Rabaul Volcanological Observatory, Rabaul, Papua New Guinea, email: rvo@datec.com.pg); Hideki Shimamura and Yuichi Nishimura (Hokkaido University, Sapporo, Japan, email: shima@lobs.sci.hokudai.ac.jp , nishi@eos.hokudai.ac.jp)

The active Rabaul volcanic complex, situated at a triple junction at the eastern end of the island of New Britain, Papua New Guinea, is currently the target of seismic tomography investigations aimed at improving the capabilities of the region's earthquake/volcano monitoring network. Eruptions in 1937 and 1994 resulted in significant fatalities and destruction within and around Rabaul. During 1997, 50 land recorders and 23 OBS were deployed in the region for 6 months. Velocity models derived from wide-angle seismic profiling using marine explosive sources form a framework for the tomographic investigations with earthquake sources (the 1997 Rabaul Earthquake Location and Caldera Structure, RELACS program). A review of earlier 1967-69 seismic data indicates the upper mantle under Rabaul at about 28-30 km depth and a lower crust (14-28 km depth) with a velocity of 7.1-7.2 km/s. Detailed RELACS profiling along two transects indicates that the upper crust is heterogeneous with high P-wave velocities (6.4-6.6 km/s) at shallow depths (3-5 km) on the western side of the currently active volcanic caldera. This may be an element of core basement from early in New Britain's history on the Mid to Late Eocene Caroline plate, or a more recent intrusive body related to faulting/magma conduits for the current volcanic activity.

JSS46/W/07-B4 1640

P-VELOCITY TOMOGRAPHY OF SHALLOW STRUCTURE BENEATH RABAUL CALDERA BASED ON LOCAL EARTHQUAKE AND EXPLOSION DATA

O. GUDMUNDSSON (Australian National University, Canberra, Australia, email: oli@rses.anu.edu.au); D.M.Finlayson (Australian Geological Survey Organisation, Canberra, Australia, email: dfinlays@agso.gov.au); I. Itikarai (Rabaul Volcano Observatory, Rabaul, Papua New Guinea, email: rvo@datec.com.pg); Y. Nishimura and H. Shimamura (Hokkaido University, Sapporo, Japan, email: nishi@eos.hokudai.ac.jp, shima@lobs.sci.hokudai.ac.jp); R.W. Johnson (Australian Geological Survey Organisation, Canberra, Australia, email: wjohnson@agso.gov.au)

The Rabaul Earthquake Location and Caldera Structure (RELACS) field project was conducted in 1997 to build detailed models of crustal structure around Rabaul caldera, Papua New Guinea, and to improve the precision o flocal earthquake location around the volcano. A part of the project is a review of active seismic data from surveys conducted in the 1960s and data collected by the Rabaul Volcano Observatory's monitoring network over the past 25 years. The seismicity of the volcano leading up to the 1994 eruptions defined an oval pattern beneath Blanche Bay, the most recent collapse structure in the caldera, 10 km wide and down to a depth of about 5 km. This pattern is interpreted to represent a ring fault above an underlying magma reservoir. We use arrival times from almost 2500 well located local earthquakes in Rabaul Caldera supplemented by travel times from local explosions conducted in 1967 and 1969 and in 1997 as part of the RELACS project to build an image of P-velocity variations in the top 5 km around Rabaul Caldera. Results show a high level of heterogeneity beneath the caldera which may be related to geothermal activity and intrusive bodies in the roof of an underlying magma reservoir.

LINEAR JOINT INVERSION OF FIRST ARRIVAL AND REFLECTED TIMES: APPLICATION TO MT. VESUVIUS VOLCANO (ITALY)

Andre HERRERO, Aldo Zollo (both at Dipartimento di Scienze Fisiche, Universita di Napoli, Napoli, Italy, email: herrero@na.infn.it)

The joint inversion of first arrival and reflected times is very useful in presence of a strong interface when the offsets used are large. In this case, the first arrivals are dominated by refracted waves. Thus, the inversion of first arrival times alone doesn't well locate in depth the velocity variations due to the trade off between velocity and depth. The introduction of first reflected times in the inversion process helps to get rid of this problem. The direct problem is solved with Podvin and Lecomte's (1991) method both for first arrivals and first reflected waves. The medium is splitted in two parts by the reflection interface. The velocity is computed in the whole medium with a bicubic spline interpolation from velocities defined at control points. The latters, with the control points vertical position of the interface, are the inversion parameters. The inverse problem is realized by a "pseudo global" search of the misfit function minimum using Downhill Simplex and Montecarlo approaches. To accelerate the inversion processes, an iterative procedure is introduced, increasing little by little the number of inversion parameters. At each iteration, the result of the previous one is taken as a-priori model. The first application is realized with the TomoVes96 data set (Gasparini et al., 1998) on Mt Vesuvius volcano, where the presence of strong limestone interface is expected. The comparison between the inversion results with and without first reflected wave arrival times shows their utility in such a case, even if the cost in computation time is much higher.

JSS46/E/06-B4 Poster 0930-02

SHALLOW AND DEEP STRUCTURES FROM ACTIVE SEISMIC AND GRAVITY DATA IN THE MT. VESUVIUS AREA (ITALY)

Roberto DE FRANCO, Grazia Caielli, Rosaria Tondi, Giancarlo Biella (Istituto di Ricerca sul Rischio Sismico, CNR, Milano, Italy, email: def@irrs.mi.cnr.it); Riccardo Barzaghi (DIIAR, Sezione Rilevamento, Politecnico, Milano, Italy)

An image of shallow and deep structures beneath the Vesuvius and surrounding area is presented. Shallow information were obtained by the results of seismic interpretation of the data acquired during TOMOVES 96 experiment and of the data collected in the active refraction experiment on Vesuvius in 1994. An new integrated sequential inversion seismo-gravity method, has been applied in order to optimize the 2-D initial models down to about 5 km depth in Somma-Vesuvius complex. The deep structures have been obtained by the reinterpretation of old seismic data (1980, 1985, 1994 seismic experiments) and some preliminary new information derived from MAREVES 97 experiment. Using the deep seismic information as constraints a 3-D image of the Moho discontinuity, has been obtained applying a gravity inversion based on the collocation method.

JSS46/W/08-B4 Poster 0930-03

SEISMIC TOMOGRAPHY OF MT. VESUVIUS VOLCANO WITH BORN'S QUANTITATIVE MIGRATION

E. AUGER (1&2) (email: auger@sungea03.na.infn.it), J. Virieux (2) (email: viri@seisme.unice.fr), A. Zollo (1) (email: aldo@sungea03.na.infn.it) (1) Dip.to di Fisica, Universita' di Napoli Federico II, Naples, Italy); (2):UMR Geosciences-Azur, Nice, France)

We present an improved version of Born's quantitative migration and its application to the data gathered during two seismic active experiments carried out on Mt. Vesuvius. It is based on the analysis of the whole waveform (time+amplitude) of the first reflected waves (PP and PS), done without an initial preprocessing of the data. The existing formalism was extended in such a way as : - to allow for a strongly irregular topography and acquisition system. - to take into account all three components of the ground movement recorded. - to invert for the anelastic attenuation of the propagation media. - to give an estimation of the impedance contrasts associated to the identified reflectors. Theoretical background: The inversion consists in computing a correction to be applied to the initial model in such a way that the L2 norm between perturbed computed and perturbed real seismograms reaches a minimum. The correction from the initial medium is applied as a sum of point-like diffractors over a regular grid. With its linearized form, an analytical gradient and an approximate Hessian can be computed and applied iteratively to the data till the minimum of the residuals is reached. We apply this inversion to the data of two.

JSS46/E/07-B4 Poster 0930-04

DETERMINATION OF THE MOHO DEPTH IN THE CAMPANIAN VOLCANIC AREA BY P-SV CONVERTED PHASE OF TELESEISMS: PRELIMINARY RESULTS

G. DE NATALE, P. Capuano, C. Troise (Osservatorio Vesuviano, Via Manzoni, 249 80123 Napoli, Italy, email: pino@osve.unina.it); B. Rosa, P. Harabaglia (Centro di Geodinamica, Univ. della Basilicata, Potenza, Italy); E. Bertrand, A. Deschamps (CNRS/UNSA, Valbonne (Nice), France, email: deschamp@faille.unice.it); P. De Gori, C. Chiarabba, G. Cimini (Istituto Nazionale di Geofisica, Via di Vigna Murata, Roma, Italy, email: doggydog@nettuno.ingrm.it)

In the framework of the TOMOVES project for seismic tomography of the Vesuvius area, we installled, in the summers of 96 and 97, broad-band digital seismic stations in and around the volcanic area of Campania region. The project, called BROADVES, has been exploited in a co-operation among GeoAzur, Nice, I.N.G., Rome and Osservatorio Vesuviano, Naples. It aims to the understanding of the deep and shallow structure of the area at a regional scale, as well as to the characterisation of the local seismicity of the volcanic environments (Vesuvius,

Campi Flegrei and Ischia). We report here the preliminary results of a study of the topography of the Mohorovicic discontinuity under the seismic array. The study is performed by the analysis of P-Sv concerted phases on teleseismic recordings. A receiver function method is used to enhance the useful signal, based on the time domain deconvolution of the vertical traces from the longitudinal ones on the seismograms. For each station the computed receiver functions are summed by a normal-movement stacking technique to image the couple of velocity and Moho depth giving the largest coherence to the P-Sv pulse on seisomograms. MOHO depth is then computed, at about 10 different stations, to give the topography of the base of the crust in an area of 4000km2 which includes the Neapolitian volcanic centers.

SHALLOW VELOCITY MODEL FOR STROMBOLI VOLCANO FROM SURFACE WAVE DISPERSION

S. PETROSINO, E. Del Pezzo, M. La Rocca, J. Ibanez, R. Maresca (Universit'di Salerno, Salerno, Via S. Allende, Baronissi (SA) 84081, Italy, Tel: 0039 089 953 804, Email: Kilauea@tin.it)

Data recorded during two seismic experiment carried out at Stromboli volcano, Italy, in May 1992 and in September 1997 were used to deduce a shallow velocity model for the north-western and south-western flanks of the volcano. Rayleigh wave group and phase velocity dispersion curves in the 2-8 Hz frequency range were obtained applying Multiple Filter Technique (MFT) and Phase Match Filter (PMF) to the seismic signals produced by the explosion quakes and recorded by a linear seismic array deployed on the north-western flank of the island (Labronzo). These dispersion curves were iteratively inverted to infer the velocity structure to a depth of about 200 m. The velocity model obtained for the north-western flank was compared with the one deduced from an analysis of the volcanic tremor with Aki's correlation technique , showing a good agreement. Multiple Filter Technique and Phase Match Filter were also applied to explosion quakes recorded by a short period seismic antenna installed during the Twin Array Experiment (September, 1997) on the south-western side of the volcano near Ginostra village. Phase velocity dispersion curve was also determined using the Zero-Lag Cross-Correlation technique, to compare it with the one obtained by the MFT and PMF analyses. The velocity model of the south-western flank was then inferred by the inversion of the group and phase velocity dispersion curves. The two investigated areas show a similar shallow velocity structure. Both the models deduced in the present work show an increase of seismic wave velocity with depth, in agreement with the geology of a stratified volcano.

DIFFRACTION AND EMISSION TOMOGRAPHY CRUSYAL STUDY IN THE NORTHERN KANTO, JAPAN

Irina J. TCHEBOTAREVA, Alexei V.Nikolaev (both at Inst. Earth Physics RAS, B.Gruzinskaya 10, Moscow 117234, Russia, email: chari@synapse.ru); Haruo Sato (Dept.Geoph., Tohoku Un., Aoba-ku, Sendai, 980-8578, Japan, email: sato@zisin.geophys.tohoku.ac.jp)

Method of emission and diffraction tomography was applied for reconstruction of 3D images of passive scatterers and of seismic emission sources within the Earth crust. Temporal array composed from 196 receivers was installed in the volcanic active region of local earthquakes. Both shear and compressional waves have been used for image reconstruction. Obtained images are distinctly similar, that is an indirect sign of reliability of the result. The location of scattering anomalies is in agreement with fontains both scattered and emission component induced by direct P and S waves of earthquakes. Images obtained by 'late coda' show that seismic emission sources differ from the location of the scattering anomalies and relate to the area of the largest ear an give rise to this effect. To resolve the problem of relation of the passive scattering and seismic emission in the coda waves it is necessary to study the dependence of the amplitude of the induced component upon the earthquake magnitude.

THREE DIMENSIONAL VELOCITY STRUCTURE CHARACTERIZED BY A LOW VELOCITY ZONE BENEATH THE HIDA MOUNTAINS IN THE CENTRAL HONSHU, JAPAN

Makoto MATSUBARA, Naoshi Hirata, Shin'ichi Sakai (Earthquake Research Institute, the University of Tokyo, 1-1-1 Yayoi Bunkyo-ku, Tokyo, JAPAN, email: mak@eri.u-tokyo.ac.jp); Ichiro Kawasaki (Toyama University, 3190 Gofuku Toyama, JAPAN)

Seismic waves suffer strong attenuation when propagating in the crust beneath high mountains. However, details of the region have not yet been clarified which attenuate seismic waves beneath the Hida Mountains located in the central Honshu, Japan. To analyze the region we deployed 44 portable seismographs in a 45-km linear array, three portable seismographs and eight temporary telemetered stations across and around the linear array in the summer of 1996. We obtained 3175 P-wave arrival time data and 2335 S-wave arrival time data from 54 events at 101 stations. We inverted the arrival times to obtain 3-D P- and S-wave velocity models by a damped least squares method (Zhao, 1992). A low velocity zone was found beneath the Hida Mountains at depths of 2 - 4 km and 12 - 20 km. P-wave velocity is 30 % lower and S-wave is 60 % lower than those in the surrounding area. The resolution of inversion was tested by a checker-board method. It is good at depths of 0 - 15 km for both P- and S-wave. A high Vp/Vs ratio (2.7) indicates that a 15 % partially molten rock exists beneath the Hida Mountains, suggesting a magma reservoir in the low velocity area.

CRUSTAL STRUCTURE UNDERNEATH MT. VESUVIUS FROM ONLAND RECORDINGS OF OFFSHORE SHOTS (MAREVES 1997): DATA PRE-PROCESSING AND PRELIMINARY INTERPRETATION

Jean VIRIEUX (CNRS, UMR GeoAzur, Nice, France); Aldo Zollo, Emmanuel Auger, Maria Rosaria Frattini, Paolo Gasparini (all at Dipartimento di Scienze Fisiche, Universita' di Napoli, Italy); Roberto De Franco, Grazia Caielli (both at Ist.Ric.Rischio Sismico, CNR, Milan, Italy); Giuseppe De Natale, Giovanni Iannaccone, Marcello Martini (all at Osservatorio Vesuviano, Naples, Italy); Roberto Scarpa (Dipartimento di Fisica, Universita' dell'Aquila, Italy)

In February 1997 the oceanographic ship NADIR (IFREMER, Brest, France) performed an offshore seismic campaign in the bay of Naples in the framework of a transit valorisation project. NADIR was equipped with eight 16-liters air guns and operated a dense network of profiles (1690 shots) with one shot per minute (spacing about 150 m) during about 30 hours. The shots were recorded on-land at 16 sites by temporary digital three-component (3C) stations, a 64-channel seismic array and 12 stations of the Observatorio Vesuviano permanent network. The acquisition layout was designed in order to image the crustal discontinuities down to Moho in the Bay of Napoli, and beneath Mt. Vesuvius and Phlegraean Fields by reflected/converted waves. Most of the recording sites were grouped in three sets at increasing distance from the volcano (maximum offset: 100 km), so to have a continuous space coverage of the crustal reflectors beneath Mt. Vesuvius and the surrounding plain. Each site was equipped with up to three 3C digital seismographs, in order to improve the signal-to-noise ratio by stacking. The recorded common receiver gathers have been pre-processed, NMO corrected and stacked together in order to enhance the phase identification and the clear detection of main reflection events from crustal discontinuities. In this paper will be shown the pre-processed seismic sections and their preliminary 2-D interpretation.

WAVEFIELD PROPERTIES OF SHALLOW TREMOR AND LONG-PERIOD EVENT AT KILAUEA VOLCANO, HAWAII

Gilberto SACCOROTTI (Osservatorio Vesuviano, Via Manzoni 249, 80123 Napoli, Italy, E-mail: gilberto@osve.unina.it); Bernard Chouet and Phillip Dawson (U.S. Geological Survey, 345 Middlefield Road, MS 977 94025 Menlo Park, CA, USA,
E-mail: chouet@usgs.gov, dawson@usgs.gov)

The wavefields of tremor and a long-period (LP) event associated with theongoing eruptive activity at Kilauea Volcano, Hawaii, are investigated using a combination of dense small-aperture (300 m) and sparse large-aperture (5 km) arrays deployed in the vicinity of the summit caldera. Measurements of azimuth and slowness for tremor recorded on the small-aperture array indicate a bimodal nature of the observed wavefield. At frequencies below 2 Hz, the wavefield is dominated by body waves impinging the array with steep incidence. These arrivals are attributed to the oceanic microseismic noise. In the 2-6 Hz band, the wavefield is dominated by waves propagating from sources located at shallow depths (<1 km) beneath the eastern edge of the Halemaumau pit crater. The hypocenter of the LP event, determined from frequency-slowness analyses combined with phase picks, appears to be located close to the source of tremor but at a shallower depth (<0.1 km). The wavefields of tremor and LP event are characterized by a complex composition of body and surface waves, whose propagation and polarization properties are strongly affected by topographic and structural features in the summit caldera region. Analyses of the directional properties of the wavefield in the 2-6 Hz band point to the directions of main scattering sources, which are consistent with pronounced velocity contrasts imaged in a high-resolution three-dimensional velocity model of the caldera region. The frequency and Q of the dominant peak observed in the spectra of the LP event may be explained as the dominant oscillation mode of a crack with scale length 20-100 m and aperture of a few centimeters filled with bubbly water. The mechanism driving the shallow tremor appears to be consistent with a sustained excitation originating in the oscillations of a bubble cloud resulting from vesiculation and degassing in the magma.

SPATIAL AND TEMPORAL VARIABILITY OF LOW FREQUENCY EARTHQUAKES AND VOLCANIC TREMOR ON MONTSERRAT

Brian BAPTIE, Richard Luckett (British Geological Survey, Murchison House, Edinburgh, UK); Jurgen Neuberg (School of Earth Sciences, University of Leeds, UK)

Low frequency earthquakes and volcanic tremor at the Soufriere Hills volcano, have been recorded on an array of broadband seismometers. We examine spatial and temporal variability in low frequency earthquakes during the extrusive phase of the eruption, between January and August 1997. Spectral analysis reveals evidence of changes in spectral properties with increasing source energy. The high correlation between spectra of the largest events both within individual swarms and over longer periods of time suggests a highly repeatable source mechanism. In general, we find that spectral properties are not coherent across the array. This leads to the conclusion that the wavefield is dominated by path and site effects characteristic of surface wave propagation. However, we present several episodes of volcanic tremor where the spectra become coherent on all components across the array. The frequency of the spectral peaks is observed to both increase and decrease with time. We observe similar behaviour preceding tremor episodes in the post-extrusive period of the eruption. In this case the tremor is thought to be closely related to ash and steam venting. Such behaviour is clearly a source effect and can be modelled by a sequence of repetitive events whose trigger frequency changes with time.

NO RESONATING MAGMA CONDUIT AT KARYMSKY VOLCANO, KAMCHATKA, RUSSIA

Jonathan M. LEES (Department of Geology and Geophysics, Yale University, New Haven, CT, 06511 email: lees@love.geology.yale.edu); Evgenii Gordeev (Geophysical Services, KOMSP, Russian Academy of Sciences, Petropavlovsk-Kamchatsky, Kamchatka, Russia, email: gord@emsp.iks.ru)

Repeating pulses from a exploding Karymsky volcano contain a rich variety of signals recorded on acoustic and seismic sensors. Several general observations regarding the pulsating train include the following facts: 1) Chugging events always follow an initial explosion, although not all explosions are followed by chugging. 2) There is almost always a lag time between the initial explosion and the commencement of intense chugging. We assume this is a preparation time where the system is building up intensity. 3) The chugging is fairly regular, with a dominant, fundamental frequency that fluctuates from 0.7 to 1.5 s. 4) Individual pulses are very uniform and are near duplicates of the initial explosive pulses. 5) A typical sequence of events has an envelope that grows rapidly in amplitude and later diminishes gradually. The pulsating sequences exhibit behavior that cannot be explained by a resonating conduit. This is clear from the correlation of amplitudes to inter-pulse time intervals. Consistent seismic arrivals appear to be keyed to the size of acoustic recording and not vice-versa, providing evidence for a shallow, oscillatory source near the vent opening. A model consisting of a sequence descrete pulses explains the data and provides a framework for understanding the dynamics of degassing at the vent.

NATURE OF VOLCANIC EARTHQUAKES AND TREMOR REVEALED BY SEISMIC OBSERVATION VERY CLOSE TO THE SOURCE REGION JUST BELOW THE SUMMIT CRATER OF ASAMA VOLCANO, JAPAN

Jun OIKAWA, Yoshiaki Ida, Hiroshi Tsuji (Earthquake Research Institute, University of Tokyo, Yayoi 1-1-1, Bunkyo-ku, Tokyo 113-0032, JAPAN, email: oikawa@eri.u-tokyo.ac.jp, ida@newsida.eri.u-tokyo.ac.jp, tsuji@komoro.eri.u-tokyo.ac.jp)

In Asama volcano, additional four seismic stations were recently installed near the summit crater in order to obtain the high quality records in closer distances to the hypocenter regions just below the crater. The waveforms of high frequency earthquakes obtained at the new stations have the sharp first break and the S-phase which has not clearly been recognized before. Low frequency events contain a long coda wave which attenuates monotonically with a dominant frequency of 1 to 3 Hz for 1 minute. Using the new data, the hypocenters of the volcanic earthquakes were determined much more accurately, particularly in depth. High frequency earthquakes and low frequency events are concentrated into a shallow zone above the depths of 1 km underneath the crater. Some high frequency events are also observed below 3 km and there is a seismic gap between the two zones. The seismic gap agrees with the location of the pressure source which is estimated from the ground deformation. It is inferred that the gap zone corresponds to a magma reservoir and that shallower seismic events occur in and around the conduit to the summit crater.

JSV47/W/31-B5 0930

LOW ATTENUATION RESONANCE OF A SPHERICAL MAGMA CHAMBER: SOURCE MECHANISM OF VOLCANIC TREMOR AT ASAMA VOLCANO, JAPAN

Eisuke FUJITA (National Research Institute for Earth Science and Disaster Prevention, Tennodai 3-1, Tsukuba, Ibaraki, 300-0006, Japan, email: Fujita@Geo.Bosai.Go.Jp); Yoshiaki Ida (Eri. University Of Tokyo, Yayoi1-1-1, Bunkyoku 113-0032, Japan, email: ida@newsida.eri.u-tokyo.ac.jp)

Volcanic tremor often has oscillating waves with some specific frequencies and attenuation factors of a spherical resonator consisting of volcanic fluid. We have investigated the source mechanism of volcanic tremor, formulating a spherical resonator and found low attenuation modes (lams) in lower modes. Lam takes as low as 0.01 times attenuation factors of higher modes. Some monotonic waveforms of volcanic tremor (lp-events) can be explained by the excitation of lam. Applying the model to the events at asama volcano, japan, both characteristic frequencies and attenuation factors are well fitted and the resonator size, velocity and density contrasts between fluid inside and elastic medium outside are estimated. The resonator about 200m radius contains fluid composed of gas and liquid mixture. Excitation of the resonance is also formulated by expanding the excited wave in the series of the eigen functions and we estimate the excitation function that represents the effect of the applied force on the observed volcanic tremor. It is inferred that the volcanic tremor at asama volcano is triggered by the combination of slow and rapid pulsive forces, suggesting the gas discharge or bubbling in magma and the nearby earthquake, respectively.

JSV47/W/24-B5 0945

THE COMPLEX FREQUENCIES OF LONG-PERIOD EVENTS AS A PROBE OF FLUID COMPOSITIONS BENEATH VOLCANOES

Hiroyuki KUMAGI, Bernard A. Chouet (both at U.S. Geological Survey, 345 Middlefield Road, MS 910, Menlo Park, CA 94025, USA, email: kumagai@seis.nagoya-u.ac.jp, chouet@chouet.wr.usgs.gov)

Long-period (LP) events have been widely observed in relation to magmatic and hydrothermal activities in volcanic areas. Their waveforms characterized by their harmonic signature have been interpreted as oscillations of a fluid-filled resonator, and mixtures of liquid and gas in the form of bubbly liquids have been mainly assumed for the fluid.
To investigate the characteristic properties of the resonator system, we analyze waveforms of LP events observed at four different volcanoes in Hawaii, Alaska, Colombia and Japan using a newly developed spectral method. This method allows an estimation of the complex frequencies of decaying sinusoids based on an autoregressive model. The results of our analysis show a wide variety of Q factors ranging between tens and several hundreds.
We compare these complex frequencies with those predicted by the fluid-filled crack model for various mixtures of liquid, gas and ash. While the oscillations of LP events with Q smaller than 50 can be explained by various combinations of liquids and gases, we find that ash-laden gases are required to explain long-lasting oscillations with Q larger than 200. The complex frequencies of LP events yield useful information on the types of fluids, and their temporal and spatial variations can be used as a probe of fluid compositions beneath volcanoes.

JSV47/W/16-B5 1000

LABORATORY FOAM FLOWS EXHIBITING LP TYPE PRESSURE OSCILLATIONS

Stephen J LANE (1), Bernard A Chouet (2), Phillip P Dawson (2), Graham A Ryan (1), Jeremy C Phillips (3) (1: Volcanic and Geohazards Research Group, Dept of Environmental Science, Lancaster University Lancaster LA1 4YQ, UK; 2: USGS, 345 Middlefield Road, Menlo Park, California 94025, USA; 3: Centre for Environmental and Geophysical Flows, School of Mathematics, University of Bristol, University Walk, Bristol BS8 1TW, UK)

The two phase gas-liquid flow of fluids in conduits is often considered to lead to the generation of long period and harmonic seismic signals at active volcanoes. These fluids could be magma-steam or water-steam in volcanic systems and could be flowing over a wide range of velocities.
We present pressure oscillation data from the laboratory simulation of magma-steam foam flows using natural gum rosin and a volatile organic solvent. These experiments were carried out over a range of volatile supersaturations generating conditions ranging from gentle unfragmented to violent fragmenting flow. Pressure oscillations were detected over the whole range of flow conditions. Spectral analysis of the oscillations showed that the dominant oscillation frequencies could be attributed to resonant oscillation in both the foam and open gas spaces within the experimental tube. Flows where foam fragmentation occurred showed a broader, higher frequency and more energetic spectrum than unfragmented flows. Some of the experimental pressure data show remarkable qualitative similarity with vertical ground velocity spectra generated by magma flow during the inflation stage of the 1st February 1996 volcanic crisis of Kilauea Volcano, Hawaii. We discuss this in relation to the proposed generation mechanisms within the experiments and Kilauea Volcano.

JSV47/W/01-B5 1045

LOCATION OF THE SEISMO-VOLCANIC SOURCE AT STROMBOLI VOLCANO USING TWO DISTINCT SEISMIC ANTENNAS

M. LA ROCCA, E. Del Pezzo, J. Ibanez, J., Almendros, G. Saccorotti, S. Petrosino, G. Alguacil, E. Carmona

In September 1997, two short period, small aperture seismic antennas were installed at Stromboli volcano (Southern Italy), with the main aim of space location of the high frequency source of the explosion quakes. The first antenna, located at Semaforo Labronzo, had an aperture of about 300 m, and consisted of 26 vertical and two 3-D seismometers.The other antenna was deployed near the Ginostra village, located on the western flank of Stromboli, in a flat area named Timpone del Fuoco. It was composed by 15 vertical and three 3-D seismometers. 75 records of explosion quakes triggered both antennas simultaneously, and were used as data set. Slowness spectra, calculated at both arrays for several time windows sliding along the seismograms, track the seismic source in 4 frequency bands centred at 1, 2, 3 and 4 Hz, with the bandwidth of 1 Hz.
Ray parameters and back-azimuths are calculated separately at the two antennas using the Zero Lag Cross-correlation method (ZLCC). Synthetic ray parameters and back-azimuths were then generated for each node of a 3-D grid encompassing the whole volcano and limited by the topography. An approximate ray-tracing in 3-D was used to perform this task, using a velocity model which in the first 200 meters from the surface was derived by a study of velocity dispersion, carried out in the same array sites, and elsewhere was fixed at reasonable values. The search for the grid coordinates which maximise in the least squares sense the probability thatthe observed data are in fact observed, was performed for both arrays and finally the productof those probability functions gives the final solution. Results show that the epicentral area covers the crater area. Some coherent phases are observed in the late portion of the seismogram, showing the presence of coherent strongly back-scattered arrivals. The pre-event noise is also well correlated in the investigated frequency range, showing similar slowness vectors than those observed for the explosion quakes.

JSV47/W/18-B5 1100

BROADBAND CHARACTERISTICS OF THE SOURCES OF EXPLOSIONS AT STROMBOLI, ITALY

Bernard CHOUET, Phillip Dawson (both at U.S. Geological Survey, 345 Middlefield Road, Menlo Park, California 94025, USA, email: chouet@chouet.wr.usgs.gov); Gilberto Saccorotti, Marcello Martini (both at Osservatorio Vesuviano, Via Manzoni 249, 80123 Naples, Italy, email: gilberto@osve.unina.it); Roberto Scarpa (Dipartimento di Fisica, Universita degli studi dell'Aquila, 67010 Coppito, L'Aquila, Italy, email: roberto.scarpa@aquila.infn.it); Gaetano De Luca and Giuliano Milana (both at Servizio Sismico Nazionale, Via Curtatone 3, 00185 Rome, Italy, email: gaetano.deluca@aquila.infn.it)

During September-October 1997, 21 three-component broadband (0.02-60 s) seismometers were deployed on the flanks of Stromboli at radial distances of 0.3-2.2 km from the active crater to investigate the source mechanism of Strombolian explosions. Over 1600 minutes of volcanic tremor interspersed with explosions were recorded over a period of 8 days. In the 2-50 s band, the very-long period (VLP) signals associated with explosions are representative of two stationary source mechanisms repeatedly activated in time. VLP particle motions are essentially linear and analyses of semblance and particle motions are consistent with a single point source located 300 m beneath the crater floor and 300 m northwest of the active vents. Similar VLP waveforms are observed at the 21 stations, indicating that the seismograms are source-dominated. The VLP ground displacement response to each explosion is marked by a compression, followed by a dilatation and terminating with another compression, which may be qualitatively interpreted as: (1) pressurization and dilation of the conduit in response to the ascent of a slug of gas; (2) depressurization and collapse of the conduit in response to mass withdrawal (bubble burst) during the eruption; and (3) repressurization and dilation of the conduit associated with the replenishment of the source with fluid. Moment tensor inversions of a subset of VLP data suggest a crack-like geometry for the source centroid. Each eruption corresponds to the evacuation of a volume of gas on the order of 1000 cubic meters.

JSV47/W/11-B5 1115

DETECTION OF A CRACK-LIKE CONDUIT BENEATH THE ACTIVE CRATER AT ASO VOLCANO FROM DENSE BROADBAND SEISMIC OBSERVATION

Hitoshi KAWAKATSU, Mare Yamamoto (both at Earthquake Research Institute, University of Tokyo, Yayoi, Bunkyo, Tokyo 113 JAPAN, email: hitosi@eri.u-tokyo.ac.jp); Satoshi Kaneshima (Department of Earth and Planetary Sciences, Faculty of Sciences, Tokyo Institute of Technology); Takehiko Mori, Tomoki Tsutsui, Yasuaki Sudo (all at Aso Volcanological Laboratory, Kyoto University)

At Aso Volcano in Kyushu, Japan, volcanic signals with unusually long periods (7-15 sec) have been observed in the near-field of the active crater,and their source is known to be located about 1.5km beneath the crater (Sassa, 1935; Kaneshima et al., Science, 1996). In August, 1997, we deployed totally 21 broadband three-component velocity seismometers temporarily around the crater in order to constrain the geometry of the LPT source. Most of these stations were located within 1 km around the Naka-dake 1-st crater and provide a good azimuthal coverage.The observed amplitude variation of LPT reveals that the source of LPT consists of an isotropic component and an inflation (deflation) of an inclined tensile crack almost parallel to the NNW to SSE trending chain of the old craters of Naka-dake. The detected buried crack has a dimension of 1.2km along the strike, which is almost equivalent to that of the old crater chain; Its top edge is located about few hundreds meters below the surface, and the crack extends 2-3km downward with a dip of 85 degrees. The fact that the extension of the crack plane meets the active fumarole at the surface suggests that the hydrothermal system beneath the Naka-dake 1st crater causes inflation and deflation of the source region and results in exciting the crack-like conduit to generate LPTs with the period of 15 sec.In November, 1998, we further deployed a dense network of broadband seismometers to observe and constrain the wave propagation along the crack (i.e., crack wave). Analysis of these data will be also presented.

JSV47/W/22-B5 1130

VERY LONG-PERIOD SEISMIC EVENTS ASSOCIATED WITH THE 1998 ACTIVITY OF IWATE VOLCANO, JAPAN

Takeshi NISHIMURA, Haruhisa Nakamichi, Satoru Tanaka, Tomokazu Kobayashi, Minemori Sato, Sadato Ueki, Hiroyuki Hamaguchi, Masakazu Ohtake, Haruo Sato, (all at Graduate School of Science, Tohoku University, Sendai 980-8578, Japan, email: nishi@zisin.geophys.tohoku.ac.jp), Eisuke Fujita (NIED, Tukuba 305-0006, Japan)

We have conducted a broad-band seismic observation at Iwate Volcano using six STS-2 seismometers and continuous recording systems (LS8000WD; 24 bit A/D, 50Hz sampling, GPS clock) since April, 1998. We observed a high activity of very long-period seismic events, although there were no significant surface activities of the volcano. The long-period events have a dominant period of about 10s and a duration of 30 s to 60 s, being often accompanied with high- frequency signals (a few Hz) at the beginning and/or the end of the long-period signals. Based on a result that particle orbits at all the stations show elliptical shapes, we estimate the hypocenters to be at a depth of a few kilometer beneath the western region of Iwate Volcano. A detailed semblance analysis further shows that each long-period event moves a few kilometer westward with a speed of a few hundred meters per second. Although pressure sources causing dilatation of the volcano, which are detected by a GPS measurement, migrated upward from an eastern deep part to a western shallow part, the long-

period events observed at the same period do not show any significant temporal changes in their hypocenters. We further determine the source mechanism of long-period events using a moment tensor waveform inversion technique in which a point source is assumed. The results show that a volumetric source in which dilatation and compression occur repeatedly can well explain the observed signals at all stations.

JSV47/W/13-B5 1145

NEW INVESTIGATIONS OF NON-DOUBLE-COUPLE EARTHQUAKE MECHANISMS AT LONG VALLEY CALDERA, CALIFORNIA

B.R. JULIAN (U. S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025, USA, email: julian@usgs.gov); G.R. Foulger (Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, UK, email: g.r.foulger@durham.ac.uk)

Some of the earliest evidence of anomalous "non-double-couple" earthquake mechanisms came from Long Valley caldera, in eastern California. Several large (magnitude ~6) earthquakes there in May 1980 produced high-quality seismic data sets that were inconsistent with simple shear faulting, and suggested source processes involving hydraulic fracturing by magmatic fluids. It has so far not proved possible, however, to determine whether the thousands of smaller earthquakes at Long Valley have non-DC mechanisms. In the summer of 1997, a network of 64 three-component digital seismometers, including six with broadband response, was operated in the south moat and around Mammoth Mountain for a three-month period that included the onset of a series of intense earthquake swarms. The stations cover the focal spheres well and provide a wealth of data that greatly improve our ability to resolve earthquake locations and mechanisms. We will present moment-tensor focal mechanisms and high-resolution relative hypocenter locations, which will resolve the question of the mechanisms of small earthquakes at Long Valley.

JSV47/W/09-B5 1200

SEISMIC STRAIN AND STRESS PATTERNS AT ETNA VOLCANO, SICILY, BETWEEN 1990 AND 1998

Graziella Barberi, Giancarlo NERI (both at Istituto di Scienze della Terra, University of Messina, Salita Sperone 31, 98166 Messina, Italy, Email: geoforum@imeuniv.unime.it); Ornella Cocina, Eugenio Privitera and Salvatore Spampinato (all at Istituto Internazionale di Vulcanologia, CNR, Piazza Roma 2, 95123 Catania, Italy. Email: cocina@iiv.ct.cnr.it).

The algorithms by Gephart and Forsyth (JGR, 1984) and Wyss et al. (JGR, 1992) for seismic stress and strain tensor computations, respectively, have been applied to shear-type earthquakes occurring beneath the Etna volcano during 1990-1998. Space-time variations of stress and strain parameters have been examined jointly with ground deformation and gravimetric data collected in the same period and reported in the literature or in technical reports by local volcano surveillance institutions. Taking also into account the information available from volcanological observations and structural geology, we propose a volcano activity scheme assuming that hydraulic pumping by magma emplaced in nearly north-south vertical structures produces the east-west orientation of the maximum compressive strain and stress found in the upper 10 Km beneath the crater area. In contrast, regional tectonics deriving from north-south slow convergence between African and European plates appear to play a dominant role in the generation of stress and strain fields at crustal depths deeper than 10 Km in the volcano area. According to our scheme, the progressive magma filling of upper crust in the pre-eruptive phases produces, sequentially, the observed gravity positive changes, cone inflation and unusual seismic strain rate in the upper 10 Km associated to an increased definition of the seismic deformation regime (i.e. very small confidence limits of the orientation). In agreement with this scheme, deflation revealed by ground deformation data during the course of the major 1991-1993 eruption was accompanied by a practically nil level of shallow seismicity.

JSV47/W/07-B5 1215

EVIDENCE FOR MAGMA AT INTERMEDIATE CRUSTAL DEPTH BELOW KILAUEA'S EAST RIFT, HAWAII, BASED ON ANOMALOUSLY HIGH B-VALUES IN KILAUEA'S SOUTH FLANK

Max WYSS, Koichiro Nagamine, Stefan Wiemer (Geophysical Institute, Univer-sity of Alaska, Fairbanks, 99775, email: max@giseis.alaska.edu); Fred Klein (U.S. Geological Survey, Menlo Park, CA, 94025)

The pattern of b-value of the frequency magnitude relation, or mean magnitude, varies little in the Kaoiki-Hilea area of Hawaii, and the b-values are normal, with b=0.8 in the top 10 km and somewhat lower values below that depth. We interpret the Kaoiki-Hilea area as relatively stable, normal Hawaiian crust. In contrast, the b-value beneath Kilauea's South Flank are anomalously high (b=1.3) at depths between 4 and 8 km, with the highest values near the East Rift zone, but extending 5 to 8 km away from the rift. We propose that the anomalously high b-values along and near the East Rift zone are due to the presence of an active magma body beneath the East Rift zone at depths of 4 to 8 km in analogy to other volcanoes where anomalously high b-values correlate with magma chambers. This supports the model of a deep magma body beneath the East Rift zone from Kilauea summit to a distance of at least 40 km down rift. The anomalously high b-values at the center of the South Flank, kilometers away from the rift, may be explained by unusually high pore pressure throughout the South Flank, or alternatively by anomalously strong heterogeneity due to extensive cracking. We hypothesise that the extensive cracking may have been acquired when this part of the South Flank, now several kilometers distant from the rift zone, was generated at the rift zone. Since its generation, this volume may have moved seaward, away from the rift, but earthquakes occurring in this volume still use the preexisting three dimensional crack distribution. Along the decollement plane at 10 km depth the b-values are exceptionally low (b=0.5) suggesting a simple one-dimensional crack distribution.

JSV47/E/02-B5 1230

A TRIAL FOR DETECTING TEMPORAL VARIATION OF SEISMIC TRANSFER FUNCTION USING ACCURATELY CONTROLLED SINUSOIDS - TOWARDS MONITORING OF GEODYNAMIC STATE

Koshun YAMAOKA, Koji Miyakawa (both at School of Science, Nagoya University, Chikusa, Nagoya 464-8602 Japan. email: yamaoka@seis.nagoya-u.ac.jp); Takahiro Kunitomo, Mineo Kumazawa (both at Tono Geoscience Center, Japan Nuclear Cycle Development Institute, Sonodo, Jorinji, Tokishi 509-5102, Japan, email: kuni tomo@tono.pnc.go.jp), ACROSS development team

We made on-site experiments of a new source-receiver system for seismic sounding, which is named ACROSS (Accurately Controlled Routinely Operated Signal System). The system uses precisely controlled sinusoids, which gives a best way to achieve high signal-to-noise ratio without destroying surrounding ground. One of the final goal of the system is to monitor the temporal variation of geodynamic state such as volcanic activity. The purpose of our experiment is to check the temporal stability of the system and to establish a practical technique to make a continuous monitoring of seismic structure. In our experimental site the sources which generage 20ton-f with centrifugal force are deployed on the ground surface where granite bedrock is exposed. The emitted elastic wave is received with two borehole seismometers deployed at 800m and 1800m deep near the fracture zones of Nojima fault which generates 1995 Kobe earthquake. We made three one-week runs and a one-month run of experiments. During each run the sources were continuously operated with frequency modulation around 20Hz and 30Hz, which produce plural components of sinusoids of constant frequency interval. The results of these experiments show that the stabilization of source-ground coupling is essential for precise monitoring of the temporal variation of velocity structure. After a correction for the coupling variation we achieved signal stability better than 1% in amplitude and 0.01 radian in phase characteristics, although temporal variation of natural origin is not identified.

PROGRAM FOR LOCATION OF HYPOCENTER COORDINATES OF VOLCANIC EARTHQUAKES USING LOCAL SEISMIC STATIONS NETWORK DATA

V.V. MYACHKIN (Institute of Physics of the Earth, Russian Academy of Sciences, 123810, Bolshaya Gruzinskaya, 10, Moscow, Russia, e-mail: myachkin@uipe-ras.scgis.ru)

The problem of accuracy of hypocentre coordinates determination in case of volcanic earthquakes is more significant than for tectonic earthquakes, because error in hypocentre position about 5 km doesn't allow one to localize the place of the future eruption. Therefore a program for determination of hypocentre parameters of local earthquakes was developed. It can either search for hypocentre coordinates and origin time simultaneously or determine the origin time independently, using 2 modifications of Vadati plot or the so-called robust method which was never used in any other algoithm. Use of external travel times calculated beforehand reduces the time for determination of wave travel times from the source to the station and thus allows the solution function minimum to be searched for at the whole poligon area, without any preliminary suppositions on its character. The program provides a picture of residuals structure near the minimum, i.e. the area of hypocentre existence, showing domains were the residual is 1.5, 2 or 3 times greater than in the minimum point, and we obtained that these domains have rather complicated configuration. Moreover, the solution often has 2 good sharp minima at different depths. The search for the solution function minimum is possible within the given limited depth range, and it allows a solution to be obtained for each minimum individually. The MINIMALM programme is successfully used to determine hypocentre parameters at the region of the Northern volcano group in Kamchatka. Hypocentre coordinates determined by this programme are in good accordance with areas of subsequent volcanic eruptions.

SEISMIC OBSERVATIONS AT MT ETNA (ITALY) SUMMIT AREA DURING STROMBOLIAN EXPLOSIONS AND THE BEGINNING OF A LAVA FLOW

Davide EREDITATO (Geological Survey of Japan, 1-1-3, Higashi, Tsukuba, Ibaraki 305, Japan, e-mail: takao@gsj.go.jp); Carmelo Bellia (University of Western Australia, Perth, Australia, e-mail: cbellia@geol.uwa.edu.au); Yuji Nishi (Geological Survey of Japan, 1-1-3, Higashi, Tsukuba, Ibaraki 305, Japan, e-mail: uwest@gsj.go.jp); Matsushima Nobuo (Geological Survey of Japan, 1-1-3, Higashi, Tsukuba, Ibaraki 305, Japan, e-mail: nobuo@gsj.go.jp); Giuseppe Patane (Istituto di Geologia e Geofisica, Universita' di Catania, Corso Italia 55, 95129, Italy); Takao Ohminato (Geological Survey of Japan, 1-1-3 Higashi, Tsukuba, Ibaraki 305, Japan, e-mail: takao@gsj.go.jp)

We conducted seismic observations in close proximity to the summit area of Mt Etna, Italy. During the observations, volcanic activity at the NE, Central, Bocca (Nuova and SE Craters was characterized by continuous gas emission, frequent small explosions, sporadic explosions and strombolian activity accompanied by a lava flow from SE Crater which started on September 15th.
A seismic network, composed of four Guralp CMG-40 (3-component characteristic frequency fo=0.033Hz) and four Mark Products L-22 3 component (fo=2Hz) sensors with 16 bit logger LS-8000SH was installed and operated from September 11th to 22th. The seismicity at the summit area of Mt. Etna mainly consists of different types of small earthquakes localized very close to the summit craters and related to their explosive activity. Most earthquakes can be detected only by the seismic stations closest to the summit craters. In addition, we observed some high frequency small earthquakes, with main spectral content above 10 Hz, showing different epicentral location and recorded by all the seismic stations. Seismicity associated with the lava flow from the SE Crater is mainly characterized by the occurrence of many small earthquakes, showing showing similar dominant frequency around 3Hz A typical increase-decrease pattern of the amplitude of volcanic tremor characterizes the summit activity preceding the summit lava outflow.

TEMPORAL EVOLUTION OF VOLCANIC EVENTS SPECTRUM

Javier PEÑA (Dept. Volcanologia, Museo Nacional de Ciencias Naturales, Jose Gutierrez Abascal 2, 28006 Madrid, Spain, e-mail: mcnp182@mncn.csic.es); Mar Astiz (Dept. Matematica Aplicada, E.T.S. Arquitectura, U.P.M., Avda. Juan de Herrara, 4, 28040 Madrid, Spain, e-mail: civgv@pinar1.csic.es); Alicia Garcia and Ramon Ortiz (Dept. Volcanologia, Museo Nacional de Ciencias Naturales, Jose Gutierrez Abascal 2, 28006 Madrid, Spain, e-mail: mcngg92@pinar1.csic.es and email: mcnor72@pinar1.csic.es)

In this work some results from the analysis of seismic events recorded in the Popocatepelt volcano are presented. The analysis is based on FFT and wavelets methods. The aim is to separate the signals by the temporal evolution of their spectral content. The FFT is only a stationary representation but appling wavelets we can obtain a good time-frequency representation of the signal. The automatic process will allow the seismic classification in real time, while they are recording at the observatory.
For volcanic crisis management the fast identification of event type is critical, taking into account that the large volume of recorded information could difficult the work. This method can facilitate this management. The basis of the method and some analysed events are shown.

ARRAY ANALYSIS OF SEISMIC NOISE WAVEFIELD AT MT. VESUVIUS VOLCANO, ITALY

G. SACCOROTTI (Dipartimento di Fisica, Università di Salerno, 84081 Baronissi Sa, Italy; e-mail: gilberto@osve.unina.it); R. Maresca (Facoltà di Scienze, Università del Sannio, maresca@physics.unisa.it); E.Del Pezzo (Osservatorio Vesuviano,: delpezzo@osve.unina.it); A. Cirillo (Dipartimento di Fisica,Università di Salerno); S. Petrosino (Osservatorio Vesuviano, e-mail: kilauea@tin.it)

A possible precursor of volcanic eruptions is the insurgence of volcanic tremor, characterised by a sustained signal lasting from several minutes to hours or days, with the distinctive characteristic of absence of clearly recognisable seismic phases. It can be overlapped to cultural ground noise, which in the case of Mt. Vesuvius is extremely high, due to the presence of a huge urban area surrounding the volcano. This is the reason why the discrimination of possible insurgent volcanic tremor may become a difficult task. For the above reasons we decided to investigate the spectral characteristics of the noise wave-field at Mt. Vesuvius in the present condition of quiescence. We deployed a seismic array of two three-component and eighteen vertical short period (4.5 Hz extended to 1 Hz) stations, with an aperture of approximately 600 meters, for a 7 months operation, about 1.5 km far away from the summit crater. A detailed spectral analysis of the noise recorded at each station was performed: temporal evolution of the spectra was investigated in short (2 minutes) and long (36 hours) time-windows; possible site effects due to local surface structure were also evaluated using spectral ratios among different stations and array-averaged spectrum. Fourier analysis shows the presence of a persistent peak around 0.5 Hz; the estimated spectral energy of secondary higher frequencies components is strongly time-dependent, showing highest values in the day-time, and so, it is presumably due to human noise sources. The frequency-slowness spectra reveal that only the signals in the frequency band centred at 0.5 Hz is coherent among the array stations, showing a back-azimuth directed toward the South, opposite to the direction of the active crater, and a slowness around 0.7 s/Km. As already observed by different authors in similar conditions (Valle del Tevere, Kilauea), the seismic energy propagating at frequencies lower than 1 Hz is interpreted as associated to marine disturbances. Results show the absence of coherent signals in the frequency band characteristic of the volcanic tremor, as expected in the present state of activity of Mt. Vesuvius.

BOREHOLE STRAINMETERS AND SEISMOMETERS FOR CONTINUOUS MONITORING OF VOLCANOES: RESULTS FROM AN EXPERIMENT ON VESUVIUS VOLCANO, ITALY

Roberto SCARPA, Antonella Amoruso and Alberto Cirella (all at Univ. dell'Aquila, IT), Luca Crescentini (Univ. di Camerino, IT), Gaetano De Luca (Serv. Sism. Naz., IT), Alan Linde and I. Selwyn Sacks (both at Carnegie Institution, Washington D.C., U.S.A.), Mario Castellano, Edoardo Del Pezzo, Mauro Di Vito, Folco Pingue, Marcello Martini, Gilberto Saccorotti and Claudia Troise (all at Osserv. Vesuviano, IT)

This research is focused on the development of borehole very broadband instruments to monitor volcanoes. It has been realized the development and the borehole installation of a strainmeter and a three-component seismometer, to detect very small signals linked to magma chamber pressure variations and magma transport. The borehole strainmeters are the most sensitive instruments developed to detect strain changes (down to 10^-12) with a wide dynamic range (>140 dB) and the borehole three-component seismometers can improve S/N by a factor 10 and will allow a more efficient detection of source parameters from volcanic earthquakes. These instruments have been installed in a hole excavated close to Mt. Vesuvius crater (2.5 km distance from the summit) and the strainmeter has been located in the Campanian ignimbritic layer (welded grey tuff) at 200 m depth, while two seismometers (Mark L22) have been set up at 70 m depth and at the surface, with a properly designed casing system. This system should constitute the first prototype of a network, consisting of 10 stations, 5 on Vesuvius and 5 on Campi Flegrei, with data transmission of high resolution signals (24 bits) to a real-time data acquisition center and alert system to control a possible reawakening of these potentially destructive volcanoes.

JSV47/E/09-B5 Poster 1400-06

HIGH RESOLUTION SPATIAL AND TEMPORAL MAPPING OF THE FREQUENCY-MAGNITUDE DISTRIBUTION IN VOLCANIC AREAS FOR STRUCTURAL ANALYSIS AND MONITORING - CAPABILITIES AND LIMITATIONS

Stefan WIEMER (Institute of Geophysics, ETH Hoenggerberg, CH-8093, Zurich, Switzerland; email: stefan@seismo.ifg.ethz.ch)

High resolution, three dimensional spatial mapping of the frequency-magnitude distribution (FMD) has been performed for 10 seismically active volcanic systems (Mount St. Helens, Long Valley, Mt. Spurr, Mt. Redoubt, Off Ito, Mt. Vesuvius, Mt. Etna, Montserat, Kilauea, Katmai). Strong and statistically highly significant contrasts in the slope of the FMD (with b-values ranging from 0.6 to 2.0) have been found on the scale of kilometers, defying the commonly held believe that volcanic areas generally exhibit a higher than normal b-value. A more sophisticated analysis reveals that instead pockets of high b-value anomalies (b>1.3) are embedded in normal crust (b~0.8). High b-values are particularly concentrated in the vicinity of magmatic bodies, which is to be expected because the physical conditions near a magmatic body (high material heterogeneity, high temperature gradients, low shear stress, and high pore pressures) all favor high b-values. Thus we have proposed that high b-values near magmatic bodies are a necessary, but not sufficient, condition, and, therefore, spatial mapping of the FMD presents a viable tool for structural investigations of volcanic systems. This talk will summarize some of the promise of this relatively new method, but also discuss the limitations and unresolved questions such as : (1) How does the hypocenter accuracy and magnitude determination influence the spatial b-value mapping? (2) Earthquake swarms and families and the resulting bi-modal FMD; (3) How can we resolve the ambiguity in the interpretation of high b-value anomalies? (4) Are temporal variations observed in b actually caused by spatial shifts in activity? (5) Can spatial and temporal mapping be useful for routine monitoring and eruption forecasting?

AN AUTOMATIC OBSERVATORY FOR VOLCANO MONITORING

RAFAEL ABELLA, Alicia Garcia, Ramon Ortiz and Marta Tarraga (all at Departamento de Volcanologia, Museo Nacional de Ciencias Naturales, CSIC, c/ Jose Gutierrez Abascal 2, 28006 Madrid, Spain, email: mcnam3k@pinar1.csic.es)

The instrumentation in active volcano requires to have equipment handy, adaptable, portable, of low cost and low energy. The tracking of volcanic activity implies open out in a sort time and in a difficult access, the instrumentation have to be able to operate automatically in a crucial conditions. Seismic methods and deformation analysis are the most used for the surveillance and study of volcanoes so we have began with a basic unit constituted by seismic station and extensometer. An acquisition multiparametric system with 8 canals have been developed based on a 16/24 bits analogue digital conversor of Analog Devices. The different sensorscan be connected, are for example extensometer, clinometer, thermometer, magnetometer. For the first evaluation of this equipment has been installed inside of a volcanic cave in the high part of Villarrica Volcano (Chile), one component seismic station, an extensometer and a thermometer. Also a three component seismic station of sort period have been installed at the base of Villarrica Volcano.

JSV47/W/15-B5 Poster 1400-08

VOLCANO-TECTONIC MICRO-EARTHQUAKE OBSERVED AT A SHORT PERIOD SEISMIC ANTENNA LOCATED AT MT. VESUVIUS (ITALY)

Bianco F., Castellano M., PETROSINO S., Carmona E., La Rocca M., Galluzzo D. and E. Del Pezzo

In November 1997 a short period seismic antenna (array) was installed on the south-western flank of Mt. Vesuvius, about 1.5 Km far from the crater, to record local micro-seismicity. The array was formed by 18 vertical component and 2 three component geophones Mark L15B electronically extended to 1 Hz and cable-connected to the acquisition system (composed by 16 bits A/D converter, anti alias filter and portable PC). The array maximum aperture was about 500 meters, with an average distance between the sensors of 50 meters. The co-ordinates of the sensors were obtained with differential GPS measurement. The array was in operation for 7 months and during this period it recorded about 300 local micro-earthquakes, more than those triggering the seismic monitoring network. About 40 seismic events were studied with array techniques: the Zero-Lag Cross-Correlation technique was used to calculate backazimuth and apparent velocity for the main direct phases of local micro-earthquakes. Polarisation properties of the first seismic phases were deduced performing a covariance matrix analysis in the time domain and used to constraint the S-wave first onset. Using a simplified 3-D ray-tracing technique we located the seismic source. Source location shows that the earthquakes recorded by the array are quite shallow, with hypocentres not deeper than 4 Km, in agreement with previous studies. The results achieved in this work show that the array techniques are useful to determine the propagation properties of the wave-field associated to micro-earthquakes as well as to discriminate primary seismic phases, becoming an useful complementary tool for the seismic monitoring of the active volcanoes.

A SEISMOLOGICAL STUDY ON REMOTELY TRIGGERED PHREATIC ERUPTION AT AKITA-YAKEYAMA VOLCANO, NORTHEASTERN JAPAN

Hiroyuki HAMAGUCHI, Sadato Ueki, Satoru Tanaka and Haruhisa Nakamichi, (all at Graduate School of Science, Tohoku University, Sendai 980-8578, Japan, email: hama@aob.geophys.tohoku.ac.jp)

We discussed the temporal variations of amplitude and frequency of volcanic tremors and subsequent impulsive long-period signals prior to the simultaneously occurrence of phreatic eruption and debris avalanche at Akita-Yakeyama, northeastern Honshu, Japan on 8:00 May 11, 1997 (JST). Precursory tremors were continuously registered by a short period seismometer (T = 1sec) at YKY station adjacent to the eruption site (distance; ca 1 km) until a sudden power failure. The small sposmatic harmonic tremors with a frequency of 2.4 Hz begun on 17:20, May 10 after 1 min passing of S waves and on 17:41 after 5 min passing the surface waves of the Iran earthquake of M7.2 (epicentral distance; ca 6,000 km). This offers probably first example of remotely triggered volcanic tremors by dynamic strains from a distant large earthquake. After a lapse of about 2 hours, the tremors re-appeared and evolved rapidly from the intermittent appearances with a single peak frequency of 2.1 Hz to the continuous ones with multiple peak frequencies between 0.7 and 2.9 Hz and with an increasing in amplitudes with a time lapse. At the final stage of precursory activity, the apparent seismic (or tremor) quiescence was recognized in the short intervals of 7:54-7:58, May 11 and then impulsive long-period signals were observed at 08:00:05. At this time, phreatic eruptions and the associated wet debris avalanche were eye-witnessed at Sumikawa spa. Long-period waves with a period of 10 sec were interpreted by the single force of 10,000 N excited by the reaction of steam ejection with horizontal column. Time-variable properties of precursory tremors and subsequent steam explosions suggest that a prevailing mechanism is pressure increases within a volume of groundwater at shallow depths.

JSV47/W/12-B5 Poster 1400-10

NON-DOUBLE COUPLE MECHANISMS IN THE SEISMICITY PRECEDING 1991-1993 ETNA VOLCANO ERUPTION

Angela SARAO, Giuliano F. Panza (both at Dipartimento di Scienze della Terra, Universita` di Trieste and The Abdus Salam International Centre for Theoretical Physics, Trieste, Italy. E-mail: angela@geosun0.univ.trieste.it), Eugenio Privitera and Ornella Cocina (both at the Istituto Internazionale di Vulcanologia, CNR, Catania, Italy)

The temporal evolution of the complete moment tensor was investigated for 28 earthquakes occurred at Mt. Etna in the period August 1990- December 1991 just preceding the biggest eruption of the last three centuries. In the seismicity investigated we found the presence of non double couple mechanisms which increase before the outbreak of the Etna eruption. Such mechanisms can be explained as related to magma injection or withdraw process whereas, for some events, the complex interaction between tectonic stress and volcanic activities has to be considered. The aim of this work, is twofold: 1) to contribute to the knowledge of the dynamics of a volcano and 2) to single out systematic features of the seismicity that can be used as alert parameters for volcanic hazard assessment and for monitoring the onset of an eruption mainly in the case of the explosive ones.

JSV47/W/06-B5 Poster 1400-11

DETECTION AND CLASSIFICATION OF SEISMIC SIGNALS OF VOLCANIC ORIGIN AT MT. MERAPI, JAVA, INDONESIA

OHRNBERGER, M., Wassermann, J., and Scherbaum, F. (all at Institute of Geosciences, University of Potsdam, P.O.Box 601553, 14415 Potsdam, E-mail: [mao,jowa,fs]@geo.uni-potsdam.de)

As being one of the most dangerous active volcanoes due to its location in a densely populated area and its eruptive activity showing doming, dome collapse and pyroclastic flows, Mt. Merapi was chosen as one of the 15 decade volcanoes during the IDNDR. Inside the interdisciplinary joint German-Indonesian research project MERAPI (Mitigation, Evaluation, Risk Assessment, and Prediction Improvement) the seismological investigations are considered as a baseline experiment supplying activity parameters for other experiments.
A continuously operating 12-station, three-component seismic network was installed in July 1997. The station-setup was realized in a combined array-network geometry, each array equipped with one broadband instrument (STS-2) and three short-period seismometers (MARK-L43D) in order to maximize the information about the observed wavefield with a limited number of stations. The enormous amount of data requires new automatic detection and classification algorithms to enable parametrization of the seismic activity with high confidence level.
In this study a feature vector for the detection task is obtained by using the waveform information at the three sub-arrays. In detail we use the maximum beampower and a coherence measure in each subarray per time step for all three components individually. Together with an averaged polarization information this analysis is performed in several frequency bands. After detection, feature vectors are used for training different classes of seismic events performing a cluster analysis in the feature vector space. This analysis is applied to the data recorded during the volcanic eruption cycle in July 1998 and compared to the results given by the Volcanological Survey of Indonesia.

LONG TERM SEISMICITY AND SOURCE CHANGES DURING DIFFERENT ACTIVITY STAGES OF MT. MERAPI (INDONESIA) USING A TWO SCALE SEISMIC ARRAY

J. WASSERMANN (Institute of Geosciences, University of Potsdam, P.O.Box 601553, 14415 Potsdam, Germany, email: jowa@geo.uni-potsdam.de), Budi E.N (Gadjah Mada University, Sekip Utara, Yogyakarta 55281, Indonesia), M. Ohrnberger (same as first author, email: mao@geo.uni-potsdam.de), J. Gossler (GeoForschungsZentrum Potsdam, P.O.Box 600751, 14407 Potsdam, Germany, email: gossler@gfz-potsdam.de)

Research on seismic signals at active volcanoes made two major developments during the last decades. Array techniques are widely used and the deployment of broadband seismometers are supposed to give new insight into source mechanisms of volcano induced seismic signals. Most realizations of these ideas suffer from the short time span of instrument deployments as well as the small aperture of the arrays. To circumvent these drawbacks and to monitor volcanic activity we have deployed a permanent network of both broadband and short-period seismometers at the IDNDR decade volcano Mt. Merapi (Indonesia) in 1997. Located on Central Java (Indonesia) Mt. Merapi is known for his large number of pyroclastic flows according to historic records. This kind of activity is caused mainly by gravitational collapse of subsequent lava domes. The network is arranged in three sub-arrays consisting of four seismometers each. After more than one year of dormancy Mt. Merapi awaked end of June 1998. This enables us to analyze all stages of dome growing, collapse and new inflation of magma using seismic array and network methods. The aim of this talk is to describe the recorded wavefield which finally ends up in source locations for the different kinds of recorded signals. We present a new technique to locate the non-impulsive volcano-induced seismic signals within the 3D structure of the volcano, following the shortest path method and using extensively the coherency of different phases at different array stations. Finally, we also present the result that the different types of signals are linked to different phases of the eruptive cycle.

PRELIMINARY RESULTS FROM THE 1998-99 DOUBLE SEISMIC ANTENNA EXPERIMENT AT DECEPTION VOLCANO, SOUTH SHETLAND ISLANDS (ANTARCTICA)

J. ALMENDROS (1), E. Carmona (1), G. Saccorotti (2), J.A. Peña (1) E. Del Pezzo (2,3), J. M. Ibáñez (1,4) and G Alguacil (1,4). (1) Instituto Andaluz de Geofisica, Universidad de Granada, Campus Universitario de Cartuja s/n, 18071 Granada, Spain. (2) Universita' degli Studi di Salerno, Dipartimento di Fisica, Via S.Allende, 84081 Baronissi, Salerno, Italy (3) Osservatorio Vesuviano - Via Manzoni 249, 80123 Napoli, Italy (4) Departamento de Física Teórica y del Cosmos. Facultad de Ciencias. Universidad de Granada. 18071 Granada, Spain

During the 1998-1999 austral summer, two dense small-aperture seismic arrays were deployed at Deception volcano, South Shetland Islands, Antarctica. These seismic antennas were deployed on the area in which the last eruption of 1970 took place. Aim of the deployment was a detailed investigation of the wave-field and source properties of the seismic signals associated to the current activity of this part of the volcano. A secondary goal consisted in the observation of the local and regional seismicity associated to the complex dynamics of the Drake-South Shetland subduction zone. Three main types of signals have been identified at both the arrays. The first type consists of short-period pulses probably related to the ice-block fall associated to the ice-melting processes. The second kind consists of short-duration, monochromatic signals with characteristic frequencies spanning the 1-3 Hz frequency interval. Propagation azimuths and slownesses of these signals are consistent with the action of extremely shallow hydrothermal sources located along or in close proximity of the array site fracture system. The last type consists of intermediate-depth tectonic earthquakes, occurring at the Drake-South Shetland subduction zone. Application of the spatial correlation method of Aki (1957, 1965) to background noise recordings from both the arrays has allowed to infer the dispersion properties of Rayleigh waves in the 0.5-8 Hz frequency band. We obtained a good fit between the experimental data and the model, suggesting that the noise wave-field is dominated by surface waves. We found extremely low values of the phase velocities, which indicates a propagation medium characterized by a thick surficial low-velocity layer, which is attributed to the unconsolidated pyroclastic deposits produced during the more recent activity. The three components of ground motion for the background noise are dominated by a broad spectral peak extending below 1 Hz, which remains sustained over time with varying amplitude. Due to the spatial and temporal persistence of this peak, we attribute the energy radiation in that particular band to the oceanic microseismic noise.

PRELIMINARY ANALYSIS OF HIGH-FREQUENCY EARTHQUAKES AT TIMANFAYA VOLCANO (LANZAROTE ISLAND, SPAIN)

J.M. IBÁÑEZ (1,2), E. Del Pezzo (3), G.Alguacil (1,2), R. Ortiz (4) and B. Chouet (5). (1) Instituto Andaluz de Geofisica, Universidad de Granada, Campus Universitario de Cartuja s/n, 18071 Granada, Spain.(2) Departamento de Física Teórica y del Cosmos. Facultad de Ciencias. Universidad de Granada. 18071 Granada. Spain (3) Osservatorio Vesuviano - Via Manzoni 249, 80123 Napoli, Italy (4) Departamento de Volcanología. Museo Nacional de Ciencias Naturales. CSIC. C/ J. Gutiérrez Abascal, 2, 28006 Madrid, Spain (5) U. S. Geological Survey. 345 Middlefield Road, MS977, Menlo park, CA 94025. USA

In this work we present the preliminary analysis of thousands of earthquakes recorded in a period of ten years in the volcanic field of Timanfaya (Lanzarote Island, Spain). These earthquakes were recorded in a short-period vertical-component seismometer. The very-local seismicity is characterised by:

- A small magnitude measured using magnitude-duration scales.
- The frequency contain is peaked at frequencies around 10-15 Hz.
- A non-impulsive first onset is observed.
- We could not identify clear S-waves arrivals.
- At some times the seismicity is overlapped on a high frequency tremor with similar spectral characteristics to the aforementioned.
- Although the seismicity seems to appear in isolated events, at some times seismic swarms take place.

The high frequency contain of the seismicity, together with the low magnitude, do not permit to record events far from the source area. The source area is located in a thermal anomaly field with a strong vertical and horizontal temperature gradient. In a few tens of meters of depth the temperature ranges between around 100 degrees of the surface to close to 600º. In order to distinguish the possible different families of earthquakes-sources we compared a select set of events by using cross-correlation techniques in the time domain. Probably the observed small differences are associated with different source positions (depth and distance to the receiver) more than with different focal mechanisms. Therefore, the small differences observed in the time and spectral domain could be associated with path effects.
There are possible mechanisms to explain this seismicty: such as rocks that have been weakened by this gradient of temperature or the possible hidrothermal activity that allows preferential seismic failure. Similar activity has been observed in other volcanoes such as those of Hawaii, White Island (New Zealand) or Vulcano (Italy).

SEISMIC UNREST AT GUAGUA PICHINCHA VOLCANO, ECUADOR: ANALYSIS OF A POSSIBLE INTRUSIVE PROCESS.

Jean-Philippe METAXIAN (IRD, Whymper 442 y Coruna, Apartado 17-12-857, Quito, Ecuador, Email: jpmetaxi@uio.satnet.net); Mario Ruiz and Minard Hall (both at Instituto Geofisico, EPN, casilla 1701-2759, Quito, Ecuador, Email: geofisico@accessinter.net).

Guagua Pichincha Volcano (4780m), situated 12 km west of Quito, has been monitored by IGEPN since 1981. Since 1990, the volcanic activity has been characterized by occasional phreatic explosions (< 10/year) occurring in the rainy months. In September 1998, following a 3 month drought, the phreatic activity increased drastically, 24 explosions being registered. On September 28, a phreatic explosion was followed by a swarm of about 50 LP multiplets characterized by an emergent onset, 35 sec durations and a dominant frequency of 1.5 Hz. After 12 hours this series of events was interrupted by a new phreatic explosion which was immediately followed by a swarm of about 900 bimodal events which lasted 17 hours. These events are characterized by an impulsive onset, 30 sec durations and a spectrum composed of two dominant peaks, one at 5-6 Hz corresponding to the first part of the signal and one at 1.5-2 Hz. The spectral analysis shows a slow decrease of the frequency with time. In October, two similar seismic episodes of less intensity were observed. The shallow depth of both LP and bimodal event swarms decreased from September to November. The seismic activity was registered by a network of 10 seismographs equipped with short period and one long period seismometers located around the caldera from 0.8 to 3 km away the dome. These episodes are interpreted to be due to minor magma injection or pressurization in the conduit at shallow depth 2-4 km.

APPLICATIONS OF AUTOREGRESSIVE AND WAVELET ANALYSIS TO THE DECONVOLUTION OF VOLCANIC LP EVENTS AND HARMONIC TREMOR

LESAGE, Philippe (LGIT and CRV, Université de Savoie, 73376 Le Bourget-du-Lac, France, email: lesage@univ-savoie.fr) Glangeaud, François and Mars, Jérôme (LIS, INPG, Grenoble, France)

The long-period events (LPE) and harmonic tremor are thought to result from the excitation of a resonator - a fluid-filled cavity - by a disturbance related to the volcanic activity. The recorded signals can be thus considered as the result of the convolution of an excitation function by the impulse response of a resonator and by the propagation function, plus noise. They are characterised by one or a few dominant spectral peaks which generally come from the oscillation modes of the resonator.
We present here some applications of the autoregressive (AR) model and of the wavelet transform to the analysis of this king of signal. (1) The AR model gives precise estimations of the frequency and attenuation factor of the resonance modes and allows to calculate the equivalent AR filters. (2) The variation with time of the harmonic components amplitudes is obtained by wavelet analysis. (3) Filtering signal by the corresponding inverse MA filters, which use the information given by the equivalent AR filters at step 1, results in the elimination of the main harmonic components and/or of particular spectral component. The residual contains the excitation function and eventually low amplitude phases that were not easily visible in the original record. Several examples are shown where the resulting excitation functions are either of short duration (LPE) or continuous (tremor).

A STUDY OF TREMOR AND LP EVENTS AT ARENAL VOLCANO, COSTA RICA. FIRST RESULTS OF A SEISMIC EXPERIMENT USING SMALL APERTURE AND RADIAL ARRAYS

LESAGE, Philippe (LGIT and CRV, Université de Savoie, 73376 Le Bourget-du-Lac, France, email: lesage@univ-savoie.fr) Mora Mauricio (Universidad de Costa Rica, San José, Costa Rica) Dorel Jacques (OPGC and CRV, Clermont-Ferrand, France); Alvarado, Guillermo (ICE, San José, Costa Rica); Métaxian, Jean-Philippe (IRD, Quito, Ecuador)

Arenal volcano has permanent strombolian activity and emits almost continuous lava flows. Its seismic activity includes LP events either associated or not to explosions, but is mainly characterised by several hours of volcanic tremor per day. In the framework of a co-operative project between French and Costarrican institutions, a seismographic experiment has been carried out in 1997 with the aim of studying wave propagation in Arenal structure and improving the knowledge of its seismic sources. Ten small aperture or linear arrays have been set up, occupying 70 sites with seismometers. A 13 stations L-shaped array and 5 tripartite 60 m wide arrays with vertical 1 Hz seismometers were deployed around the volcano in order to test a method of tremor source location. Two semi-circular arrays with 3 components seismometers were set up with the object to obtain information on the seismic structure and wave type by using the spatial correlation method. Seismic signals were also recorded along two radial profiles, respectively of 16 stations, 3 km long to the west and of 9 stations, 1.8 km long to the east, to study the variations with distance of wave amplitude and polarisation. The data set was completed by a continuous recording broadband station, an acoustic sensor and observations from the digital permanent seismic network of OSIVAM-ICE. Among the preliminary results presented here, a striking observation is strong site effects in several stations of both radial profiles. This emphasises that great caution must be used when interpreting spectral, amplitude and polarisation data obtained in isolated stations.

PRESSURE COOKERS AS VOLCANO ANALOGUES

Jonathan M. LEES and Edward W. Bolton (both at Department of Geology and Geophysics, Yale University, New Haven, CT, 06511)

We present a quantitative analysis of the oscillations of a household pressure cooker and relate the model to physical parameters in exploding volcanos in Kamchatka, Russia, and Sangay, Ecuador. Degassing of volcanos with viscous plugs produce several levels of periodicity, as does a pressure cooker held in a state of unstable equilibrium. The pressure cooker consists of a sequence of conduits where escaping, high temperature gases are inhibited by a weight that closes, or chokes off, the flow. The balance between the constraining weight and the internal pressure of the main chamber can be shown to produce a variety of oscillatory solutions, some of which exhibit chaotic behavior. We model the pressure cooker behavior by developing a system of coupled differential equations the relate the equation of motion for the constraining weight, pressure in the conduit, temperature and pressure in the boiling chamber, friction and ram effect, and production of gases at the source.
Observations at several exploding volcanos show a quasi-periodic explosion cycle that includes, on occasion, a higher frequency (1 Hz) tremor, called chugging. Chugging is a world wide phenomena and has been observed at Karymsky Volcano, Kamchatka, Sangay Volcano, Ecuador, Langila, Papua-New Guinea, and Semeru, Indonesia. These processes appear to be analogous to physical processes observed in the kitchen pressure cooker.

VARIATIONS IN SOURCE TYPE OF NON-DOUBLE-COUPLE EARTHQUAKES IN VOLCANIC AREAS

G.R. FOULGER (Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, Email: g.r.foulger@durham.ac.uk) and B.R. Julian (U. S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025, U.S.A., Email: julian@usgs.gov)

Volcanic and volcano-geothermal areas typically generate high levels of small magnitude earthquake activity, sometimes as continuous background activity and sometimes as transient swarms. Industrial exploitation of geothermal resources can also induce earthquakes. Such earthquakes are probably caused by hydraulic or magmatic fracturing or by the rapid transport of fluids. Although the appearance of the seismograms of such earthquakes are generally indistinguishable from those of common "tectonic" earthquakes, they often have non-double-couple focal mechanisms. Whereas such mechanisms were widely disbelieved a decade ago, now several case histories of detailed studies of non-double-couple earthquakes from volcanic and geothermal areas have accumulated. It is clear that there are systematic variations in their source types, as well as common features. Earthquakes from the Hengill-Grensdalur volcano-geothermal area, Iceland, have explosive mechanisms with CLVD components of varying sign and strength. In contrast, industrially-induced earthquakes from The Geysers geothermal area, California, along with other areas, have isotropic components of both signs, which are systematically correlated with the CLVD component. These observed trends have the potential to cast light on the source processes of these exotic types of earthquakes, and thus on fluid motion in magmatic and hydrothermal systems.

A PROBABILISTIC APPROACH FOR THE ESTIMATE OF THE SLOWNESS VECTOR FROM SEISMIC ARRAY DATA

Dr Gilberto SACCOROTTI (Osservatorio Vesuviano - Centro di Sorveglianza, Via Manzoni 249, Naploi, Itlay. Email: giberto@osve.unina.it) and E. Del Pezzo

Array analyses in volcano seismology is the main tool for detecting and quantifying the complex wave-field associated to the volcanic activity, mainly the volcanic tremor and the long period events. The methods based on the analysis of the signal in the frequency domain, or spectral methods (MUSIC algorithm), take the main vantage of both resolving closely-spaced sources and computer speed, but severely fail in the analysis of short duration signals. Conversely, the time domain methods, based on the cross-correlation estimate of signal pairs, can be applied even for short pulses.Both for time and frequency domain techniques, an exhaustive view of the errors associated to the slowness vector estimate does not exist. The estimate of the error is important in the inversion of the slowness vector for source location. In the present work we develop a method based on a probabilistic formalism, which allows for a complete definition of the uncertainties in the estimate of frequency-slowness spectrum based on the measure of the zero-lag cross-correlation. The method is based on the estimation of the theoretical frequency-slowness power spectrum, which can be expressed as the convolution of the true signal with the array response pattern. The application of the Bayes theorem allows for the final estimate of the data probability density function. The method is tested with synthetics using waveforms resembling the most common volcanic earthquakes, and applied to real data as an example.

PROSPECTS OF THE QUANTITATIVE TIME FORECAST OF VOLCANIC ERUPTIONS

Alexander I. MALYSHEV (Institute of Geology and Geochemistry, Urals Branch of RAS, Pochtovy per 7, Ekaterinburg, SU-620151, Russia, email: root@igg.e-burg.su)

It is known that many strong eruptions are anticipated by the periods of long-duration and steady increase of volcanic activity. Revealing and study of fore-paroxysmal activizations represent large interest for the forecast of strong eruptions. During the study of Bezymjanny volcano eruptions in 1980-1987 the fact of hyperbolic activization of deformational-extrusive process before explosive-effusive eruptions was established. Further studying of revealed laws and their comparison with empirical dependences of development of various natural processes have allowed to conclude that there is the wide class of self-developing natural processes, dynamics of which is described by the nonlinear differential equation of the second order. The attempts of using these laws for the forecast of eruptions were quite successful, however the accuracy of time forecast of eruption did not exceed a semiquantitative level. Technique, allowing confidently to reveal laws of development of natural processes, is at the moment developed. For a class of eruptions, with steady fore-culmination prepa-ration, this technique allows to increase accuracy of paroxysm time forecast up to a quantitative level.

DECEPTION ISLAND VOLCANO (ANTARCTICA): SEISMO VOLCANIC SOURCE ANALYSIS

J.M. IBÁÑEZ (1,2), J, Almendros (1), E, Del Pezzo (3), G. Alguacil (1,2), M. La Rocca (4), A. García (5) and R. Ortiz (5).(1) Instituto Andaluz de Geofísica. Universidad de Granada. Campus de Cartuja s/n. 18071 Granada. Spain. (2) Departamento de Física Teórica y del Cosmos. Facultad de Ciencias. Universidad de Granada. 18071 Granada, Spain. (3) Osservatorio Vesuviano. Via A. During the Antarctic summers of 1994-95, 1995-96 and 1996-97 we monitorised the seismic activity of Deception Island volcano (South Shetland Island, Antarctica) by a short-period small-aperture dense seismic array. We recorded thousands of seismic events and analysed hundreds of them in base of their good signal to noise ratio. The main part of the set of seismic events is composed by pure seismo-volcanic signals such, as volcanic tremor and long period events. Other recorded signals presented a shape and spectral contain that permitted us named them as hybrid events. Only some tens of tectonic earthquakes have been recorded and were classified in three groups: volcano-tectonic earthquakes (located inside of the island), regional seismicity and intermediate-focus earthquakes (focal depth between 50 and 120 km). To locate the position of the seismo-volcanic source we used the Zero-Lag Cross-Correlation technique. The back-azimuth between source and array and the apparent slowness of the coherent arrivals were obtained. To determine the epicentral distance of the volcanic signals we have introduced, to the above technique, the approximation of a circular incoming wave front. Using polarisation analysis and energy determination we completed these analyses. From them we can establish the follow observations: All the seismo-volcanic events are composed by two types of seismic waves, P waves and surface waves (mainly Rayleigh waves). No S-waves have been observed in these volcanic events. P-waves are concentrated at high frequencies and surface waves are located at the low-frequency predominant peaks. Volcanic tremor, long period events and hybrid share the same source area and the same array parameters at all frequency bands. It is possible to model the seismic source, at low frequencies, using the Fluid Driven Crack model, under the assumption of water, as fluid, with gas bubbles (water vapour). From these observations, the interaction of molten water (originated in the extended glacier areas of the island) with hot materials (we have evidences of magma in the vicinity of the source area) could be the most probable source model of the observed volcano-seismicity in Deception Island.

LOCAL SEISMICITY AND ABSENCE OF OBSERVABLE VOLCANIC TREMOR AT TEIDE VOLCANO (CANARY ISLANDS, SPAIN)

J, ALMENDROS (1), J.M. Ibáñez (1,2), G. Alguacil (1,2), J. Morales (1,2), E, Del Pezzo (3), M. La Rocca (4), R. Ortiz (5), V. Araña (5) and M.J. Blanco (6). (1)Instituto Andaluz de Geofísica. Universidad de Granada. Campus de Cartuja s/n. 18071 Granada. Spain. (2)Departamento de Física Teórica y del Cosmos. Facultad de Ciencias. Universidad de Granada. 18071 Granada, Spain. (3)Osservatorio Vesuviano. Via A. Manzoni, 249. 80123 Napoli, Italy. (4)Dipartimento di Fisica. Universita di Salerno. Via Salvador Allende. 84081 Baronissi, Salerno, Italy. (6)Delegación Regional del Instituto Geográfico Nacional en Canarias. 38001 Santa Cruz de Tenerife, Spain.

Data analysed in the present work correspond to a 40 days field experiment carried out in Teide volcano (Canary Islands, Spain) with two short-period small-aperture dense seismic antennas in 1994. The objective of this experiment was to detect, analyse and locate the local seismicity. We analysed also the background seismic noise to investigate the possible presence of pure volcanic signals, especially volcanic tremor.
From a set of 76 events, we selected 21 of them in base of their good signal to noise ratio and the possibility to locate their seismic source using the seismic antennas. A visual classification in base of the S-P time and shape has permitted us to establish three groups: local seismicity (S-P time between 3 and 5 seconds), volcano-tectonic earthquakes (S-P time smaller than 3 seconds), and non-natural earthquakes (mainly artificial explosions). These earthquakes have been located by applying the Zero Lag Cross-Correlation technique and the inverse ray-tracing procedure. Those earthquakes that were recorded simultaneously by both seismic antennas were also located by intersecting both back-azimuths.
The analysis of the seismicity has revealed that the amount of seismicity in Teide volcano is moderated. This seismicity could be distributed in three main areas: Inside of the Caldera edifice (below the Teide-Pico Viejo complex), in the border of the Caldera Edifice (possibly related with the 1704-05 eruption) and in the border of the island. At the present, this activity is the only indicator of the volcano dynamic.
The analysis of the back-ground seismic noise has revealed that, at frequencies lower than 2 Hz, the Oceanic Load signal is predominant over other signals, even over local earthquakes with magnitude 2.0. Due to that, although if in the Teide area were present a week volcanic tremor, or other volcanic signals with predominant peaks below 2 Hz, these signals could be very difficult to observe.

THE AUSTRALIAN UPPER MANTLE - A CONTINENTAL SYNTHESIS

B.L.N. KENNETT, E. Debayle (Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia, email: Brian.Kennett@anu.edu.au); Y. Kaiho (Japan Marine Science and Technology Center, 2-15 Natsushima-cho, Yokosuka 237, Japan)

The combination of body wave and surface wave studies of the Australian continent using the abundant regional seismic sources places strong constraints on the nature of the lithosphere, the underlying asthenosphere and the mantle transition zone. The centre and west of Australia, with Proterozoic to Archaean surface exposure, is characterised by a thick lithosphere characterised by very fast shear wavespeeds extending to at least 200 km. Along the eastern seaboard there is a relatively thin lithosphere with a well developed low velocity zone for shear waves around 150 km deep. In the transitional region the structures are more complex with some high velocity material extending to at least 150 km below Phanerozoic surface rocks. The boundary of the thick lithosphere does not display any simple relation to the "Tasman line" which marks the eastern extent of Precambrian surface rocks. The asthenosphere displays significant seismic attenuation compared with the very low loss in the

cratonic lithosphere. Although the high seismic velocities in central Australia extend to 200 km, the pattern of azimuthal anisotropy derived from Rayleigh waves shows a significant change in pattern with depth a largely east-west pattern of fast wave speeds at 100 km depth is replaced at 150 km by a pattern with a marked trend nearly north-south, in concordance with the current direction of plate motion. This change occurs within the zone of high shear wavespeed and so it would appear that deformation must be occurring in the base of the lithosphere.

POLARIZATION ANISOTROPY IN THE AUSTRALIAN UPPER MANTLE FROM SIMULTANEOUS INVERSION OF RAYLEIGH AND LOVE WAVEFORMS

Y. HIYOSHI, E. Debayle, B.L.N. Kennett (All at Reserach School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia. Email: hiyoshi@rses.anu.edu.au)

Events from the earthquake belt along the northern continental margin of Australia have been recorded for a decade at several permanent broad-band stations in the continent. The surface wave portion of these seismograms provides a unique opportunity for upper mantle investigation exploiting almost pure continental epicenter-station paths beneath Australia. Simultaneous waveform inversion of Rayleigh and Love seismograms including several overtones allows the determination of the polarization anisotropy of the S waves as well as the SV wave speed and attenuation factor (Q) in the upper mantle beneath each epicenter-station path. This approach has been applied to the vertical and tangential components of seismograms recorded at two permanent stations (NWAO - IRIS and CAN - GEOSCOPE) in Australia for epicenters are distributed along the northern continental margin. We invert for the anisotropic parameter Xi, the SV wave speed and the quality factor (Q). Our results suggest that the upper mantle beneath western Australia has (1) a low velocity zone associated with strong attenuation lying between about 200 km and 400 km depth; and (2) polarization anisotropy reaching down to at least 300 km depth.

JSA48/E/02-B5 0920

MAPPING THE LITHOSPHERE-ASTHENOSPHERE BOUNDARY (LAB) THROUGH CHANGES IN SEISMIC ANISOTROPY

J. PLOMEROVA, V. Babuska, D. Kouba (Geophysical Institute, Czech Acad. Sci., 14131 Praha 4, Czech Republic, email: jpl@ig.cas.cz)

The alignment of olivine crystals is the dominant source of seismic anisotropy in the subcrustal lithosphere and asthenosphere. Different constituents of large-scale anisotropy related to the crust, mantle lithosphere and sub-lithospheric mantle can be traced in depth distributions of the radial and azimuthal anisotropy of surface waves. Thus Earth's boundaries, such as the M-discontinuity or LAB in the upper mantle, as physical boundaries, can be detected by distinct changes of seismic anisotropy. These changes map orientations of a large-scale fabric of different tectonic settings and geological age. The M-discontinuity can be understood as an intra-lithosphere boundary between anisotropic structures of crustal composition and a frozen-in olivine anisotropy in the mantle lithosphere. Similarly, the LAB can represent a change of this frozen-in anisotropy to the present-day anisotropy in the sub-lithospheric mantle related to the upper mantle flow. 3D velocity images of the upper mantle from body wave tomographies map the LAB as a top boundary of the low-velocity zone, considering isotropic wave propagation. Beneath the Precambrian shields and platforms, where a steeply oriented olivine fabric was deduced from surface-wave analyses, the velocity contrast related to the LAB can increase in particular directions. Due to long wave-lengths, the surface waves suffer from laterally integrated effects, but possess a good vertical resolution allowing us to extract gross features of the LAB. Depths of the LAB between 200 and 250 km for the Archean cratons and around 100 km on the average beneath the Phanerozoic regions, are estimated from the radial and azimutal anisotropy of surface waves.

DEPTH RESOLUTION OF UPPER MANTLE RESISTIVITY MODELS FROM ELECTRO-MAGNETIC RESPONSES ON CONTINENTS

Ulrich SCHMUCKER (geophysikalisches Institut, Herzberger Landstr. 180, D-37075 Gÿttingen)

The depth range from 100 to 400 km is the most unaccessible one for electromagnetic induction studies, involving natural source fields between 1 and 6 hours period. at these periods local magnetotelluric MT sounding curves have split at most sites into two distinct branches of maximum and minimum apparent resistivity, at least on continents, while global geomagnetic deep soundings GDS start at 400 km, which is the penetration depth of the fourth harmonic of daily variations. The resulting gap towards unsplit MT results could be closed with regional GDS, notably in jet regions, but this possibility has been rarely used so far.
It has been found that MT phases from 6 to 24 hours period reproduce most faithfully global GDS phases of daily variations (for the ra-maximum branch) and thus can be utilized tentatively to close the gap. How does this incomplete knowledge constrain resistivity models for the continental upper mantle, and will it be sufficient for detecting fine structures, which could be associated with Gutenberg's low velocity layer? This question will be addressed, also in conjunction with empirical GDS and MT data. From global GDS alone the upper mantle appears as featureless, moderately resistive region of 70 Wm, which is the expected value for the prevailing temperatures, and no need seems to exist for special effects lowering resistivity in Gutenberg's layer. How accurate would MT phases have to be, from 1 to 6 hours period, for a finer resolution?

JSA48/P/01-B5 1000

A MAP ON THE CONDUCTIVE ASTHENOSPHERE OF THE PANNONIAN BASIN AND LIMITATION IN ITS CONSTRUCTION

Antal Äd´m (Geodetic and Geophysical Research Institute of the Hungarian Academy of Sciences, H-9401 Sopron, POB 5, Hungary, email: adam@ggki.hu

In the early sixties it has been stated on the basis of deep magnetotelluric soundings that the conductive asthenosphere is upwelling to a depth of 60 km in the central part of the Pannonian Basin (Hungary) in close connection with the high heat flow of the area (~100 mW/m2) and it deepens towards the rim of the Basin and reaches in the platforms (e.g. EEP) 100-200 km. Beneath deep extensional basins (e.g. 7 km deep Bækæs graben) the asthenosphere can even reach depth of 40-50 km. It was certainly a plume in the Miocene synrift era having strong ultramafic intrusion in the crust.
It has been tried to construct a map about the depth of the conductive asthenosphere in the Pannonian Basin with correction of the EM distortions (static shift, 3D inhomogeneity Æ decomposition). The author points to the difficulty of the corrections and compares the map with the results obtained by other geophysical methods (first of all by deep seismics and tomography).

PETROLOGIC AND GEOPHYSICAL CHARACTERISTICS OF THE LITHOSPHERE-ASTHENOSPHERE BOUNDARY THROUGH EARTH'S EVOLUTION

Suzanne Y. O'REILLY, William L. Griffin, (GEMOC National Key Centre, Dept of Earth and Planetary Sciences, Macquarie University, NSW, 2109, Australia, Email: sue.oreilly@mq.edu.au, bill.griffin@mq.edu.au; WLG also at CSIRO EM, PO Box 136, N. Ryde, NSW 2113, Australia)

The lithosphere-asthenosphere boundary (LAB) is an interface that reflects the fundamental evolution of the Earth into major geochemical reservoirs driven by global thermal processes. The depth to the LAB varies significantly with the tectonothermal age of lithosphere domains and is a function of the geochemical nature of the lithospheric mantle column and its thermal state which determine its density and rheological response. The Earth's lithospheric mantle is non-convecting and does not mix easily: therefore it carries a geochemical imprint of major melting events and subsequent fluid fluxes (metasomatism). Lithospheric mantle has undergone significant (probably multiple) melting and is depleted in "basaltic" components such as Fe, Al, Ca and Ti. Asthenosphere by contrast, is "fertile" (rich in basaltic components) and geochemically more homogeneous than lithosphere because it is convecting. Mantle xenoliths and their disaggregated minerals (especially garnet and chromite) brought to the surface in basalts and kimberlites, can be used to construct sections of the spatial distribution of rock types with depth in the lithospheric mantle, to estimate empirical palaeogeotherms, and to locate the depth to the LAB. This geochemically determined LAB depth coincides with estimations of depth using geophysical datasets, especially seismic refraction and magnetotelluric. We have established that the mean geochemical composition of the subcontinental lithospheric mantle shows an episodic, secular and apparently irreversible change from Archean to Proterozoic to Phanerozoic. Density and seismic measurements and calculations for these mantle types show increasing density and a decrease in Vp and Vs with decreasing age. Geothermal gradients increase concomitantly and average depths to the LAB decrease from about 220 km to 180 km to 100 km respectively. Density and thermal differences in these distinctive mantle volumes determine the relative buoyancy of the specific lithospheric mantle column relative to asthenosphere. Thus the geochemical composition and thermal state of lithospheric mantle may control the location of the LAB through time and result in the different geophysical signatures.

JSA48/E/10-B5 1110

HOW THICK IS THE LITHOSPHERE IN THE CENTRAL FENNOSCANDIAN SHIELD? IMPLICATIONS FROM MANTLE XENOLITHS, THERMAL AND RHEOLOGICAL MODELS

Ilmo T. KUKKONEN, Petri Peltonen (both at Geological Survey of Finland, P.O. Box 96, FIN-02151 Espoo, Finland, e-mail: ilmo.kukkonen@gsf.fi)

Thermobarometric studies of kimberlite-hosted mantle xenoliths in eastern Finland, the central Fennoscandian Shield, suggest an exceptionally thick lithosphere in this area, at least 240 km. All recovered xenoliths are lithospheric in character, contain no primary volatile-bearing minerals, and carry no evidence of an asthenosphere. The thermobarometric data were used to calibrate a 2 dimensional thermal lithosphere model, and the xenoliths are in an agreement with a conductive geotherm corresponding to a surface heat flow density value of 36 mW/m2. A direct estimate from the thermobarometric data suggests a temperature gradient of 3.7 +- 0.6 K/km and heat flow density of 11 +- 4 mW/m2 in the mantle which is lower than usually considered for the continental mantle. Using the calibrated geotherm, a rheological model of the lithosphere was constructed, and it suggests that the mechanical thickness of the lithosphere is only 130-185 km, depending on the applied values of rheological parameters and creep strength of mantle rocks. The seismic lithosphere thickness is poorly known in this area, but the available data suggest values comparable to the rheological lithosphere thickness. The central part of the shield apparently has a thick root under the rheological lithosphere, and it is transported together with the lithospheric plate as a thermal boundary layer. Our results suggest possible absence or only a very weakly developed partially molten asthenospheric layer under this part of the shield, but do not exclude its existence at depths exceeding 240 km.

JSA48/E/08-B5 1130

MELT-PERIDOTITE INTERACTION AT THE LITHOSPHERE-PLUME BOUNDARY: IMPLICATION FOR THE MECHANISM OF LITHOSPHERIC THINNING

Yigang XU (Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, 510640 Wushan Guangzhou, P.R. China, email: gdjzh@public.guangzhou.gd.cn); Jean-Louis Bodinier (Geofluides-Bassin-Eau, UMRC5569, CNRS, Universite Montpellier 2, F-34095, Montpellier, France); Martin A. Menzies (Geology department, Royal Holloway University of London, Egham, Surrey RW20 OEX, UK)

Poikiloblastic harzburgite xenoliths from Boree, French Massif Central have been interpreted as the deepest spinel facies mantle segments samples by alkalis basalts. However, there exists considerable debate about their petrogenesis. The previous cumulative and isochemical recrystallization models are inadequate when the petrologic characteristics of these poikiloblastic samples are taken into account. On the basis of the newly acquired petrologic, geochemical data and trace element numerical modeling, it is believed that the Boree poikiloblastic peridotites were formed as a results of melt-percolation in a lherzolite precursor during lithospheric erosion by an upwelling plume. If our interpretation is correct, this study provides the evidence for the thermal erosion of the lithosphere accompanied by pervasive porous flow of the asthenospheric melts. This latter process assists the lithospheric erosion by modifying microstructure and modal composition of peridotite and then enhancing permeability of the MBL. Coupled with the thermal effect, this process is able to weaken the lithosphere allowing its mechanical removal by asthenosphere.

JSA48/E/07-B5 1150

THE THERMAL CHARACTERISTICS OF LAB DEDUCED FROM MAGSAT MODEL

Xiaoqing GAO (Lanzhou Institute of Plateau Atmospheric Physics, CAS, 730000 Lanzhou, P.R.China, email: xqgao@lzu.edu.cn); Giovanni P Gregori (Istituto di Fisica dell'Atmosfera, CNR, 00133 Rome, Italy, email: gregori@atmos.ifa.rm.cnr.it)

It is well known that electric currents exist in the Earth. The Earth's magnetic field is produced by the currents. These currents can produce heat because of the resistance of the material of the Earth(called Joule heat).This electric current can be derived from geomagnetic field data

or model. Till now, the best geomagnetic field del(MAGSAT) had been gotten by satellite global observation in 1979-1980. By this model, the global distribution of Joule Heat on ALB(Asthenosphere-Lithosphere Boundary) (direct proprotion to electric current square) had been calculated. It is found that the distribution of Joule Heat on ALB matches the global geothermal zones very well. And the strongest Joule's Heating is located under Tibet Plateau, the youngest and the highest plateau on the Earth. It seems that the geothermal heat mostly comes from ALB, it is controlled by Joule's Heating process.

JSA48/P/04-B5 1210

THE THERMAL CHARACTERISTICS OF THE LITHOSPHERE-ASTHENOSPHERE BOUNDARY

Leonid LEVIN (Centre GEON Regional Geophysical and Geoenvironmental Data, 119034, Chisty per. 4, Moscow, Russia, email: moscow@geon.msk.ru)

A determination of the position of the thermal boundary between the lithosphere and the asthenosphere is based n the data of heat flow used for calculation of depths of the isotherms 600 and 1200oC. This boundary is characterized by inversion of viscosity between the lithosphere and asthenosphere and varies in a wide depth's range from more than 300 km near shields of cratons to less than 5-10 km under rifts of mid-oceanic ridges. At the background of the epth's change, this boundary rises in the zones of the asthenosphere upwelling which are confined to different large tectonic elements of the oceans and continents. In some orogens, there are two boundaries with inversion of viscosity - the upper is above the asthenolenses i.e. intracrustal zones of partial melting and the lower coincides with the top of the asthenosphere proper. The upwelling zones migrated repeatedly in time and space and the reent lithosphere/asthenosphere boundary was formed only at the neotectnoic stage.

JSA48/E/13-B5 1230

HIGH RESOLUTION IMAGE OF THE LITHOSPHERE-ASTHENOSPHERE BOUNDARY IN CONTINENT OF CHINA AND ITS ADJACENT AREA

Zhu JIESHOU, Cao Jamin, Cao Xiaolin, Zhang Xuemei (Dept. of Geophysics, Chengdu University of Technology, Chengdu 610059, China, email: zhujs@cdit,edu.cn)

Recently, due to the setting and observing of the global observation system of geophysics and geodesy, it became possible to do seismic tomography in detail to view the three-dimensional structure of the deep interior of the Earth. The high resolution seismic surface wave tomographic image for the Lithosphere-Asthenosphere Boundary (LAB) will provide the lateral heterogeneity of the upper mantle, and deep background of craton, mountain ranges, rifts and basins of the continent.
We have collected about more than 4000 long period digital seismic records from 21 stations of GSN and CDSN, which located at China, Japan, Thailand, India, Russia, Indonesia. The high resolution tomographic inversion had been conducted by processing these surface wave data. The three-dimensional velocity image from earthb 60o 0N in latitude and from 60o 0E to 160o0E in longitude. The lateral variation of LAB mainly reflects the differences of the combinative continental blocks in China and its adjacent area. The thickened lithosphere (140-250 km) located at Tarim, Yangtze, Ordos, Indo-China block and Indian plate. The thinning lithosphere (70o=-100 km) mainly appears in rifting zones or graben such as Songliao and North China subsiding zone, and southeastern coastal folding belt, in the orogenic belts such as North-South tectonic belt in central China and Qinling-Dabieshan mountain range, and in the marginal sea (South China Sea, East China Sea, Japan sea, etc). The lower boundary of asthenosphere is clearly shown from 200 to 300 km depth. There obviously exist low velocity asthenosphereo which is related with upwelling plume at shallow part of the mantle in west Pacific margin. The hot plumes possibly caused by upwelling heat flow that originated by plate's friction in the subduction zone.

JSA48/W/03-B5 1400

HEAT TRANSPORT IN STAGNANT LID CONVECTION WITH TEMPERATURE AND PRESSURE DEPENDENT NEWTONIAN OR NON-NEWTONIAN RHEOLOGY

Caroline DUMOULIN, M.P. Doin, L. Fleitout (Ecole Normale Superieure, France,
Email: dumoulin@jadeite.ens.fr)

A numerical model of two-dimensional Rayleigh-Benard convection is used to study the relationship between the surface heat flow (or Nusselt number) and the viscosity at the base of the lithosphere. Newtonian or non-Newtonian, temperature and pressure-dependent rheologies are considered. In the high Rayleigh number time-dependent regime, calculations yield : Nu proportional to Ra**0.33/beff, where beff is the effective dependence of viscosity with temperature at the base of the upper thermal boundary layer and Ra is the Rayleigh number calculated with the effective viscosity at the base of the upper thermal boundary layer. The heat flow is the same for Newtonian and non-Newtonian rheologie`s if the activation energy in the non-Newtonian case is twice the activation energy in the Newtonian case. In this chaotic regime the heat transfer appears to be controlled by secondary instabilities developing in thermal boundary layers. These thermals are advected along the large scale flow. The above relationship is not valid at low heat flow where a stationary regime prevails and for simulations forced into steady state. In these cases, the Nusselt number follows a trend Nu proportional to Ra**0.2/beff for a Newtonian rheology, as predicted by the boundary layer theory. We argue that the equilibrium lithospheric thickness beneath old oceans or continents is controlled by the development of thermals detaching from the thermal boundary layers. Assuming this, we can estimate the viscosity at the base of the stable oceanic lithosphere. If the contribution of secondary convection to the surface heat flux amounts to 40 to 50 mW.m**-2, the asthenospheric viscosity is predicted to be between 2.10**18 and 3.10**19 Pa.s.

MODELS OF SOUTH-WEST PART OF BAIKAL RIFT DEFORMATION BY THE EXPERIMENTAL DATA

Vladimir Timofeev, Dmitry Ardukov (Institute of Geophysics UIGGM SB RAS, Koptug pr. 3, 630090, Novosibirsk, Russia, email: sari@uiggm.nsc.ru); Bernard DUCARME (Observatoire Royal de Belgique, Avenue Circulaire 3, 1180 Bruxelles, Belgium, email: B.Ducarme@oma.be); Arnautov G.P., Kalish E.N., Stus Y.F. (Institute of Automatic and Electrometry SB RAS, Koptug pr., 1, Novosibirsk, Russia); A.Y. Ribushkin, V.M. Semibalamut (Siberian EMLP GS SB RAS, Lavrientiv pr.,13/3, 630090, Novosibirsk, Russia)

Results of 1990-1995 strain measurements in the underground gallery of Talaya station (51.68 N, 103.65 E, Baikal rift) and results of annual measurements of gravity are discussed. Determination of main axis strain were got. Maximum variation were got for shear strain, annual value 3W10-6, maximum changes was got for strong earthquake M=6.5 period. Deviatoric tectonic stress was near 0.6 MPa. Stability of gravity field by laser gravimeter GABL-M measurements was near the error level 0.5-1.0 microGal. From this determination level of vertical movement was got near 1mm per year. The Budiansky-Amazigo (fault slip and lithospheric creep) model and Elsasser two-layer (lithosphere-asthenosphere) model were examined by using our experimental results. We got the value of asthenospheric viscosity (1.2W 1020 PaWs) from the calculation with experimental strain results and Elsasser model. The deviatoric tectonic stress for Siberian platform litosphera (18 MPa) was got from the calculation by using the GPS data for Irkutsk station (3cm/ y, 1010N), the value of the asthenospheric viscosity and Elsasser model.

TWO STAGE LITHOSPHERE DELAMINATION: A GEODYNAMIC MODEL FOR MESO-CENOZOIC VOLCANISM OF THE NORTH-EASTERN REGION OF NORTH CHINA CRATON AND RELATED DEPTH CHANGE OF LITHOSPHERE-ASTHENOSPHERE BOUNDARY

Yang WANG (Lab. for Geothermics, Institute of Geology, Chinese Academy of Sciences, P.O.Box 9825, Beijing 100029, China, email: thalassa@263.net)

From Triassic to Neogene, five volcanic activities had occurred in the north-eastern region of North China Craton. The first is Triassic small scale basaltic volcanism, which Nd,Sr,Pb isotopes are characterized by the existence of subducted oceanic crust and EM II type mantle source; the second is Jurassic tranchyandesitic volcanism, which is dominated by EM I type source; the third is Early Cretaceous rhyolitic volcanism, which is also characterized by EM I source; the fourth and fifth volcanism occurred in Palaeogene and Neogene respectively, which sources represent a mixture of primary mantle(PM) and depleted mantle(DM) components. Related to these volcanism and extension in Cenozoic, the depth of lithosphere-asthenosphere boundary(LAB) ascended from about 150 km in Late Palaeozoic to about 50 km in present. Based on the mineralogical and petrological studies on these volcanic rocks and the mantle fragments in them, and numerical simulation of small scale mantle convection, we proposed a geodynamic model, two stage lithosphere delamination, to explain the origin of volcanism and related geochemical characteristics. The first stage delamination started in Triassic, and the basalt came from the lower part of lithosphere mantle, in where ancient subducted oceanic lithosphere stored. The delamination induced the forced convection of asthenosphere, and Jurassic volcanism was originated by the break off of the upper boundary layer of convection cell. Early Cretaceous volcanism was related to the melting of underplating material which ascended from lower mantle. The LAB under the north-eastern region of North China Craton ascended from ~150 km to ~80 km after the first stage delamination. The second delamination occurred in Cenozoic. It induced the melting of subcontinental lithosphere of North China Craton, which has PM and DM characteristics; and caused the depth of LAB under this region ascending from ~80 km to 50-60 km. Nowadays all of isotope geochemistry, mineralogy and petrology evidences support our idea that, two stage lithosphere delamination induced Meso-Cenozoic volcanism in the north-eastern region of North China Craton, and resulted in the ascending of LAB beneath this region.

LITHOSPHERIC STRUCTURE OF DHARWAR CRATON USING MAGNETOTELLURIC STUDIES

S.G. Gokarn, C.K. RAO, Gautam Gupta (Indian Institute of Geomagnetism Colaba, Mumbai, email: kamesh@iig.iigm.res.in)

The Dharwar craton is a part of the South Indian craton, bounded on the north by the Kaladgi and Bhima basins, on the east by the Eastern Ghat mobile belt and on the south by the granulitic terrains of Kerala and Tamilnadu. On the basis of the nature of the metamorphosis of the schist belts, Dharwar craton is divided into the eastern and western Dharwar groups, the line of divide coinciding with the Chitradurga fault. The eastern Dharwar rocks show a low pressure metamorphism with younger granitic intrusives, where as in the western Dharwar region, the intermediate metamorphic grades are observed.
Magnetotelluric studies were conducted over a 350 km long E-W profile with an interstation spacing of 5-10 km. The data shows mostly a one dimensional structure, except some two dimensional effects near Hebsur which is located on the Chitradurga fault. The crustal structure on the east of the Chitradurga fault is "normal as observed in other stable continental regions, with 15-18 km thick crust overlying a mid-crustal conductor. The lower crust and the upper mantle have a resistivity of 1000 ohm-m. A conductive layer is delineated at a depths of about 180 km presumably due to liquid phase, normally associated with the lithosphere-asthenosphere boundary. On the west of Chitradurga fault, the crustal structure is uncharacteristic of the Precambrian cratons. The crustal thickness is higher (22-25 km) and the mid-crustal conductor which is normally observed in the cratonic regions is absent here. The lowe crust and upper mantle have a resistivity of 1000 ohm-m. The Chitradurga fault zone is not associated with any appreciable conductivity changes and is thus delineated as a deep vertical divide between the regions with different crustal thicknesses and crustal configurations near Hebsur extending in depth up to the bottom of the upper crust.

JSA48/E/03-B5 1515

DEGENERATION OF SUBLITHOSPHERIC MANTLE BENEATH THE CRATONIC AREAS OF THE INDIAN PENINSULAR SHIELD

O.P. PANDEY, P.K. Agrawal (National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India, email: postmast@csngri.rec.nic.in)

Recently, there has been a growing curiosity to understand the deformation of the deep continental roots beneath the Archean- early Proterozoic terrains of the world. These studies suggested the possibility of shearing of sublithospheric mantle caused by plate motion beneath ancient cratonic roots. In the present work, we study the thermal structure beneath the cratonic regions of the Indian shield, which include Aravalli and Singhbhum cratons in the north, Bastar craton in the central, and Dharwar craton and granulite terrain in the southern peninsula. The study reveals a large lithospheric thickness variation from 65 km in the Singhbhum craton to 148 km in the Archean Dharwars. An estimate of 104 km average depth to the top of asthenosphere beneath these cratons conforms well with the findings from other studies and is found to be less than half the 200-400 km thick lithosphere in other stable areas of the earth. Similarly, the average reduced flow of about 35 mW/m2 and Moho temperature of 555 C (range 400-730 C) in these areas are found much higher than their counterparts in the world. Thus, our study indicates a large scale deformation of the sublithospheric mantle beneath the Indian shield since Meso-Proterozoic times and questions the hitherto believed tectonic stability of the cratons.

MAGNETOTELLURICS OF UPPER LITOSPHERE ON THE SOUTH RUSSIAN FAR EAST

Alexander VOITENOK (Institute of Tectonics and Geophysics, RUSSIA, Email: u153vaa@rtzi.ru)

During a long period of time in the south of Far East of Russia were carried out magnetotelluric sounding. The works were carried out by the various executors using the equipment with various sensitivity and frequency characteristics. The points of researches are located on a rarefied network of extended profiles. The purpose of the majority soundings was study of conducting formations in the crust and the top mantle. The geoelectric situation in region is dual. On the one hand, in region are absent powerful shallow layers of conducting formations. The sedimentary cover conductivity , as a rule, does not exceed 20 Simens. This factor is favorable for studing depth conducting derivations. On the other hand, the wide circulation of galvanic distortions of impedance dependences is characteristic of high-resistance surface derivations. Everywhere the static shift of dependences have place. So, the data processing method must be oriented on the previous exception of static shifts. Three methods of exeption were used. 1) The averaging in square window. This method inevitably lead to the loss of information. It was used in general for old data, with absent phase. 2) Shift of obtained amplitude curves to overlay them low-frequency parts with the normal model's curve. Unfortunately, often is difficult to estimate, how correctly overlay is executed. 3) The simultaneous interpretation of impedance's amplitude and phase for simple 1D layered model with small layes count. Simultaneously with the definition of model parameters , the value of static shift may be defined as one of model parameters. This method, I consider, is more useful and perspective and it is well coordinated with first two methods. After the obtaining of static shift, amplitude curves may be corrected on this shift's value. Then the more exact inverse is carried out for the depth conductivity structure discovering. For studing of distortion effects, which are caused by lateral discontinuities , the finite element's modelling is executed. The following results were obtained: 1) The lower crust's conductive layer is detected almost everywhere, but it is fragmental under ancient geological structures. 2) Thin conductive layer was detected in upper crust of ancient structures on the depth near 10 km. 3) The asthenosphere was not detected under the old structures, but it was detected under the young structures, in particular near to sea coast. So, the main tendency is observed and it show, that the upper litosphere's conductivity is growing with transition to younger geological structures.

LITHOSPHERE-ASTHENOSPHERE BOUNDARY AS A DENSITY DISCONTINUITY

Miroslav BIELIK (Geophysical Institute, Slovak Academy of Sciences, Dubravska cesta 9, 842 28 Bratislava, Slovak republic, email: geofmiro@savba.sk); Robert Lillie (Dept of Geosciences, Oregon State University, Corvallis, Oregon, 97331-5506, USA, email: lillier@bcc.orst.edu); Jan Sefara (Department of Applied and Environmental Geophysics, Comenius University, Mlynska dolina, 84215 Bratislava, Slovak republic, email: geofyzika@fns.uniba.sk)

Recent extensive gravimetric study involving integrated application of other geophysical and geological constrains in different European collisional and extensional regions indicates that lithosphere-asthenosphere boundary is also observed as a density boundary. Geophysical characterization of the lithosphere-asthenosphere boundary in the Western Carpathians and the Pannonian basin is also presented. Modelling of gravity anomalies by isostatically balancing effects of topography, the crust-mantle boundary and the lithosphere-asthenosphere boundary for the lithosphere-asthenosphere system as a whole suggestes a relatively small (about -30 kgm-3) density contrast. The results of integrated interpretations in the Eastern Alpine-Carpathian-Pannonian basin-Transylvanian basin region and Scandinavian Caledonides clear show that the lithosphere-asthenosphere boundary is necessery take into considaration for density modelling of long-wavelength gravity anomalies. This boundary is playing important role in analysis and better understanding of the observed gravity anomalies in different tectonic setting.

JOULE HEAT DISTRIBUTION AND GEOTHERMAL ZONES

Xiaoqing GAO (Lanzhou Institute of Plateau Atmospheric Physics, CAS, 730000 Lanzhou, P.R. China, email: xqgao@lzu.edu.cn); Giovanni P Gregori(Istituto di Fisica dell'Atmosfera, CNR, 00133 Rome, Italy, email: gregori@atmos.ifa.rm.cnr.it)

According to the Geodynamo Theory, electric current exists in the Earth. It can produce heat because of the resistance of the material of the Earth.This electric current can be derived from geomagnetic field data or model. Till now, the best geomagnetic field model(MAGSAT) was gotten by satellite global observation in 1979-1980. By this model, the global distribution of Joule Heat on ALB(Asthenosphere-Lithosphere Boundary) (direct proprotion to electric current square) had been gotten.It is surprisingly found that the distribution of Joule Heat on ALB matches the global geothermal zones very well.And the strongest Joule's Heating is located below Tibet Plateau, the youngest and the highest plateau on the Earth. It seems that the geothermal heat mostly comes from ALB, it is contralled by Joule's Heating process.

SEISMIC IMAGE OF LITHOSPHERE BENEATH THE EASTERN TIBET

G. L. KOSAREV (Institute of Physics of the Earth, B. Gruzinskaya 10, Moscow, 123810, Russia, email: kosarev@synapse.ru), R. Kind, S. V. Sobolev, X. Yuan, W. Hanka (all at GeoForshungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany), S. Oreshin (Institute of Physics of the Earth, B. Gruzinskaya 10, Moscow, 123810, Russia)

A new method of imaging of the lithosphere structure in a vertical cross-section from a set of observed receiver functions has been applied to the data of two experiments: 1991-1992 Sino-American Tibet PASSCAL experiment, and 1994 international INDEPTH II experiment. The image along the vertical North-South profile crossing the Tibetan Plateau is analyzed. Moho discontinuity, the inner crustal structure, 410 km, 660 km discontinuities in the mantle transition zone are clearly seen along the whole profile. We were able to resolve the laterally inhomogeneous behavior of low-velocity zones and some discontinuities inside the Earth crust. An inclined discontinuity dipping to the north from the 100 km to 250 km depth is a continuation of earlier discovered inclined structures inside the Earth crust in the Zangbo suture zone. This discontinuity is interpreted as the upper boundary of the subducting Indian lithosphere. Under northern Tibet a less clear south dipping structure is also identified. We are also trying to interpret these observations.

DEEP SEISMIC STRUCTURE OF THE BAIKAL RIFT: HYPOTHESES AND REALITY

V. V. Mordvinova (Institute of the Earth's Crust, Irkutsk, Russia); L. P. Vinnik, G. L. KOSAREV, S. I. Oreshin, A. V. Treusov (all at Institute of Physics of the Earth, B. Gruzinskaya 10, Moscow, 123810, Russia, email: kosarev@synapse.ru)

We present an analysis of digital seismic records that were obtained in the cooperative Russian-American teleseismic experiment of 1992. It was believed previously that an asthenospheric upwelling, which reaches the bottom of the crust is present underneath the rift zone. Our tomographic analysis indicates, however, that the lithosphere-asthenosphere boundary is indeed uplifted underneath the rift zone, but the depth of the boundary is 100 - 150 km. The value of the scaling coefficient for the lateral variations of the S and P residuals fits the theoretical values for thermal or compositional variations in the absence of melting (around 2.0). The waveforms and amplitudes of the Ps converted phases from the Moho boundary are similar in the rift zone and the neighbouring regions. To summarize, our study reveals a thick subcrustal lithosphere underneath the rift zone and allows first time to reconcile seismic data with the values of heat flow and the estimates of elastic thickness of the lithosphere based on the gravity modelling.

CHARACTERIZATION OF THE LITHOSHPERE-ASTHENOSPHERE BOUNDARY IN THE PRICASPIAN BASIN, RUSSIA

Uri Shigaev, Leonid ANISSIMOV (Saratov State University, Astrakhanskaya83, Saratov 410026, Russia, email: anisimov.gl.sgu@oda.ssu.runnet.ru)

Examination of electrical conductivity of the crust and mantle in the Pricaspian Basin shows two main layers with high conductivity: the upper layer (10-15 km) with conductivity to 1000 Sm and specific resistivity of 15-20 Omm, and lower layer (70-80 km in the inner part of the basin and 100-110 km in the outer part of the basin) with conductivity to 6000-8000 Sm and specific resistivity of 10 Omm. These layers correspond to low P-and S wave velocity layers. The Basin is characterized by thermal heterogeneity with increased heat flow in the central part. These data prove the point of view that the mantle surface is higher in the central part of the Basin. Mantle uplift is the main reason of the consolidated section thinning and subsiding the Basin during Permian, Triassic and Neogene periods. Basin subsidence formed dilatancy zones along the perimeter of structure and activated he migration processes from the mantle to the sedimentary section. Lithosphere-Asthenosphee boundary is a zone with the fluid generation and rising this surface activizes this process. Upper layer with the high conductivity corresponds to upper part of the basement and reflect increasing water content in this interval. Taking into account these data, we presuppose the occurrence of more permeable zones on the contacts: "sedimentary section-crust" and "crust-mantle".

TIDAL INTERNAL WAVES GENERATION OVER SUBMARINE RIDGES, ENERGY TRANSFER TO HIGH FREQUENCY INTERNAL WAVES AND TURBULENCE

Eugene Morozov (Shirshov Institute of Oceanology, 36, Nakhimovsky st., 117851, Moscow, Russia, e-mail: internal@redline.ru)

We analyze tidal internal waves generated near the Emperor Ridge in the North Pacific. Internal waves are studied on the basis of data of Russian and US moorings set from both sides of the ridge. A great amount of CTD hydrographic measurements are also available in the region. This allows us to analyze the oceanic turbulence and fine structure which occurs in the ocean due to breaking internal waves. The stations near the ridge show well expressed fine structure with homogeneous steps of tens of meters, the distant stations are more smooth and demonstrate no finestructure. Calculations of spectra from these vertical profiles give different levels of spectral densities. Those near the ridge are significantly above the GM background dropped background spectra. We interpret this as breaking of intensive tidal internal waves, generation of high frequency internal waves, and formation of fine structure. The results of the observations are confirmed by a non-linear numerical model of the generation of tidal internal waves over the ridge. The model describes their propagation and dissipation with generation of short period internal wave trains and turbulence. It is shown that internal tides propagating from submarine ridges strain the vertical structure of hydrographic fields, which can be registered by usual CTD-profiling. Analysis of CTD profiles over great squares in the oceanic basins with account for these properties can indicate areas of intermittent turbulence in the ocean which is caused by breaking internal waves. This analysis

of standard oceanographic data is less expensive than special measurements which include deployment of moored buoys in the ocean.

REGULAR BURSTS IN THE SEDIMENT-STRATIFIED, OSCILLATING BOTTOM BOUNDARY LAYER: MODEL RESULTS

Boris A. KAGAN and Konstantin B. Utkin (both at Shirshov Institute of Oceanology, Russian Academy of Sciences, St.Petersburg Branch, 30 Pervaya Liniya, 199053 St.Petersburg, Russia, email: kgn@GK3103.spb.edu)

A model based on the 2.5-level turbulence closure scheme and on a parameterization of the processes of sedimentation and entrainment at the top of the bed-load layer is employed to simulate the vertical structure of the sediment-stratified, oscillating bottom boundary layer (BBL). The model predicts regular bursts arising during an oscillation cycle every time when, under certain conditions, entrainment of suspended particles from the bed-load layer is terminated. The regular bursts differ from the random bursts associated with the intermittency of small-scale turbulence in the viscous and buffer sublayers in many respects. In particular, the former are due to the interaction between hydrodynamic and sedimentological processes; more specifically, to the release of the turbulent kinetic energy expended for maintaining particles in suspension. Also, unlike the random bursts, the regular ones do not produce significant contributions to the Reynolds stress, and their timescale is a function of the suspension Froude number, the Reynolds number, the nondimensional critical friction velocity at which sediment particles begin to go into suspension, the relative settling velocity of suspended particles and the Strouhal number. For fixed values of the first four above-mentioned parameters, the regular burst timescale is the smaller the greater is the Strouhal number or, all other factors being the same, the greater is the oscillation frequency. That is apparently why no bursts have been observed in the BBL beneath wind waves, whereas in the tidally induced BBL these have become common.

JSP49/W/04-B5 0910

SEAMOUNT TURBULENCE: GENERATION AND DECAY

Iossif Lozovatsky (P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences Moscow, 117851, Russia; also at Department of Mechanical and Aerospace Engineering, Arizona State University, Tempe, AZ, 85287-9809, USA, email: i.lozovatsky@asu.edu

Turbulent measurements above summits and at the rims of seamounts Erving and Ampere in Eastern Atlantic revealed an enormous enhancement of turbulent mixing with the mean kinetic energy dissipation rate of = 6x10-8 W/kg. The mean eddy and scalar diffusivities are in the range of (3.8-5.1)x10-4 m2/s with 90% confidence limits of (3.1-6.1)x10-4 m2/s. This implies that the averaged mixing rate in a 60-mile diameter and 150 m high region surrounding seamount Erving is 30-60 times than that of the far field value. At the place of generation, the diffusivities, averaged over the stratified water column were as high as (1-2)x10-3 m2/s; a similar result was reported for Fieberling seamount (e.g., Kunze and Tool, 1997). Our observations showed that the turbulent "columns" are possibly detached from the bottom. Their origin appears to be related to the internal-wave shear, rather than to the bottom-roughness induced turbulence. More regular, frictional boundary layers occupy about 30 % of the water column above the summit of the Ampere seamount. The dissipation rate within these stratified, non-fully mixed layers was high, (1-9)x10-7 W/kg, and corresponding scalar diffusivities ranged (5-70)x10-4 m2/s. Turbulence upstream of the seamount is almost unaffected by the topography, showing a low background level of 6x10-10 W/kg. Downstream of the summit, decreases from 6x10-8 to about (1-2)x10-9 W/kg, over a distance of 36 miles. This decay can be reasonably approximated by an inverse function of the horizontal distance normalized by the buoyancy mixing scale LB at the site of turbulence generation. The data taken from other regions, e.g. turbulent wakes downstream of the Ampere seamount and small Howland Island, also follow the power low trend (x/LB)-1, showing the versatility of the results obtained.

JSP49/W/22-B5 0930

ABYSSAL TURBULENCE

ROBERT B. SCOTT: Mathematics, UCL, Gower Street, London, WC1E 6BT, UK

Deep ocean turbulent mixing is believed to be important in controlling the large scale meridional overturning rate. Munk suggested in 1966 that deep ocean mixing may be much stronger near boundaries than in the interior, and this has been vindicated by direct measurements of microscale turbulence. While direct measurements reflect local mixing rates, one must use budget studies to indirectly infer the time average volume integrated mixing rates. Wunsch has suggested using the source of mechanical energy as a means of inferring the abyssal mixing rates. Recently it has been demonstrated that the flux of mechanical energy from the winds to the surface geostrophic flow F(Kg) can be well quantified using TOPEX/Poseidon (TP) data and recent gravity models. Turbulence theory suggests that the geostrophic energy must be dissipated by interactions with the bottom. Thus F(Kg), along with tidal forcing, are important in that they provide a power source for driving small scale, abyssal turbulence and mixing. In this work, the time mean field of F(Kg), and the factors affecting the reliability of this estimate, are reviewed for the World Ocean. The global mean is comparable to the mean rate of sun and moon tidal forcing. The new results are the presentation of the time variability of F(Kg) integrated over the World Ocean and various subregions. The time varying component in some cases exceeds the time mean and can result in short periods of atmospheric braking of oceanic surface flow. Factors controlling the variability in F(Kg) are identified for the TP time period. We also speculate on the longer time scale variability of power sources driving abyssal turbulence and the effects on global circulation and northern climate.

JSP49/W/10-B5 0950

DOUBLE DIFFUSIVE MIXING PROCESSES IN THE OYASHIO FRONTAL REGION

Jiro Yoshida, Hideki Nagashima and Moh Nagasaka(all at Department of Ocean Sciences, Tokyo University Fisheries, 4-5-7 Konan, Minato, Tokyo Japan 108-8477, email: jiroy@tokyo-u-fish.ac.jp; nagasima@bimelan.tokyo-u-fish.ac.jp)

Along the north eastern coast of Japan, the Kuroshio(warm and salty water) and the Oyashio (relatively cold and fresh water) directly contact and forms the so-called perturbed area. Warm core rings are sometime detached from the Kuroshio in this area and flows northward. Between this perturbed area and the Oyashio, clear frontal region is formed and is sometimes called as Oyashio Front. At this frontal region, vertical profiles of temperature and salinity often show complex structures such as temperature inversion layers, step structures and so on. These structures sometimes traced over several kilometers in horizontal direction, and were considered to be interleaving processes driven by double diffusive convection. In the present study, focusing upon these interleaving processes, the time history of layer formation is analyzed by intensive XBT and CTD surveys. The characteristic features of the layer are discussed statistically, and the effective horizontal and vertical diffusivities are estimated by simple advection-diffusion model. These results are compared with the previous ones obtained by Meddy studies, C-SALT , and NATRE, and the role of double diffusive mixing in this area is also significant and might affect the decay processes of Warm core rings

JSP49/W/08-B5 1010

INTERNAL WAVES, TURBULENCE AND INTRUSION OF SHELF WATER INTO THE KUROSHIO NEAR THE SHELF BREAK IN THE EAST CHINA SEA

Takeshi MATSUNO, Shotaro Ohsaki and In-Seong Han(Faculty of Fisheries, Nagasaki University, Nagasaki, 852-8521 Japan, email: matsuno@net.nagasaki-u.ac.jp)

Measurements of short time scale fluctuations with moored current meters were carried out near the shelf break in the East China Sea. Short time scale internal waves with periods of 10 to 30 minutes, which is slightly larger than the Brunt-Vaisala period, were frequently detected. Some of internal waves have borelike shape in time series of temperature and current velocity. Propagation speed of the borelike internal waves was 0.5 or 0.6 m/s which was estimated from two moorings with distance of 200 m. Shorter time scale fluctuations often follow the internal waves. This suggests that breaking of internal waves would generate turbulent fluctuations. These turbulent fluctuations could make vertical mixing, however, we did not find distinct occurrence of vertical mixing just after the significant turbulent fluctuations. However, we sometimes found evidences of offshore intrusion of shelf-bottom high turbid water into the Kuroshio. The intrusion tends to be developed when predominant pycnocline is formed just above the shelf break. It is suggested that enhancement of the intrusion should depend on intensification of internal waves associated with turbulent fluctuations, though we did not find a direct evidence yet. Such cross-shelf fluxes related to internal waves and turbulent fluctuations might play an important role on material and energy transports between the shelf water and the Kuroshio.

JSP49/E/07-B5 Invited 1050

STRATIFIED FLOW OVER TOPOGRAPHY: THE ROLE OF SMALL SCALE ENTRAINMENT AND MIXING IN FLOW ESTABLISHMENT

David FARMER (Institute of Ocean Sciences, Sidney, B.C., V814B2 Canada, email: farmerd@dfo-mpo.gc.ca) and Laurence Armi (Scripps Institution of Oceanography, La Jolla, California 92093-0230 USA, email: larmi@ucsd.edu)

Stratified flow over topography is examined in the context of its establishment from rest. A key element of numerical and steady state analytical solutions for large amplitude topographic flow is the splitting of streamlines which then enclose a trapped wedge of mixed fluid above the rapidly moving deeper layer. Measurements have been acquired which illustrate the development of this wedge and the role played by small scale instabilities and mixing formed initially by the acceleration of subcritical stratified flow over the obstacle crest. The volume of trapped fluid progressively increases with time, permitting the primary flow to descend beneath it over the lee face of the obstacle. Throughout the evolution of this flow, small scale instability and consequent entrainment would seem to be a prime candidate for producung the weakly stratified wedge, thus allowing establishment of the downslope flow to take place. Velocity structure of instabilities within the entrainment zone is observed and the associated entrainment rate determined. The entrainment is sufficient to produce a slow downstream motion within the upper layer and a density step between the layers that decreases with downstream distance. The resulting internal hydraulic response is explained in terms of a theory which accommodates the spatially variable density difference across the sheared interface. The measurements described here were acquired in a coastal inlet subject to gradually changing tidal currents. It is proposed that the observed mechanism for flow establishment also has application to atmospheric flow over mountains.

JSP49/L/01-B5 Invited 1110

STRATIFIED FLOW OVER TOPOGRAPHY: HYDRAULIC FRONTS

Laurence ARMI (Scripps Institution of Oceanography, La Jolla, California 92093-0230 USA, email: larmi@ucsd.edu) and David Farmer (Institute of Ocean Sciences, Sidney, B.C., V814B2 Canada, email: farmerd@dfo-mpo.gc.ca)

When stratified fluid is strongly forced over topography, the resulting flow includes a splitting streamline which then encloses a trapped wedge of mixed fluid above the rapidly moving deeper layer. In response to changes in the forcing, the location of this bifurcation or hydraulic front was observered to move either upstream or downstream. The movement of the hydraulic front is in response to either an increase or decrease of the tidal flow speed or as a result of changes in the density of fluid in the wedge itself. The position of the hydraulic front is explained in terms of a quasisteady theory proposed earlier for two-layer flows and the turbulent structures on the hydraulic front are compared with those observed in recent laboratory experiments on an accelerating baroclinic shear layer. The measurements described here were acquired in a coastal inlet subject to gradually changing tidal currents. It is proposed that the observations also have application to atmospheric flows over mountains.

JSP49/W/12-B5 1130

SPATIAL EVOLUTION OF HYDRAULICALLY CONTROLLED FLOWS TO DOWNSLOPE CURRENTS

GENO PAWLAK and Larry Armi (School of Oceanography, University of Washington USA)

The developing region of a steady downslope current in transition from a hydraulically controlled arrested wedge flow is examined through a set of laboratory experiments. The mixing and entrainment mechanisms at the shear interface are explored with the use of imaging techniques. The initial, unstable accelerating region, characterized by rapid development, low shear layer Richardson numbers and high entrainment rates, is quickly limited by the effects of stratification which suppress the vortex pairing mechanism. However, the continuing source of energy from the accelerating flow destabilizes the mixing layer to a shredding type of vortex interaction. The shredding mechanism results in a weakly entraining, well mixed shear layer which evolves towards a steady downslope current for a constant bottom slope. Rates of entrainment of fluid into the turbulent mixing region for each regime are calculated for the various slopes considered.

ENERGY TRANSFER AND MIXING NEAR A DENSITY INTERFACE

A. A. BIDOKHTI and M.Saghafi (both at institute of Geophysics, Tehran University, P.O. Box 14155-6466: Tehran, Iran. email: bidokhti@chamran.tu.ac.ir)

The problem of mixing and energy transfer across a density interface some distance from the source of turbulent energy, has important applications in geophysical flows. Quite a few experiments have been done, in order to understand arid quantify the processes involved (e.g Turner 1976, Linden 1981 and McGrath et.al. 1997).
Results are presented from experiments in which, mechanical grid turbulence is introduced in a homogeneous layer in contact with a stratified layer. Flow visualisation and direct measurements of salinity field (using fast response salinity probes) near the interface, are presented. With a step profile in density, we obtain an entrainment velocity proportional to Ri-n (where Ri is the overall Richardson number and $n \approx 1$). Engulfment, eddy impengment are important when the interface is close to the turbulence source. As the distance increases (for Ri>30), internal waves breaking near the interface seems to occur more often (e.g. McGrath et. al. 1997). However the case with stratified lower layer (with a linear profile), shows that interfacial internal waves are more pronounced than before. Also some of the energy is transferred to stratified layer and appear as internal waves which seem to have interactions. Internal waves exist in the entire depth of stratified layer. Salinity signals show that the amplitude of the waves decay with depth exponentially. Modulations of the signals indicate the presence of different modes, but the dominant frequency is close to N, the buoyancy frequency.

GENERATION AND REFLECTION OF PERIODIC INTERNAL WAVES: EXACT SOLUTIONS AND LABORATORY EXPERIMENTS

Yuli D. Chashechkin, Yuri S. Ilyinykh and Yuri V. Kistovich (all at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, E-mail: chakin@ipmnet.ru)

We investigate analytically and experimentally 2D and 3D periodic internal waves generation problem in an exponentially stratified viscous fluid. The wave source is plane strip or vertical cylinder tube periodically oscillating along its surface. The linearized governing equations are solved by integral transform method. The exact boundary conditions on the surface of a body as well as the governing equations are satisfied if, in addition to propagating internal wave beams, internal boundary layers on the emitting surfaces are taking into account. On the basis of these two eigen-forms of fluid motion we calculate wave amplitudes and evolution of the wave shape along the beam. The number of maxima in the wave amplitude cross-section depends on the ratio of source width by intrinsic viscous wave scale. The distance from the source where the bi-modal beam is transformed into the uni-modal one is defined. The spatial decay of the wave is different due to the geometry of the problem. Schlieren visualization and probe measurements of a periodic wave pattern confirm the theoretical results for the far wave field. The absolute values of calculated and measured wave amplitudes differ by a factor less then 1.3. Indirect evidences of the internal boundary layers are presented.

STOKES FLOW INDUCED BY PERIODIC INTERNAL WAVES

Yuli D.Chashechkin and Yuri V. Kistovich (both at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, E-mail: chakin@ipmnet.ru)

We study problem of propagation non-linear 2D periodic internal waves in exponentially stratified viscous fluid. The solution of complete set of governing equations is expanded in series on harmonics of the main frequency. The average flow is described by the term with zero frequency. As a seed disturbance the infinitesimal solution of linearized equations is taken. In the second order approximation the explicit expression for stream function of the main Stokes flow is received as quadratic differential form of the stream function of seed infinitesimal waves. As an example we calculate Stokes flow induced by a beam of periodic internal waves generated by a point dipole source. Explicit formula are received in the intrinsic frame where one of the axes is directed along a beam and the other is directed transversely. Total discharge in a beam is absent, that is fluid is moving in one direction in the upper part of a beam and in the opposite direction in the lower part. Patterns of stream lines are calculated for different models of mass source (dipole, quadruple). Stokes flow induced by a single beam tends to zero when kinematic viscosity goes to zero. In a domain of intersection of wave beams from several sources Stokes flow exists even in an ideal fluid. Calculated pattern of stream function describing reflection of an periodic wave beam off a sloping solid plane includes both reflected internal waves and a boundary current on the reflected surface

ESTIMATES OF DEEP-OCEAN TIDAL DISSIPATION FROM THE TOPEX / POSEIDON GLOBAL TIDE MODELS

JOHN A CHURCH1,2 Ole B. Anderson3, Richard Coleman1,2,4 and Neil J. White1,2 1Antarctic CRC, Hobart, Tasmania, Australia 2CSIRO Marine Research, Hobart, Tasmania, Australia 3National Survey, Geodetic Division, Copenhagen, Denmark 4University of Tasmania, Hobart, Tasmania, Australia

The TOPEX/POSEIDON models of global sea-surface tidal elevation are used to estimate tidal currents, assuming linear bottom friction. For the M2 tide, the derived currents satisfy the continuity equation to a rms residual of about 0.2 mm s-1. However, there is a clear correlation between these residuals and the underlying topographic features. From the surface height fields, the derived current fields and the residuals from the continuity equation, the tidal energy budget can be computed. The energy input by the astronomical potential almost exactly balances the divergence associated with the tidal currents. Residuals from the energy equation, ie the deep water dissipation, are positive almost everywhere and are maximum over major topographic features, such as the mid-ocean ridge in the South Atlantic, around New Zealand and near a number of regions where internal tide generation is known to be strong. The bottom dissipation estimates are combined with hydrographic data to estimate vertical mixing rates in the deep ocean.

TIDAL ENERGY AVAILABLE FOR DEEP OCEAN MIXING: BOUNDS FROM ALTIMETRY DATA

GARY D. EGBERT (College of Oceanic and Atmospheric Sciences, Oregon State University, 104 Ocean. Admin. Bldg, Corvallis, OR 97331, email: egbert@oce.orst.edu) Richard D. Ray (Goddard Space Flight Center, NASA, Greenbelt, MD, email: rray@geodesy2.gsfc.nasa.gov)

Maintenance of the large-scale thermohaline circulation has long presented a problem to oceaonographers. Observed mixing rates in the pelagic ocean are an order of magnitude too small to balance the rate at which dense bottom water is created at high latitudes. Recent observational and theoretical work suggests that much of this mixing may occur in hot spots near areas of rough topography (e.g., mid-ocean ridges and island arcs). Barotropic tidal currents provide a very plausible source of energy to maintain these mixing processes. Topex/Poseidon satellite altimetry data have made precise mapping of open ocean tidal elevations possible for the first time. We can thus obtain empirical, spatially localized, estimates of barotropic tidal dissipation. These provide an upper bound on the amount of tidal energy that is dissipated in the deep ocean, and hence is available for deep mixing. We will present and compare maps of open ocean tidal energy flux divergence, and estimates of tidal energy flux into shallow seas, derived from T/P altimetry data using both formal data assimilation methods and empirical approaches. With the data assimilation methods we can place formal error bars on the fluxes. Our results show that 20-25% of tidal energy dissipation occurs outside of the shallow seas, the traditional sink for tidal energy. This suggests that up to 1 TW of energy may be available from the tides (lunar and solar) for mixing the deep ocean. The dissipation indeed appears to be concentrated over areas of rough topography.

ENERGY TRANSFER IN THE SMALL-SCALE OCEANIC INTERNAL WAVE SPECTRUM

Ryo FURUE (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan, email: furufuru@ccsr.u-tokyo.ac.jp)

We examine energy transfers within a high-wavenumber portion of the oceanic internal wave spectrum by direct numerical simulations. The domain is a rectangular box of 100 m x 100 m x 128 m and the flow field is initialized with the Garrett-Munk (GM) spectrum. The GM flow field of larger horizontal scales is represented as a horizontal shear flow of an infinite horizontal scale. We compare cases with and without this shear flow to assess effects of the large scale GM flow field on the energy transfer. We find that wavenumber-local interactions dominate and transfer energy mainly to high horizontal wavenumber regions and that the modeled rate of energy transfer (1-4 x 10^-10 W/kg) is comparable to observed values in the main thermocline. The contribution of the large-scale flow is found to be not very large although the presence of the large-scale flow does enhance vertical transfer by Doppler spreading mechanism.
From these results, we propose the following scenario of the energy transfer. There are two paths of energy flux in the spectrum. In one, energy is transferred to vertically small scales at horizontally medium scales, and ultimately to dissipation scales, by scale-separated interactions such as described by the eikonal approximation. In the other, energy is transferred to horizontally small scales, where strong wavenumber-local interactions increasingly dominate and transfer energy to dissipation scales.

THE IMPACT OF NON-LINEAR WAVES ON THE DISSIPATION OF INTERNAL TIDAL ENERGY AT A SHELF BREAK

Mark E. Inall (University of the Highlands and Islands project, Scottish Association for Marine Science, Dunstaffnage Marine Laboratory, P.O. Box 3, Oban, PA34 4AD, UK, Email: mei@dml.ac.uk), Tom P. Rippeth (School of Ocean Sciences, University of Wales Bangor, Anglesey LL59 5EY, UK), Toby J. Sherwin (UCES, University of Wales Bangor, Anglesey LL59 5EY, UK)

The vertical and temporal structure of the dissipation of turbulent kinetic energy within the internal tide at a location 5 km shoreward of the shelf break on the Malin Shelf has been determined using a combination of the free-fall FLY profiler and Acoustic Doppler Current Profilers (ADCPs). Two distinct internal wave regimes were encountered: Period I in which large amplitude high frequency non-linear internal waves (NIWs) occurred (around neap tides), and Period II in which the internal wave spectral continuum was not dominated by any particular frequency band (around spring tides). Empirical Orthogonal Function (EOF) analysis shows that for the low frequency waves 76% of the variance was described by mode 1, rising to 95% for the high frequency waves. During period I, the dissipation and vertical mixing were dominated by the NIWs, with 70% of the dissipation occurring in the bottom boundary layer. During period II, the depth integrated dissipation was more evenly distributed throughout the tidal cycle, whereas vertical mixing was concentrated in one hour long episode of elevated thermocline dissipation coincident with weakened stratification. During both I and II approximately 30% of the total measured dissipation occurred within the thermocline when averaged over 12.4 hours, the remainder occurred within the BBL. Tidal average values for depth integrated dissipation and vertical eddy diffusivity for regime I (II) were 1.1x10-2 Wm-3 (4.0x10-2 Wm-3) and 5 cm2s-1 (12 cm2s-1) respectively.

OBSERVATIONS AND K-EPS MODEL SIMULATIONS OF TURBULENT MIXING IN STRATIFIED TIDAL FLOW

Jossy P. JACOB and Hartmut Peters (both at Rosenstiel School of Marine and Atmospheric Science, University of Miami, USA. email: hpeters@rsmas.miami.edu); Helmut Baumert (Hydromod Scientific Consultants, Wedel, Germany. email: baumert@hydromod.de)

This paper addresses the question how well second-moment turbulence closure models can simulate tidally driven mixing in fast flowing shallow estuaries. We employ a 1-D numerical k-eps model (Burchard and Baumert, 1995, JGR Oceans, 100, 8523), nudging the model velocity and stratification towards the observations. This is necessary because the estuarine momentum and mass balances are not one-dimensional, advective terms being unknown or poorly known. As a result of the nudging, simulated and real turbulence evolve in very similar shear and stratification. The modeled turbulent kinetic energy and dissipation rate are recast into a turbulent length scale and dissipation, both to be compared quantitatively with observations. Extensive observations of the turbulent dissipation rate and of turbulent overturning scales were made in the Hudson River in 1994/95 in conditions of shallow water (15 m depth typical), energetic tides (velocities of 1-2 m/s), mostly strong stratification (2-18 psu top-to-bottom salinity difference) and strong shear. Shear, stratification and turbulent mixing showed pronounced tidal and fortnightly variations.
The k-eps model is able to simulate turbulent dissipation rates and length scales fairly well. Comparing both parameters to their observed counterparts is crucial to determining adjustable model constants.

TURBULENCE PARAMETERIZATION FOR PBL DISPERSION MODELS IN ALL STABILITY CONDITIONS

Gervásio Annes Degrazia (Universidade Federal de Santa Maria -UFSM, Santa Maria-RS-Brazil, CEP 97.119-900, Email: degrazia@ccne.ufsm.br) CLÁUDIA JACONDINO DE CAMPOS (Universidade Federal de Pelotas-UFPel, Pelotas-RS-Brazil, CEP 96.010-900, Email: cjcampos@ufpel.tche.br)

Accounting for the current knowledge of the Planetary Boundary Layer (PBL) structure and characteristics, a new set of turbulence parameterizations to be used in atmospheric dispersion models has been derived. The expressions for the vertical profiles of the velocity standard deviation, Lagrangian and Eulerian length scale and time scale and diffusion coefficient are proposed. The classical statistical diffusion theory, the observed spectral properties and measured characteristics of energy containing eddies are used to estimate these parameters. The results of this new method are shown to agree with previously determined parameterizations. In addition, these parameterizations give continuous values for the PBL at all elevations and all stability conditions from unstable, neutral to stable. It is the aim of this work to present the general derivations of these expressions and to show how they compare to previous results. Finally a validation of the present parameterization, obtained by inserting it in a Lagrangian particle model, will be shown. The Copenhagen data set is simulated. This data set is particularly suited for this validation, since most of the Copenhagen tracer experiments were performed in stability conditions that are the result of the relative combination of wind shear and buoyancy forces. As a consequence, a parameterization scheme, able to deal contemporary with neutral and slightly convective condition, is preferred.

COEFFICIENT OF TURBULENT DIFFUSION AT A TROPOSPHERIC ALTITUDES

George JANDIERI (department of Physics, Georgian Technical University, 77 Kostava str., Tbilisi 380075, Georgia, email: jandieri@access.sanet.ge) Anzor Gvelesiani (Institute of Geophysics of the Georgian Academy of Sciences, 1 Rukhadze str., Tbilisi 380093, Georgia) Zhuzhuna Diasamidze, Vladimir Glonti and Mzia Diasamidze (all three at Department of Physics, Batumi State University, 35 Ninoshvili str., Batumi, Georgia)

New statistical model of the distribution of pollutant mean concentration is presented at lowest atmospheric turbulent layers. Statistical description of turbulent diffusion is payed attention by means of stochastic diffusion equation. Source of pollutant is deterministic function of coordinates and time. Velocity field describes homogeneous and stationary process. General expression of passive impurity concentration distribution is obtained. Coefficient of turbulent diffusion is expressed in terms of coefficient of molecular diffusion and arbitrary correlation tensor of the vector field of velocity fluctuation. Knowledge of the components of the turbulent diffusion coefficient makes it possible to restore the values of spatial-temporal parameters typical of a stochastically inhomogeneous medium. In particular, distribution of pollutant at anomalous meteorological conditions such as calm is of interest. Numerical simulations of normalized concentration distribution against distance are carried out at stationary and nonstationary cases. Globul formation mechanism is observed in nonstationary case for different values of the turbulent flow velocity. They have different linear dimentions and existence time.

THE EFFECT OF DIFFUSION INSTABILITY IN A LOWER TURBULENT ATMOSPHERIC LAYERS

George JANDIERI (department of Physics, Georgian Technical University, 77 Kostava str., Tbilisi 380075, Georgia, email: jandieri@access.sanet.ge) Anzor Gvelesiani (Institute of Geophysics of the Georgian Academy of Sciences, 1 Rukhadze str., Tbilisi 380093, Georgia) Vladimir Glonti, Guram Varshalomidze and Mzia Diasamidze (all three at Department of Physics, Batumi State University, 35 Ninoshvili str., Batumi, Georgia)

Turbulence favours the mixing of different impurities in random media. Interaction of impurities leads to temporal evolution of medium inhomogeneous structure and it passes to the metastable state. Diffusion instability is investigated by means of solution of stochastic integro-differential equation for the mean concentration of impurities in a randomly inhomogeneous media. Potential energy (PE) of interaction between impurities plays significant role. If PE is positive we can introduce effective diffusion coefficient while it is not justified at any chemical reactions. If PE is negative, critical concentration is exist from which diffusion instability is beginning. Model of PE is supposed using similarity method. Function characterizing PE has potential well at small distances and has wavy character at great distances. New approximation of spatial-temporal distribution of impurity concentration is proposed by solving stochastic diffusion equation using Picard's method. Concentration fluctuations are caused by velocity pulsations. Incompressibility and isotropy of turbulent medium are not use. Knowledge of statistical parameters of fluctuating media and distribution of the mean concentration of impurities allow us to restore characteristic linear dimensions of diffusible particles.

DIFFUSING OF A PASSIVE TRACERS IN RANDOM FLOWS. SOME RESULTS OF NUMERICAL SIMULATION.

KONSTANTIN KOSHEL and Olga Alexandrova (both at Pacific Oceanological Institute, FEB RAS, 43,Bultiyskay str., Vladivostok, 690068, Russia, Email: wave@online.vladivostok.ru)

The diffusion of a passive tracers in a two-dimensional random velocity field is considered. On the basis of diffusion equations solution as a functional integral the method of numerical simulation of a problem is offered. By numerical simulation dynamics of formation of cluster structures is studied. The role of molecular diffusion in such situation and degree of effects connected with potential and solenoidal components of velocity fields is estimated. The behavior of a tracers as in diffusion approximation, and for infinite temporary radius of a correlation is investigated.
All calculations are done for one realization of a velocity field. For other realizations the distribution of an impurity essentially varies, however common behaviour difined by parameters of a problem is saved. The results of simulation will well be agreeed with analytical results obtained by V.I. Klyatskin and A.I. Saichev (JETP. 1997. V. 111. N 4. P. 1297. In Russian). The molecular diffusion renders noticeable influence to distribution of partiñles of an impurity, thereby increasing common square of area occupied by impurity, however influence of this effect to compression of partiñles along trajectorny is unsignificant. On the other hand an incompressible component in a velocity field poorly influences effect of grouping of partiñles in clusters, but essentially decelerates compression of partiñles along trajectorny. Results for case of a velocity field with an infinite radius of correlation on time allow to assume, that the qualitative behaviour of an impurity in this case is saved, however numerical and it is possible also functional performances of process vary. ‰

DECOMPOSITION OF WIND VELOCITY FLUCTUATIONS INTO WAVE AND TURBULENT SIGNALS USING WAVELET TRANSFORM

Nisia Krusche (Dept. Geociencias, Fundação Universidade De Rio Grande, C.P. 474, 96201-900 Rio Grande Rs, Brazil) And Osvaldo L. L. Moraes (Dept. Física, Universidade Federal De Santa Maria, 97119-900 Santa Maria, Rs, Brazil)

In the stably stratified atmospheric boundary layer, spectra might be affected by several kinds of Waves. Since the problem of turbulent diffusion is closely related to the spectra of wind velocity Fluctuations, there is a need to separate the contributions of those waves from that of Turbulence. Discrete wavelet transform was applied to temperature and vertical velocity Fluctuations measured in candiota, rs (31o28´s, 53o 40´w), sampled with a frequency of 10 Hz. In this data set, waves have been detected through cospectral techniques. As a result, a Wave was identified in both series, which was 90o out of phase, as expected. Therefore, this Method may be used to decompose the series in two signals, one containing the wave and Other corresponding to random turbulence of the flow.

OVERTURNING LENGTH SCALE AS AN INDICATOR OF THE WASTEWATER NEAR FIELD

Vlado MALACIC (Marine Biological Station, National Institute of Biology, Piran, 6330, Slovenia, email: malacic@nib.si)

During a period of calm weather and stratified water column of a shallow (depth = 21 m) semi-enclosed sea, six surveys of the wastewater near-field of two adjacent submarine diffuser outfalls, with a low sewage ouflow rate (usually less than 220 l/s), were conducted with a fine-scale CTD probe. The survey area of 780m_740m was monitored with the free-falling probe at 30-31 stations. Vertical velocity of the probe was nearly constant, 1 m/s, and the data was retrieved at a frequency of 50 Hz, providing a vertical resolution of 2.5 cm.
When using a fine-scale CTD it has been observed that from the vertical distribution of 'virtual' displacements (Thorpe displacements) of particles with a sampled density, by which each particle would gain a statically stable position, the length scale of overturning events could be estimated, through an appropriate averaging process.
Within the turbulent wastewater field the fluctuations of temperature were of the order of 0.1 oC, and of salinity less than 0.05 psu, generating overturning. The vertical extent of the overturning events could well be determined using the maximum vertical displacement, or the Thorpe length scale. Both scales also indicate the thickness of the neutrally buoyant subsurface wastewater field. Distribution of these length-scales over the diffussors show a clear picture of the wastewater field(s) of a thickness smaller than 1m in windless, stratified conditions, which is otherwise hard to obtain without costly experiments (dye tracers).

PROPAGATION AND DISSIPATION OF TIDAL INTERNAL WAVES IN THE NORTH PACIFIC ON THE BASIS OF THE MEGAPOLYGON DATA, AN EXPERIMENT WITH 170 MOORED BUOYS

Eugene MOROZOV (Shirshov Institute of Oceanology, 36, Nakhimovsky st., 117851, Moscow, Russia, e-mail: internal@redline.ru)

Tidal semidiurnal internal waves generated over the Emperor Ridge in the North Pacific are analyzed on the basis of a vast cluster of moorings in the area between 38 - 42 N and 152 - 158 E. The cluster of 170 moored buoys was set for two months in this region with a distance of 24 miles between moorings. The current and temperature meters were set at 120 m and 1200 m levels. This cluster of moorings with current meters forms an antenna to study eddies and tidal internal waves and their variability. The maximum distance between the utmost western and eastern moorings exceeded 450 km. The wave lengths of tidal internal waves vary between 130 and 150 km, while the change of the direction of their propagation is insignificant. Westerly waves are dominating indicating that the Emperor Ridge is the source area. The cluster of buoys was divided into two parts to obtain independent data sets for evaluating wave parameters. The wave lengths and direction of propagation measured at both parts of the study area gave approximately the same results. The results did not change in the analysis of the first and the second months of the time series. The maximum amplitudes of the waves in the eastern part of the study area exceed 40 m, whereas in the western part they were about 15-20 m or less. Decay of the waves is estimated as 5% of the energy over one wave length. Similar results were obtained from the data of US moorings in this area and also from the moorings east of the Emperor Ridge.

A NUMERICAL EXPERIMENT ON THERMOBARIC CONVECTION

Miyako Naya and Hideki Nagashima (Department of Ocean Sciences, Tokyo University of Fisheries, Konan,Minato, Tokyo Japan 108-8477. E-mail: nagasima@bimelan.tokyo-u-fish.ac.jp)

Predictions of vertical convection and deep water formation in the polar region need to include the nonlinear equation of state. In the present study, a numerical experiment on thermobaric convection is carried out based on the non-linear equation of state in which the thermal expansion coefficient is a function of pressure_@together with temperature and salinity. A two-dimensional non-hydrostatic model is used with the calculating domain of 8km in horizontal and 4km in vertical directions. The onset of convection is well explained by a linear stability analysis of Rayleigh-Benard problem and the convection develops and reveals thermobaric enhanced turbulence. Next, the double diffusive effect is taken into consideration, because the typical vertical profile in the polar sea shows high activity of double diffusion. In the numerical model, the vertical diffusivities of heat and salt are parameterized by using empirical flux law (Kelly:1990). The result shows that the double diffusive effect reduces the onset of thermobaric convection.

STIMULATION OF LARGE-SCALE ANTICYCLONIC CIRCULATION IN THE OCEAN VIA SALT FINGERS CONVECTION

Anatoly Pereskokov (Russian Research Institute of Hydrometeorological Information - World Data Centre, 6 Korolyov St , Obninsk 249020, Russia, email: peres@meteo.ru)

A further progress in understanding of the nature of the ocean large-scale circulation relates first of all to the estimate of the processes effectiveness generating the mixing in the ocean picnocline. Diapicnic transfer due to salt fingers convection appears to be the significant climate-forming factor (Pereskokov, Fedorov, 1985). Evidence of this is the displacement of regions of the increased temperature from equatorial latitudes to the subtropics with the

increase in depth. It is shown that in the core of waters with thermohaline conditions favourable for the development of salt fingers convection which is found in all oceans in the layers between horizons 300 and 600 m, their volumetric shares in the North Pacific, South Pacific, and the Indian ocean are close to 70% and increases to 80% in the South Pacific and almost to 93% - in the North Atlantic. In such a case, an overwhelming majority of the values of density ratio lie within of 1.7-5.0 for the entire World Ocean and within of 1.7-2.5 - for the Atlantic. These limits for the density ratio are typical for conditions in which the effect of salt fingers is most pronounced. Via this vertical heat transfer from upper layers to deep waters salt fingers convection stimulates large-scale anticyclonic circulation contributing to the development of cores of warm (with less density) waters in subtropics. Probably it is not easy to find the numerical support of this hypothesis, but the fact itself that it is already on the level of 200 m that the wind energy can account for only 30% of the observed values of the current speed, is indirect evidence in favour of the assumption made.

RICHARDSON NUMBER AS AN INDICATOR OF TURBULENT STRATIFICATION AND LARGE EDDY DIFFUSION

Prof .KPR Vittal Murty.(DCM,INPE,Av.dos Astronautos1758,caixa postal 515,Sao jose dos campos-sp-BRAZIL, cep-12201-010, email: murty@met.inpe.br)

Richardson number(Ri),a non-dimentional number which is a ratio of thermal and kinetic forces is an indicator of surface layer turbulence.It is closely associated with turbulence production terms in the equation of turbulent energy balance.In this article the turbulent state of the surface layer is studied as a function of Ri based on Pantanal gradient observation data. Pantanal is located in the westren part of central Braziland is well noted for its flora and fauna. An International Pantanal Experiment(IPE_1) was conducted in May 1998,which is a part of broad experimental program to study the weather and climate of this region.The gradient observations of wind and temperature obtained in IPE_1were used in the present study.The three different forms of Ri namely bulk, gradient and flux form are estimated and compared. The various functions of Ri as envisaged by Pristley, Pasquill, Gurevitch and Riderwere estimated and discussed. The variation of horizontal velocity variance with Ri was studied for a clear and cloudy day.This shows an Increase of variance with decrease of Ri and the slope which also varies indicate the large eddy diffusion in the area

TURBULENT CONVECTION AND MIXING IN A LABORATORY MODEL OF THE CONVECTIVELY-DRIVEN FLOW IN PARTIALLY-ENCLOSED SEAS

T. MAXWORTHY and Th. Grimm, Department of Aerospace and Mechanical Engineering, University of Southern California. Los Angeles, CA 90089-1191, USA.

Turbulent convection and mixing play a major role in a variety of natural hydrodynamical systems. A special class of such systems are those in which convection drives exchange flows in a channel that is closed at one end and has a lateral contraction and/or a sill at the other, open, end. Typical examples of such "partially-enclosed seas" are the Red and Mediterranean Seas, the Persian Gulf and the fjords that indent many coastlines. The present work focuses on the spatial distribution and scaling of the density difference (g') between the inflowing and outflowing fluid layers at the exit and the characteristics of the turbulent mixing that takes place at the closed end of the sea.
Using a long, water-filled channel, fitted with buoyancy sources at its upper surface, experiments were conducted to investigate the influence of the geometry of the strait and the channel as well as the magnitude of the buoyancy flux. Firstly, we have found that the scaling law:
g' = const. Bo^2/3 x/h^4/3
best describes the distribution of the observed density difference along the channel. Where Bo is the buoyancy flux, x the distance from the closed end of the channel and h its depth at the open end (sill). The numerical value of the constant depends on the hydraulic conditions at the exit and these, in turn, depend on the details of the channel geometry. This scaling law holds for the experimental results and appears to be valid for a number of natural systems as well. Secondly, we discuss, in detail, the flow conditions that are responsible for the turbulence and mixing, at the closed end of the channel, that ultimately account for the observed density distribution.

PARTICLE DISPERSION AND MIXING INDUCED BY BREAKING INTERNAL GRAVITY WAVES

P. BOURUET-AUBERTOT, C. Koudella & C. Staquet DAMTP, U. of Cambridge, Silver Street, Cambridge, CB3 9EW, UK Lab. de Physique, E.N.S. de Lyon, 46 allee d'Italie, F69364 Lyon Cedex 07 L.E.G.I., BP 53, F38041 Grenoble Cedex 9

Our study focuses upon diapycnal mixing induced by a breaking gravity wave. The primary wave we consider is of small amplitude (statically stable), a case for which the breaking process mostly involves two-dimensional instabilities. The dynamics of the waves have been previously analyzed by means of two-dimensional direct numerical simulations and three-dimensional calculations will also be reported. Diapycnal mixing is inferred both from particle dispersion and from potential energy budgets, and the two methods are found to lead to the same prediction for the diapycnal diffusivity. This is of particular interest regarding the interpretation of in situ measurements. The diapycnal diffusivity is found to depend on the turbulent Froude number squared, a dependency which we shall relate to the instability process of the primary wave.

JSP49/E/05-B5 1440

MIXING IN A STABLY STRATIFIED SHEAR LAYER

Chantal STAQUET (LEGI, BP 53, 38041 Grenoble cdx 9, France,
email: Chantal.Staquet@hmg.inpg.fr)

We have investigated the mixing properties of a stably stratified shear layer in two and three dimensions, using a new analysis of mixing proposed by Winters et al. (1995) and Winters and d'Asaro (1996). This analysis provides an exact expression for the diapycnal flux of density; it relies on a stable density profile obtained by sorting adiabatically the fluid parcels so that the heaviest has the lowest altitude. The interest in the new analysis is that mixing rates, such as the mixing efficiency or the diapycnal diffusivity, can be computed instantaneously whatever the flow regime, even if unsteady and strongly nonlinear. We found that the maximum value, as a function of time, of the flux Richardson number depends upon the vertical scale of the instability triggering turbulence, being larger for a larger vertical scale. When the vertical scales of the flow collapse and a weakly nonlinear regime is eventually reached, the predictions of the analysis coincide with those by the Osborn-Cox model. Interestingly, the mixing efficiency relaxes toward an asymptotic value close to 0.25, when the flow is three-dimensional or two-dimensional with strong stratification. In the latter case, the normalized turbulent diffusivity is found to depend on the inverse of the Richardson number, a parameterization that is identical to that often used in large scale circulation models. It is noteworthy that the same law is found in breaking internal gravity waves.

MIXING IN DOWNSLOPE FLOWS INTO STRATIFIED ENVIRONMENTS

Peter G. BAINES, CSIRO Atmospheric Research, PMB No. 1, Aspendale, Australia 3195

The properties of downslope flows may be significantly affected by density variation in the environment. Oceanic examples are downslope flows at high latitudes in the North Atlantic and around Antarctica, driven by surface cooling and brine rejection due to freezing of sea water, and nocturnal flows in the atmosphere driven by radiative surface cooling on slopes.
This paper presents a description of laboratory experiments on downslope flows with stratified environmental fluid, with a dynamical interpretation of the observations, and with measurements of the relevant quantities to enable application of these results to larger scale models. The experiments were carried out in a glass-sided tank 80 cm high and 299 cm long, filled with uniformly salt-stratified water, in which two-dimensional downslope flows of width 23 cm were generated. For each run, a continuous two-dimensional source of dense salty water was introduced at the top of a sloping bottom, for a finite time that depended on the strength of the source and was typically of several minutes duration. Density profiles were measured before the downflow, and some time after it, when all residual motion had ceased. Taking the difference between these two profiles gave quantitative information about the variation of the downflow with downslope distance, the final disposition of the introduced fluid, and the redistribution of the ambient stratification.
A wide range of differing behaviour was observed, depending on the slope angle, the parameter M (which depends on the mass flux, buoyancy and stratification) and the Reynolds number. The thickness of the density current is generally uniform with downslope distance, but the current exchanges fluid with the environment by the processes of turbulent entrainment into it and more significantly, detrainment from it. The latter is generally the stronger process for small slope angles, where mixing mostly occurs at the upper boundary of the current, but for steeper slope angles (30 degrees and larger) the mixing penetrates deeper, and entrainment is dominant. These processes may be quantified by entrainment and detrainment coefficients for modelling purposes.

DEPENDENCE OF MIXING EFFICIENCY ON INITIAL STRATIFICATION IN SHEAR LAYERS

C.P. CAULFIELD (Centre for Environmental and Geophysical Flows and School of Mathematics, University of Bristol, University Walk, Bristol, BS8 1TW, UK, Email: c.p.caulfield@bris.ac.uk) and W.R. Peltier (Department of Physics, University of Toronto, Toronto, ON M5S 1A7, Canada, Email: peltier@atmosp.physics.utoronto.ca)

We investigate the detailed nature of the "mixing transition" through which intense turbulence may develop in stratified free shear layers. We explicitly quantify the time-evolving irreversible mixing which occurs within the flow. We consider in detail the variation in the character of the mixing processes with the initial ambient stratification.
Using the numerical data from a sequence of three-dimensional simulations with varying stratification, we accurately track the nonlinear amplification of streamwise vortex streaks, verifying that they are well-predicted by secondary stability analysis, and that they are due to a convective destabilization of the periphery of a Kelvin-Helmholtz billow. At all times we calculate the minimal potential energy of the system accessible by (notional) adiabatic rearrangement of fluid parcels, and so quantify continuously the irreversible "mixing".
Vortex stretching leads eventually to a violent subcritical vortex-vortex collision which drives the dominant mixing process in the flow life cycle. An appropriate definition of the "mixing efficiency" implies that the irreversible small-scale mixing of the density which is triggered by shear layer transition leads inevitably to a density "staircase", with regions of well-mixed fluid separated by narrow regions of relatively strong density gradient.

TURBULENT MIXING AND DISSIPATION ACCOMPANYING KELVIN-HELMHOLTZ INSTABILITY

DAVID C. FRITTS and Joseph A. Werne, Colorado Research Associates, 3380 Mitchell Lane, Boulder, CO 80301 USA

The Kelvin-Helmholtz (KH) instability is a major source of turbulence and mixing in stratified and sheared fluids. However, numerical simulations have only recently achieved sufficient resolution to describe the generation and mixing accompanying an extended inertial range of turbulence. Instabilities arise in the outer portions of the KH billows, penetrate into the billow cores thereafter, and lead ultimately to a layer of turbulence that becomes nearly homogeneous horizontally. Turbulence rapidly mixes the fluid initially within the billow cores, leading to a nearly adiabatic layer with large velocity and thermal gradients above and below. Energy and thermal dissipation profiles exhibit considerable spatial and temporal variability and non-Gaussian statistics, particularly at the edges of the mixing zone. As the turbulence layer restratifies, a dynamically stable shear flow is achieved.

JSP49/W/21-B5 1620

QUANTITATIVE RESULTS ON TURBULENT PATCHES IN THE STRATOSPHERE

J.-R. ALISSE and C. Sidi Service d'Aeronomie du CNRS BP 3 91371 Verrieres-le-Buisson France

The small-scale three-dimensional turbulent activity in the stably stratified atmosphere mainly dwells in isolated patches, with a larger horizontal extent than the vertical one. These structures are usually described as pancakes; they are believed to be completely mixed and hence should display sharp boundary transitions at their edges. Using high-resolution measurements of temperature and velocities profiles, obtained from a balloon-borne instrumentation, we present quantitative results on these patches. From the analysis of Richardson numbers, dissipation rates, Ozmidov, Thorpe and Kolmogorov scales within each layer, a typical pattern emerges, associating low Richardson numbers and significative Thorpe scales. It is noteworthy that the Ozmidov and Thorpe scales are usually quite smaller than the eyeballing thickness of the patches, as observed too in the ocean. Associated with the weak available potential energy dissipation rates, these elements suggest that in almost all the patches the mixing is imperfect. This may be related to the generating processes and life cycle of the patches and has important outcomes for the estimation of a vertical diffusivity on the large-scale tracer fields linked to this small scale turbulent activity.

JSP49/W/01-B5 1640

DISSIPATION IN SHEAR-FREE TURBULENCE NEAR BOUNDARIES

Miguel A.C.TEIXEIRA and Stephen E. Belcher (both at Department of Meteorology, University of Reading, Earley Gate, PO Box 243, Reading RG6 6BB, UK, email: miguel@met.reading.ac.uk)

Processes such as gas transfer across gas-liquid interfaces are controlled by small-scale turbulence near the interface. Modelling these flows is complex, partly because turbulence dissipation is notoriously difficult to represent in closure models, particularly near boundaries. Hence, we investigate the fundamental dynamics of turbulence near interfaces.
Most closure models are developed for solid walls, but recent DNS of shear-free turbulence near boundaries shows significant differences between flows bounded by solid walls and those bounded by free surfaces. Here, we develop a simple model for the rapid distortion of turbulence by such boundaries, which shows how viscous processes lead to the differences between solid walls and free surfaces. The new model produces profiles of Reynolds stresses and turbulence dissipation rates that are in good quantitative agreement with DNS data at short times. As in previous rapid distortion studies, this short time model is able to predict correctly qualitative features of the Reynolds stress and dissipation profiles at longer times.
We conclude that the new model captures the essential physics of the problem and that blocking and the dynamics of the viscous boundary layer are the essential factors determining the shape of the turbulent Reynolds stresses and dissipation profiles near the boundary. The differences between model results and DNS data at long times can be attributed both to the neglected nonlinear effects and to turbulence decay due to dissipation. This highlights the importance of correctly representing dissipation in near-wall closure modelling.

A STUDY OF TURBULENT REGIME AS REVEALED BY VECTORIAL AS WELL AS SCALAR VARIANCE.

PROF.KPR Vittal Murty

This article presents a detailed study of he variances of wind components ,temperature and humidity estimated from the data obtained from three dimensional fast response sonic anemometer during May 1998 which is a part of inter-disciplinary Pantanal experiment(IPE-1).Pantanal is the largest wet land in the world.It is located in central -west Brazil It has ecological and socio- economic significance.There is large seasonal variation in meteorological and hydrological parameters in this region,marked by dry wintersand wet summers.The variances of wind components for pure mechanical turbulence are constantand agree fairly with the the values reported by Panofsky and Dutton.It shold be mentioned that the values of velocity variance lie between the values obtained from earlier expeditions for flat and rolling terrain. Thisindicate that the terriagn features of Pantanal are in between flatand rolling terraigns. The vertical varince is scaled with Monin -Obukhov length scale(L).It is minimum at nuetral condition increasing with stability as well as in-stability. An interesting feature is the relation between horizontal variance and Richardson number.The slope of the curve varies for aclear day and cloudy day thus is a function synoptic scale disturbance.BOth the Scalar variances of temperature and humidity showed a similar variation with Z/L (here Z is the height of observation and and L monin-obukhov length scale) Both the parameters showed a discontinuity at Z/L = 0.

SST ANOMALIES, VERTICAL TURBULENT MIXING AND SUBMARINE EARTHQUAKES

M.A. NOSOV, M.V. (Lomonosov Moscow State University Faculty of Physics Moscow State University Russia) B.W Levin., S.N. Skachko

The appearance of large-scale (~500 km) cool SST anomalies were discovered in the epicenter regions of strong underwater earthquakes. In our opinion the mechanism of the SST anomaly origin was certainly connected with an export of cold lower water layers to the ocean surface as a result of intensive turbulent mixing generated by seismic bottom motions. These SST anomalies may lead to some obvious and at the same time important consequences and accompanying phenomena should be studied. Among all the phenomena we single out the following: 1)export of the nutrients toward upper water layers where there is an usual shortage of the substances causing an increase of the productivity (like in an upwelling zone), 2)generation of large amplitude internal waves (much larger than internal tsunami waves) as a result of evolution of the anomaly stratification zone; 3)the appearance of the cool SST anomaly should cause a response of the atmosphere. This study is aimed to reveal the mechanism of the turbulence generation above the moving bottom. The numerical model of the process is based on the equation of the balance of the turbulence energy in stratified fluid and equation of turbulent heat transfer. The results of this study gives us grounds to state that submarine earthquakes can produce large scale cool SST anomalies above the pleistoseismic zone by means of intensification of the vertical turbulent exchange.

VESICULATION DURING MAGMA ASCENT: GAS PRESSURE, DEHYDRATION AND FRAGMENTATION

Nadav Lensky, Anatoly Chekhmir, Vladimir Lyakhovsky and Oded NAVON (Institute of Earth Sciences, Hebrew University, Jerusalem, 91904, ISRAEL, email oded@vms.huji.ac.il)

We used experimental and numerical simulations to study the growth of water bubbles in silicic melts under variable pressure. Rhyolitic obsidian was hydrated at 150 MPa (850 C), vesiculated and equilibrated at 110 MPa (700 C) and decompressed gradually, from 110 MPa to 70 MPa. Bubble growth under variable pressure from initial to final radius was documented by comparing photos of individual bubbles before and after decompression. The experiments were simulated using a modification of the model of Lyakhovsky et al. (1995) that accounts for the effects of variable pressure and the dependence of viscosity and diffusivity on both temperature and concentration of water. The excellent agreement of measured and simulated radii confirms the accuracy of the modified code.The model is now combined with conduit flow models in order to examine the evolution of bubbles during magma ascent. The model assumes steady-state flow and a known magma mass discharge through a cylindrical conduit of a given radius. Magma with known initial water content and bubble number density is introduced at the bottom of the conduit and allowed to ascend at a velocity which is determined by the mass flux. The model follows the expansion of bubbles, the ascent velocity and the gas pressure in the bubbles. For a reasonable choice of parameters, the water content of the melt initially follows the equilibrium value and is determined by the ambient pressure. Later, gas pressure increases above ambient, as magma acceleration and increasing melt viscosities prevent equilibrium dehydration of the melt shell around the bubbles. This excess pressure along with increasing viscosity and strain rates may lead to magma fragmentation.

THERMODYNAMIC AND KINETIC CONSIDERATION OF MAGMA FRAGMENTATION AS A RAREFACTION SHOCK WAVE

ATSUSHI TORAMARU (Department of Earth Sciences, Kanazawa University, Kanazawa, Kakumamachi, Ishikawa 920-1192, Japan, email toratora@kenroku.kanazawa-u.ac.jp)

Fragmentation of magma during explosive volcanic eruptions must be related to the dynamics of vesiculation process such as nucleation, growth, expansion, deformation and coalescence of bubbles. I present the role of magma vesiculation on the magma fragmentation from the view points of the thermodynamics and kinetics. The entropy consideration shows that the fragmentation of magma can possibly propagates as a rarefaction shock wave if the negative curvature part exists on the pressure-specific volume curve (P-V curve). On the P-V curve for a vesiculating magma the negative curvature can exist due to two kinetic effects of vesiculation: nucleation of bubbles and melt viscosity as a function of volatile concentration and time scale of decompression. The former can be called the nucleation wave, the later should be the fragmentation wave. Applying the entropy criterion for the rarefaction shock wave to vesiculating magma and taking into account the viscoelastic rheology of melt, I derive the condition of presence of fragmentation wave as function of decompression rate, silica and water contents. The fragmentation wave as a rarefaction shock wave is caused by the suppressed expansion of bubbles. As an numerical result, the propagation of magma fragmentation can be a rarefaction shock wave if the decompression time scale is approximately less than the relaxation time scale. This stability condition of fragmentation wave as a rarefaction shock wave may correspond to the transition between the explosive eruption to the lava dome growth in eruption styles.

VS2/W/16-B3 0910

THE INFLUENCE OF FRAGMENTATION CRITERION ON EXPLOSIVE FLOW DYNAMICS IN HIGH-VISCOUS GAS-SATURATED MAGMAS

Oleg MELNIK (Moscow State University, Institute of Mechanics, 117192, 1-Mitchurinskii prosp, Moscow, Russia, email melnik@inmech.msu.su); Stephen Sparks (Earth Sciences, Bristol University, Wills Memorial Building, Queen's Road, Bristol, BS8 1RJ, UK, email Steve.Sparks@bristol.ac.uk).

The influence of the fragmentation criterion on the discharge rate of explosive eruption is studied by using unsteady 1D code. Mechanical model takes into account the existence of two different flow regimes - bubbly melt flow and gas-particle dispersion flow. They are separated by a fragmentation region, modelled by means of a discontinuity. To study the influence of fragmentation criterion the problem of initiation of explosive eruption by a lava dome collapse is considered.
Three different fragmentation mechanisms are studied: fixed volume concentration of bubbles before the fragmentation, fixed overpressure in the growing bubble due to the viscous resistance of surrounding melt and strain induced fragmentation. In the case of fixed volume concentration criterion the velocity of the fragmentation wave and discharge rate decrease monotonically and the eruption comes to a steady condition. In case of the two other criteria fragmentation occurs discretely in time. The fragmentation wave stops and magma rise without fragmentation occurs before the conditions become suitable for new fragmentation event. Each fragmentation event causes a pulse in discharge rate. Seismic data and observations for Soufriere Hills volcano explosive eruptions (1995-1998) shows the existence of pulses. The angular platy shapes of pumice ejecta in this eruption also supports a brittle fragmentation mechanism.

THE ASH PROBLEM: HYDRODYNAMIC VERSUS BRITTLE FRAGMENTATION

Bernd ZIMANOWSKI, Ralf Buettner, and Ines Caffier (all at Physikalisch Vulkanologisches Labor, Universitaet Wuerzburg, Pleicherwall 1, D-97070 Wuerzburg, Germany, e-mail: zimano@geologie.uni-wuerzburg.de); Kenneth Wohletz (EES-1, MS D462 Los Alamos National Laboratory, Los Alamos, NM 87545, USA, email: wohletz@lanl.gov)

The deposits of explosive volcanic eruptions are characterized by the abundance of ash-sized pyroclasts. Highly energetic eruptions produce a significantly high proportion of fine ash particles (diameters < 64 µm). Short time ("explosive") formation of such small particles (in contrary to a grinding process) requires particular fragmentation mechanisms. Currently two different models of fragmentation are generally considered, based upon the relationship between characteristic times for deformation and viscous relaxation; one were viscous relaxation is faster and magma deforms as a liquid, leading to hydrodynamic fragmentation modes; the other were deformation proceeds faster than viscous relaxation, leading to brittle-type fragmentation mechanisms. Combining experimental results and model calculations for the case of basaltic magmas the efficiancy of both mechanisms is compared and the requirements for the volcanic apparatus are discussed in respect to a satisfying physical explanation of the particle-size distributions of pyroclastic deposits.

EXPLOSIVE DYNAMICS AND RELATED PHYSICAL FEATURES OF PHREATOMAGMATIC DIATREMES, HOPI BUTTES, ARIZONA, USA

Jason HOOTEN (Geology Department, Northern Arizona University, Box 4099, Flagstaff, AZ, USA, email:jah23@dana.ucc.nau.edu); Michael Ort (Geology Department, Northern Arizona University, Box 4099, Flagstaff, AZ, USA, email: Michael.Ort@ nau.edu)

The Mio-Pliocene Hopi Buttes volcanic field, located in northcentral Arizona, contains approximately 300 individual vents. Within this region, nephelinite and monchiquite magmas were erupted into water-saturated sediments, resulting in a variety of hydrovolcanic features. Field study of the diatreme portion of these volcanic remnants reveals a consistent change in textural facies within varying levels of the exposed vent structures. At present, the diatremes are exposed 150 to 270 meters below the pre-eruptive surface. Confining pressures calculated for individual diatremes range from 11 to 30 bars, consistent with experimentally derived parameters for optimal explosive effectiveness within fuel-coolant interactions. Approximations of the initial water-melt ratios within individual explosive buds are also consistent with experimental values for mass water-melt ratios necessary for ideal thermodynamic efficiency. The outcrop geometry of many of the diatremes becomes increasingly tabular in shape with greater depth. This change in diatreme morphology is accompanied by a transition in vent facies deposits. Upper diatreme exposures containing massive, pelletal-textured tuffaceous breccias typically grade downward into hypabyssal aphanitic nephelinite or monchiquite. Inconsistencies between diatreme morphology, facies characteristics, and the current elevation of exposure suggest that the magnitude and/or duration of the eruption controls the boring depth of individual vents.

CONTRASTING FRAGMENTATION AND TRANSPORTATION DYNAMICS IN THE AGNANO MONTE SPINA ERUPTION (4.1 KA) AT PHLEGREAN FIELDS (SOUTHERN ITALY)

Pierfracnesco DELLINO and Luigi La Volpe (both at Dipartemento Geomineralogico, Universit=E0 degli Studi di Bari, Via E. Orabona 4, 70125 -Bari, Italy, email: dellino@lgxserver.uniba.it) Giovanni Orsi and Roberto Isaia (both at Osservatorio Vesuviano, Via Manzoni, 249, 80132 - Naples, Italy, email: orsi@osve.unina.it

Pyroclastic deposits of the Agnano - Monte Spina eruption have been studied, in order to define the fragmentation and transportation processes operating in the various phases of activity. The detailed analysis of structural and textural features of deposits has suggested that a complex and variable eruptive style has occurred during the eruption.
To unravel the complexities in the eruption dynamics, grain size and Scanning Electron Microscopy (SEM) data have been elaborated by means of multivariate statistical techniques of the type of Cluster and Factor analyses. Interpretation of results has lead to the distinction of end - member deposits due to pure magmatic activity, characterized by coarse pumice fragmentation and emplaced by plinian fallout dynamics, and end - member deposits due to pure hydromagmatic activity, characterized by fine ash fragmentation and emplaced by surge. Between the two end - members, deposits which show the contemporaneous presence of the two fragmentation dynamics have been recognized. Some of the latter are related to energetic and stationary turbulent and dilute surge flows, others to a complex interplay between ash surge flow with contemporaneous ballistic fallout. In this case vesiculated fragments derive from decompression processes occurring as a consequence of the hydromagmatic pulse.

VS2/W/13-B3 1050

THE PAGOSA PEAK DACITE, SAN JUAN VOLCANIC FIELD, COLORADO: A VOLUMINOUS FOUNTAIN-FED SILICIC PYROCLASTIC DEPOSIT RESULTING FROM BRITTLE MAGMA FRAGMENTATION AT LOW VESICULARITY

Olivier BACHMANN and Michael Dungan (Département de Minéralogie, Université de Genève, rue des Maraîchers, 13, 1211 GENEVE 4, Switzerland, email: bachmann@sc2a.unige.ch) Peter Lipman (U.S. Geological Survey, 345 Middlefield Rd, Menlo Park, CA, USA, email: plipman@mojave.wr.usgs.gov)

The Pagosa Peak dacite, a voluminous (200-300 km3) precursor to the enormous 28-Ma Fish Canyon Tuff, was erupted by pyroclastic fountaining and is associated with syn-eruptive block-faulting rather than caldera collapse. Pagosa Peak dacite deposits display a high aspect ratio (~1:50), evidence of rheomorphic flow, coarse granulometry (40-60 % of magmatic "blobs" up to 4 meters in diameter in a fine-grained matrix), and a lack of lithic fragments. Non-welded blobs are less vesicular (20-30 % ves.) than typical silicic pumices (~75 %). These unusual textures are interpreted as a reflection of a low-energy eruptive mechanism due to inefficient fragmentation. Analogous to process observed by Alidibirov and Dingwell (1996; Nature, vol. 380),fragmentation was probably triggered by brittle fracturing of the viscous magma at much lower vesicularities than the common bubble packing limit. Fracture propagation may have been provoked by shear stress, as a consequence of magma ascent in narrow conduits that opened during syn-eruptive block-faulting and subsidence of the magma chamber roof. This inefficient fragmentation mechanism, perhaps associated with partial degassing during relatively slow magma rise, resulted in a low altitude column that fed highly concentrated pyroclastic flows. Rapid emplacement and coarse granulometry maximized heat retention and allowed rheomorphic flow to occur.

VS2/E/02-B3 1110

THE INFLUENCE OF PYROCLAST GRAIN-SIZE DISTRIBUTION ON THE DYNAMICS OF COLLAPSING COLUMNS AND PYROCLASTIC FLOWS

Augusto NERI (Consiglio Nazionale delle Ricerche, Pisa I-56126, Italy, Email: neri@dst.unipi.it); Giovanni Macedonio (Osservatorio Vesuviano, Napoli I-80123, Italy, Email: macedon@osve.unina.it) Dimitri Gidaspow (Illinois Institute of Technology, Chicago 60616, USA, Email: gidaspow@charlie.cns.iit.edu) Franco Barberi (Dip. Protezione Civile, Rome I-00185, Italy)

A transient, two-dimensional, thermofluid dynamic flow model was developed to simulate the multiparticle and multicomponent nature of collapsing volcanic columns and pyroclastic flows. The model accounts for full mechanical and thermal non-equilibrium conditions between a multicomponent gas phase and N particulate phases representative of pyroclast distribution.

Pyroclast phases are characterized by specific physical properties such as diameter, density, specific heat, thermal conductivity, and viscosity. The partial differential equations representative of mass, momentum, and energy conservation of each phase were solved numerically on an axisymmetric physical domain. Three simulations were carried out by using different grain-size and gas compositions of the eruptive mixture at the vent. Six particulate phases were considered representative of pyroclasts ranging from a few microns up to a few millimeters in diameter, whereas tha gas phase consists of water vapor, carbon dioxide and air. Simulation results show that, with a constant vent diameter, mass flow-rate and water content, fine-grained particle distributions produce thicker and more mobile currents, larger runout distances, and a greater elutriated mass than the coarse-grained distribution.

VS2/E/13-B3 1130

PERIODIC VULCANIAN EXPLOSIONS AT MONTSERRAT (ANTILLES), AUGUST 1997

T. DRUITT (Magmas et Volcans UMR 6524 & CNRS, Clermont-Ferrand, France, and Montserrat Volcano Observatory, druitt@opgc.univ-bpclermont.fr); C. Harford, R. Herd, R., Luckett, B. Voight and others (Montserrat Volcano Observatory)

In August, September, and October 1997, there occurred 75 vulcanian explosions from the South Soufriere Hills lava dome. We present a quantitative analysis of the 11 eruptions that took place between 5 and 12 August, based on measured eruption column heights, video footage, ballistic data, and seismic signals. The August explosions occurred every 10 to 12 hours from a 300 m-diameter crater excavated in the dome. Each lasted several tens of seconds, followed by a waning phase of about an hour. The mass of magma erupted was in each case about 109 kg, with peak discharge rates of 1.5 to 2.5 x 107 kgs-1. Between 10 and 40 % of this mass collapsed back from 300 to 350 m above the dome to form thin, highly mobile pumice flows, which travelled as far as 5.5 km. The flows had initial speeds of up to 60ms-1, then decelerated to about 10 ms-1. The convective plumes reached heights of 9 to 14 km and exhibited superbuoyant behaviour, first decelerating, then re-accelerating as they rose. Eruption velocities were between 120 and 170 ms-1, and dense blocks 70 cm in diameter were thrown ballistically up to 1.7 km from the dome centre. Each explosion excavated the conduit to a depth of 1 to 1.5 km. The conduit was then re-filled at about 10 m3s-1 prior to the next explosion. Fragmentation during these eruptions occurred by a brittle spallation mechanism, producing platy pumice clasts. Application of theoretical models suggests fragmentation pressures in the range 3 to 15 MPa and gas contents of 1 to 1.5 wt%. The latter are consistent with bulk-magma water contents estimated from melt inclusion analyses and observed phenocryst contents. This implies that the magma lost little gas during ascent between eruptions and that the explosions were magmatically driven. External water played little role in these eruptions.

VS2/W/14-B3 1150

DYNAMICS OF THE JUNE 25 1997 PYROCLASTIC FLOWS OF SOUFRIERE HILLS VOLCANO, MONTSERRAT

COLE PD, (Dept of Geology, University of Luton, Luton UK, paul.cole@luton.ac.uk), Loughlin S C, (British Geological Survey, Edinburgh, EH9 3LE, UK, s.loughlin@bgs.ac.uk); Luckett R, (Montserrat Volcano Observatory); Sparks RSJ, (Dept of Geology, University of Bristol, Bristol BS8 1RJ, UK); Pyle DM (Dept of Earth Sciences, University of Cambridge CB2 3EQ, UK)

The June 25 1997 pyroclastic flows are some of the largest volume dome collapse events to have occurred during the current eruption. The flows had a total run out of 6.8 km from the dome, and surveys of the deposits indicate that a total of 5 x106 m3 of dome material was involved. Analysis of video, seismic and eyewitness evidence indicate that there were 3 separate flow pulses that occurred over a 20 minute period. Each flow pulse was more voluminous and energetic than the last. Seismic data allows identification of the onset of each flow pulse. Flow 1 was restricted to the confines of the valley with only minor surge spillage and had a maximum run out of 4.7 km and mean velocity of 15 m/s. Flow pulse 2, which began 2.6 mins after pulse 1, had a run out of 6.8 km and a mean velocity of 16 m/s. Flow pulse 3, which began 8 mins after the onset of pulse 2, had a mean velocity of 22 m/s. These estimates agree well with velocities calculated from superelevation of flow deposits in medial and distal regions of 20 m/s below Harris at 4 km and 8m/s at 5.8 km. Ash cloud surges detached from flow pulses 2 and 3 along the lower part of Mosquito Ghaut. Surges were particularly extensive with pulse 3, spilled west onto Farrells plain, climbing 60 m up Windy Hill indicating a velocity of between 35 and 37m/s at 2 km. The dilute ash cloud surge transformed into a dense pyroclastic flow moving a further 3.5 km out of the surge effected area down the Dyers River Valley. Calculations using the Chezy flow equation allow partitioning of flow volumes for each flow pulse. The volumes are: 6.5 x 105 m3 (Pulse 1), 1.55 x 106 m3 (Pulse 2), 3.8 x 106 m3 (Pulse 3).

VS2/W/03-B3 1210

CHANGE IN PARTICLE ORIENTATION AND SHAPE IN VOLCANIC BRECCIAS AS A FUNCTION OF TRANSPORT DISTANCE: A PHOTO-STATISTICAL METHOD

D. KARÁTSON and T. Telbisz (Eötvös University, Department of Physical Geography, 1083 Budapest, Ludovika tér 2, Hungary) O. Sztanó (Eötvös University, Department of Geology, 1085 Budapest, Múzeum krt. 4/a, Hungary)

Volcanic breccias, such as caldera collapse and lag breccias, block- and ash-flow deposits, and proximal facies of lahars, are investigated by a photo-statistical method. Photos of scaled outcrops from the Carpathians and Japan and some other regions, are scanned, and their fabric is analysed by image-processing and statistical softwares. Numbers of analysed particles, of millimetric to metric size, range from 300 to 1200.
For the orientation of particles, it is found that caldera collapse and lag breccias, with no significant transport, are almost randomly oriented. In contrast, the majority of particles in block- and ash-flow deposits very near (0.5-2 km) to the vent shows a parallel arrangement, corresponding to the inferred flow directions. This orientation is characteristic not only of longitudinal but also of oblique and plan-view sections. In some cases, clast imbrication is also observed.
In deeply eroded, collapsed lava dome products of the Miocene Börzsöny volcano in Hungary, massive or autobrecciated roots of domes pass upwards into coarse-grained breccias, probably proximal facies of block- and ash-flow deposits. These breccias show random particle orientation relative to more distal counterparts. Particles in these products tend to be more circular and less elongate than the further transported equivalents, perhaps due to the hot, viscuous initial fragmentation of the lava dome.

VS2/E/07-B3 1230

ERUPTION OF LAGUNA CALDERA BETWEEN 42,000-47,000 YEARS AGO

Sandra G. CATANE (National Institute of Geological Sciences, University of the Philippines, Diliman, Quezon City, Philippines, email: catane@phivolcs.dost.gov.ph); Ma. Carmencita B. Arpa (Philippine Institute of Volcanology and Seismology, C.P. Garcia Ave., Diliman, Quezon City, Philippines, email: carmen@phivolcs.dost.gov.ph)

Metropolitan Manila sits atop a landmass that was built up from a shallow marine environment mainly by deposition of voluminous pyroclastic materials. At least three episodes of calderagenic eruptions were dated: (1) 5,000 ybp, (2) 27,000-29,000 ybp, and (3) 42,000-47,000 ybp. These ruptions are associated with nearby caldera centers, Taal and Laguna. The earliest eruption (42,000-47,000 ybp) that is related to Laguna caldera had significantly altered the surrounding landscapes by reclaiming part of Manila Bay. The Laguna Lake, which was originally part of Manila Bay, became a separate body of water due to the deposition of voluminous pyroclastic deposits. Pyroclastic flows blanketed wide areas around the caldera and deposits reached as far as 70 km from the source.
The eruption produced a compositionally unique set of deposits – pumiceous units at the base, grading into mixed pumice-scoria deposits at the middle to scoriaceous varieties at the top of the sequence. SiO2 contents of juvenile clasts range between 54-64%. Texturally, the pyroclastic deposits vary from an unwelded base to strongly welded top reflecting possible changes in composition and volatile content or eruption mechanism. Pyroclastic flows were accompanied by surges but no distinctive plinian fall was recognized. It is likely that pyroclastic flows were fed not by a tall eruption column but rather by a low maintained pyroclastic fountain.

MONITORING OF MAGMA FRAGMENTATION BY ELECTRICAL FIELD MEASUREMENTS

Ralf Buettner and Bernd ZIMANOWSKI (both at Physikalisch-Vulkanologisches Labor, Universtaet Wuerzburg, Pleicherwall 1, D-97070 Wuerzburg, Germany, email: zimano@geologie.uni-wuerzburg.de); Helmut Roeder (Institut fuer Geophysik, Universitaet Stuttgart, Richard-Wagner-Straße 44, D-70184 Stuttgart, Germany)

Explosive volcanic eruptions are characterized by intensive magma fragmentation, which dominates the heat transfer from the magma and the conversion to mechanical energy. The fragmentation energy thus represents a proportional part of the total kinetic energy released during explosive volcanism. A method for the quantification of magma fragmentation during the eruption would allow direct measurement of the total kinetic energy release.
If a material gets fragmented on a short time scale its electrostatic equilibrium is disturbed by the formation of new surface. Expansion of the fragmented system results in fluctuations of the electrostatic field. Depending on the electrical properties of the fragmented material and the surounding media these fluctuations can be detected once a significant amount of new surface area is created. Based on these considerations a method was developed in the lab and successfully tested at Stromboli volcano (Sicily), which allows to distinguish and quantify different eruption styles during real time surveillance operation.

FRAGMENTATION BEHAVIOUR OF A LABORATORY ANALOGUE TO EXPLOSIVE MAGMATIC FLOWS

Graham A RYAN9 (1), Stephen J Lane (2), Jeremy C Phillips (3) (4) (Volcanic and Geohazards Research Group, Department of Environmental Science, Lancaster University Lancaster LA1 4YQ, UK); (3) (Centre for Environmental and Geophysical Flows, School of Mathematics, University of Bristol, University Walk, Bristol BS8 1TW, UK).

The rapid decompression of volumes of gum rosin organic solvent solution to varying degrees of supersaturation results in the generation of a foam flow. The liquid increases in viscosity as the volatile phase degasses in similar fashion to dehydrating magma. Flows of low supersaturation accelerate slowly and no fragmentation is observed. As supersaturation is increased fragmentation occurs and becomes more extensive. The most highly supersaturated flows generate several hundred foam fragments from a few 100 ml of starting solution. We present data on the number, size, velocity and acceleration of fragments from flows with a range of supersaturations. These data show that fragmentation does not take place at a discrete diameter 'fragmentation level'. Fragmentation begins with the development of gas pockets at the tube wall which grow to the of the tube as the foam deforms plastically. The detected increase in foam slug numbers with height in the tube indicates that fragmentation continues along the entire length of the tube. Foam fragments are observed to expand as pressure decreases up the tube, but most of the flow expansion takes place in the gas pockets between the foam slugs. Velocity measurements indicate that the flow is moving at close to sound speed.

FORMING OF BEZYMYANNYI PYROCLASTIC FLOWS, KAMCHATKA

Alexander I. MALYSHEV (Institute of Geology and Geochemistry, Urals Branch of RAS, Pochtovy per 7, Ekaterinburg, SU-620151, Russia, email root@igg.e-burg.su)

The field observations under forming of Bezymyannyi pyroclastic flows have shown that the movement of pyroclastic flows represents itself a complex self-organizing process. This process has a number of features, which are peculiar both to autoexplosive avalanches, and pyroclastic flows, but at the expense of scale effect more distinctly are traced during the directed paroxysmal eruptions of the volcano. The most essential features are the following. 1) Continuous subhorizontal and subvertical differentiation of moving pyroclastic particles on granulometric composition and the speed of movement under the influence of force of weight and energy of extending gases, including the newly formed at the expense of autoexplosivity effect. 2) The absence of the precisely expressed border between the heavier bottom part of a flow of heated pyroclastic particles, under which it is usually understood a proper pyroclastic flow, and the lighter top part, usually called the accompanying a pyroclastic flow "ash cloud". 3) Specific reaction of a flow of heated pyroclastic particles on the being expressed in the fact that the heavier parts of flow are moving in complete conformity with a relief of a district, and the lighter ones ignore this relief. After pyroclastic flow division into lighter and heavy parts the process of pyroclastic particles differentiation is going on. From the heavier part, of the flow deflected on relief, allocation of lighter and faster pyroclastic particles at once begins, and during the rectilinear movement of the lighter part of the flow in its basement at once it begins to be accumulated more coarse-fragmental material. 4) A long interval of time, during which the eruption of a flow heated pyroclastic particles, is going on. Therefore the deposits of final portions of heated pyroclastic particles sharply contrast with primary deposits of a catastrophic pyroclastic flow. These features cause a great variety of pyroclastic deposits.

ANALYSIS OF THE EVOLUTION OF THE ASH CLOUD FROM THE DECEMBER 26, 1997 (BOXING DAY) DOME COLLAPSE OF SOUFRIERE HILLS VOLCANO, MONTSERRAT USING GOES-8 IMAGERY

Ms. Gari C. MAYBERRY, (Michigan Technological University, Department of Geological Sciences, gcmayber@mtu.edu); Dr. Bill I. Rose, (Michigan Technological University, Department of Geological Sciences); Dr. Gregg Bluth, (Michigan Technological University,Department of Geological Sciences)

There have been many serious incidents of aircraft encountering volcanic clouds in the past. By studying volcanic clouds we can monitor their paths, as well as learn more about their evolution, in an effort to mitigate the hazard they pose to aircraft.
The December 26, 1997 dome collapse of Soufriere Hills volcano, Montserrat resulted in a pyroclastic flow that descended the White River Valley ~4km and traveled across the sea an unknown distance. The slope failure and subsequent dome collapse occurred around 0700Z and lasted approximately 15 minutes and an associated volcanic ash cloud rose to an altitude of 47,000 ft. (14.3 km). The volcanic cloud was observed by the geostationary (GOES-8) satellite every 30 minutes, which resulted in a comprehensive record of its evolution. Seventeen images of the volcanic cloud, between 0715Z and 2345Z, were analyzed. The brightness temperature difference (BTD) between bands 4(10.3-11.3 microns) and 5 (11.5-12.5 microns) of GOES-8 was used to distinguish the ash cloud from meteorological clouds. Ash clouds have a negative BTD while meteorological clouds have a positive BTD (Prata, GRL 16: 1293-1296, 1989). BTD data are used to map the volcanic cloud and retrieve basic data about the area of the cloud, mass of the fine ash particles (<10 microns radius), and the optical depth (Wen and Rose, JGR 99:5421-5431, 1994).
The volcanic cloud moved rapidly 20-28 km/hr to the south east until around 1145Z when it became more transparent and began to dissipate. The largest band 4 optical depth (~3) occurred at 0745Z, shortly after the eruption began, and rapidly decreased to about .3 less than 2 hours after the onset of the eruption. From about 0845Z to 1045Z the ash signal of the volcanic cloud was obscured by "masking", which was caused by a cloud of liquid water droplets with a positive BTD. The cloud with the positive BTD may have overlain or mixed with volcanic cloud, which obscured negative BTD values of the ash cloud. We speculate the water-rich cloud was the result of the interaction of the pyroclastic cloud with the sea, and its subsequent rise and interaction with the volcanic cloud.

BEHAVIOUR OF GASES DURING ERUPTIONS OF BEZYMYANNYI VOLCANO

Alexander I. MALYSHEV (Institute of Geology and Geochemistry, Urals Branch of RAS, Pochtovy per 7, Ekaterinburg, SU-620151, Russia, email root@igg.e-burg.su)

In the report the results of field observations under the behaviour of gases during eruptions of a volcano Bezymyannyi are considered. All the variety of character of historical eruptions of Bezymyannyi is determined by a mode of expansion of gases. Two groups of eruptions are singled out. The eruptions of the first group correspond to an avalanche degassing of a juvenile material, original wide-ranging break of gases. The character of eruptions of the second group is defined by relatively quiet expansion of gases inside the juvenile material. Four types of degassing processes are fixed: a) degassing of the juvenile material occurs at the expense of migration of gases on long-living zones of the increased cracking in construction of a volcano; b) allocation and quiet expansion of gases inside magma; c) autoexplosive degassing; d) degassing during the provoked explosivity. Dynamics of explosive eruptions of Bezymyannyi is determined mainly by autoexplosivity, that is the avalanche degassing of the juvenile material on decompression cracks. High pressure of gases causes the formation of the crack itself, or even of the whole system of the branching cracks extending deep into the aerated and viscous juvenile material. Along the surface of these cracks there is a fragmentation of the juvenile material, and from the surface of cracks deep into the juvenile material it occurs the spreading of a wave of splitting. The gas, extending on cracks, with the seized particles of splitting is taken out on a surface as gas-ash emissions. During intensive receipt on earth surface of the viscous, high-temperature and gas-saturated juvenile material this phenomenon occurs in mass scale and amplifies at the expense of the provoked explosivity. These processes result in an intensive fragmentation of the juvenile material and the formation of pyroclastic flows.

A MODEL OF THE INTERACTION OF A FISSURE ERUPTION WITH A HORIZONTAL TUNNEL

Andrew WOODS and Steve Sparks, Centre for Environmental and Geophysical Flows, University of Bristol, Bristol, England (e-mail a.w.woods@bris.ac.uk); Chuck Connor and Brittain Hill, Centrefor Nuclear Waste Regulatory Analysis, Southwest Research Institute, San Antonio, Texas (e-mail cconnor@swri.edu)

We describe a series of calculations aimed at quantifying the activity which might result when an ascending dike intersects a horizontal tunnel at atmospheric pressure. This allows the magma to decompress rapidly down the tunnel. We examine both water poor basaltic magma, assumed to be incompressible and water-rich basaltic magma (2-3%) as two end member models.The motion of volatile poor magma along the tunnel involves driving pressures up to 10-100 atmospheres and so the magma will advance along the tunnel at speeds up to tens of metres per second. The motion of a volatile rich magma initially produces an expansion wave propagating down the tunnel. We predict that a shock wave develops in the air ahead of the expanding mixture, with a pressure jump across the shock as large as several atmospheres. The fragmented magma-volatile mixture following the shock moves with speeds up to 100-150 m/s. Once the shock wave reaches the end of the tunnel, it is reflected and the pressure in the tunnel gradually builds up. This model of magma behaviour in a horizontal tunnel will be used to constrain the consequences of basaltic volcanic activity, should an eruption occur within the proposed Yucca Mountain, Nevada, high-level radioactive waste repository. This waste storage facility is located within a basaltic volcanic field and is required to isolate radioactive waste in tunnels during its projected 10,000 yr performance period.

CHARACTERIZING THE SHAPES OF PYROCLASTS IN DISTAL FALLOUT MATERIAL TO IMPROVE OUR UNDERSTANDING OF FALLOUT RATES AND TRANSPORT

C M RILEY, G J S Bluth, W I Rose (All at: Geological Engineering and Sciences, Michigan Technological University, Houghton, MI, 49931, email: cmriley@mtu.edu)

A significant hazard from large-scale volcanic eruptions is ash which can be transported great distances and deposit irregularly and in unusually thick amounts far from the volcanic source. One influence on volcanic ash transport is particle shape which affects the aerodynamic properties responsible for particle separation and fallout, the interaction of particles with the atmosphere, and remote sensing measurements of ash particle concentrations. The main objectives of this study are to characterize the shape and determine terminal settling velocities for ash particles so that these data can be used to improve transport models and remote sensing algorithms. A total of 1,300 andesitic ash particles were measured from the August 1992 Spurr eruption. The majority of particles are subrounded silicate pumice fragments, with < 10% glass bubble-wall shards. Size distribution data for the sample show the sample is bimodal, which indicates aggregation played a role in fallout. In general, actual mean diameters for each settling velocity group were larger than expected if the particles were assumed spherical. We show that this is due to particle shape influences rather than density effects. The larger than expected diameters for particles in given terminal settling velocity groups suggests that the irregular shape of these particles decreases their settling rate. This is at odds with current transport modeling results which show that particles fall out faster than expected and suggests that another factor such as aggregation may be of greater importance in the fallout of andesitic particles. The Spurr particles are representative of vulcanian to subplinian andesitic eruptions but are unlike more irregular-shaped rhyolitic particles often formed in plinian eruptions.

PRODUCTION OF EXPERIMENTAL PYROCLASTS BY EXPLOSIVE VESICULATION OF A VISCOUS LIQUID

Jon BLOWER (email Jon.Blower@bris.ac.uk), Heidy Mader (emailH.M.Mader@bris.ac.uk); Jeremy Phillips (email J.C.Phillips@bris.ac.uk);(Department of Earth Sciences, Wills Memorial Building, Queens Road, Bristol BS8 1RJ, UK)

In recent years, the study of explosive two-phase flows in the laboratory has revealed much information about the processes operating in a volcanic conduit during an eruption. The experiments discussed here use a solution of gum rosin in acetone (GRA) as an analogue for hydrated magmas. The dependence of the GRA liquid viscosity on its volatile (acetone) content reproduces the dependence of magma (rhyolite) viscosity on its water content. The diffusivities of the corresponding volatile species (water and acetone) are comparable in magnitude. When decompressed from atmospheric pressure to a partial vacuum in a shock-tube, the GRA solution vesiculates into a rapidly-evolving two-phase flow. Under certain experimental conditions the flow may fragment, producing solid foam fragments, which are analogous to volcanic pumice.
Results are presented from a series of experiments in which a range of liquid viscosities and volatile supersaturations are investigated, and a variety of degassing behaviours observed, from gentle boiling to explosive disruption of the liquid. Where solid foam is produced, its vesicularity (volume expansion) is observed to be primarily dependent on the viscosity of the parent GRA liquid, with the volatile supersaturation having a more minor effect. Bubble coalescence and the development of permeability within the foam are also major controls on its expansion. The production and preservation of strained vesicles in the foam is facilitated by high strain rates in the flow and high liquid viscosities. The velocity of the flows (measured from video camera footage) is dependent on both the liquid viscosity and the volatile supersaturation. The fragmentation of the liquid is thought to be ductile, occurring through progressive thinning of bubble walls and bubble coalescence. Bubble growth occurs largely through decompressional expansion, with diffusional mass transfer being less important. Currently in progress is a more detailed comparison of the internal textures of both the experimental pyroclasts and natural pumices. These are related to eruptive processes. The dynamic evolution of the foam is also under close study using high speed cine photography.

SEDIMENTOLOGY OF THE BLAST SURGE DEPOSIT OF DECEMBER 26TH 1997, SOUFRIERE HILLS VOLCANO, MONTSERRAT

L.J.RITCHIE and P.D.Cole (both at the Centre for Volcanic Studies, Department of Environment, Geography and Geology, Luton University, Park Square, Luton, LU1 3JU); R.S.J.Sparks (Department for Earth Sciences, Bristol University, Bristol, BS8 1RJ)

On 26th December 1997, sector collapse of the Soufriere Hills lava dome resulted in a debris avalanche with subsequent generation of a valley confined pyroclastic flow and associated destructive pyroclastic blast type surge which devastated an area of 9.2km2.
The blast surge deposit is characterised by a sandy, fines-rich layer typically overlying a coarser, fines-poor layer, capped by an accretionary lapilli fallout layer. Strong lateral facies variations occur over a wide range of scales with metre scale transitions strongly influenced by topography. The deposit fines and thins rapidly with distance from source. Proximally, extreme lateral facies variations occur with local low angle hummocky breccia sheets being developed. Evidence exists for at least two separate surge/ blast events. Sharp marginal boundaries strongly related to topography delimit a coarse-grained flow deposit on the upper surface which corresponds to the second blast event.
Grainsize analyses show good facies distinction and median diameter v sorting correlations. Evidence indicates that particle size sorting occurred during explosive expansion of the collapsing lava dome such that the resulting surge cloud initially was graded in both size and density. Strong lateral and vertical variations in grainsize indicate further efficient sorting during transport. Experimental modelling of grainsize and density segregation is in progress.

CONSTRAINTS ON SHALLOW BASALTIC SUBVOLCANIC CONDUIT DIMENSIONS

Brittain HILL, Charles Connor (CNWRA, Box 28510 San Antonio TX USA 78228, bhill@swri.edu), Philip Doubik (State University of New York, Buffalo NY USA 14260)

Shallow (0–2 km) subvolcanic conduit dimensions are important parameters for many eruption process models. Xenoliths from the 1975 Tolbachik (Kamchatka) violent strombolian basaltic eruption constrain changes in conduit dimensions through time. Early phases of the Cone 1 eruption sustained 6-12 km tephra columns, with fall deposits containing 0.001-0.01 vol% crustal xenoliths from Quaternary volcanic (0-1 km deep) and Tertiary sedimentary (1-4 km) rocks. Later eruption stages produced both lavas and 2-5 km high tephra columns, with 0.01-1 vol% xenoliths in falls. The 3x10^5 m^3 (DRE) of xenoliths in Cone 1 juvenile falls represents a cylindrical conduit 15 m in diameter and 1.7 km deep. Simultaneous eruption of tephra and lava suggests an annulus of degassed magma adhered to conduit walls, enhancing entrainment; little entrainment occurred early in an apparent droplet flow regime. The Cone 1 eruption ended with 12 hr of hydromagmatic tephra falls containing 3x10^6 m^3 (70 vol%) xenoliths. The conduit must have widened from 15 to 48 m to produce this xenolith volume.
Subvolcanic conduits in the 4 Ma San Rafael field (USA) are exposed at about 1 km paleodepths. Surveyed conduits (12) range from 2-m diameter buds along dikes with little wall-rock disruption, to 60-m wide cylindrical plugs with variable degrees of wall-rock brecciation and xenolith entrainment. Brecciated conduit margins to 5 m thick appear analogous to annular flow regimes at Cone 1. Several larger conduits, however, have a 0-6 m xenolith-poor annulus with 10-40 m inner core of extensive xenolith breccias and pervasive low-temperature hydrothermal alteration. These conduits appear analogous to late-stage hydromagmatic events at Cone 1. Conduit diameters 40-60 m also occur with relatively low amounts of xenoliths, suggest these eruptions lacked hydromagmatic activity. Models of basaltic cinder cone eruptions should consider subvolcanic conduit diameters on the order of 10-60 m in evaluating mass-flow processes.

AN EXPERIMENTAL APPROACH TO QUANTIFYING THE RHEOLOGY OF VESICULATED MELTS

Ed LLEWELLIN and Heidy Mader (both at Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queens Rd, Bristol BS8 1RJ, UK, e-mail: ed.llewellin@bristol.ac.uk)

Vesiculated flows are ubiquitous in nature. They are known to be non-Newtonian, strongly visco-elastic and subject to breakdown. Whilst some information on the properties of foams and bubble suspensions with very large and very small gas volume fraction is available, the rheological properties of bubble suspensions with gas volume fraction in the geologically important midrange (25-75%) have not been quantified. This represents a serious impediment to the understanding of shallow and surface volcanic processes, especially the multiphase flow of gas and liquids in the upper conduit during explosive and effusive eruptions.
Work is in progress to study the flow properties of foams and bubble suspensions using analogue fluids. Golden syrup foam with intermediate gas volume fraction and bubble size distribution is made using a commercial aerator. The bubble size distribution is determined using a specially-designed cell and image recognition software. Oscillatory viscometry techniques are used to measure the flow properties; a sample of the foam is subjected to a sinusoidally varying shear stress over a range of amplitudes. The strain rate thus induced in the sample also varies sinusoidally but with a phase shift relative to the stress, the magnitude of which depends on the relative importance of the viscous and elastic properties of the foam allowing the two effects to be separated. The amplitudes are chosen to be small enough that the foam is not destroyed by the testing, ensuring that the results are repeatable.
This poster describes oscillatory viscometry, the techniques used for making the foams and measuring bubble size distribution and presents preliminary data relating the viscous and elastic components of deformation to the shear stress applied and the gas volume fraction of the foam. Future work will be carried out using larger net strain and strain rates to explore the parameters which cause the fragmentation of the foams.

CONTRASTING ERUPTION MECHANISMS OF COGENETIC, LARGE-VOLUME IGNIMBRITES FROM THE LA PACANA CALDERA, NORTH CHILE

Jan LINDSAY, Axel Schmitt and Robert Trumbull (GeoForschungsZentrum Potsdam, Division 4.2, Potsdam, Germany, email kiwi@gfz-potsdam.de)

Pre-eruptive H2O contents and pumice characteristics of two large-volume ignimbrites (combined minimum volume 1,700 km3) from the La Pacana caldera imply different eruption mechanisms. Pumices in the caldera-forming dacitic Atana ignimbrite are dense and crystal rich (35–45% crystals). This ignimbrite occurs as a homogenous single flow unit, and lacks a basal plinian. It overlies the rhyolitic Toconao ignimbrite, which is characterised by distinctive, crystal-poor (<1% crystals) tube pumices, and which has a very thin basal plinian. Stratigraphy and pumice chemistry indicate that these units erupted from a zoned magma chamber. A minimum pressure of 200 MPa is inferred from mineral barometry. The Toconao magma was cooler (735°C) and more volatile rich (6 wt.% H2O) than the Atana magma (790°C; 2-3 wt.% H2O), and represents the evolved cap of the chamber. Calculated viscosities are distinct for the Toconao and Atana magmas (106 and 108 Pa s respectively).
The contrast in physical characteristics of these two magmas is a function of crystallinity and volatile content. Toconao tube pumices reflect eruption of a relatively viscous, almost aphyric magma, whose high pre-eruptive H2O contents facilitated eruption by volatile oversaturation, and sustained a plinian column. In contrast, magmatic water in the Atana was probably too low to build up a critical overpressure in the magma chamber, as the Atana melt was at best only close to H2O saturation at inferred pre-eruptive conditions. An external mechanism is therefore needed to trigger eruption of the Atana magma.

MAGMA FRAGMENTATION DURING THE PLINIAN PHASE OF THE MINOAN ERUPTION (SANTORINI, GREECE), AS INFERRED BY DEPOSIT FEATURES AND PYROCLAST TEXTURES

Jacopo TADDEUCCI (Dottorato di Ricerca, Dipartimento di Scienze della Terra, Università "La Sapienza", P.le A. Moro 5, 00185, Roma, Italy. Email: jac.punny@iol.it), Kenneth Wohletz (EES-1 MS D462, Los Alamos National Laboratory, Los Alamos, NM 87545, USA. Email: wohletz@lanl.gov)

Pyroclastic deposits result from a combination of eruptive and transport processes. In study of the Minoan Tephra we describe features of the pumice fall deposit that allow us to distinguish transport from fragmentation effects. A 6-m-thick pumice fall deposit, corresponding to Phase 1 products of the Minoan eruption, as identified by previous workers, shows three interlayered ash flow beds as thick as 10 cm near its top. We collected samples from the base to the top of the section at an intervall of 40 cm for the first 5 m, and every 5 cm in the top portion, which includes the flow break. Laboratory studies comprise granulometry with application of the Sequential Fragmentation/Transport theory (SFT), componentry, pumice morphology and crystallinity determination. In addition we use grain-size distributions of artificially broken pumices (of the same deposit) for control and comparison. Concerning the transport process, normal grading of pumices and lithics from the base of the deposit to the ash flow break, and reverse from there to the top, is assumed to record a cycle of column waning before and then waxing after the ash flow break. Transport sorting of pumice and ash at the sample locality is considered to be rather limited because of i) poor sorting coefficient (1-2.7 Phi units) in comparison to other fall deposits, and ii) strong similarity between the size distributions of the artificial shards and of the fall deposit, suggesting that the size distribution of the deposit mainly reflects the fragmentation mechanism and only slightly that of transport. As for the fragmentation mechanism, a development factor, based on SFT parameters of the size distribution, decreases upward from the base of the deposit to the flow break, indicating an increasing efficiency but shorter duration of the fragmentation process. Free crystals are released from the magma through fragmentation process, so the observed increase in the ratio of free crystals content of the deposit vs. crystal content of the pumices confirms a better fragmentation toward the flow break.

MULTI-PHASE THERMOFLUID AXISYMMETRIC TRANSIENT DYNAMIC MODELING OF THE AUGUST 1997 VULCANIAN EXPLOSIONS AT SOUFRIERE HILLS VOLCANO, MONTSERRAT: INITIAL CONDUIT CONDITIONS AND PROFILES AND THEIR INFLUENCE ON NEAR-VENT MODEL RESULTS

A.B. CLARKE (Penn State University, Department of Geosciences, University Park, PA 16802, USA; 814-863-3965; email: aclarke@geosc.psu.edu); A. NERI (CNR-CSGSDA, Department of Earth Sciences, Pisa, Italy); B. Voight (Penn State University); G. Macedonio (Osservatorio Vesuviano, Napoli, ITA); T.H. Druitt (Universite Blaise Pascal, Departement des Sciences de la Terra et URA 10, Clermont-Ferrand, France)

Between August 4 and 12, 1997 at the Soufriere Hills Volcano, Montserrat, 12 discrete, relatively short-duration (tens of seconds) vulcanian eruptions occurred through the andesite dome complex. These eruptions were characterized by an early phase of axisymmetric ballistic throw-out, followed by fountain collapse that sent predominantly pumiceous pyroclastic flows radially from the crater to distances of several km, and by rise of convective plumes to altitudes from 9 to 14 km. We and staff members of the Montserrat Volcano Observatory closely documented the eruptions with photographs, video footage, observation and instrumentation. Previously determined estimates of conduit diameter and magma temperature were used in conjunction with ballistic ranges and angles, pumice vesicularity, and estimated DRE volumes to calculate the length, pressure, and solid/gas volume fraction at the top of the conduit prior to the explosions. Using these well-constrained basic conduit parameters, we have modeled the conduit in several different ways. Models vary from simple to complex, the latter incorporating non-linear gas solubility laws, non-linear viscosity variations, which result in non-linear pressure variations with depth, and losses due to cap rock fracture and fragmentation of magma. Coupling of these conduit models, which provide initial conditions, with a transient multi-phase thermofluid dynamics model allows simulation of the transient, short-pulse eruptions of the Soufriere Hills volcano in 1997. Effects of axisymmetric simplifications are minimized near the event, thus this region is addressed here, although further modeling will explore evolution of phenomena beyond this region. Good qualitative agreement occurs between the observed eruptions and results of some models. Certain models simulate reasonably well important aspects of plume generation, such as behavior and timing, the near-vent cloud shape, and the separation of the cloud into collapsing mixture and convective plume.

THE 1983 ERUPTION OF COLO VOLCANO, UNA-UNA ISLAND, INDONESIA

Raffaello TRIGILA (1) (trigila@axrma.uniroma1.it), Aida M. Conte (2), Carmela Freda (2), Danilo M. Palladin (1), PierGiorgio Scarlato (4), Jacopo Taddeucci (3) (1) Dipartimento di Scienze della Terra, Università "La Sapienza", P.le A. Moro 5, 00185 Roma, Italy); (2) (C.N.R. - C.S.E.S.M.R. c/o Dipartimento di Scienze della Terra, Università "La Sapienza", Roma, Italy); (4) (I.N.G., V.di Vigna Murata 605, 00143 Roma, Italy; (3) Dottorato di Ricerca, Dipartimento di Scienze della Terra, Università "La Sapienza", Roma Italy)

From July 18 to October 9, 1983, after a repose period of 85 years, an eruption of the Colo Volcano, comprising at least sixty explosive phases, devastated the island of Una-Una, Sulawesi, Indonesia. The eruptive products include a decimeter-thick pumice fall horizont, diffuse ash fall and channellized, massive, lithic-rich pyroclastic flow deposits with associated lahar and alluvial deposits. On the basis of field evidence, grain-size, componentry and SEM data, the eruption dynamics is interpreted in terms of an early climactic, Plinian-type eruptive phase and a number of Vulcanian-type ash explosions characterizing the following activity phases. The eruption, triggered by strong earthquakes with epicenters situated nearby, was initially driven by the volatile pressure increase in a dacitic, crystal rich, water-saturated magma body under closed system conditions. Later on, the magma interaction with external water become a major process responsible for magma fragmentation and repeated, short-lived explosive phases. Crystallization experiments and thermodynamic calculations indicate the magma body crystallizing conditions were approaching 3 km depth; T= 900° C and 3.5 wt% dissolved water content.

THE EVOLUTION OF KOKO CRATER TUFF CONE AND KAHAULOA TUFF RING, O'AHU, HAWAI'I AND THE FACTORS INFLUENCING CONE VERSUS RING GENERATION

Ian SKILLING (Department of Geology, Rhodes University, Grahamstown, South Africa, email: ips@rock.ru.ac.za)

Kahauloa tuff ring and Koko Crater tuff cone are two immediately adjacent craters which were erupted on the Koko fissure in SE O'ahu about 30000yrs ago. A detailed facies model and stratigraphy is presented. This combined with SEM and petrographic study suggests that Koko was erupted in an open water, relatively sand-free environment but Kahauloa was erupted in a littoral environment with abundant sand. Koko is dominated by "Surtseyan" wet fall deposits and their redeposited equivalents, whilst Kahauloa comprises mostly "Taalian" base surge deposits. Interaction of magma with wet sand rather than water alone may have generated more bouyant eruption plumes and a ring rather than a cone. Alternatively, the fact that surge events at Kahualoa are nearly always preceded by "vent-clearing" blocky fall deposits, suggests that a "closed" vent may have been a factor in the generation of rings rather than cones. The very close proximity (both spatially and temporally) of both craters probably implies that the subsurface hydrology was similar, though hydrological influences on cone versus ring generation cannot be excluded "U-shaped" erosion channels were first described from Koko by Fisher (1977) and attributed to surge erosion. There is little evidence of this at Koko or Kahauloa, were channels and scours appear mostly to have been formed by steep-slope stream drainage, either by cold water and/or hot water condensed from steam during accretionary lapilli-forming events.

BASALTIC MAGMA FRAGMENTATION MECHANISMS WITHIN MUDDY TO SANDY WET SEDIMENTS: A TEXTURAL STUDY OF PEPERITES FROM WELGESIEN, SOUTH AFRICA

Ian SKILLING (Department of Geology, Rhodes University, Grahamstown, South Africa, email: ips@rock.ru.ac.za)

Basaltic peperitic clasts occur within laharic debris flows at Welgesien, South Africa and were examined using SEM and optical microscopy. The basalt was degassed (or was volatile-poor) prior to visco-plastic laminar to convolute mixing with wet muddy to sandy lacustrine sediments, at depths <200m below the palaeosurface. Peperitic textures are almost entirely due to magma interaction with external water in sediment pore space. The peperites preserve an end-member process of magma-water interaction, without the additional factor of accompanying expansion of juvenile volatiles. Basaltic magma laminae or tendrils were fragmented into individual globules or strings of globules by local vesiculation of sediment trapped between areas of magma. Magma fragmentation was essentially a non-explosive process. Peperites are important rocks for the study of magma fragmentation mechanisms as they preserve aspects of the behaviour of the coolant during fragmentation. SEM-scale study is essential to understand the initial stages of magma fragmentation in particular. The importance of such essentially in-situ, fragmentation of magma prior to eruption is not clear, and has important implications for the interpretation of eruption mechanisms from the study of vitriclast morphologies.

SEQUENCE AND ERUPTIVE STYLE OF THE 1783 ERUPTION OF ASAMA VOLCANO, CENTRAL JAPAN - A CASE STUDY OF AN EXPLOSIVE ERUPTION OF HETEROGENEOUS, ANDESITIC MAGMA

MAYA YASUI (Dept. of Earth Sciences, Nihon University, 3-25-40, Sakura-josui, Setagayaku, Tokyo 156-8550, JAPAN, email: yasui@peacock.iis.chs.nihon-u.ac.jp); Takehiro KOYAGUCHI (Earthquake Research Institute, University of Tokyo, 1-1-1, Yayoi, Bunkyoku, Tokyo 113-0032, JAPAN, email: tak@eri.u-tokyo.ac.jp)

The 1783 A.D. eruption of Asama Volcano, central Japan is characterized by diverse modes of eruption, abundant eruptive units and a wide variety of petrological heterogeneities. Main events occurred on the last four days in its three-month activity. After 2 August, plinian pumice falls and pyroclastic flows generated alternatively. The climactic phase was initiated with the most intense plinian eruption in the evening of 4 August and followed by generation of pyroclastic flows. A pyroclastic cone built up near the vent associated with the fountaining from the plinian eruption column and it rapidly grew during the climax of the plinian phase. The pyroclastic cone rose out on the steep outer slope of pre-existing volcanic edifice generating clastogenic lava flows. Small-scale pyroclastic flows which originated from partial collapse of the cone occurred as minor events. Bulk rock chemical composition of the 1783 eruptive products range from 60 to 64 wt. % in SiO2 content. Essential materials of pumice fall deposits is more silicic (typically 63 wt. % SiO2) than those of pyroclastic flow deposits (61% SiO2), and the lava flow has intermediate composition (62% SiO2). The groundmass of the essential materials show compositionally heterogeneous features (e.g. banding or eutaxitic texture) in both hand-specimen scale and microscopic scale. Evidence of magma mixing such as disequilibrium mineral assemblages is common. Phenocrysts in the heterogeneous essential materials are commonly fragmented, which suggests that each essential material experienced repetitive disruption and coalescence during ascent. The complex features of heterogeneity of the 1783 eruptive products can be explained by the following four processes; 1) compositionally zoned magmas were produced before the eruption in a magma chamber, 2) the zoned magma mechanically mingled together within the conduit during magma evacuation, 3) fine-scale heterogeneous texture resulted from repetitive disruption of coalescence of the co-mingled pyroclasts, and 4) these heterogeneous features were further modified by welding and/or secondary flowage after emplacement; partial collapse of densely welded part of the pyroclastic cone resulted in highly homogenized clastogenic lava flow of intermediate composition.

FLOW PATTERNS OF OVERPRESSURED VOLCANIC JETS

Tomaso Esposti Ongaro (Universita' di Pisa and Consiglio Nazionale delle Ricerche, Pisa I-56126, Italy, Email: ongaro@dst.unipi.it) Augusto NERI (Consiglio Nazionale delle Ricerche, Pisa I-56126, Italy, Email: neri@dst.unipi.it)

Volcanic jet dynamics were investigated by using a transient, two-dimensional, and two-phase flow model. The model accounts for mechanical and thermal non-equilibrium between a gas phase and a solid particulate phase representative of pyroclasts. The model equations were solved by a numerical technique able to treat both subsonic and supersonic flows as well as shock waves. Simulation results describe the formation of a vertical jet leaving a vent and expanding by decompression into a volcanic crater. Several simulations were carried out by using different conduit exit conditions and crater geometries. Two types of flow patterns were recognized in good agreement with laboratory experiments. According to the first, decompression and compression waves are repeatedly reflected along the jet axis and boundary. Such a flow pattern appears to be steady and favored by smaller overpressures and crater opening angles. The second flow pattern exibits a Mach reflection normal to the axis of the jet with the formation of a compressive shock and tangential slip lines. The resulting flow configuration appears to be quite transient and able to produce some instability of the jet. The Mach reflection pattern is obtained with higher overpressures of the jet as well as greater opening angles of the crater.

NEAR VENT AND VENT FILLING PYROCLASTIC BRECCIA DEPOSITS OF AN ERODED TUFF RING COMPLEX AT PIGROOT HILL, CENTRAL OTAGO, NEW ZEALAND

Karoly NEMETH. (Geology Department, University of Otago, PO Box.56., Dunedin, New Zealand, email: karoly.nemeth@stonebow.otago.ac.nz)

The Pigroot Hill is located in Central Otago (Dunedin Volcanic Complex), and is primarily built up by basic volcaniclastic and lava rocks formed between 16-12 Ma. In the lower level of the hill, near vent, subaerial, base surge and fall out beds are exposed, and covered by late Hawaiian spatter deposits with large spindle bombs and small clastogenetic lavaflows. The top of the hill is built up by late lava flows and dikes mostly olivine basaltic and atlantite composition. Alongside dikes, remnants of explosion sites are identified. In south, explosion breccias are exposed in 5 well distinguished area with a former collapsed tuff ring rim. Fall out and base surge beds unconformably underlie the coarse grained vent breccia pipes and interpreted as near vent phreatomagmatic deposits of a former tuff ring. The bedded tuff contain large number of features characteristic of base surge origin such as dune bedding, unsorting, undulatory bedding, impact sags, accidental lithics. The bedding clearly indicates sliding and collapse events in near vent position. The juvenile fragments are altered sideromelane glass with highly vesiculated tachylite suggesting phreatomagmatic explosive interaction between subsurface water and uprising magma in shallow level. Large number of angular dense, crystalline fragments represent disrupted clasts from previous volcanic sequences from deep subvolcanic region. Above the bedded lapilli tuff, a coarse grained pyroclastic breccia occur.The breccia consist of large fluidal, vesicular and crystalline, dense olivine basaltic fragments. Cored bombs, irregular shaped, baked mudstone and large limonitic sandstone blocks, small fragments of tuff and deep excavated schist are also common. The well defined distribution of the pyroclastic breccia, the facies relation with the lower bedded lapilli tuff, and the common relation with dikes suggest local explosion pipes where the uprising melt interacted with limited water.

COMPLEX COMPOSITIONAL ZONATION IN AN IGNIMBRITE FLOW-UNIT FROM LOS HUMEROS CALDERA, MEXICO

Gerardo CARRASCO-NUNEZ (Unidad de Investigacion en Ciencias de la Tierra, Instituto de Geologia, Campus Juriquilla, UNAM, Apdo. Postal 1-742, Queretaro, Qro. 76230, Mexico. email: gerardoc@conin.unicit.unam.mx); Michael J. Branney (Department of Geology, University of Leicester, University Road, Leicester LE1, 7RH, United Kingdom, email: MJB26@leicester.ac.uk)

Compositional zoning is a common feature of moderate-to-large volume ignimbrites. Several become more mafic with height, a feature thought to record progressive eruptive withdrawal from a compositionally stratified agma-chamber, with the eruption progressively tapping deeper, denser parts of the chamber. A single flow unit of the 0.1 Ma Zaragoza ignimbrite (ca. 12 km3), in eastern central Mexico, shows unusually complex zonation. Its eruption was accompanied by collapse of Los Potreros caldera, located within the larger Los Humeros caldera (Ferriz and Mahood, 1984). Around 16 km S of Potreros caldera, a basal plinian pumice-fall layer, < 20 cm thick, is overlain by thin surge and flow deposits, totalling < 20 cm-thick, and these are overlain by a single massive ignimbrite flow unit, 15 m thick. The ignimbrite is non-indurated, and generally shows an upward increase in the maximum and mean sizes of pumice lapilli, together with a decrease in sorting.
The colour of the ignimbrite changes gradationally upwards, from white at the base through to grey, purple (middle part), pink to yellow at the top. Apart from local oxidation effects, the colour changes correlate in general with changes in the proportion of at least four different types of pumice clast: white and pale-brown rhyodacite pumice (67-68 % SiO2),brown-orange and grey dacite pumice (64 66 % SiO2), black and dark-greyandesite pumice (58-61 % SiO2), and banded (magma-mingled) pumices. The basal part of the deposit comprises entirely rhyodacite pumice. The proportion of dacite, andesite and banded pumice increases with height, toward the middle of the flow-unit, which contain mostly andesite and dacite pumices and without any rhyodacite pumice. Toward the top, rhyodacite pumice appears again, and the proportion of andesite and dacite pumice clasts decreases. The uppermost part is fines-poor, and comprises mostly rhyodacite pumice with rare dacite pumice.

THE REASON WHY FRAGMENTATION DEGREE OF FALLOUT ASH VARIED DURING THE 1988-1989 ERUPTIONS OF TOKACHI-DAKE, HOKKAIDO, NORTHERN JAPAN

Mario YOSHIDA (Graduate School of Science, Hokkaido University, N10W8 Kita-ku, Sapporo 060-0810, JAPAN, Email: mario@cosmos.sci.hokudai.ac.jp); Yuichi Nishimura (Institute of Seismology and Volcanology, Hokkaido University, Sobetsu-onsen 59, Usu-gun, Hokkaido 052-0103, JAPAN, Email:nishi@eos.hokudai.ac.jp)

Fragmentation degree of fallout ash is defined as weight % of particles finer than 0.125 mm at the site of normalized distance from the vent (i.e., the application of F-value; Walker, 1973). The degree of the fallout ash during the 1988-1989 phreatic to phreatomagmatic eruptions of Tokachi-dake ranged from 5 % to 98 %. The ash was ejected from the same vent, and main components of the fine ash particles are accessory lithic and mineral fragments in every eruptive phase. Average of roundness (Wadell, 1932) of coarse ash also ranged from 0.3 (subrounded) to 0.6 (well-rounded), and it correlates normally with the fragmentation degree. We assume that the higher degree of fragmentation was due to the longer duration of attrition of the particles when they passed through the conduit. The most likely explanation of the long duration of attrition is stable and mild relieving of the pressure with the progress of clearing and widening of the conduit. Our model is supported by the other observational fact: eruption tremors. The tremors associated with high-fragmented ash eruptions lasted long time (more than several hours) and show spectra in which high-frequency powers are weakened.

EXPERIMENTAL POLYDISPERSE SUSPENSION CURRENTS AND IMPLICATIONS FOR PYROCLASTIC FLOW TRANSPORT

CHOUX C. and Druitt T.(both at Departement des Sciences de la Terre, 5, Rue Kessler, 63000 Clermont Ferrand, France, Email: choux@opgc.univ-bpclermont.fr)

Pyroclastic density currents range from dilute suspensions to highly concentrated granular avalanches. They are highly polydisperse and commonly contain particles of two different densities (pumices and lithics). In order to better understand the segregation processes possible in such currents, we have carried out a series of experiments using aqueous suspension flows with a range of concentrations (1 to 22 vol. %) in a horizontal lock-exchange flume, 5 m. long. The suspensions consist of particles of silicon carbide (3.2 g. cm-3 ; 1mm to 10mm) and dried vegetal matter (1.4 g. cm-3 ; 3mm to 30mm) in equal proportions. Each component population has an approximately log-normal size distribution, and the two populations are in initial hydraulic equivalence. The water-immersed densities of the two components scale to those of lithics and pumices in gas. Some preliminary results are reported in this poster. Particle populations in the deposits from dilute experimental flows are found to be in approximate hydraulic equivalence. With increasing suspension concentration, light particles become increasingly displaced downstream in the deposit due to buoyancy effects in the flow, and the proximal part of the deposit becomes strongly enriched in the dense component. Deposits from concentrated suspensions have two distinct layers, even though the size distribution of the initial suspension is continuous. In one series of experiments (16% concentration), the flows were filmed in order to reconstruct the manner in which the layered deposit aggraded in space and time from the moving flow. The experimental results were compared with vertical and lateral grading observed in some natural ignimbrites.

VOLCANIC GLASS STUDY OF VOLCANICLASTIC DEPOSITS OF TIHANY-TYPE AND NORMAL MAAR VOLCANOES OF THE BAKONY- BALATON HIGHLAND VOLCANIC FIELD (BBHVF), HUNGARY

Karoly NEMETH and Ulrike Martin, (Geology Department, University of Otago POBox 56., Dunedin, New Zealand,e-mail:karoly.nemeth@stonebow.otago.ac.nz)

The BBHVF, active in late Miocene, is located in the Pannonian Basin and contains two different maar type volcanoes. The water source of phreatomagmatic explosions is from an upper thick, clastic sediment pile and/or from underlying karstwater rich formations. Two different type of maar developed depending on water source. Each has a characteristic volcanic glass type. Where the main water source of hydromagmatic explosions was restricted to the upper, thick clastic sediment pile, normal maar volcanoes developed. In areas where both the karst water and the relatively thin water rich clastic sediment played important roles to fuel the magma\water interactions, Tihany-type maar volcanoes developed. Microprobe analysis of volcanic glass (94-99 % total) showed composition from basalt, trachy basalt, andesite basalt to andesite or even dacitie which data differ from the previous, lava rock based results. The textural analysis showed that there are two types of glass. The common type of glass is non-oriented, microcrystalline, non or slightly vesiculated, slightly elongated, usually fractured. This is formed by strong and sudden cooling of low crystalised magma due to interaction with water. This type of glass are common from normal maar volcanoes. The second glass type is the most common, oriented microcrystalline textured, bended, elongated, slightly vesiculated. It must have been formed when slightly crystallised magma met with water in shallow level. This glass type is common from pyroclastic rocks which are abundant in deep seated (karst water bearing) rock fragments. The paradox of occurrence of deep seated fragments and the "shallow region" (low confining pressure) formed volcanic glass can be solved with operating open, water filled fractures during the explosions, giving free way for karst water to high speed uprising magma to produce phreatomagmatic explosions, and form Tihany-type maar volcanoes.

WET AND DRY SURGE DEPOSITS: FIELD STUDIES AND EXPERIMENTS

Piero Dellino and Luigi La Volpe (both at Dipartemento Geomineralogico,Universit=E0 degli studi di Bari, Via E. Orabona 4, 70125 - Bari, Italy, email: dellino@lgxserver.uniba.it) Bernd Zimanowski, Ralf Buettner, and Volker Lorenz (all at Physikalisch-Vulkanologisches Labor, Universitaet Wuerzburg, Pleicherwall 1, D-97070 Wuerzburg, Germany, email: zimano@geologie.uni-wuerzburg.de)

Surge deposits of phreatomagmatic origin, commonly found in volcanic islands, show various structural and textural features and, with respect to the magma/water interaction processes leading to their formation, are subdivided into two types: a) wet surges and b) dry surges. It is assumed, that the amount of external water during explosive fragmentation, transport and deposition controls the characteristics leading to this classification, i.e. wet surge deposits form once the amount of water by far exceeds the volume needed to drive the phreatomagmatic eruption mechanism and dry surge deposits are generated when the amount of external water is more or less restricted to this value. For the case of La Fossa di Vulcano (Sicily) experimental and field studies were combined to investigate the physical frame conditions and the nature of the physical processes that lead to the formation of such deposits. Typical pyroclasts of both types of deposit could be produced in laboratory experiments using remelted volcanic rocks from Vulcano island, that have a composition very close to the magma erupted during the formation of the natural wet and dry surge deposits of La Fossa.

THE ERUPTIVE DEPOSITS OF A SMALL EMERGENT VOLCANO AT THE OTAGO PENINSULA, NEW ZEALAND

Ulrike MARTIN (Geology Department, Otago University, PO Box 56, Dunedin, New Zealand, email: ulrike.martin@stonebow.otago.ac.nz)

The Sandfly Bay pyroclastic succession at The Otago Peninsula, South Island. New Zealand, comprises partly preserved rim beds of a basaltic tuff cone, belonging to the Miocene Dunedin Volcanic Complex (DVC). The bulk of the DVC is considered to have developed subaerially, but recent studies have delineated several small submarine or Surtseyan volcanoes, one of which is the Sandfly Bay succession. The succession consists of four parts; (1) a vent marked by radiating dikes and peperites, which is approximately 100m in diameter; (2) a thick massive to slightly bedded pillow/hyaloclastite unit; (3) a massive tephra unit; (4) a bedded tephra unit with wave-formed structures at the bottom and well developed unidirectional cross-stratification and sharp bedding planes at the top. Peperites constitute the upper vent-filling, and formed when hot magma intruded wet unconsolidated tephra. Pillow fragments in the massive hyaloclastite unit record initial thermal quenching and fragmentation of erupting basalt. The tephra forming the ring, in both the massive and the bedded unit, comprises juvenile vesiculated sideromelane clasts, sideromelane glass shards, feldspar and large pyroxene crystals up to 1cm. The absence of accidental lithics suggests a shallow explosion level, above the substrate. Beds dip radially outward from the vent at 20-30o. Alternating coarse-grained crystal-rich beds and fine-grained beds form the uppermost unit. The wave-generated structures indicate shoaling of an initially submarine edifice, while the upper part represents the subaerial stage of volcanic activity at Sandfly Bay. The tuff cone is interpreted to have been constructed over a massive hyaloclastite unit that formed below sea level and resulted from a moderately explosive eruption, inferred to have been driven by magma/water interaction in a water-rich environment. The submarine part of the emergent volcano is more massive, coarse-grained and glassy, distinct from the subaerial part.

ON THE FORMATION OF SPINDLE BOMBS IN A SUBMARINE VENT AT BOULDER BEACH, DUNEDIN VOLCANIC COMPLEX, NEW ZEALAND

Ulrike MARTIN & Karoly Nemeth (Geology Department, Otago University, PO Box 56, Dunedin, New Zealand; email: ulrike.martin@stonebow.otago.ac.nz;

Fusiform "bombs" usually form explosively in subaerial settings such as lava fountain-spatter eruptions, and similar features can develop intrusively when dikes enter unconsolidated wet sediment to form globular peperites. At Boulder Beach unusual kinds of spindle bombs have been formed in a submarine vent. Volcanic rocks of trachytic in composition exposed at Boulder Beach belong to the Dunedin Volcanic Complex (DVC), which makes up the Otago Peninsula near Dunedin, New Zealand. The volcaniclastic deposits record a variety of gravity flows from a subaqueous eruption. The strongly hydrothermally altered vent, which was invaded by dikes, is surrounded by a tephra-ring. The tephra comprises alternating massive coarse-grained and bedded fine-grained layers, formed of pumice, dense crystalline trachytic clasts, glass-shards, feldspar-and quartz crystals and minor sedimentary clasts from underlying strata. Characteristic of the fine-grained beds is cross-stratification, scour-fillings, normal-graded lithic clasts and inverse-graded pumice clasts. Locally present are large lithic clasts up to 20cm, whereas pumice clasts are up to 8 cm. The succession is interpreted to have been formed during shallow marine magmatic/hydromagmatic eruption with deposition from density currents, shed directly from a subaqueous eruption column. The chaotic vent tephra contains fusi-form bombs which where formed while dikes invaded the vent. They formed due to magma/water interaction. The high water/magma ratio led to a mildly explosive fragmentation in the vent slurry. The large bombs retained heat long enough to deform plastically and settled slowly in the fluidized slurry. Fluidisation in the vent sediment is shown as "Schlieren" around the bombs. The spindle-shaped bombs and blocks are vesiculated and vesicles are usually filled with chalcedony. Further away from the feeder-dike there are large bombs with bomb-sags, deposited by backfall during eruption. The original bedding features in the vent have been destroyed due to fluidization along margins of intruding dikes. The basalt-dikes have irregular forms and are strongly chilled.

A SIGNIFICANT HAZARD FROM LARGE-SCALE VOLCANIC ERUPTIONS IS ASH

C. RILEY (Geological and Engineering Sciences, Michigan Technological University, 1400 Townsend Drive, Houghton, MI, 49931 USA, Email: cmriley@mtu.edu)

A significant hazard from large-scale volcanic eruptions is ash which can be transported great distances and deposit irregularly and in unusually thick amounts far from the volcanic source. One influence on volcanic ash transport is particle shape which affects the aerodynamic properties responsible for particle separation and fallout, the interaction of particles with the atmosphere, and remote sensing measurements of ash particle concentrations. The main objectives of this study are to characterize the shape and determine terminal settling velocities for ash particles so that these data can be used to improve transport models and remote sensing algorithms.
A total of 1,300 andesitic ash particles were measured from the August 1992 Spurr eruption. The majority of particles are subrounded silicate pumice fragments, with < 10% glass bubble-wall shards. Size distribution data for the sample show the sample is bimodal, which indicates aggregation played a role in fallout. In general, actual mean diameters for each settling velocity group were larger than expected if the particles were assumed spherical. We show that this is due to particle shape influences rather than density effects. The larger than expected diameters for particles in given terminal settling velocity groups suggests that the irregular shape of these particles decreases their settling rate. This is at odds with current transport modeling results which show that particles fall out faster than expected and suggests that another factor such as aggregation may be of greater importance in the fallout of andesitic particles. The Spurr particles are representative of vulcanian to subplinian andesitic eruptions but are unlike more irregular-shaped rhyolitic particles often formed in plinian eruptions.

AN APPROACH TO 3D MODEL OF PYROCLASTIC FLOW DYNAMICS AND ITS APPLICATION TO THE AZUFRAL RIVER CHANNEL AT GALERAS VOLCANO, COLOMBIA

GUSTAVO CORDOBA (Universidad de Narinno, Colombia, email gcordoba@altavista.net); Peter Rutschmann (Laboratory of Hydraulics, Hydrology and Glaciology of the ETHZ, Zurich, email rutschmann@vaw.baum.ethz.ch); Greg Valentine (Los Alamos National Laboratory, USA, email gav@vega.lanl.gov)

Galeras volcano is one of the most active volcanoes in the word, more than 500.000 people are living within its influenced area. The Azufral river channel down directly from the crater zone without topographic barriers and a pyroclastic flow could affect the Consaca town and it surrounding area. The compressible full Navier-Stokes equation is used to describe the 3D motion of a possible pyroclastic flow from a collapsing eruption column from the crater vent in direction to Consaca town descending through the Azufral river basin. The change of the bulk density is taken into account from the variation of the particle volume fraction in the state equation. The resulting set of equations is solved numerically by using the Finite Element Method Toolbox (FEMTOOL) developed at the Laboratory of Hydraulics, Hydrology and Glaciology of the ETHZ, Zurich.

FIVE PARALLEL BRECCIATED FELSIC DIKES, OBSERVED AT CENTRAL KII PENINSULA, SW JAPAN

Yutaka WADA, (nara University of Education, Japan, email:ywada@nara-edu.ac.jp)

Five parallel brecciated felsic dikes, observed at central Kii Peninsula, SW Japan, show a continuous facies change from magmatic to clastic. Each of dikes is ca. 30-50m wide in maximum, and the maximum length of segments observed is more than 1.5km. Their host rocks are pre-Tertiary sedimentary rocks constituting an accretionary prism (Chichibu belt). The magmatic facies consists of inhomogenous aphyric rhyolite with amoeboid clots (several centimeters in diameter) of porphyritic rhyolite. Perlitic cracks are also developed in the porphyritic clots. The clastic facies is unsorted and consists of juvenile and accidental fragments (maximum diameter is ca. 50cm) and sand-sized matrix with mineral and rock fragments. While the juvenile fragments are mostly of porphyritic rhyolite showing angular with glassy chilled margins or amoeboid in shape, a few aphyric lens- or wisp-shaped rhyolite are also observed. Some accidental fragments are deforming in ductile regime, others are breaking in brittle regime. Based on these observations, it is inferred that after the rhyolitic magmas (porphyritic and aphyric) had intruded into wet and unconsolidated sediment underlying the consolidated accretionary prism, they intruded into the above prism. This emplacement is inferred to be occurred at middle Miocene (13.7_}0.7Ma) based on K/Ar dating (K-feldspar). Previously some plant and foraminifera fossils dated Eocene have been reported in the clastic facies, however, suggesting that some part of these dikes were occupied by breccias collapsed down from the above. Furthermore, the dikes seem to be a part of an arc-like distribution as a whole according to the previous works. Thus these dikes may be a possible feeder channel for the pyroclastics and may also suggest a pre-eruptive process within dike fractures feeding magma, although whether it was reached to the earth_fs surface or not is unclear from the field observations.

STRAIN-INDUCED MAGMA FRAGMENTATION AND NON-EQUILIBRIUM FLOW DYNAMICS IN VOLCANIC CONDUITS

Paolo PAPALE (Istituto Nazionale di Geofisica, via S. Maria 53, I-56126 Pisa, Italy, email papale@dst.unipi.it)

Magma fragmentation during ascent to the Earth's surface is investigated by umerical simulations of multiphase, non-equilibrium flow of liquid magma, gas exsolving from the liquid, and crystals.
The numerical model uses most recent models to calculate magma properties as a function of magma composition and phase distribution.
The possible occurrence of magma fragmentation as due to overcoming of a critical strain-rate corresponding to rate-limited crossing of the glass transition is investigated, by means of Maxwell relation and published experimental data on fragmentation of thin magma fibers in a rapidly increasing stress field. Such investigation is conducted by means of a parametric study where many different possible eruptive conditions in terms of conduit size, mass flow-rate, magma composition, volatile content and composition, and crystal content and distribution are taken into account. The results show that strain-induced magma fragmentation occurs at a gas volume fraction range identical to the measured range of pumice vesicularity for several eruptions throughout the world, following the development of a narrow region in the conduit where magma viscosity and strain-rate increase more and more rapidly. When plotted against magma viscosity, the gas volume fraction at fragmentation gives a decreasing trend similar to that which has been previously found on the basis of measurements on volcanic products. Furthermore, the model predicts the conditions that do not lead to strain-induced magma fragmentation, that include cases where basaltic magma composition is used, thus allowing to discriminate between explosive and effusive eruption conditions.

WE PRESENT THE APPLICATION OF CFD MODELLING OF VOLCANIC JETS ON DIGITAL ELEVATION MODELS (DEM'S)

Alfredo Mahar Francisco LAGMAY, University of Cambridge, Cambridge, UK,
Email: amfal2@esc.cam.ac.uk

We present the application of CFD modelling of volcanic jets on Digital Elevation Models (DEM's) to studies on explosive volcanism. By conducting numerical flow modelling on actual topography (represented by a DEM), we generate output that tell about the dynamics of explosive eruptions. In particular, our results illustrate the remarkable amount contributed by decompression to the radius of the basal gas thrust column. It also shows that the basal region

of the eruption column can be inclined as it exits from asymmetric craters. We present case studies on Mount St. Helens, Mount Pelee, Mayon and Iriga volcanoes to illustrate these effects. The graphic display of the numerical analysis also provides an excellent visualisation tool for generating insights into the nature of volcanic phenomena related to eruption columns such as the formation and emplacement of pyroclastic flows. This type of modelling is useful for hazards assessment and risk mitigation.

ERUPTIVE PROCESS, EFFECTS AND DEPOSITS OF THE 1996 AND ANCIENT BASALTIC PHREATOMAGMATIC ERUPTIONS IN KARYMSKOYE LAKE, KAMCHATKA, RUSSIA

Alexander BELOUSOV and Marina Belousova (Institute of Volcanic Geology and Geochemistry, Petropavlovsk-Kamchatsky, Russia, email: A.Belousov@relcom.ru)

On 2-3 January, 1996 an explosive eruption with a discharge rate of basaltic magma of ~106 kg/s occurred in Karymskoye lake through an initial water depth ~50 m. Characteristics of the deposits together with analyses of a videotape of several explosions have allowed us to model the eruptive events. Initial vent-clearing phreatic explosions ejected blocks of country rocks (up to 3m diameter) to distances up to 1.3 km. Then followed 10 to 20 hours of phreatomagmatic Surtseyan activity (100-200 outbursts of water-gas-pyroclastic mixtures to heights up to 1 km, with initial velocities of 110 m/s). The eruption slugs collapsed back into the lake producing base surges (runout up to 1.3 km; average velocity 12.5 m/s). The eruptive cloud rose to a convective height of 3 km depositing a thin distal fall deposit. The eruption ended with the ejection of scoria crust bombs (specific basaltic bombs with dense core and scoriaceous crust). Pyroclasts of the eruption are mostly poorly to moderately vesicular juvenile basaltic particles shaped by a combination of vesiculation of magma and magma-water interaction. Ninety five percent of the products (0.047 km3) formed an underwater tuff ring composed of parallel layers of moderately to poorly sorted lapilli ash and ash lapilli (Md -3.9-0.6f; sorting 1.5-3.2f), each 10-60 cm thick. They were deposited by water-rich base surges that originated from collapses of Surtseyan type slugs. More widespread hazards of the eruption were tsunamis and lahars. At distances less than 1.3 km from the crater, base surges and ballistics were very destructive. Eruptive activity in the lake before 1996 has included two phreatomagmatic eruptions about 4800 14C yrs BP.

POWERFUL PYROCLASTIC SURGE AT BEZYMIANNY VOLCANO ON MAY 9-10, 1997, KAMCHATKA, RUSSIA

Marina BELOUSOVA and Alexander Belousov (Institute of Volcanic Geology and Geochemistry, Petropavlovsk-Kamchatsky, Russia, email: A.Belousov@relcom.ru); Barry Voight (The Pennsylvania State University, USA, email: voight@ems.psu.edu)

We have reconstructed the course of the May 9-10, 1997 explosive eruption of Bezymianny volcano from its pyroclastic stratigraphy. The first event of the eruption was an explosive outburst through the top of the dome producing a powerful pyroclastic surge. The surge covered 30km2 over an elliptical-shaped area, extending as far as 7 km SE from the crater. Its volume is 107m3. Temperature of the surge cloud was < 200oC. It deposited a blanket of massive to vaguely laminated gravelly sand (Md -1.2…3.7_, sorting 1.2…3_) of moderately vesiculated andesite. Thickness of the blanket is variable and declines both on ridge crests, and with distance from the source. The maximum observed thickness of the deposit is 30cm, 4km from the dome. The deposit becomes finer grained and better sorted with distance away from the source with maximal diameter of juvenile clasts decreasing from 46cm to 4cm. The surge represented a single short pulse of an inflated, hot, dry gas-pyroclastic mixture, which was likely formed by collapse of the powerful initial explosion fountain. Impact of the surge on several meters of snow filling the crater and the surrounding flank caused extensive lahars which travelled more than 30 km. Following the surge, block-and-ash pyroclastic flows as much as 4.7km long with total volume 0.02km3 were erupted. They were accompanied by short-lived subplinian eruption column from which widely scattered airfall clasts of pumice, to 10cm diameter, were deposited. The explosive activity destroyed the top of the dome, forming a funnel-shaped crater 200m across, breached to the east. From the crater a short flow of degassed lava was extruded out at the end of the eruption.

DETAILED HISTORY OF THE ITALIAN EXPLOSIVE VOLCANISM AS DOCUMENTED WITHIN A 110 KA SEDIMENT RECORD OF LAGO GRANDE DI MONTICCHIO (MT. VULTURE, SOUTHERN ITALY)

Sabine WULF, Jörg F.W. Negendank, Jens Mingram & Bernd Zolitschka (GeoForschungsZentrum Potsdam, PB 3.3 Sedimente und Beckenbildung, Telegrafenberg, D-14473 Potsdam, Germany, email: wulf@gfz-potsdam.de)

Sediment cores from Lago Grande di Monticchio, a maar lake in the Monte Vulture volcanic district (southern Italy), were recovered for interdisciplinary palaeoclimatic and palaeoenvironmental investigations. The partly laminated sediment record spanning the last 110 ka provides 340 tephra layers originating mostly from the Roman Comagmatic Province. Therefore, in addition to radiocarbon and Ar/Ar dates, detailed tephrochronological studies have been initiated in order to confirm the varve- and sedimentation rate chronology of the record. Microscopic studies and geochemical investigations on glass shards using microprobe techniques are in progress to specify the petrology of all tephra layers. At least 33 tephra layers are correlated with Plinian as well as Subplinian eruptions of Somma-Vesuvius (<27 ka). Most of the tephras (n>100) originate from explosive eruptions of Ischia (including the "Mt. Epomeo Green Tuff", 56 ka) and the Phlegrean Fields (including the "Campanian Ignimbrite", 33 ka), as well as of the Alban Hills (>20 ka, youngest products) and Sabatini in earlier times ("Tufo di Bracciano", 89 ka). Up to now three tephra layers have been related to explosive eruptions of Etna ("Biancavilla Ignimbrite", 16.5 ka and 18 ka) and Pantelleria ("Ante-Green-Ignimbrite", 74.5 ka). Therefore, studies of the tephrochronological record of Lago Grande di Monticchio will contribute both to a better knowledge of explosive activities of the Campanian volcanoes (e.g. paleowind pattern) and to correlations with isochronous tephra markers of other lacustrine and marine sediments from the Mediterranean (teleconnection).

WIDESPREAD PUMICE AND ASH (IGNIMBRITE) AT THE NORTHERN CAUCASUS 2.8 MA YEARS AGO

Nickolai V.Koronovsky (Faculty of Geology,Moscow State Lomonosov University, Moscow 119899, Russia, E-mail:koronovsky@dynamo.geol.msu.ru

Allmost instant explosion and following -2.5 km subsidence of the Upper Chegem caldera (Northen Caucasus) has happened 2.8 years ago that led to northward spreading of rhyolitic ignimbrites at distance about 100 km. Thickness of this sheet was 300 m with area about 1500 square km.
At the periphery this cover (sheet) consists of pumice train. Movement of the masses exploded was carried out permanently in the aerozole form until the total sheet has been formed. Under compaction volume decreased up to 1/3 of initial value. The riolite sheet overlaped late-Miocene questa-type relief. The primary melting magmatic zone was located at depth 20-25 km.

RECONSTRUCTING VOLCANIC ERUPTIONS AND GLACIAL EXTENTS USING EVIDENCE OF LAVA-ICE INTERACTION

David T. LESCINSKY and Jonathan H. Fink (both at Department of Geology, Box 871404, Arizona State University, Tempe, AZ, 85287-1404, United States, e-mail: Lescinsky@asu.edu)

Abundant evidence of lava-ice interaction has been found in the Cascades volcanic arc of the western United States and Canada. Features considered indicative of lava-ice interaction include: thick lava flows with steep marginal walls, abundant glass, and well-developed contraction fractures. These features were produced as lava quenched against steep ice walls caused by erosion and undercutting associated with warm meltwater runoff. Lava-ice interaction features are found on the flanks of volcanoes, and in areas with no current glaciation, indicating that during the lava flow eruptions, glaciers must have been much thicker and more widely distributed.
By identifying features indicative of lava-ice interaction we can reconstruct past eruptions and syneruptive glacial extents. Lava quench margins can be used to map out the location and size of the glaciers at the time of eruption. In some locations, preserved quench margins extend all of the way to the tops of flows, indicating ice thicknesses greater than several hundred meters. In other locations, quench margins give way to scoriaceous lava consistent with subaerial emplacement. The transition between lava-ice interaction features and apparently subaerial deposits can then be used to map out the upper boundary of the ice. Certain types of lava flow fractures show evidence of abundant water and can be used to indicate where lava flows have traveled subglacially or where meltwater has been trapped. Using these approaches, we have reconstructed the eruptions of the Mazama Ridge flow at Mount Rainier, Washington and a smaller andesite flow near Moraine Lake at South Sister, Oregon.
Reconstructions of this sort are important from both volcanic hazards and climatological standpoints. Age-dating of these eruptions allows us to determine the timing and extent of past glaciations. And eruption reconstructions allow us to better assess hazards posed by future lava-ice interaction.

RECENT STRUCTURAL EVOLUTION OF THE CUMBRE VIEJA VOLCANO, LA PALMA, CANARY ISLANDS AND ITS TIMING RELATIVE TO CLIMATE CHANGE

S.J. DAY (Benfield Greig Hazard Research Centre, University College London, Gower Street, London WC1E 6BT, U.K.; e-mail s.day@ucl.ac.uk); J.C. Carracedo (Estacion Volcanologica de Canarias, CSIC, 38206 La Laguna, Tenerife, Spain); H. Guillou (Centre des Faibles Radioactivités, CEA-CNRS, 91198 Gif-sur-Yvette, France); P. Gravestock (Dept. of Geography & Geology, Cheltenham & Gloucester College of Higher Education, Cheltenham GL50 4AZ, U.K.).

The Cumbre Vieja volcano is the youngest component of the island of La Palma. It is a very steep - sided oceanic island volcano, of a type which may undergo large - scale lateral collapse with little precursory deformation. Detailed mapping and radiometric dating has revealed structural reconfiguration of the volcanic rift zones and underlying dyke swarms of the volcano, reflecting the onset of incipient flank instability, which can be correlated with climate change events. For most of its history the Cumbre Vieja volcano was characterised by a triple ("Mercedes Star") volcanic rift zone geometry. Radiometric dating indicates that it grew to its present size from about 125 ka onwards, but rapid erosion of exposed hyaloclastites during the syn - glacial low sea level stand produced major coastal cliffs: the resulting stratigraphy of cliff- and platform- forming lavas may be of general use in mapping syn -glacial oceanic island volcanoes. In the post - glacial period the structure of the volcano has evolved rapidly. Since 7 ka the triple – rift geometry has been replaced by a N-S trending rift zone which transects the volcano, and by E-W trending en echelon fissure arrays on the western flank. This structural reconfiguration indicates weakening of the western flank of the volcano, which may be related to an increase in pore fluid pressures resulting from a post - glacial rise in the water table which is also reflected in an increase in the amount of phreatomagmatic explosive activity.

POSSIBLE RELATIONSHIPS BETWEEN CLIMATE CHANGE, A PAST GIANT LATERAL COLLAPSE AND MODERN FLANK INSTABILITY OF FOGO, CAPE VERDE ISLANDS

S.J. DAY (Benfield Greig Hazard Research Centre, Department of Geological Sciences, University College London, Gower Street, London WC1E 6BT, U.K., e-mail s.day@ucl.ac.uk); S.I.N. Heleno da Silva & J.F.B.D. Fonseca (both at: Departamento de Fisica, Instituto Superior Tecnico, Av. Rovisco Pais 1, 1049-001 LISBOA, Portugal); P. Harrop & R. Burgess (both at: Department of Geology, University of Manchester, Oxford Road, Manchester M13 9PL, U.K.).

Fogo island is a large and extremely steep oceanic island in the Cape Verde archipelago. It has a large (c. 9 km across) east - facing summit lateral collapse structure, the Monte Amarelo collapse, with a probable volume of at least 150 - 200 km3. For most of its history the Monte Amarelo volcano had a small but productive central vent complex, which was removed by the collapse, and radial rift zones fed by laterally - propagating dykes. Shortly before the collapse these were replaced by north - south trending arrays of en echelon, vertically – propagating dykes. Coastal morphology indicates that the relatively recent Monte Amarelo collapse occurred before the end of the last glaciation, and perhaps as far back as the relatively humid early glacial period. The later Cha das Caldeiras volcano which has grown within the collapse scar has undergone a parallel structural reconfiguration during the latter part of the Holocene which suggests that it is evolving towards an unstable condition. The early stages of this structural reconfiguration appear to have occurred during an inferred humid period, most probably the mid - Holocene climatic optimum when adjacent areas of Africa were much wetter than they are at the present day. The likely mechanistic link between climate change and volcano instability is an increase in pore fluid pressurisation effects (Elsworth & Voight 1995; Elsworth & Day, in press) due to elevated water tables in humid periods as discussed elsewhere in this session by Day et al.: radiometric data will provide a test of this hypothesis.

EXPLOSIVITY OF SOUTH-ITALIAN VOLCANOES AND CLIMATE CHANGE DURING THE LAST 110,000 YEARS

Sabine WULF, Jörg F.W. Negendank, Jens Mingram, Bernd Zolitschka (GeoForschungsZentrum Potsdam, PB 3.3 Sedimente und Beckenbildung, Telegrafenberg, D-14473 Potsdam, Germany, email: wulf@gfz-potsdam.de) & Heinz Vos (Forschungszentrum Juelich, Institute for Chemistry and Dynamics of the Geosphere, D-52425 Juelich, Germany, email h.vos@fz-juelich.de)

A 110 ka sediment record, recovered from Lago Grande di Monticchio (Mt. Vulture, southern Italy), provides 340 tephra layers which have been precisely dated by an independent varve and sedimentation rate chronology. Based on tephrochronological studies most tephras originate from Campanian and Roman volcanoes located 100 to 200 km west of Lago Grande di Monticchio. Abundant explosive eruptions are recorded between 110,000 and 75,000 yr, 40,000 and 27,000 yr as well as between 15,000 and 4000 yr ago in the sediment sequence of Monticchio. These intervals are linked to relatively warm periods, e.g. marine oxygen isotope stages 5c, 3 and 1 (the Holocene) reflecting also periods of higher sea leavels. We hypothesize that such periods increase the pressure on the roots of the volcanoes, provide larger amounts of ground water reacting with the magma chamber and trigger more explosive eruptions. This is supported by intervals with minor volcanic activity between 75,000 and 40,000 yr and between 27,000 and 15,000 yr ago that can be related to the colder marine oxygen isotope stages 4 and 2 during the last glaciation. However, this may also reflect variations of the Mediterranean wind pattern. Time series analysis of these data is in progress to check whether periodicities like e.g. Milankovich cycles are a detectable feature of the explosive volcanic activity data from Lago Grande di Monticchio.

RECORD OF EPISODIC EXPLOSIVE VOLCANISM AND CLIMATE CHANGE OVER THE LAST 6 MA IN THE NORTH ATLANTIC

Christian LACASSE (GEOMAR, Department of Volcanology and Petrology, Wischhofstrasse 1-3, D-24148 Kiel, Germany, email: clacasse@geomar.de); Hans-Ulrich Schmincke (GEOMAR, Department of Volcanology and Petrology, Wischhofstrasse 1-3, D-24148 Kiel, Germany,
email: hschmincke@geomar.de).

A composite record of explosive volcanism in the North Atlantic for the last 6 Ma is presented based on the recovery of tephra layers at five ODP sites: sites 907 (Iceland Plateau), 985 (Norway Basin), 983 and 984 (Iceland Basin) of Leg 162, and site 919 (Irminger Basin) of Leg 152. All the visible tephra layers were systematically sampled in two adjacent drilling holes to study the most complete record of deposition at each site. Age control of about 40 major eruptions was derived from the revised magnetic stratigraphy and full recovery of the sediment. Planktic and benthic oxygen isotope records (*18O, o/oo PDB) available for the upper most sequence were used to refine the age model of the eruptions for the 0-1 Ma time interval. Major element analyses of the glass component of the tephra indicate either bimodal compositions (mafic and silicic) with very few intermediate glasses or unimodal compositions. CIPW norms were calculated from the composition of silicic glasses (rhyolitic or trachytic) that are present in more than 95 percents of the tephra layers. Normative plots of silicic glasses in three component system albite-quartz-orthoclase are shown for the six one-million-year time intervals and compared with those obtained from a geochemical database of central volcanoes in Iceland. With the exception of three, likely erupted from volcanic sources along the Jan Mayen ridge, all the tephra layers were derived from large explosive eruptions along the main rift system and the off-rift volcanic zones in Iceland.
Activity along both Icelandic volcanic zones can be traced within each time interval, with the 3-4 Ma period characterized by the highest frequency of eruption, between one and two large events every 100ka. Comparison with a climate proxy record after Shackleton et al. (1984) clearly shows that these more frequent large explosive eruptions occurred during a climatic transition which led to the onset of glaciations in the North Atlantic, but without showing at first sights any direct link such as a possible triggering mechanism (glacier loading/unloading) or feedback mechanism (volcanic winters).

DID ASIAN MONSOON DYNAMICS INFLUENCE THE TIMING OF MT. PINATUBO'S ERUPTION?

Peter CARL (Climate Dynamics Project, c/o Forschungsverbund Berlin, Hausvogteiplatz 5-7, D -10117 Berlin, Germany, email: pcarl@spclim5.wias-berlin.de)

The East and South Asian summer monsoon season elapsed dynamically abnormal in 1991. An excessive northern hemisphere atmospheric mass load had been co-operatively built up in 1990 by the tropospheric biennial oscillation and the monsoon's retreat into a pronounced "Indian summer" type autumn. The status of the Southern Oscillation was prepared for El Nino to occur but kept frustrated by this internal asymmetry until autumn 1991. Consistently, both winter and summer monsoons - yet synoptically severe - have been dynamically less excited than normal. Fed by a southwards displaced Western Pacific High, Mei-Yu over East Asia commenced early by a month. Start-up over Kerala of the south-west monsoon dated normal but came along without onset vortex and advanced very fast, to end up in extreme stagnation. Mt. Pinatubo exploded at June 15, just when this monsoon's advance had stopped - as if a valve opened to maintain the angular momentum tendency. The length-of-day record does indeed not show any event-like signal, but global methane data unveil a rare phase coincidence across the annual forcing cycle, resulting in the strong growth rate anomaly that peaks in June 1991. A structural change is also announced in the dynamic interplay between summer and winter monsoon as seen in onset dates from the southern tip of peninsular India. The question arises if internal dynamics of the atmosphere-land system might have triggered this eruption.

EXTERNAL MODULATION OF VOLCANIC ACTIVITY

NEUBERG, Jurgen W (School of Earth Sciences, Leeds, e-mail: locko@earth.leeds.ac.uk)

Time and again seismo-volcanic activity that shows a clear diurnal and semi-diurnal modulation is related to the earth's tidal stress field as an external triggering mechanism. A critical overview is presented here based on several data sets from Stromboli volcano, Italy, Mt Ruapehu, New Zealand, and Merapi, Bromo and Batur, Indonesia, where in some cases also weather data are incorporated. A comparison with theoretical body tides in the spectral domain reveals evidence against any correlation between seismo-volcanic activity and tidal stress. However, other weather parameters such as temperature and barometric presssure show the same diurnal and semi-diurnal modulation and are, therefore, candidates for possible external modulation. Special emphasis is given to the detection and separation of man-made signals.

SEA-LEVEL CHANGE MODULATION OF EXPLOSIVE VOLCANIC ERUPTIONS

W. J. McGUIRE, (Benfield Greig Hazard Research Centre, Department of Geological Sciences, University College London, Gower Street, London WC1E 6BT. Email: w.mcguire@ucl.ac.uk)

Volcanic activity has often been linked with dramatic environmental changes in the Quaternary, either by driving climate modification or in response to major changes in the environment. Although the case for large explosive eruptions causing small, brief, falls in global temperatures is convincing, neither the evidence nor the mechanisms for longer episodes of volcano-induced cooling are yet clear. Contrastingly, recent research based on ice-core data suggests that rapid climate change over the past 100,000 years triggered an increase in volcanism. Through examination of the ages of tephra layers in deep-sea sediment cores, a statistical analysis is presented that links the frequency of explosive activity at volcanoes in the Mediterranean to the rate of late Quaternary sea-level change. The non-linear correlation between the two is tentatively explained in terms of the dynamic responses of coastal and island volcanoes to stress-related influences on a range of spatial scales. The correlation supports a mechanism or mechanisms whereby climate-driven growth and decay of large ice sheets can influence the eruptive behaviour of distant volcanic edifices via large, rapid changes in global sea level.

DO GIANT COLLAPSES OF VOLCANOES TEND TO OCCUR IN WARM, WET INTERGLACIAL PERIODS AND IF SO, WHY?

S.J. DAY and W.J. McGuire (both at: Benfield Greig Hazard Research Centre, Department of Geological Sciences, University College London, Gower Street, London WC1E 6BT, U.K., e-mail s.day@ucl.ac.uk); D. Elsworth (Department of Energy and Geo-Environmental Engineering, The Pennsylvania State University, 110 Hosler Building, University Park PA 16802-5000, U.S.A.); J.C. Carracedo (Estacion Volcanologica de Canarias, CSIC, La Laguna, Tenerife, Spain) & H. Guillou (Centre de Faibles Radioactivities, Laboratoire Mixte CEA - CNRS, 91198 Gif sur Yvette, France).

Giant lateral collapses of oceanic island volcanoes may be triggered by various processes which are influenced by climate. Low sea level stands during glaciations will tend to destabilise volcano flanks by the removal of lateral buttressing forces and intense coastal erosion of hyaloclastite sequences. However, most mid- to low- latitude oceanic islands were arid during glacial periods; the consequent major falls in water tables decreased the pore fluid pressurisation effects which appear to be the dominant mechanism for volcano destabilisation during rift zone eruptions (Elsworth & Voight 1995; Elsworth & Day, in press). Conversely, penetration of salt water into the cores of the volcanoes during dry periods may weaken them by alteration. Most of the destabilising effects of low sea level stands are permanent. In contrast, low - latitude oceanic climates are generally most humid during interglacials and it is in these periods that water tables are highest. Thus, in general, volcano instability will be greatest in the period after the end of glaciations, when the destabilising effects of pore pressure increases are greatest and reinforce the effects of earlier coastal erosion and volcanic core alteration. This prediction is consistent with limited available age data for giant lateral collapses and associated submarine debris avalanches and megaturbidites in the Quaternary. These consistently occur in warm, humid interglacial and interstadial periods, often (but not always) close to their start and not necessarily during periods of rapid sea level change.

ERUPTIONS OF PAVLOF VOLCANO, ALASKA, AND THEIR POSSIBLE MODULATION BY OCEAN LOAD AND TECTONIC STRESSES: RE-EVALUATION OF THE HYPOTHESIS BASED ON NEW DATA FROM 1984-1998

Stephen R. MCNUTT (Alaska Volcano Observatory, Geophysical Institute, University of Alaska Fairbanks, 903 Koyukuk Drive, P.O. Box 757320, Fairbanks, AK 99775, USA, email: steve@giseis.alaska.edu)

Thirteen of sixteen magmatic eruptions at Pavlof Volcano in nine of the years from 1973 to 1998 have occurred between September 9 and December 29. New statistical tests show that the distribution of eruptions is non-random at a 99.5 percent confidence level. Volumes of erupted material range from 0.3 to 16 x 106 m3 (dense rock equivalent). A significant correlation exists between the eruptions and yearly nontidal variations in sea level and may result from ocean loading. Calculated volume changes beneath the volcano due to ocean loading are from 0.02 to 0.6 times eruption volumes, and it is postulated that the volcano acts as a long-period (several months) volume strain meter, with lava being preferentially erupted when strain beneath the volcano is compressive. Previous observations of a tilt reversal from 1978-1980, and new observations of 1) tectonic activity and eruptions in the spring and summer of 1986, and 2) a M=6.9 earthquake nearby in May 1993, also suggest tectonic modulation of eruptions. The volcano appears to be responsive to small, slow changes in ambient stresses or strains, and these changes may modify or trigger eruptions.

VS3/E/02-B3 **1550**

VOLCANICLASTIC SEDIMENTATION IN COASTAL ENVIRONMENTS: THE INTERPLAY BETWEEN VOLCANISM AND QUATERNARY SEA LEVEL CHANGES (LATIUM, CENTRAL ITALY)

D. DE RITA, M. Fabbri, I. Mazzini, P. Paccara, A. Sposato, A. Trigari, G. Giordano (Dipartimento di Scienze Geologiche, Università Roma Tre, L.go S. Leonardo Murialdo 1, 00146, Roma, Italia)

Quaternary alcali-potassic explosive volcanism developed along the western coast of the Italian peninsula related to back-arc extension of the Tyrrhenian basin. Volcaniclastic sedimentation along the coast of Latium records the interplay of volcanism and Quaternary sea level changes. Most of the large volume pyroclastic flows from Latian volcanoes were erupted during low stands of the sea level; their deposits occur at the base of unconformity bounded stratigraphic units. Detailed stratigraphic correlations between the stratigraphy of volcanic products of Northern Latium and volcaniclastic sedimentation along the coast allowed to identify four first order, regionally extended stratigraphic units (synthems) bounded at the base and top by erosional unconformities that developed during sea level low stands (ice ages) and comprised in age between 0.60 Ma and 0.12 Ma. The area appears to have been relatively stable tectonically, as vertical aggradation is little compared to lateral aggradation. Erosion during low stands of the sea level incided each synthem approximately to the base of the unit, so that successive synthems are laterally juxtaposed rather than vertically.

VS3/W/25-B3 1620

FIRE AND ICE: IS THERE A CAUSAL RELATIONSHIP BETWEEN GLACIAL MAXIMA AND MINIMA AND THE ERUPTABILITY OF MAGMA AT LARGE CONTINENTAL ARC VOLCANOES?

Michael DUNGAN, Bradley Singer, and Yann Vinzce. (Département de Minéralogie, Université de Genève, 1211 Genève 4, Switzerland, email dungan@terre.unige.ch); Ren Thompson (U.S. Geological Survey, Denver Federal Center, Denver CO 80225 USA)

Episodic loading by ice during glacial maxima may reduce the eruption probability of mafic magma. Ice accumulation rates on high-standing volcanic edifices greatly exceed the regional average, and erosion during glaciation may remove substantial volumes from the summit and flanks: i.e., the local decrease in compressive stress imposed on conduit systems following ice retreat may be considerable. A petrologic, photogrammetric, paleomagnetic, and geochronological study of the Tatara-San Pedro complex (36° S, Chilean Andes) identified a positive correlation between the ages of basal flows overlying erosional unconformities and the ages of global ice-volume minima inferred from the marine oxygen isotope record (Singer et al., 1997; GSA Bull). New 40Ar/39Ar dates show that some apparent correlations were fortuitous. After elimination of K-Ar dates that give disturbed young ages due to argon loss, the 40Ar/39Ar data still support a correlation between the timing of ice retreat and the ages of basal flows. Present age data from Tatara-San Pedro are too few and insufficiently precise to distinguish definitively between simple preservation of flows emplaced onto erosion surfaces following ice retreat versus suppression of volcanism during glacial maxima followed by high eruption rates after unloading, but they offer hints that large edifices may grow rapidly shortly after ice retreat. Modelling of the intra-edifice stresses imposed by peak ice cover conditions and their consequences for eruptive behavior is an essential step in addressing this question, and field-geochronological investigations of other volcanoes also are needed to test for a general relationship and to assess whether late Quaternary lavas can be dated with sufficient precision to constrain short-term eruption rates.

VS3/W/26-B3 1630

RECONSTRUCTING VOLCANIC ERUPTIONS AND GLACIAL EXTENTS USING EVIDENCE OF LAVA-ICE INTERACTION

David T. LESCINSKY and Jonathan H. Fink (both at Department of Geology, Box 871404, Arizona State University, Tempe, AZ, 85287-1404, United States, e-mail: Lescinsky@asu.edu)

Abundant evidence of lava-ice interaction has been found in the Cascades volcanic arc of the western United States and Canada. Features considered indicative of lava-ice interaction include: thick lava flows with steep marginal walls, abundant glass, and well-developed contraction fractures. These features were produced as lava quenched against steep ice walls caused by erosion and undercutting associated with warm meltwater runoff. Lava-ice interaction features are found on the flanks of volcanoes, and in areas with no current glaciation, indicating that during the lava flow eruptions, glaciers must have been much thicker and more widely distributed.

By identifying features indicative of lava-ice interaction we can reconstruct past eruptions and syneruptive glacial extents. Lava quench margins can be used to map out the location and size of the glaciers at the time of eruption. In some locations, preserved quench margins extend all of the way to the tops of flows, indicating ice thicknesses greater than several hundred meters. In other locations, quench margins give way to scoriaceous lava consistent with subaerial emplacement. The transition between lava-ice interaction features and apparently subaerial deposits can then be used to map out the upper boundary of the ice. Certain types of lava flow fractures show evidence of abundant water and can be used to indicate where lava flows have traveled subglacially or where meltwater has been trapped. Using these approaches, we have reconstructed the eruptions of the Mazama Ridge flow at Mount Rainier, Washington and a smaller andesite flow near Moraine Lake at South Sister, Oregon.

Reconstructions of this sort are important from both volcanic hazards and climatological standpoints. Age-dating of these eruptions allows us to determine the timing and extent of past glaciations. And eruption reconstructions allow us to better assess hazards posed by future lava-ice interaction.

VS3/E/04-B3 1650

RELATIONSHIP BETWEEN HISTORICAL ACTIVITY OF FUJI VOLCANO, JAPAN, AND INTERPLATE EARTHQUAKES NEAR THE VOLCANO

Masato KOYAMA (Faculty of Education, Shizuoka University, 836 Oya, Shizuoka 422-8529, Japan, email: mkoyama@ed.shizuoka.ac.jp)

All available historical documents and paintings, which record abnormal phenomena relating (or possibly relating) to the activity of Fuji Volcano, Japan, were re-examined and classified according to reliability of each document. Reliable descriptions were correlated with eruptive products, and several eruptive events were newly identified. Volcanic activity of Fuji Volcano was in high-level from the 9th to 11th century; in this period at least 7 reliable and 5 possible eruptions occurred. Although only 2 reliable and 1 possible records of eruption exist from the 12th to the early 17th century, this low-level activity is probably due to a lack of enough records. After the middle 17th century, plenty of historical records suggest that the activity is generally low except for the 1707 eruption, which is one of the most voluminous and explosive eruptions in the history of Fuji Volcano. At least thirteen interplate earthquakes (M8 or possible M8 class) have occurred near Fuji Volcano (in east Nankai and Sagami Troughs) since the 9th century. Both the troughs correspond to the convergent boundary between the Philippine Sea plate and the Japan arc. Eleven of the 13 interplate earthquakes occurred coincidently with volcanic events (eruption, rumbling, or change in geothermal activity) of Fuji Volcano within a interval of +-25 years. Most impressive examples are the 1703 rumbling and the 1707 eruption. The former was 35 days behind the 1703 Genroku Kanto earthquake (M7.9-8.2) at Sagami Trough and the latter was 49 days behind the 1707 Hoei Nankai earthquake (M8.4) at Nankai Trough.

VERTICAL COMPONENTS OF STRONG GROUND MOTION

Bruce A. BOLT (Department of Geology and Geophysics, University of California, Berkeley, CA, 94720, USA, email: boltuc@socrates.berkeley.edu)

Differences in wave pattern and coherency between vertical and horizontal components of strong ground motions have been described often in various earthquakes recorded in different parts of the world. Higher frequency content of the vertical ground motions also occurs in alluvial basins compared with the horizontal motions. Reliable estimation of uniform hazard spectra for vertical seismic excitation is dependent on a better understanding of these differences.
Observations from seismic arrays and accelerometers in recent earthquakes provide detail of spectral differences between vertical and horizontal strong seismic motions in alluvial basins. The preferred explanation is that the most energetic of such high-frequency vertical ground accelerations are generated by S-to-P seismic wave conversion within the transition zone between the underlying bedrock and the overlying sedimentary layers. The differences in combined scattering and anelastic attenuation for P and S waves predict the observed spectral differences of the vertical motions between rock and deep alluvium sites. This model also accounts for the frequency content differences between the vertical and horizontal motion ratios at sites in alluvial basins compared with rock sites at similar distance ranges. The high-frequency cut off of the acceleration power spectrum, fmax, is a useful comparison parameter.

ST3/W/07-B3 0845

MODELLING THE DIFFERENTIAL MOTION INDUCED BY SEISMIC WAVES AT THE BASE OF BRIDGE PIERS

Giuliano F. Panza (Dip. di Scienze della Terra, Universita` di Trieste and The Abdus Salam nternational Centre for Theoretical Physics, Trieste, Italy. E-mail: panza@geosun0.univ.trieste.it), Fabio Romanelli and Franco Vaccari (both at Dip. di Scienze della Terra, Universita` di Trieste and GNDT, CNR, Rome, Italy)

The relative motion measured at the base of bridge piers, due to seismic waves generated by nearby and far seismic sources is modelled. Synthetic seismograms are generated by a hybrid technique that combines the advantages of modal summation and finite differences. Relative motion is studied between adjacent piers as well as relative to the extremes of the bridge. The longitudinal, transverse and vertical displacements, velocities and accelerations are considered, in the frequency range up to 6 Hz. It has been found that the relative motion between piers can be of the order of the seismic input amplitude.

ST3/W/35-B3 0900

LINEAR AND NONLINEAR BEHAVIORS OF SOFT SOIL LAYERS USING LOTUNG DOWNHOLE ARRAY IN TAIWAN

HUANG HUEY-CHU, Shieh Chie-Song and Chiu Hung-Chie (Institute of Applied Geophysics National Chung Cheng University Ming-Hsiung, Chia-Yi, 621 Taiwan, R.O.C. TEL: 886-5-2720411 ext.6399 FAX: 886-5-2720807 E-mail: seihuey@eq.ccu.edu.tw)

We analyse the acceleration records of a vertical array to study the linear and nonlinear behaviour of the soft soil layers at LSST site, Lotung, Taiwan. This array includes five triaxial accelerometers deployed at depths of 0m, 6m, 11m, 17m and 47m. During a 6-year operation from 1985 to 1990, 29 earthquakes (4.0 6.5) triggered this array. The maximum PGA value is 257 gals recorded at the surface station. Spectral analyses show that the strong motion causes the peaks of ratio to shift to lower predominant frequencies. The averaged spectral ratio of 15 well recorded weak motion records are selected as a reference, the shift of the maximum predominant frequency can reach 20%. Comparing to the weak motions, the strong motions also decrease the amplification factor. The maximum reduction of the amplification can reach 50%. Besides, the results of waveform simulation show that the linear model based on the Haskell method can well predict the weak motions (PGA < 60 gals) at various depths. However, this linear model does not work for the strong motion data (PGA > 150 gals). Here the non-linear numerical scheme, such as DESRA-2, is required and can significantly improve the simulation results although the PGA value on the surface station is still underestimated. Overall, it is feasible to predict the strong motions for a horizontal layered structure.

ST3/W/49-B3 0915

SITE AMPLIFICATIONS ESTIMATES OF THE GEMONA (NE ITALY) ALLUVIAL FAN AND COMPARISON WITH OBSERVATIONS

Giovanni Costa, Francesco MARRARA and Peter Suhadolc (Dipartimento di Scienze della Terra, University of Trieste, via E. Weiss 1, 34127 Trieste, Italy E-mail: costa@geosun0.univ.trieste.it)

The area of Gemona is characterised by terrigenous sediments, which are covered locally by a thin Quaternary layer, forming a sedimentary basin. The centre of the city of Gemona is located at the margin of this sedimentary basin on an alluvial fan. The city has been completely destroyed during the 1976 Friuli earthquake. Three of the accelerometric stations of the Friuli Strong Motion Network have been installed in the area in order to study the seismic response of the alluvial fan and the sedimentary basin. The seismic response of the April 12, 1997 a Ml=5.6 event occurred at Bovec (Slovenia) about 40 km from Gemona, has been modelled with a hybrid technique, and the results have been compared with the observations. The hybrid technique combines the analytical method of the modal summation with the numerical method of the finite differences. The seismic response has been analysed in time and frequency domain up to 5 Hz, for the SH and P-SV components. The differences and affinities of the ground-motion as derived from simulation and observation are shown. The comparison of strong motion records with the synthetic signals allow a validation of the prediction and an improvement of the available models, in areas, as Gemona, where few geological and geotechnical data are available. The validated numerical simulations may then be scaled to events with different magnitude, not only to estimate the variability of ground motion in the area, but also to determine the response spectra, the maximum peak ground accelerations, Arias Intensities, and other engineering parameters.

ST3/W/44-B3 0930

MEMORY-OPTIMIZED 3D FINITE-ELEMENT MODELING OF SEISMIC GROUND MOTION IN TOPOGRAPHIC STRUCTURES

Erik Bystricky, Peter MOCZO and Jozef Kristek (all in Geophysical Institute, Slovak Academy of Sciences, Dubravska cesta 9, 84228 Bratislava, Slovak Republic, email: geofpemo@savba.sk)

The existence and importance of an effect of free-surface topography on seismic ground motion is well known. Local topography can cause amplification of ground motion and consequently damage to buildings in the populated areas. Modelling of seismic ground motion in topographic structures is, however, not an easy task if realistic model of medium has to be considered. The finite-element (FE) method allows to include both relatively complex material heterogeneity and free-surface topography. This is because it allows to cover a computational region naturally with irregular mesh of elements of different size and geometry. The problem is that the FE method requires considerable computer memory and time. In order to make the FE modelling more efficient a core memory optimisation is applied to the FE algorithm. The whole computational region can be considered as a set of general surfaces of nodes. In the core memory optimisation only a limited number of surfaces is kept in core memory at one time and the maximum possible number of time updates is performed for these surfaces. The subset of surfaces repeatedly moves throughout the model space until the desired time window is computed. The optimisation significantly reduces core memory requirements and makes the FE method more affordable for seismic ground motion modelling.

ST3/W/20-B3 0945

FINITE-DIFFERENCE MODELING OF SITE EFFECTS IN THE GRENOBLE BASIN

Pierre-Yves BARD (Laboratoire Central des Ponts-et-Chaussees and Observatoire de Grenoble, BP 53 - 38041 Grenoble Cedex - France, email: Pierre-Yves.Bard@lgit.obs.ujf-grenoble.fr), Jozef Kristek, Peter Moczo (both in Geophysical Institute, Slovak Academy of Sciences, Dubravska cesta 9, 842 28 Bratislava, Slovak Republic, email: geofpemo@savba.sk) and Judith Riepl-Thomas (Institut de Protection et de Surete Nucleaire, 92265 Fontenay-aux-Roses, email: jriepl@berlin.far.cea.fr).

The Grenoble area is located at the confluent of three relatively narrow alpine glacier valleys (typically 5 km in width), which are filled with thick quaternary, post-glacial deposits (up to 900 m thick). This geological configuration exhibits a large thickness over width ratio, which is typical of many other alpine valleys. The area is characterised by moderate historic and instrumental seismic activity, with active faults having the potential for at least magnitude 5 to 5.5 events within 10 km of the city. Instrumental recordings obtained at various locations within the city from several local and regional earthquakes consistently exhibit large amplifications over a broad frequency range (a factor exceeding 10 from 0.3 Hz to 5 Hz), as well as very rapid spatial variations and long durations that cannot be explained by 1D modelling. We thus performed a 3D finite-difference modelling using a fourth-order displacement-stress finite-difference scheme with combined memory optimisation developed in Bratislava. The computations are performed for two local, small events that were well recorded inside the town: a magnitude 2.5 located at 10 km to the north-east ("Lancey" event, 21/09/95), and a magnitude 3.5 event located 15 km to the south ("Laffrey" event, 11/01/98). The computations are carried out up to a frequency of 2 Hz, and the source is represented by point sources. A satisfactory quantitative agreement is obtained with observed records, so that we plan to use this FD modelling to anticipate ground motion at other locations inside the valley through an improved understanding of 2D and 3D effects, and for larger events (up to magnitude 5.5) as well.

ST3/E/31-B3 1000

CHARACTER OF STRONG GROUND MOTION AND GEOLOGICAL STUCTURE IN LIJIANG BASIN, CHINA

Lequn JIANG(Seismological Bureau of Yunnan Province, 650041 Kunming, China, Email: ydj@public.km.yn.cn); Junpei Akamatsu (Disaster Prevention Research institute, Kyoto University, 611-0011, Uji, Japan, Email: akamatsu@drs.dpri.kyoto-u.ac.jp)

The 1951 Jianchuan earthquake with M6.3 and the 1996 Lijiang earthquake caused serious loss of lives and property in Lijiang basin. Despite lack of instrument recorder of ground motion, the character of strong ground motion was understood through detail investigation of seismic hazard including geographical distribution of human loss in these two earthquakes. Though the epicenter's locations and the strike of seismogenic faults were different, the anomalous intensity distributions caused by two earthquakes were almost the same in Lijiang basin. The serious damages were occurred in Zhonghai village which was about 40 km north-west from the 1951 Jianchuan earthquake's epicenter and also about 40 km south from 1996 Lijiang earthquake's epicenter in these two earthquakes. In order to make sure the local geologic structure which causes anomalous intensity distribution, YSB and Sino-Japanese research term made a lot of research work in Lijiang basin including seismic observation, microtremor survey, deep seismic sounding, reflection survey, gravity survey, boring, underground radar survey and so on. Data analysis shows that there are at least two kinds of geologic structure which cause anomalous distribution of intensity in this area. 1. Bedrock subsides steeply at basin edges by about 400m and the depth to bedrock in the center reaches 1,200m or more. The focussing effect of seismic energy by paraboloid-like bedrock of Lijiang basin is one of the possible causes for the anomalous distribution of intensity. 2.Lijiang area is a geological conjunction zone. Jianchuan-Lijiang fault, Xueshan fault and some other faults divided this area into several tectonic blocks. Effect of the boundaries between crustal blocks is another one of the possible causes for the anomalous distribution of intensity.

ST3/E/10-B3 1045

ANALYSES OF STRONG GROUND MOTIONS RECORDED DURING JIASHI EARTHQUAKES

Li-Li XIE and Mingzhu Guo (Institute of Engineering Mechanics, China Seismological Bureau, 29 Xuefu Road, Harbin, 150080, China, email: llxie@public.hr.hl.cn)

During the four months from the January to the April 1997, there were seven earthquakes of the magnitude greater than Ms 6 occurred in the Jiashi Area of the Xinjiang Uygur Autonomous Region. All the epicenters of the earthquakes were located in a narrow rectangular area of 18x9Km with latitude from N39 31' to N39 41' and longitude E76 57' to E77 03'. During the earthquakes, a small array, consisting of four strong motion accelerographs and about 8.5-170Km respectively far from the epicentral area, recorded the strong ground motions for all events.
In this paper, the characteristics of the recorded ground motions were analysed. Some interesting results, such as coherency of the ground motions, ratio of vertical to horizontal components, spectral characteristics, etc are presented.

ST3/E/26-B3 1100

THE LIMITATION OF H/V RATIO IN ESTIMATING THE SITE RESPONSE OF LAYERED MEDIUM

Hung-Chie CHIU, (Institute of Earth Sciences, Academia Sinica, P.O. Box 1-55 Nankang, Taipei, Taiwan, R.O.C., email: chiu@earth.sinica.edu.tw) Ta-liang Teng (Department of Earth Sciences, University of Southern California, Los Angeles, CA 90089-0740, email: lteng@coda.usc.edu) Xiaofei Chen (Department of Geophysics, Peiking University, Beijing, China, email: xfchen@pku.edu.cn)

Spectral ratio between horizontal and vertical components (H/V ratio) has been widely applied to site response estimation recently. However, the physical basis behind this ratio is still unclear. Furthermore, most studies indicated that the H/V ratio only can predict the fundamental resonant frequency but very few researchers claimed that this ratio could estimate the amplification factor. Although many researchers have attempted to verify this method, none of them have fully explored this problem. This paper presents an extensive analysis of the H/V ratio and gives one possible approach to verify the controversial assumptions that made for developing the H/V method. We also give a reasonable explanation to the observations. According to our analyses, the H/V ratio can well estimate the fundamental resonant frequency for a simple layered model with a simple source, and this method may fail in all other cases because of noise, multi-layered-medium or complicate-source effects. Numerical validation based on synthetic seismograms also supports our assessment.

ST3/W/30-B3 1115

REAL-TIME MAPPING OF POST EARTHQUAKE STRONG-GROUND MOTION

YI-BEN TSAI (Institute of Geophysics, National Central University, Chung- Li, Taiwan, Email: ybtsai@eqm.gep.ncu.edu.tw), Yih-Min Wu, Jau- Yi Lin(Both at Central Weather Bureau,64 Kung Yuan Road, Taipei, Taiwan, Email: ludan@ss2.cwb.gov.tw), and Chang-Chi Young (Institute of Geophysics, National Central University, Chung- Li, Taiwan)

We have combined the functions of two advanced accelerograph networks in Taiwan to develop a method for detailed real-time mapping of post- earthquake strong ground motion. The first is a real-time accelerograph network of 60 stations which provides rapid earthquake reports for the public. The station spacings of this network are about 20km x 20km. The second is a stand-alone free- field accelerograph network. The station spacings of this network are about 5kmX5km. Since its first deployment in 1992, the second network has recorded tens of thousands of ground motion accelerograms. We have used these records to establish relative local site response function at each free-field accelerograph station with respect to a nearby real-time network station. By this way, once the real-time network station records strong ground motion from a damaging earthquake, we can immediately calculate the ground motion response spectrum at each station by multiplying the observed response spectrum at the reference station from the earthquake with the relative local site response function. We have tested this method for the Taipei Basin area with excellent results. We are currently expanding the tests to other areas of Taiwan.

ST3/E/25-B3 1130

A MEASURE OF GROUND MOTION INTENSITY

KOOROSH SHARIF (Institute of Geophysics, Tehran University, email: mraeesi@iman.ut.ac.ir) . R. Gheitanchi (Institute of Geophysics, Tehran University, email: rghchee@chamran.ut.ac.ir)

Quantification of the damage potential of ground motions is desirable for various reasons. Such a quantity facilitates comparison among different types of ground motions. Morever, rational design limit states may be established by employing a single quantity, which represents the damage potential of the ground motion, expected at a given site. However, this quantity should reflect the influences of basic excitation and system characteristics contributing to the seismic response of structural systems. There are various studies in earthquake engineering literature devoted to the quantification of the damage potential; they describe different physical values in term of different physical units. Arias (1970) introduced a measure of ground motion intensity as the area under the spectrum of total energy absorbed by undamped single degree of freedom (SDOF) system at the end of the ground excitation. But a SDOF system is a discrete system and it does not reflect all characteristics of ground motion. It might be better that we use a continuous system as a vertical elastic rod that is attached to the earth instead of a discrete system that interacts with the excitation. In this paper we introduce the intensity of ground motion as the total energy absorbed by a vertical elastic rod with a length of one meter which is vibrated longitudinally and torsionally by ground motion. The results are in agreement with the observed ground motion intensity.

ST3/E/37-B3 1145

THE DISTRIBUTION OF GROUND STRAIN AND GROUND FAILURE CAUSED BY A MODERATE EARTHQUAKE IN SOUTHWESTERN TAIWAN

Yeong-Tein Yeh, Han-Yih Peng, Kuo-Liang Wen and Shui-Bei Yu (All at Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, R.O.C., Email: ytyeh@earth.sinica.edu.tw)

On July 17, 1998, an earthquake with magnitude 6.2 in Richter scale occurred in Rui-Li, Chia-Yi, Taiwan. The epicenter is located at 23"X 30.78"F N and 120"X 37.98"F E and the focal depth is about 6 km. The earthquake caused some ground failure, landslide, and building damage. There are 5 deaths and 17 injuries. It has been the most damaging earthquake occurred in southwestern (SW) Taiwan since 1964. The strong ground motions induced by this earthquake were recorded by 79 out of around 110 observation stations, in SW Taiwan, installed by the Central Weather Bureau, Taiwan in the past years. In this research, we used these strong motion recordings to estimate the distribution of ground strains. First of all, single station estimation method was used to calculate the 9 components of displacement gradient tensors. Then, the co-ordinate strains and/or the principle strains are deduced for each observational site. The observed maximum strain is about 200m in N81"XW at near epicenter distance. In the meantime, the GPS measurements of coseismic ground deformations were also used to estimate the corresponding ground strains for comparison. Finally, the estimated strain distribution will be discussed and compared with the ground damage pattern caused by this earthquake.

ST3/E/39-B3 1200

ON-LINE WORLD-WIDE STRONG GROUND MOTION DATABASE (SMDB) AND SYNTACTIC WAVEFORM CLASSIFICATION

A.D. GVISHIANI, A.A. Burtsev, M.N. Zhizhin, CGDS, Molodezhnaya Str. 3, GC, Moscow, 117296, Russia; +7-095-1334339; Email: gvi@wdcb.rssi.ru; J. Bonnin, EOPGS, 5 rue Descartes, F-67084 Strasbourg Cedex, France; +33-88416368; Email: bonnin@selene.u-strasbg.fr

The SMDB is a relational seismic waveform data base of accelerograms in the near fields of strong earthquakes, which allows using WWW-browser to retrieve the waveforms together with a set of essential parameters of events, stations and instruments. You may select from more then 23000 records of ground acceleration, velocity and displacement were recorded during well-known strong earthquakes. They describe 786 events recorded by 1235 stations all over the world in the period of time 1933 - 1994. To get data, one may fill in a query form, and retrieve a list of records containing set of essential parameters of related events, sites and instruments. The listed records can be dynamically plotted. One can also find description of recent strong earthquakes on the Web site in half an hour delay. "Syntactic Pattern Recognition Scheme" (SPARS) does classification of the SMDB by wavelet analysis and syntactic pattern recognition. Please consult us to get digital data from SMDB. WWW: http://www.wdcb.rssi.ru/CGDS/ E-mail: gvi@wdcb.rssi.ru
The problem of seismic resistance and vulnerability of potential building constructions becomes more and more important with time. To do seismic engineering calculations accelerograms recorded in the nearfield of strong earthquakes epicenters occurred in those regions are needed. If they are not available similar records from other regions are used. The principal problem is: what is definition of "similar records" and how to find them? The CGDS/EMSC Strong Motion Data Base (SMDB) and Syntactic Pattern Recognition Scheme tackles this problem.

ST3/E/44-B3 1215

PRE-INSTRUMENTAL EARTHQUAKES IN A LOW-SEISMICITY REGION: REINTERPRETATION OF THE 16 NOVEMBER 1931 EVENTS IN CENTRAL FINLAND

Paivi MANTYNIEMI (Institute of Seismology, University of Helsinki, Helsinki, Finland, email: paivi@seismo.helsinki.fi)

The largest earthquake known to have occurred in a given region may not have been devastating but is nevertheless of importance when evaluating the seismic hazard. This applies to central Finland, too, where only non-instrumental data are available for the more noted events. This study deals with some of the problems involved in assessing the macro-seismic intensity at the lower degrees where many of the classification factors depend solely on human perception.
The maximum intensities of the main shock in central Finland on 16 November 1931 and its largest aftershock have previously been assessed as 6 and 5 (MCS), respectively. The reconsideration of the data is motivated by some features of the earlier analysis such as a strong emphasis given to local anomalies and a confusion between felt and heard effects.
A total of about 800 reports with noted effects, including questionnaire data, free format descriptions, and interviews, are available for the main shock. For the present study, newspapers were scanned for additional information of the events.
These data are used in assessing the intensity on the European Macro-seismic Scale of 1992 (Gruenthal, 1993). Statistical methods are applied, and the outputs compared with that of the earlier analysis. Special attention is given to assessing the quality of the observations. A brief commentary on the possible effects of a similar earthquake today is included.

Wednesday 28 July PM

ST3/W/34-B3 1400

NEAR-SOURCE INVERSION FOR THE APRIL 12, 1998 BOVEC EARTHQUAKE

Angela Sarao` and Peter Suhadolc (both at Dipartimento di Scienze della Terra, Universita` di Trieste and The Abdus Salam International Centre for Theoretical Physics, Trieste, Italy.
E-mail: angela@geosun0.univ.trieste.it)

On April 12, 1998 a 5.6 magnitude earthquake occurred in NW Slovenia near the border with Italy. It was a dextral strike-slip mechanism with small tensile component. The main shock was followed by aftershocks, the strongest one (M=4.6) located few kilometers away from the main shock. To gain insight into the rupture process we have inverted the three-component accelerograms of the main event, recorded by the Friuli accelerometric network, for different sizes and positions of the fault. The results of the inversions allow us to single out the main features of the rupture process which is characterised by two big patches of energy release on the fault. Our results are compared with the geotectonic evidences for the region under study. Solutions obtained inverting velocities and displacements at different frequencies are also discussed.

ST3/W/09-B3 1415

THE RETRIEVAL OF THE EARTHQUAKE RUPTURING PROCESS BY STRONG MOTION DATA: RESULTS FROM A BLIND TEST

Angela Sarao`, Peter Suhadolc (both at Dipartimento di Scienze della Terra, Universita` di Trieste and The Abdus Salam International Centre for Theoretical Physics, Trieste, Italy.
E-mail: angela@geosun0.univ.trieste.it) and Shamita Das (Dept. of Earth Sciences, University of Oxford, England)

A “blind test” has been performed to determine if different methods of analyzing the accelerograms to retrieve details of the earthquake rupturing process lead to similar results. Synthetic accelerograms, to be used as observed data, are computed using the multimodal summation method for an extended source. The moment distribution used to generate the synthetic data was kept secret by one of the authors and only some parameters of the input model such as the seismic moment, focal mechanism and hypocentral location and fault area extension were known. The results obtained by the most suitable procedure for such kind of study, are thoroughly discussed. The inverse problem is solved using the Das-Kostrov method of linear programming with additional physically-based stabilizing constraints. We present the results obtained when 1) each grid is allowed to slip only once; 2) the grids can slip more than once; 3) using only the vertical or the horizontal components; 4) using only seismograms whose amplitudes were comparable to each other. For most of the cases the fit of the waveforms is quite good and the location of the main energy release can be identified on the fault.

ST3/W/40-B3 1430

SPECTRAL GROUND MOTION ATTENUATION FOR SWITZERLAND AND A FIRST APPLICATION TO SEISMIC HAZARD EVALUATION IN THE VALAIS

Patrick SMIT (Department of Civil and Environmental Engineering, Imperial College of Science, Technology and Medicine, London SW15 3LR, UK, email: p.smit@ic.ac.uk) Erik Ruttener (Zurich Re, Risk Management, General Guisan-Quai 26, 8022 Zurich, CH, email: erik.ruettener@zurich.com)

The quantitative models used for the anti-seismic design of buildings in Switzerland are based on macro-seismic observations and ground motion acceleration data from adjacent countries. The lack of strong-motion data led in 1983 to the decision to install a national strong-motion network in Switzerland. In 1992 63 digital free-field and dam-related stations were deployed by a governmental working group and subsequently extended to 95 stations. The recordings of this network and the seismograph network, both operated by the Swiss Seismological Service, allow nowadays deriving own attenuation models for peak ground acceleration and spectral ground accelerations. The paper presents the empirical scaling of Fourier amplitude spectra and peak acceleration of earthquake induced ground motion with respect to local-magnitude and hypocentral-distance, valid for rock sites in Switzerland and the adjacent areas. These models are applied to the calculation of seismic hazard curves for the middle and upper Valais (southwestern Switzerland). These areas show the highest seismic activity, historically as well as in this century. The results are in good accordance with estimated macroseismic intensity values for the same return period, as obtained in earlier studies.

ST3/E/52-B3 1445

STRONG GROUND MOTION ATTENUATION RELATIONSHIPS FOR THE CAUCASUS

Patrick SMIT (Department of Civil and Environmental Engineering, Imperial College of Science, Technology and Medicine, London SW15 3LR, UK, email: p.smit@ic.ac.uk) Valery ARZOUMANIAN (National Survey for Seismic Protection of the Republic of Armenia, 375054 Yerevan, Armenia, email: arz@nssp.yerphi.am) Zurab Javakhishvili (Institute of Geophysics; Georgian Academy of Sciences, 380093 Tbilisi, Georgia, email: zjavakh@hotmail.com), Sergej Arefiev (Unified Institute Physics of the Earth, Russian Academy of Sciences, 123810 Moscow, Russia, email: arefiev@synapse.ru)

The paper presents the first predictive relation for horizontal and vertical peak ground acceleration and 5% damped maximum absolute acceleration spectrum, appropriate for predicting earthquake ground motion in the Caucasus. The empirical attenuation models were developed based on data from the permanent digital strong motion network installed in 1990 in the epicentral area of the 1988 Spitak (Armenia) earthquake and several temporary networks in the epicentral area of strong earthquakes in the Caucasus and the adjacent area (7.7Ms Manjil, 20.6.1991; 7.0Ms Racha, 29.4.1991; 6.8mb Erzincan, 15.3.1992). The instruments and operation of the permanent and temporary networks were jointly funded by the Swiss Disaster Relief Unit. Today the permanent digital strong-motion network comprises 12 digital free-field stations in the northern part of Armenia and Georgia and are operated by national agencies. This network is complemented by 16 analog strong motion instruments installed all over Armenia and structure-related arrays in the Metsamor nuclear power plant (Armenia) and the Inguri arch dam (Georgia).
The attenuation models, which are considered applicable for estimating free-field ground motions on alluvium from earthquakes in the Caucasus with magnitudes between 3 and 7, were successfully adopted in the calculation of the seismic hazard of Georgia.

ST3/W/18-B3 1500

REGIONAL WAVE ATTENUATION FROM WEAK MOTION DATA

P. L. Bragato, A. Govoni and D. SLEJKO (Osservatorio Geofisico Sperimentale, Trieste, Italy, e-mail: dslejko@ogs.trieste.it)

Attenuation relations for the main seismic hazard quantities (peak ground acceleration, spectral acceleration, etc.) are computed from strong motion data and, consequently, are valid in the high to medium magnitude range only. This is reasonable as seismic hazard maps for high seismicity regions are dominated by the contribution of the largest earthquakes. The scarcity of strong motion data limits the definition of specific attenuation relations of geographical and/or tectonic validity. In this work we explore the possibility of using large data sets of digital seismometric data available today for extending and validating attenuation relations in the weak motion regime and getting better spatial resolution at sub-regional scale. Key steps to this goal are reliability of the acquisition process, robustness of inversion procedures, and homogeneity of data set characteristics.

ST3/E/02-B3 1515

USING DATA FROM SMALL TO MODERATE MAGNITUDE EARTHQUAKES TO CONSTRAIN ATTENUATION FUNCTIONS

Gary GIBSON (Seismology Research Centre, 2 Park Drive, Bundoora, Victoria 3083, Australia, email: gary@seis.com.au)

Attenuation functions give ground motion as a function of earthquake size and distance. Most have been derived using data from earthquakes in the range from magnitude Mw 5 to Mw 7. This applies for functions giving any measure of ground motion, such as peak ground acceleration, peak ground velocity, intensity, Fourier spectra or response spectra.
Functions have been published for a wide range of tectonic environments, with some functions emphasising smaller events and some larger, and some functions emphasising motion at closer distances and others at greater distances. Superimposed ground motion plots using published functions for earthquakes of magnitude Mw 6 show some scatter. Few on-scale recordings of strong motion data are available from nearby earthquakes in the range from Mw 7 to Mw 9. When computing ground motion recurrence (earthquake hazard), it is necessary to extrapolate out of the magnitude and distance ranges in which the functions were derived. For large events, the various published functions produce much greater scatter in ground motion estimates than for Mw 6. If the same attenuation functions are used to extrapolate to smaller earthquakes, there is a similar very wide scatter in estimated ground motion. In this case data are available, but often have not been used in the derivation of the functions. Although the weaker motion from small earthquakes represents little earthquake hazard, it can constrain the rate of change of ground motion with both magnitude and distance. It can also be used to evaluate methods for dealing with source dimension in attenuation functions. If data from smaller earthquakes are used in the derivation of attenuation functions, then the extrapolation to critical large events should be more reliable. Spectral attenuation functions using data from small nearby events will show their high acceleration, high frequency motion, but with low displacement and low hazard.

ST3/E/29-B3 1530

THE ATTENUATION RESEARCH OF THE STRONG GROUND DISPLACEMENT IN CHINA

CHEN PEISHAN Li Baokun Bai Tongxia (Institute of Geophysics, China Seismological Bureau, Beijing, 100081)

We have found from the fracture mechanics rupture model of = earthquakes that the peak ground acceleration PGA and velocity PGV and = displacement PGD strongly depend on the tectonic ambient shear stress = value =A6=D30. =A6=D30 value is introduced into the predictive equation = of PGD by us, at the same time the dependence of predominant frequency = of PGD fd on magnitude is considered. Based on both improvements, the = predictive equation of PGD(CLB98d) has been derived from theoretical = analysis. It has been tested by observation data that this predictive = equation is suitable for epicentral distance range = =A1=F7=3D10=A1=AA250km and magnitude range Mw=3D4=A1=AA7.2. There are = different =A6=D30 values in different regions all over the world, but = the influence of =A6=D30 value on PGD is not large. =20. Key words: tectonic ambient shear stress field, peak ground = displacement, predictive equation, predominant frequency.=20.

PGA AND RESPONSE SPECTRA ATTENUATION RELATIONS DEDUCED FROM THE GULF OF CORINTH (GREECE) STRONG MOTION DATABANK

D. DIAGOURTAS and K. Makropoulos (both at Dept. of Geophysics & Geothermy, Univ. of Athens, 157 84 Zografou, Greece, E-mail: ddiagour@cc.uoa.gr)

An extensive databank constructed from high quality strong motion data accumulated during the last 7 years by RASMON (Rion-Anririon Strong Motion) Network, w. Gulf of Corinth (Greece), is used to derive PGA and response spectra local attenuation relationships. The results show remarkable differences between sites located off the north and south coasts of the Gulf which is attributed to corresponding differences in the local geological settings, emphasising thus, the usefulness and necessity of such approach towards a more realistic a-seismic design.

ST3/W/03-B3 1630

NUMERICAL MODELLING OF THE VRANCEA SOURCE INFLUENCE ON THE LOCAL SEISMIC RESPONSE IN BUCHAREST

C.L. MOLDOVEANU ([1] National Institute for Earth Physics, Bucharest, Romania; [2] Dipartimento di Scienze della Terra, Universita' di Trieste, Italy; Email: carmen@geosun0.univ.trieste.it) G. F. Panza ([2] Dipartimento di Scienze della Terra, Universita' di Trieste, Italy; [3] The Abdus Salam International Centre for Theoretical Physics, Trieste, Italy; Email: panza@geosun0.univ.trieste.it)

The Vrancea region, characterised by strong intermediate-depth earthquakes, represents the main source to be considered for the seismic risk mapping both at the national (Romania) and the regional level (south-eastern Europe). The mapping of the seismic ground motion in Bucharest, the main city affected by this source, is carried out using a complex hybrid waveform modelling that combines the modal summation and the finite difference schemes, and allows us easy parametric tests. The information necessary for the numerical simulations takes into consideration the source, the averaged regional model and the local structure for Bucharest. The two scenario earthquakes we consider, representative for the seismicity of the region, correspond to the March 4, 1977 (Mw=7.4), and May 30, 1990 (Mw=6.9) Vrancea events. The site effects are analysed in order to define generally valid ground motion parameters, to be used in the seismic hazard estimations. The synthetic signals and the local response are nicely compared with the damage observed in Bucharest for the March 4, 1977 Vrancea event, the strongest earthquake that hit the city in modern time.
We show that using the 2-D hybrid waveform modelling we can make realistic predictions for the possible seismic input which can compensate the lack of strong motion records, available only for a few events that occurred in the last 20-30 years. The synthetic ground motion database can lead to a reliable mapping of the local seismic hazard of Bucharest.

ST3/W/01-B3 1645

SEISMIC GROUND MOTION SIMULATION FOR THE 1995 KOBE EARTHQUAKE

Jozef Kristek, Peter MOCZO (both in Geophysical Institute, Slovak Academy of Sciences, Dubravska cesta 9, 84228 Bratislava, Slovak Republic, email: geofpemo@savba.sk), Kojiro Irikura, Tomotaka Iwata and Haruko Sekiguchi (all in Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, 611, Japan, email: irikura@egmdpri01.dpri.kyoto-u.ac.jp)

The long-period (T>1s) seismic ground motion during the 17 January 1995 Hyogo-ken Nanbu (Kobe), Japan, earthquake is numerically simulated and compared with the recorded ground motions in the Kobe area. Since the main goal is to understand the observed damage belt in Kobe, only a part of the Osaka sedimentary basin is considered in the simulation. A 3D model of the medium is that constructed by Iwata et al. (1998) on the basis of all available geophysical and geologic data. Besides the reference three-layer basin model certain modifications are also considered for comparison. The complex rupture process is modelled using a kinematic fault model of Sekiguchi et al. (1998) obtained by inversion of strong-motion velocity seismograms. The rupture process is simulated by activating point dislocation sources distributed over five fault segments. Both the rupture process and wave propagation are numerically simulated by the 4th-order displacement-stress finite-difference scheme on a staggered grid. Efficiency of the simulation is significantly increased using a discontinuous spatial grid and memory optimisation. A discontinuous grid that combines spatial grids with grid spacings h and 3h reduces the total number of grid points (Kristek et al., 1998). The combined memory optimisation (CDMO, Moczo et al., 1999) reduces core and disk memory requirements. Synthetic ground motion from several simulations are analysed and compared with the recorded ground motion in order to validate the model and discuss main factors forming the ground motion anomaly in the Kobe area.

ST3/W/50-B3 1700

STRONG MOTION PREDICTION FOR SCENARIO EARTHQUAKES ON ACTIVE FAULTS

KOJIRO IRIKURA(1) and Katsuhiro Kamae(2) (1) Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, Phone: 81 774 38 4060, FAX: 81 774 33 5866, Email: irikura@egmdpri01.dpri.kyoto-u.ac.jp; (2) Reactor Research Institute, Kyoto University, Noda, Kumatori-cho, Sennai-gun, Osaka 590-0494, Japan, Phone: 81 724 51 2369, FAX: 81 724 51 2603, Email: kamae@kuca.rri.kyoto-u.ac.jp

A method of strong motion prediction for future earthquakes is proposed to mitigate earthquake damage in urbanised areas surrounded by seismogenic active faults. The lesson from the 1995 Hyogo-ken Nanbu (Kobe) earthquake shows the importance of evaluating a

S

synergistic effect of source and local geology effects, which produced killer pulses causing heavy damage in Kobe and adjacent cities. To consider such effects, we propose a hybrid method estimating Green's functions, deterministic and stochastic approaches in low (< 1 Hz) and high (> 1 Hz) frequency range, respectively. Source characterisations of scenario earthquakes shall be made, based on geological investigations of capable earthquake faults and seismological studies of source models. Rupture starting and termination areas of the scenario earthquakes would be evaluated from segmentation and grouping of active faults based on branching features of seismic surface ruptures. The heterogeneous slip distribution in the source area is inferred, based on some statistical analyses of source inversion results using strong ground motion data for recent earthquakes. We examine this method by comparing peak ground velocity and acceleration of estimated ground motion and damage distribution in past damaged earthquakes such as 1948 Fukui and Tottori earthquakes. Then, we apply to simulate strong ground motions for hypothetical large earthquakes in the Osaka metropolitan area.

ST3/W/37-B3 1715

PHYSICALLY CONSTRAINDED SOURCE MODELS FOR BROADBAND GROUND MOTION SYNTHETICS

ALEXEI TUMARKIN, Institute for Crustal Studies, University of California, Santa Barbara, CA 93106-1100, USA; email: alexei@crustal.ucsb.edu

Reliable ground motion prediction is not possible without a formalised and validated procedure for choosing a detailed description of the rupture time history of the simulated earthquake. While numerous source inversion studies provide valuable information on source complexities, they are limited to low frequencies (below 0.5-1 Hz). An attempt to predict ground motions from a future earthquake by specifying only its seismic moment is doomed to failure. Accordingly the highly successful stochastic approach (Hanks and McGuire, 1981; Boore, 1983) based on the w-squared spectral model (Aki, 1967; Brune, 1970), requires two characteristics - moment and stress parameter. It can be shown, that instead of the formal stress parameter, one can use the apparent stress, that has a clear physical meaning being proportional to the ratio of the total radiated energy and the moment (Randall, 1973; Tumarkin, 1999). The radiated seismic energy was considered as a fundamental quantitative measure of earthquake's size long before the seismic moment or even the magnitude were introduced into practice (Golitzin, 1915; Jeffreys, 1923). The main result of our study is that using two constraints - moment and energy - one can reduce the model uncertainty of predictions by narrowing the range of possible combinations of slip, rise time, rupture time and hypocenter location for any extended source model. Our studies of the temporal evolution of the apparent stress revealed an interesting feature observed both for earthquakes and dynamic rupture models. The initial stage of a rupture process is characterised by a sharp increase of the apparent stress to values exceeding the final number by a factor of 3-4, then it quickly stabilises around its final value. This characteristic behaviour can be used to further constrain the source models.

ST3/W/46-B3 1730

HYBRID-EMPIRICAL MODEL FOR ESTIMATING STRONG GROUND MOTION IN REGIONS OF FEW STRONG-MOTION RECORDINGS

KENNETH W. CAMPBELL (EQE International, 6555 S. Olympus Dr., Evergreen, CO 80439, USA, email: KCampbell@eqe.com

The hybrid-empirical model is an alternative to the purely theoretical models commonly used to estimate strong ground motion in regions of few recordings. Theoretical models have become the de facto engineering standard for estimating ground motions in such regions. However, theoretical models lack the empirical basis that is inherent in purely empirical models. The model is considered a "hybrid" because it uses modified empirical estimates from a host region other than that for which the predictions are made. These empirical estimates are modified using simple theoretical techniques to account for differences in the source, propagation, and site characteristics between the host and target regions. An inherent strength of the hybrid-empirical model is its reliance on ground-motion models that are well constrained by actual strong-motion recordings. As a result, observations rather than theoretical assumptions control the magnitude- and distance-scaling characteristics of the model. The aspect of the model is particularly important for ground-motion estimates in the near-source region of large-magnitude earthquakes, which are strongly affected by the complex characteristics of the rupture process. Additional strengths of the model are its explicit incorporation of uncertainty and its reliance on relative rather than absolute theoretical ground-motion predictions. In its current form, the hybrid-empirical model is applied to a selected target region as follows. First, several candidate empirical attenuation relationships for generic rock are selected from a host region (e.g., California). Second, seismological and crustal parameters are selected for both the host and target regions to use in the theoretical estimation of ground motion in these regions. Third, a theoretical stochastic simulation model is used to develop ratios of peak and spectral strong-motion parameters between the target and host regions. Fourth, the ratios are used to adjust the empirical ground-motion estimates from the host region. Finally, the adjusted empirical estimates are weighted and used to develop scenario response spectra and/or regional attenuation relationships for the target region.

STUDIES ON TECTONICS, SEISMICITY AND OCCURRENCES OF MAJOR EARTHQUAKES IN NORTH-EAST INIDA

D.Shanker (Department of Earthquake Engineering,University of Roorkee Roorkee-247667, India. E-Mail: quake@rurkiu.ernet.in)

Last two decades have witnessed considerable development in the field of seismological investigations. A number of approaches have been given for seismic hazard evaluation and earthquake prediction. The north-east India region(18(to 32(N and 84(to 100(teast. The stress pattern in the basin is directed towards northeast. The seismicity and stress distribution pattern of Burmese arc are due to downward bending of the zone around 24(N caused by southeast flow of Tibetan plateau. The region also exhibits

ST3/W/04-B4 0945

PALEOSEISMIC INVESTIGATIONS ALONG THE ROER VALLEY GRABEN

Bernard Dost, Laslo Evers (both at KNMI, P.O.Box 201, 3730 AE De Bilt, the Netherlands).br Ad Lokhorst (NITG-TNO, Postbus 157, 2000 AD Haarlem, the Netherlands) Meindert W. van den Berg (NITG-TNO, Postbus 511, 8000 AM Zwolle, the Netherlands)

The seismic risk of the Netherlands and immediate Surroundings is calculated on the basis of historical seismicity. The region is regarded a low seismicity area, although in 1992 the Roermond earthquake (Ml= 5.8) showed the impact of an occasional larger event. The historical period is rather short and large events occurring at a longer return rate will be missed in the analysis. In order to estimate the significance of possible prehistoric events a palaeoseismic investigation is being carried out along the Peel boundary fault, bordering the seismic active Roer valley graben to the North. During 1998 site selection was made for the construction of a trench. Important criteria in the site selection are the detection of a surface expression of the scarp and the possibility of dating at a high time resolution. The availability of different sources of data (areal photographs, seismic reflection lines, geomorphological data) provided a starting point. In particular a 117 years long time series of levelling data provided rates of vertical movements in the area. Accurate dating is envisaged by selection of the trench in river terraces, which are very well dated. Zooming in on possible trench locations further requires the acquisition of shallow reflection seismics, electrical tomography and ground penetrating radar. It is planned to finalise site selection early 1999 and to start trenching in April/May 1999. In the presentation an overview will be given of the status of the project and future plans. The project is part of the EC funded PALEOSIS program.

ST3/E/07-B4 1000

REAPPRAISAL OF A XVI CENTURY EARTHQUAKE COMBINING HISTORICAL, GEOLOGICAL AND INSTRUMENTAL INFORMATION

Gianluca Valensise (Istituto Nazionale di Geofisica, Roma, Italy); MARCO MUCCIARELLi (Universit` della Basilicata, Potenza, Italy, email: mucciarelli@unibas.it) Maria Rosaria Gallipoli (I.M.A.A.A.-C.N.R., Tito Scalo, Italy); Riccardo Caputo (Universit` della Basilicata, Potenza, Italy)

The earthquake occurred during 1561 in Southern Italy heavily struck a Zone known as Vallo di Diano. This is the only destructive earthquake whose epicenter is attributed to that valley. Two problems arise about this epicentral location: 1) the distribution of reported effect is highly asymmetrical, possibly reflecting population distribution at that time, 2) some geologist maintain that there is no evidence for ongoing active tectonics in the Vallo di Diano area. Further doubts are cast by the fact that there is a very well known active zone few km away: the Val d'Agri, whose 1857 event is described in the monumental work of Robert Mallet, and for which no data is available about the 1561 event. The basic question behind our work is the following: Is it possible that both expert judgement and computer techniques have up to now placed the 1561 epicentre in the wrong place, driven by asymmetrical distribution of observations and by site effects enhancing damage in the alluvial valley? To try to answer this question, we performed site amplification measurements to have a sort of "station correction" for each locality involved, so to be able to understand if the intensity assigned on the basis of historical information is somehow biased by the presence of local effects. Then we studied some plausible scenarios of rupture propagation on finite faults to derive the best fit possible between observed intensity and theoretical models compatible with geological information.

ST3/P/02-B4 1015

IZOSEISMAL MAP AND TECTONICAL POSITION OF THE KOMÀROM EARTHQUAKE OF 1763.

Rudolf Gutdeutsch (Institutue of Meterology and Geophysics, University Wien, Nordbergstr. 17, A-1090 Wien) Gyozo Szeidovitz and PÉTER VARGA (Geodetic and Geophysical Research Institute of HAS, 9401 Sopron, P.O.Box 5. Hungary, email: varga@ggki.hu)

One of the largest earthquakes of the last five centuries in Carpatian basin occured in Komarom on 28. June 1763. The earthquake was felt over a very large area. This earthquake is significant not only because of its seismotectonic implication, but also for the earthquake hazard assessment of Gabcikovo/Nagymaros Barrage System. On the damages caused by this earthquake quite correct pictures and texts are at authors disposal from Gyor and Komárom what allows an accurate determination of the sesimic intensities in these cities. On the areal distribution of the shocks informations were collected from the notice of losses recorded by the expert groups comissioned by Queen Maria Theresia. These committees consisted of bricklayer, carpenter, and mayor's counsellor. The reconstruction cost of every church, the manor houses and public houses was listed in detail and the sum of rebuilding of farm hauses was given. (In this relation etnographic informations on the architecture of willage buildings was also considered). Based on the above data the isoseismal map of the earthquake of 1763 was completed with significant reliability. The detailed study of the tertier basin morphology and different geohysical data (magnetotelluric and seismic profiles, gravimetric and magnetic maps) allows to interpret the tectonic position of this seismic event and to estimate its focal depth. Based on the reinterpretation of the earthquake of 1763 the statistics of the regional seismicity was also carried out.

ST3/W/42-B4 1030

PROBABILISTIC SEISMIC HAZARD MAPPING IN NORTHERN EGYPT

MOHAMMAD G. AL-IBIARY (Geology Dept., Faculty of Science, Helwan University, Cairo 11795, Egypt, e-mail: ibiary@frcu.eun.eg) Ramses Albert (National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt); Ahmed Abuel-Atta (Geophysics Dept, Faculty of Science, Ain-Shams University, Cairo, Egypt) and Ahmed Deif (National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt)

The expected ground motion at different return periods in Northern Egypt is mapped employing the probabilistic approach. The seismic sources were defined and their boundaries were delineated utilising the seismicity of the Eastern Mediterranean region, slip rates, maximum observed intensity, maximum expected earthquake magnitude, maximum expected acceleration and their fault plane solutions correlating the earthquake epicenters with the geological and geophysical data.
For the sake of for seismic risk evaluation, eight intensity-dependent attenuation models were produced in the present study for eight different directions around the epicenter (the north, north-east, east, south-east, south, south-west, west, and north-west). They were converted from intensity into acceleration models using a simple intensity-acceleration relationship. A regional acceleration-dependent model was also derived.

Using an appropriate seismic hazard model, the maximum expected acceleration with a probability of 90% not being occurred during the next 50, 100, and 500 years in Northern Egypt are calculated and contoured. The authors aim to contribute new hazard maps that can be used in the Building Codes, regional land-use planning, emergency preparedness and in the reinsurance analyses. The contributed maps also serve in designating several regions in Northern Egypt for subsequent seismological, geological and geophysical research.

ST3/W/21-B4 1115

NEW METHODOLOGY AND THE SEISMIC HAZARD MAPS OF NORTHERN EURASIA

Valentin I. ULOMOV (Schmidt United Institute of Physics of the Earth, Russian Academy of Sciences, Bol'shaya Gruzinskaya, 10, Moscow, 123810 Russia, email: ulomov@uipe-ras.scgis.ru

Comprehensive studies on the General Seismic Zoning (GSZ-97) of Northern Eurasia, including the territories of the Russia and other CIS republics and adjacent seismic regions, have been accomplished. The basic differences between the new methods and the previously used ones are as follows: the harmonized and standardized Lineament-Domain-Focal (LDF) model of earthquake source zones (ESZ) based on the fractal lattice regularization of the seismogeodynamic processes was developed; for the entire territory of Northern Eurasia the uniform ESZ model was created; seismic source size and orientation (rather than point sources previously considered) were used at all GSZ stages, from the identification of ESZ to the evaluation of strong ground motions; various non-standard data on regional seismicity (fractal structure; nonlinear earthquake recurrence; nonlinear seismic effect attenuation etc.) and earthquake sources (size, orientation, predominantly distance between sources with different magnitude etc.) were applied. The new method of creation of the ESZ model and their application to the seismic hazard assessment is named EAST -97 (Earthquake Adequate Source Technology). The GSZ-97 complete set consists of three maps: (1) GSZ-97-A, (2) GSZ-97-B and (3) GSZ-97-C, which 90%-s', 95%-s' and 99%-s' probability of not excess of MSK-64 intensity in 50 years. The GSZ-97-À map of Northern Eurasia was submitted in peak accelerations (PGA) and will enter by some component of the GSHAP Map (look http://seismo.ethz.ch/hazard/gshap/). For territory of Russia the GSZ-97 (A,B.C) maps were officially included in National Building Code. All materials are submitted in the electronic form with use of Geographical Information System (GIS ESRI).

ST3/E/43-B4 1130

ON THE METHOD OF SEISMIC REGIONALIZATION OF THE FENNOSCANDIAN SHIELD

BELA ASSINOVSKAYA (Geodynamical Laboratory, CAO RAS, Bolshoi pr.50G, V.O., 199034, Saint-Petersburg, Russia, email: bela@ba2248.spb.edu)

The seismic regionalisation methods are probably the least developed and formalised among the all seismic hazard assessment stages. Due to this fact certain regions especially with weak seismic activity areas such as the Fennoscandian Shield seem groundlessly large and generalised. Whereas the maximum earthquake magnitude(Mmax) is low as for the Fennoscandian Shield the simple cell square for assessment of Mmax should not exceed the area 10x10 km. Development of Mmax determination method described by us earlier is suggested. The method is based on the geological information and the most possible full data on the rock mechanical properties of the crust simple cell. This work uses relationships between accumulated energy and calculated strike slip rock strength at the depth of earthquake sources taking into an account pressure and temperature. In the Fennoscandian Shield conditions Early Proterozoic granite batholite intrusions formed in compression environment have the most seismotectonic potential that becomes less as geometry intrusion changing. Gneissic rocks with the same quartz contents as in granite, have lesser strike slip strength. The method was used to estimate Mmax in the region of seismic profile Kostamuksha -Pechenga on the north-east of the Fennoscandian Shield.

ST3/E/18-B4 1145

A PROBABILISTIC SEISMIC HAZARD MAP OF INDIA AND ADJOINING REGIONS: AN EXERCISE TOWARDS GSHAP

S C BHATIA and H K Gupta (Both at National Geophysical Research Institute, Uppal Road, Hyderabad-500007, India, E-mail: postmast@csngri.ren.nic.in)

This paper presents the results of the seismic hazard assessment exercise carried out in the framework of GSHAP (Global Seismic Hazard Assessment Program) over the Indian region , in the back drop of a review of the seismic hazard / zoning maps of India. The GSHAP exercise for India region started with computations over the GSHAP Test Area #8, bounded by latitudes 20N - 40N and longitudes 85E-105E. In continuation of the test area exercise, the region bounded by latitudes 0N-40N and longitudes 65E-100E was considered for the preparation of a seismic hazard map of India and adjoining regions. Based on the seismotectonic information, 86 potential seismic source zones were delineated. A catalog of main shocks was prepared by merging several local catalogs with the NOAA catalog, and removing duplicates, aftershocks and earthquakes without any magnitude. Using the probabilistic hazard assessment approach of McGuire, adopted by GSHAP, the Peak Ground Accelerations (PGA) were computed for exceedence level for 10 % probability in 50 years, as per the hazard definition adopted by GSHAP, at locations defined by a grid of 0.5 X 0.5 degrees. Since no reliable estimates of attenuation values are available for the Indian region, the global attenuation relation of Joyner and Boore was used. The PGA values over the grid were contoured to obtain a seismic hazard map. The hazard map depicts prominent highs of the order of 0.35g in the seismically active zones like the Burmese arc, North-eastern India, eastern Himalaya, etc. The other seismically active zones indicate PGA values of the order of 0.25 g. The major concerns that have emerged are that the Indian region poses a lot of problems for data homogenisation and the seismic hazard maps are strongly influenced by the size and shape of seismic source zones.

ST3/P/05-B4 1200

SEISMIC ZONING MAPS OF THE REGION OF ALGIERS (ALGERIA)

Youcef BOUHADAD, Laouami, Nacer. and Djamel El-Foul. (National center of applied Research in Earthquakes Engineering (CGS). 1, Rue Kadour Rahim, H.Dey Alger-Algé ria).

For the large city of Algiers earthquake hazard constitutes a serious and permanent threat for human lives as well as for properties. In the past, it was strongly hit by destructive earthquakes such as the 1716 event whose intensity reached X (Mercalli scale)and which claimed about twenty thousand human lives. In this paper it is proposed to predict seismic hazard in terms of values of maximum accelerations in some characteristic sites within the studied region. A seismic zoning was done by calculating hazard at different sites in the grid of IO km X IO Km using the probabilistic approach. In this study, the steps described below were performed:
1) Identification of all seismic sources capable of generating earthquakes in the future. The Algiers region lying in a compressive inter-plate region, earthquakes are mainly produced by active faults which are sometimes blind and associated to asymmetric folds. New techniques such as the digital elevation models to identify such faults are used.
2) Source parameters such as b-value, N(mO), Slip rate, maximum magnitude, and dip are assessed for each seismic source.
3) Conceming the ground motion attenuation a locally strong motion data was collected during the Ms= 6.1 Chenoua earthquake of October 29, 1989 and the Ms=5.6 Ain Benian-Algiers earthquake of September 4, 1996 using the local accelerograph Network as a part of the National Network previously deployed in the North of Algeria. Based on this data, a local attenuation relationship is developed. We used also the Worldwide developed attenuation relationships such as Ambraseys (I995) and Sadigh & al. (I989).
Results are presented as relationships between amplitudes of Peak Ground Accelerations (PGA) and annual frequencies of exceedance of those amplitudes as well as maps of the mean values of PGA for different return periods.
Key words: Earthquakes- Algiers-Hazard- strong motion- maps- seismic zoning- active fault-seismotectonics- probabilistics.

ST3/W/36-B4 1215

NEW TRENDS IN SEISMIC HAZARD EVALUATION IN GREECE

Stylianos KOUTRAKIS (Geophysical Laboratory, School of Geology, Aristotle University of Thessaloniki, Thessaloniki 540 06, Greece, email: stelios@lemnos.geo.auth.gr); Vassilis N. Margaris and Panagiotis K. Koliopoulos (both at Institute of Engineering Seismology and Earthquake Engineering, P.O. Box 53, 55102 Finikas, Thessaloniki, Greece, email: margaris@itsak.gr); George F. Karakaisis (Geophysical Laboratory, School of Geology, Aristotle University of Thessaloniki, Thessaloniki 540 06, Greece, email: karakais@geo.auth.gr)

Based on a growing number of observations indicating that some strong motion parameters, such as the peak ground acceleration and the peak ground velocity and ground displacement, exhibit rather weak correlation with the observed damage distribution, many researchers have suggested that the study of the strong ground motion duration, as well as of its energy content, may enhance the ability of choosing the proper design earthquake. Moreover, in some cases of the earthquake-resistant design the seismic hazard assessment is required to be represented in the form of acceleration time histories, in which the duration and energy characteristics play a significant role.
In the present study, a considerable number of strong ground motion components concerning recent, moderate to strong, earthquakes which occurred in Greece are used. For most of them the significant (or Husid) duration and several values of bracketed duration, corresponding to levels between 0% and 10%g, have been taken from the existing literature, while for earthquakes which occurred in Greece since 1994, these duration-related parameters are calculated and attenuation relationships are derived. On the basis of these data, the seismic hazard for the area of Greece for various return periods is calculated, in terms of the expected strong motion duration. The results are subsequently compared with existing seismic hazard maps based on other strong motion parameters (e.g. pga, etc).

ST3/E/53-B4 1230

SEISMIC HAZARD ANALYSIS AND SENSITIVITY ANALYSIS FOR THE KRESNA REGION (SW BULGARIA)

TORILD VAN ECK (Seismological Division, KNMI, PO Box 201, 3730 AE De Bilt, Netherlands. E-mail: vaneck@knmi.nl); Savka Dineva (Geophysical Institute, BAS, Ac.G Bonchev st. bl.3, 1113 Sofia, Bulgaria. E-mail: dgm-sid@geophys.bas.bg); Renata Rotondi (Consiglio Nazionale della Ricerche, Via Ampere 56, 20131 Milan, Italy. E-mail: reni@iami.mi.cnr.it) and Valeri Gitis (Inst. Information & Transmission Problems, RAS, B. Karetny 19, Moscow, Russia. E-mail: gitis@iitp.ru)

The region around Kresna (SW-Bulgaria) is tectonically complicated. The NNW-SSE oriented Struma lineament, a fault zone of older tectonic origin, is overlain by younger, SW-NE oriented, seismic active faults. A re-analysis of the observed seismicity since 1985 provided new locations, a new crustal velocity model and stress tensors. Further, the available earthquake catalogue for the region has been re-analysed in order to obtain a seismicity model. This seismicity model together with all available seismotectonic and geophysical data have been analysed to evaluate possible non-linear relationships between seismic activity, b-value or fractal dimension, RTL criterion and available geoscientific data.
This new information has been interpreted into a seismotectonic model of the region for a Probabilistic Seismic Hazard Analysis (PSHA). Presently, few ground acceleration measurements are available. Therefore using different peak ground acceleration relations and different PSHA approaches with a variety of models we made a sensitivity analysis. This enables us to access the major source of uncertainty, besides the ground motion attenuation.

SOME RESULTS OF SEISMIC HAZARD ANALYSIS OF BELGIUM

VLADIMIR MIHAILOV(1), Dragi Dojcinovski(1), Thierry Camelbeeck(2) and Roland Verbeiren(2) 1)Institute of Earthquake Engineering and Engineering Seismology at the University St. "Cyril and Methodius'; P.O.Box. 101, 91000 Skopje, Republic of Macedonia 2)Royal Observatory of Belgium, Av. Circulaire 3,B-1180 Brussels, Belgium

In recent years, the seismic hazard analysis has been recognised as an important part of earthquake engineering. Most of parameters and aspects associated with the seismic hazard analysis, however, have been studied for a long time, but an increasing interest in this field has been observed in the past fifteen years. As a result of this interest currently, there is a considerable work done in the area of probabilistic estimations of seismic load parameters. Since the best practical presentation of seismic loading for a given region or site is in term of seismic hazard maps (e.g. isoseismal and iso-acceleration maps), a lot of maps for different geographical regions were developed. The usefulness of such maps is to a considerable extent a function of the type and amount of information they contain. The seismicity in Belgium is an example of an intraplate zone with low seismic activity and sporadic large events. The region can be subdivided in seven seismogenic zones with different tectonic characteristics. Based on existing seismological and tectonic data, a model of the seismicity of Belgium and the neighbouring countries was elaborated. Using on all these data and the assumptions related to the nature of occurrence of earthquakes, analysis of the seismic hazard has been carried out for the territory of Belgium and several maps and diagrams have been obtained. The purpose of this paper is to outline briefly the factors believed to be important in preparation of the seismic zoning maps (seismic hazard maps), to present the concept of mapping technique, together with some seismic hazard maps of Belgium.

SEISMIC HAZARD ANALYSIS OF THE CITY OF SOFIA

Slavey SLAVOV (Department of Meteorology&Geophysics, University of Sofia, 5 James Bourchier blvd, Sofia-1126, Bulgaria, email: slav@phys.uni-sofia.bg); Franco VACCARI and Giuliano Francesco PANZA (both at Department of Earth Sciences, University of Trieste,4 Weiss street,Trieste-34127,Italy, email: panza@geosun0.univ.trieste.it)

The importance of Sofia, as an administrative and economical center of Bulgaria defines the significance of the seismological investigations in the city. During the past century, Sofia has suffered damages caused by shallow depth earthquakes. The strongest earthquake in the region occurred on 18.09.1858. The hypocenter has been under the town itself and the intensity is evaluated to be destructive - IX MSK. The last strong event M=5 has occurred in 1928 and following the recurrence relationship for the Sofia valley, we have to expect next strong event within next 5 years. The lack of strong recent earthquakes makes crucial the using of realistic modelling techniques for defining the seismic input for Sofia. The necessary input data have been critically discussed. The influence of the both distant and local sources has been estimated. A hybrid technique, based on modal summation and finite differences is used to simulate the strong ground motion in the city of Sofia. The results of the numerical modelling are presented as acceleration time series, PGA maps, PGV/PGA plots and spectral amplifications for different cross sections. Detailed modelling of the ground motions for realistic heterogeneous media up to 10 Hz can be immediately used in the design of new seismo-resistant constructions and in the reinforcement of existing buildings, without having to wait for a strong earthquake to occur.

ST3/W/45-B4 1430

LOCAL RECURRENCE TIME, A NEW CONCEPT IN EARTHQUAKE HAZARD ASSESSMENT

M. WYSS, S. Wiemer Geophysical Institute, University of Alaska, Fairbanks, AK, 99775-7320, email: max@giseis.alaska.edu, 907 474 5529 D. Schorlemmer, Technische Universitaet, Berlin.

We define TL(M) as the recurrence time calculated from the local b- and a-values of the frequency magnitude distribution (earthquakes within 5 to 10 km from each point of interest). The value of TL(M) varies by several orders of magnitude over distances of 10 km because b- and a-values vary strongly. We argue that the hazard due to earth-quakes (of any magnitude) more than about 10 km distant from the site of interest is negligible compared to the hazard posed by the largest earthquake that can occur be-low a site, without rupturing the surface. The TL(M) estimates the probability of this earthquake happening. Earthquake recurrence times and hazard maps are routinely computed using a single overall b-value and a smoothed a-value distribution. We pro-pose that a more accurate description of the hazard can be obtained by computing TL(M). Spatially separating low and high b-value zones may be key to improving hazard mapping, because only the highly stressed (hence low b-value) volumes contain information about recurrence time. Adding events from neighboUring low stress areas of faults (high b-value volumes) only biases the recurrence time estimate towards unrealistically long intervals. Further we propose that anomalously low TL(M)-values map asperities, based on the correlation of TL(M) minima along the Parkfield and the Mor-gan Hill segments of the San Andreas fault system with known asperities. Testing this hypothesis along the San Jacinto-Elsinore faults we found that out of six historic main shocks (1899-1968), five ruptured substantial parts of four asperities mapped by our method, based on the modern earthquake catalog (M*1.2, 1981.0-1998.7). We estimate the probability for this correlation to occur at random as 7 10-4. The Anza gap is mapped as an asperity by our method. The b-values range from 0.5 to 1.8 over distances of 10 km. Volumes with approximately constant b-values have radii of r=8*6 km. The observation of five minima of TL(M) along the SJ, compared to only two along the E fault zone agrees with the geologically estimated slip rates along the two fault systems (about a factor of two higher on the SJ than on the E fault).

ST3/E/24-B4 1445

IMPROVING AFTERSHOCK HAZARD ASSESSMENT BY INCORPORATING THE SPATIALVARIABILITY OF AFTERSHOCK ACTIVITY

Stefan WIEMER (Institute of Geophysics, ETH Hoenggerberg, CH-8093, Zurich, Switzerland; email: stefan@seismo.ifg.ethz.ch)

We propose that real-time probabilistic aftershock hazard assessment can be significantly improved by incorporating spatial information about the characteristics of the aftershock decay rate, the local activity, and the earthquake size distribution. There is solid evidence from several aftershock sequences that the characteristics of aftershocks, and hence the probabilities of moderate magnitude aftershocks, vary strongly as a function of space. In recent studies, it has been demonstrated that both the b- and p-values vary significantly and systematically by up to a factor of three along the strike of aftershock zones. The observed variations are likely related to both the slip history as well as the tectonic setting. High b-values are often in the vicinity of high slip areas. For the Landers case, the slowest aftershock decay rate (lowest p-value) coincides with the Kickapoo shear zone and may be related to high pore pressure in this region. In addition, the seismicity rates (as measured by 'a' in log N = a-bM) vary spatially, possibly proportional to the static stress change caused by the main shock. Because the generally used estimation of the aftershock hazard assessment, introduced by Reasenberg and Jones, relies on all three of these parameters (a, b and p), we find that the probability of a large and potentially damaging aftershock varies substantially and significantly with location. The results for the Landers and Northridge aftershock sequences confirm that the aftershock probability indeed varies with location by several orders of magnitude.

PROBABILISTIC MODELS FOR EARTHQUAKE HAZARD ASSESSMENT IN THE INDIAN AND SURROUNDING REGIONS

Avadh RAM;Harsh Singh (Both at Dept. of Geophysics, Banaras Hindu University, Varanasi-221005, India; tel: +91 542 317074; email: aram@banaras.ernet.in)

A seismicity map of the Indian subcontinent has been prepared using the earthquakes obtained from the National Earthquake Information Centre and International Seismological Centre for the period 1963-1994. The seismicity in the main Himalayan seismic belt is due to the collision between the Indian plate and the Eurasian plate. The earthquakes in this region are generally correlated with the known regional thrusts like the Main Boundary Thrust and the Main Central Thrust. Six different zones have been identified on the basis of clustering of events (5<M<7) from the seismicity map starting from the Sulaiman & Kirthar ranges in the north-west, Hindukush and Pamir, Central Himalayas, north-east Himalaya and part of Andaman. The probability of different magnitude threshold has been evaluated using the Gutenberg - Richter formula logN=a-bM for magnitude distribution. The constants a and b have been computed for each region and found to vary within different limits. The Lognormal, Weibull, Gamma and Exponential portability models have been used to find the distribution of events from each region. The method of moments and the method of maximum likelihood estimates have been used to compute and verify model parameters for different sets of data. It has been found that the Lognormal and Weibull models are more plausible as compared to the other two models. The probability of occurrence of an earthquake rises between 0.9 and 1.0 at the time period of 100 months for the region A, C and E. The regions BS and BD have the time period of 90 and 50 months respectively for the high probability values. The region D and F indicate the time period of more than 100 months. The peak ground acceleration associated with the observed data has also been computed. This diagram illustrates the higher peak ground acceleration in the area of shallow focus earthquakes and lower accelerations in the regions of deep focus earthquakes.

INTENSITY OBSERVATIONS AND SOURCE PARAMETERS OF CALIFORNIA EARTHQUAKES

W. H. BAKUN (U S Geological Survey, 345 Middlefield Rd MS977, Menlo Park, CA 94025, USA. E-mail: bakun@andreas.wr.usgs.gov)

Seismologists use intensity values to assign source parameters to historical earthquakes, using empirical relations calibrated with the instrumental source parameters of recent shocks. While a good estimate of the magnitude of an historical earthquake is our primary goal, we also want to know, among other things, the location of the earthquake and the causative fault or tectonic structure. Independent estimates of the magnitude and location of historical shocks often do not differ significantly, but the subjective techniques usually used (e.g., contouring the intensity data and estimating an isoseismal area) rarely provide the objective estimates of the parameter uncertainty that are useful in seismic hazard assessment.
Analysis of Modified Mercalli intensity (MMI) observations for recent California earthquakes provides a strategy for bounding the moment magnitude M and the epicentral region of historical California earthquakes for different levels of confidence and number of MMI (W. H. Bakun and C. M. Wentworth, Earthquake location and magnitude from seismic intensity data, Bull. Seismol. Soc. Am., v. 87, pp. 1502-1521, 1997). Estimates of M from intensities are in good agreement with the instrumental magnitudes for M * 5.5 northern California shocks since 1900. The intensity center is the geographic point that best satisfies the MMI data in a least-squares sense; the intensity center corresponds more to the moment centroid of the earthquake source than to the epicenter. The geographic locations of confidence level contours bounding the epicentral region are controlled by the number of MMI available, by the degree to which MMI observations are available at near distances for all azimuth sectors from the epicenter, and by the internal consistency of the MMI observations. Even for recent California earthquakes with hundreds of reliable MMI observations, the confidence level contours bounding the epicentral region usually contain more than one active fault, so that the causative fault of historical California shocks cannot be determined with high confidence from MMI observations alone.

ST3/W/27-B4 1530

RENEWAL RECURRENCE MODELS FOR LARGE EARTHQUAKES IN JAPAN

Kunihiko Shimazaki (Earthquake Research Institute, University of Tokyo. 1-1-1 Yayoi, Bunkyo-ku, Tokyo 113-0032, Japan, email: nikosh@eri.u-tokyo.ac.jp)Kazushige Kawase (Science and Technology Agency, Now at Geographical Survey Institute, Japan, email: kawase@gsi-mc.go.jp); Kenji Satake (Geological Survey of Japan, email: satake@gsj.go.jp); Yasuhiro Suzuki (Aichi Prefect. Univ., Japan, email: y-suzuki@ist.aichi-pu.ac.jp); Yosihiko Ogata (Inst. Statistical Mathematics, Japan, email: ogata@sunyo.ism.ac.jp); Masajiro Imoto (Inst. Disaster Prevention and Earth Sci., Japan, email: imoto@bosai.go.jp) and Takashi Kumamoto (Tokyo Metropolitan Univ., Japan, email: kuma@geog.metro-u.ac.jp)

Four renewal models, i.e. log normal, gamma, Weibull, and double exponential distributions together with exponential distribution (i.e. Poisson process) are examined on how well these models apply to actual data of inter-event intervals of large earthquakes in Japan. In contrast to Nishenko and Buland's study in 1987, we treat a small number of sequences with relatively many events, i.e. six sequences and total of forty inter-event intervals; eighteen and twenty-two repeat times for two interplate and four intraplate sequences, respectively. The maximum likelihood estimates of the parameters for the above statistical models are obtained for each sequence, and Akaike's Information Criterion (AIC) is calculated for each model. In all cases the Poisson process shows the worst fit to the data, significantly poorer than other models. Among the rest of the models, none is significantly better than the others. We tentatively choose log normal and assume a common standard deviation for the intraplate sequences. We found that AIC for the common standard deviation is smaller than AIC for the case with different standard deviations estimated for each sequence. It shows that the common standard deviation explains the data set better than different standard deviations for each sequence so far as the four examples of Japanese intraplate earthquake sequence are concerned. For the time being, we plan to apply this common standard deviation of 0.23 to other intraplate sequences with small number of inter-event intervals.

DETERMINISTIC HAZARD COMPUTATION FOR ROMANIAN CRUSTAL AND SUBCRUSTAL EARTHQUAKES

M. Radulian ([1] National Institute for Earth Physics, P. O. Box MG-2, Bucharest, Romania, Email: mircea@infp.ifa.ro) C. L. MOLDOVEANU ([1] National Institute for Earth Physics, Bucharest, Romania; [2] Dipartimento di Scienze della Terra, Universita' di Trieste, Italy; Email: carmen@geosun0.univ.trieste.it) F. Vaccari ([2] Dipartimento di Scienze della Terra, Universita' di Trieste, Italy; [3] GNDT – CNR, Rome, Italy; Email: vaccari@geosun0.univ.trieste.it) N. Mandrescu ([1] National Institute for Earth Physics, P. O. Box MG-2, Bucharest, Romania, Email: mandrescu@infp.ifa.ro) G. F. Panza ([2] Dipartimento di Scienze della Terra, Universita' di Trieste, Italy; [4] The Abdus Salam International Centre for Theoretical Physics, SAND Group, Trieste, Italy; Email: panza@geosun0.univ.trieste.it)

The evaluation of the seismic hazard for the Romanian territory is carried out separately for crustal (h < 60 km) and subcrustal (h > 60 km) earthquakes. Synthetic P-SV and SH seismograms are generated by the modal summation technique (Panza, 1985; Florsch et al., 1991) on a regular grid covering the whole territory of the country. The structural input modelling consists of 14 polygons with 1-D average structure, and the source modelling consists of 13 seismogenic zones with specific seismicity and focal mechanism. The frequency range spans the interval 0.005 - 1 Hz and a scaled point double-couple models the source process. The results are expressed in terms of maximum displacement, maximum velocity and design ground acceleration. Vrancea subcrustal earthquakes control the resulted seismic hazard. The previous hazard maps underestimate the hazard level in the southeastern part of the country due to the crustal earthquakes in the Shabla area.
The deterministic method addresses some issues largely neglected in probabilistic hazard analysis, e.g. how crustal properties affect attenuation. The parametric study shows that the hazard level is very sensitive to the maximum magnitude, average depth and focal mechanism variation. Possible scenarios can be easily constructed for different source and structural parameters.

ST3/W/19-B4 1630

A MUTUALLY CONSISTENT SEISMIC-HAZARD SOURCE MODEL FOR SOUTHERN CALIFORNIA

Edward H FIELD, James F. Dolan (both at Dept. of Earth Sciences, University of Southern California, Los Angeles, CA 90089-0740, USA, Email: field@usc.edu), and David D. Jackson (Dept. of Earth and Space Sciences, University of California, Los Angeles, 405 Hilgard Ave., Los Angeles, CA 90024-1567, USA)

The first attempt to integrate geological, geodetic, and observed seismicity data into a probabilistic-hazard source model predicted a rate of magnitude 6 to 7 earthquakes significantly greater than that observed historically (WGCEP, 1995). One explanation was that the discrepancy, or apparent earthquake deficit, is an artefact of the upper magnitude limit built into the model. This was controversial, however, because removing the discrepancy required earthquakes larger than are seen in the geological record, and larger than implied from empirical relationships between fault dimension and magnitude. Although several papers have addressed this issue, an alternative, integrated source model without an apparent deficit has not yet appeared. We present a simple geologically based approach for constructing such a model which agrees well with the historical record and does not invoke any unsubstantiated phenomena. The following factors are found to be influential: the b-value and minimum magnitude applied to Gutenberg-Richter seismicity; the percentage of moment released in characteristic earthquakes; a round-off error in the moment-magnitude definition; bias due to historical catalog incompleteness; careful adherence to the conservation of seismic moment rate; uncertainty in magnitudes estimates obtained from empirical regressions; allowing multi-segment ruptures (cascades); and the time dependence of recurrence rates. The previous apparent deficit is shown to have resulted from a combination of these factors. None alone caused the problem, nor solves it. The model presented here is relatively robust with respect to these factors.

ST3/W/02-B4 1645

DETERMINISTIC SEISMIC HAZARD IN THE CIRCUM-MEDITERRANEAN DOMAIN

Giuliano F. PANZA (Dip. di Scienze della Terra, Universita` di Trieste and The Abdus Salam International Centre for Theoretical Physics, Trieste, Italy. E-mail: panza@geosun0.univ.trieste.it), and Franco Vaccari (Dip. di Scienze della Terra, Universita` di Trieste and CNR-GNDT, Rome, Italy)

The deterministic procedure for seismic hazard assessment developed at the Department of Earth Sciences of the University of Trieste in the framework of the CNR-GNDT activities has been applied to several countries in the Mediterranean and Circumpannonian regions as the result of comprehensive international cooperations. The main effort has been to harmonize Eastern and Western Europe in terms of seismic safety compliance. Characteristic parameters of seismogenic zones and regional structural models have been assembled and synthetic seismograms have been computed for a dense grid of sites covering the investigated area. Special attention has been paid to the intermediate depth events occurring in Vrancea (Romania). Results are shown in terms of maximum displacement, velocities and Design Ground Acceleration.

ST3/W/29-B4 1700

THE DETERMINATION OF EARTHQUAKE MAGNITUDE FROM HISTORICAL DATA IN THE EUROPEAN PARAMETRIC CATALOGUES: A REVIEW

Alessandro Rebez (Osservatorio Geofisico Sperimentale, Trieste, Italy, Email: rebez@ogs.trieste.it). Massimiliano STUCCHI (Istituto di Ricerca sul Rischio Sismico, CNR, Milano, Italy, Email: stucchi@irrs.mi.cnr.it. Ruben Tatevossian (Institute of Physics of the Earth, Moskva, Russia, Email: tatev@synapse.ru).

Magnitude determination from historical data is one of the most controversial issues in the compilation of parametric earthquake catalogues. In Europe, where more than 30 parametric catalogues cover a rather limited area, several, different procedures are in use, giving rise to large in-homogeneity in the data available to the users. In the frame of the EC project "A Basic European Earthquake Catalogue..." a survey was performed with the aim of investigating which procedures are used, in theory and in practice. The results show either largely inhomogeneous procedures, or even gaps from theory to practice, probably due to the introduction of "hidden" assumptions or personal judgement. Gaps are easily detectable for earthquakes located in areas covered by more catalogues (e.g. frontier areas, where the same events can be given varied sizes), while they are not for earthquakes located in distant areas. As a result of the survey and the work carried out in the project, some conclusions can be drawn. First, that intensity data points allow the use of formalised, repeatable procedures which limit, to a certain extent, the subjectivity of most procedures, including the drawing of isoseismal maps. Second, that such procedures may require case-by-case calibration, due to unavoidable inhomogeneous data distribution. Third, that such procedures can be applied to a limited number of strong events and that, therefore, lot of efforts are required for moderate to minor earthquakes.

ST3/E/21-B4 1715

METHODOLOGICAL CONSIDERATIONS OF PROBABILISTIC SEISMIC HAZARD MAPPING

R.M.W. MUSSON (British Geological Survey, West Mains Road, Edinburgh, EH9 3LA, UK, Email: R.Musson@bgs.ac.uk)

The study of seismic hazard is perhaps the most practically oriented aspect of earthquake seismology. As such, it should not be treated in an idealised or academic manner, but with regard to the needs of the consumers of the final product. This has important consequences when it comes to the topic of probabilistic seismic hazard maps. Who are these for? Historically, early studies of probabilistic seismic hazard tended to be done for engineers for specific design requirements. Consequently, there has been a tendency to treat seismic hazard maps as a sort of pan-national study for engineers, who can identify the design requirements for any site by picking them from the map. A dissenting point of view argues that seismic hazard maps are by their very nature too generalised to be used in this way; that such maps provide a first indication of relative hazard and should not be a substitute for site studies. There are, therefore, a number of interesting and important methodological questions to be asked: what are the practical differences in undertaking a seismic hazard map from calculating hazard for a site? Should probabilistic seismic hazard maps have the same degree of conservatism as site studies? How can seismologists meet the needs of different audiences? An engineer may think in terms of ground acceleration, but this parameter probably means little to people in other professions who still need access to seismic hazard data, but in a form they can understand. These are questions that need to be addressed directly; one should not leave them to be answered by default.

ST3/E/27-B4 1730

SEISMIC MOMENT RATE IN THE SEISMIC HAZARD ASSESSMENT IN NORTH VIETNAM AND SURROUNDING AREA

PHAN -TRONG Trinh (1), Thierry Winter (2) 1. Institute of Geological Science, NCNST, Vien Dia Chat, Nghiado, Cau giay, Hanoi, Vietnam, Fax : 84 4 8362886, E-mail: pttrinh@refer.edu.vn. 2.Bureau Geologique et Mine, Paris, France

The estimation of seismic risk in Vietnam is carried out in following successive stages: A seismic hazard assessment carried out through both the connections, at various scales, of the structural geology with seismicity. The estimate of the seismogenic capability of the active faults identified through satellite image, topographic and geological map, field survey and earthquake catalogue. A seismic risk assessment of the regional seismic hazard on the site corresponding to the occurrence of design earthquake magnitude such as: maximum credible earthquake (MCE), maximum design earthquake (MDE) consisting of an earthquake having 10% risk of occurrence during the service-life of dam (100 years), the operating basis earthquake (OBE) consisting of an earthquake having a 50% risk of occurrence during the service life of dam and peak ground acceleration (PGA) corresponding to MCE, MDE and OBE,. Maximum credible Earthquake is estimated from combination of various methods: fault segment, fault surface, seismic moment and fault slip rate. We test to combine seismic data and geological data by using seismic moment rate to estimate maximum credible earthquake. Some examples in the estimation of seismic risk for hydropower dam design are presented. Many arguments of remote sensing, geomorphology, geology, geodesy, state of stress attest the intensive actual tectonic activity in Vietnam. However, the poorness of the seismological network prevents accurate localisation of moderate seismicity. For this region, using pure probabilistic model or historical approaches to select a seismic risk in structure design will be quite random. The combination of the deterministic and probabilistic analysis was performed in several stages. The application of the seismic risk assessment for many hydropower sites in Vietnam such as: Song Ca, Hoa Binh and Son La stations is presented in detail. MDE is 6.3 - 6.5 for Song Ca fault, 6.9 - 7.0 for Nam Chou fault. OBE is 5.6 - 6.1 for Song Ca fault, 6.3 - 6.5 for Nam Chou fault. Various attenuation laws based on world wide data recorded in near field (Campbell) and by Xiang based on Yunnan data (next to Vietnam) are used to calculate Peak Ground Acceleration. The above-mentioned MDE magnitude should induce at the dam site a PGA of about 0.35 - 0.39 g. The OBE magnitude should induce at the dam site a PGA of about 0.24 - 0.31 g.

PECULIARITIES OF SEISMIC REACTION ON MOLDOVA REPUBLIC'S TERRITORY

Vasile Alkaz, Anatol ROMAN and Eugene Isichko (all at Institute of Geophysics and Geology, Moldavian Academy of Sciences, Academy str. 3, Kishinev, MD-2028, Moldova, email: drumea@geo.moldova.su)

Systematic instrumental engineering observations were started in Moldova in the 1970-s. Three subsequent strong intermediate-depth Carpathian earthquakes: 4.03.1077 (M=7.2), 30.08.1986 (M=7.0), 30.05.1990 (M=6.9) provided rich instrumental and macro-seismic data. Joint analysis of that material has revealed some peculiarities in the manifestation of different local geologic- engineering factors during the above mentioned earthquakes. The difference in the estimated intensity values at various sites reach 2 points and more (MSK-64 scale). The recordings are the wide frequency band processes: considerably predominating are the oscillations with periods 0,1 - 0,7 s. Comparisons of the observed response spectra with design spectra are made. Real impacts exceed 1,5 - 1,8 times those given in the normative document in the high frequency range (0,1 - 0,3 s). In the 0,3 - 0,6 interval normative curve overlaps the real impact on the ground. In the range of long periods (over 0,7 s) the real seismic loads again exceed the rated ones. A proposal has been made to improve the national seismic design code taking into consideration the results obtained from the experimental data. It has been shown that for specific regional conditions such factors as thickness of soft soil, shear waves velocity, high impedance contrast between the clay-sandy layers and limestone basement play a decisive role in forming the amplitude level and spectral composition on motions occurring on surface. It has also been established that the influence of water-logging, lithology is less than traditionally adopted. The unusually high level of damage to modern structures has been observed, resulting from resonance phenomena pertinent to soil-structure system.

INTERNATIONAL DECADE FOR NATURAL DISASTER REDUCTION (IDNDR)

Robert M. HAMILTON (Chair, IDNDR Scientific and Technical Committee, National Research Council, Washington, DC, USA, Email: bhamilto@nas.edu)

The IDNDR was adopted for the 1990s to focus world attention on opportunities to reduce the impacts of natural hazards, including earthquakes, windstorms, tsunamis, floods, landslides, volcanic eruptions, wildfires, grasshopper and locust infestations, and drought and desertification. Substantial losses in many industrialized and developing countries prompted this initiative. Its importance is underscored by migration of populations into hazard-prone areas and their concentration in megacities, which are particularly vulnerable owing to their complex infrastructures. In looking beyond the Decade, the IDNDR Scientific and Technical Committee identified five major challenges: 1) Integrated risk management - Natural disaster mitigation can be effective only if it is an integral, high-priority part of the overall planning and development process. 2) Mega-disasters - Megacities are poorly prepared to face the disruption that a natural disaster brings and face losses on an unprecedented scale. 3) Ecosystem vulnerability - Natural hazards can substantially impact landscape and habitat and can combine with human-induced hazards into a greatly enhanced threat. 4) Disaster management capabilities of developing countries - Expertise must be increased in many developing countries to promote adoption of sound disaster prevention practices. 5) Co-ordination and implementation - The growing impact of natural disasters demonstrates the need to further advance mitigation through well co-ordinated activities. This will require a UN oversight unit to co-ordinate activities in the program areas of: advancing the frontiers of hazard mitigation science and technology; implementing programs of education, training and technology transfer; monitoring hazards phenomena, and providing early warning where possible; and promoting and implementing mitigation as an integral part of economic development.

ST3/E/40-B5 0845

SEISMIC RISK ASSESSMENT IN REPUBLIC OF MOLDOVA

Vasile ALKAZ, Anatol Drumea and Eugene Isichko (all at Institute of Geophysics and Geology, Moldavian Academy of Sciences, Academy str. 3, Kishinev, MD-2028, Moldova, email: drumea@geo.moldova.su)

The contribution presents the first attempt to evaluate the seismic risk distribution in Republic of Moldova. This territory systematically suffers heavy damage and losses as a consequence of the intermediate depth earthquakes sources located in Vrancea zone, Romania. So, the disaster effect of the last strong earthquake (August, 30, 1986, M=7,0) was represented by 2 deaths, 561 injured persons, 1169 completely destroyed buildings, 800 millions US $ direct loss. In the framework of investigation the seismic risk has been determined as a convolution of earthquake hazard and seismic vulnerability. Earthquake hazard has been evaluated on the basis of the map of maximum seismic intensity observed. The seismic vulnerability was determined as a convolution of physical environment vulnerability, quality of structures (number of suffered earthquakes), population features and relative value of loss. The vulnerability of physical environment was estimated on the basis of the map, which was produced taking into account the areas affected by landsliding, liquefaction, different densification capacity and degree of slope abruptness. The spatial distribution and density of the population were considered the main important factors, determining the population features in the investigated territory. As a measure of relative value of loss the index of economical activity each of districts was assumed. On the basis of these data the map of relative seismic risk has been performed. According to it, the seismic risk reaches levels of concern - first of all in Kishinev city and regions, were secondary effects of earthquakes are more likely.

ST3/W/43-B5 0900

RE-EVALUATION OF THE LARGEST EARTHQUAKES IN THE NORTHERN UPPER RHINEGRABEN (GERMANY) SINCE THE YEAR 858

Diethelm KAISER (Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Burgweg 11, 07749 Jena, Germany, email: kaiser@geo.uni-jena.de) Christa Hammerl, Rolf Gutdeutsch (both at Institut für Meteorologie und Geophysik, Universität Wien, Nordbergstraße 14, 1090 Wien, Austria, email: rudolf.gutdeutsch@univie.ac.at)

The northern part of the Upper Rhingraben is part of the European Cenozoic rift system and displays moderate seismic activity. Six entries of this region in the earthquake catalogue of Germany have been verified by the investigation of historical records: (1) Mainz 1. January 858, I0=VII-VIII, N=3; (2) Mainz 14. February 1445, I0=VIII, N=1; (3) Mainz-Münchweiler 18. May 1733, I0=VII, N=33; (4) Groß-Gerau 1. November 1869 4:07, I0=VII, N=172; (5) Lorsch 10. February 1871 I0=VII, N=128; (6) Lorsch 16. February 1871 I0=VII, N=0; (N=number of towns with reported effects). Entry (1) is so poorly documented that it was not possible to determine the epicenter and the maximum intensity. Entry (2) indicates ground subsidence but not an earthquake. Entry (3) is associated with an earthquake with epicentral co-ordinates 7.95°E, 49.68°N, I0=VII without a specified focal depth. Earthquake (4) was downgraded to I0=VI-VII using the criteria of the European Macroseismic Scale. The epicentral intensity and co-ordinates of earthquake (5) have been confirmed; the focal depth was estimated to 7 km. Entry (6) is the result of a dating error and was deleted.
In addition we verified and developed empirical relations between I0, local magnitude ML, felt area, and focal depth. The equation relating ML with the felt area as developed by Musson (1996) for earthquakes in the U.K. appeared as the most reliable as compared to others (e.g. Kárník 1969). For earthquake (5) we determined ML=4.9. The re-evaluation of the largest earthquakes in the northern Upper Rhinegraben has a significant influence on seismic hazard estimates.

ST3/W/13-B5 0915

INPUT EARTHQUAKE HAZARD VALUES OF THE THIVA-OROPOS REGION(CENTRAL GREECE) FOR SEISMIC RISK ESTIMATES

Vladimír SCHENK, ZdeHka Schenková and Pavel Kottnauer (all at Institute of Rock Structure and Mechanics, Academy of Sciences, CZ-182 09 Praha 8, The Czech Republic, email: schenk@ irsm.cas.cz)

Recent seismic risk estimates need reliable earthquake hazard inputs that have to involve damage effects caused both by tectonic structures of area and by seismogeological site conditions. The Thiva-Oropos zone belongs to seismically high-active zones of central Greece that neighbours on its south-west margin with the area of the Gulf of Corinth and is elongated to north-east direction. That elongation could be joined with an existence of geological structures that further, in the north-east part of Greece, can possibly coincide with structures close to the North Anatolian fault. For the hazard calculations all available published data as well as unpublished seismic data monitored by the local seismic array of the National Observatory of Athens (Drakatos, Kalogeras and Papadopoulos) were applied. At the beginning the standard earthquake hazard assessment for the Thiva-Oropos seismoactive zone will be presented. This approach uses an earthquake data base to which statistical methods are applied in order to determine the "regional" hazard values for the whole area. Then seismogeological site conditions at the studied area will be introduced into the earthquake hazard process. The site conditions, characterised mostly by differences in seismic wave velocities and bulk densities, will show how big variety in the hazard outputs can appear. An attempt to introduce any corrections caused by the presence of active tectonic elements will be demonstrated. Finally, the earthquake hazard outputs will be discussed from the viewpoint of their direct application to the seismic risk estimates. The presented calculations were realised under the EC INCO-Copernicus ASPELEA Project No ERBIC 15CT97 0200.

ST3/E/05-B5 0930

AN EXPERIMENT OF SEISMIC RISK ASSESSMENT FOR SOFIA CITY

Larionov V.I.*, Ranguelov B.**, FROLOVA N.I.***, Ugarov A.N.**** Agency on Monitoring and Forecast of Emergency Situations, Ministry of Emergency Situations of Russian Federation **Geophysical Institute, Bulgarian Academy of Sciences***Seismological Center of IGE, Russian Academy of Sciences****Extreme Situations Research Center

The territory of Bulgaria is characterized by high level of seismic hazard. According to the map of possible seismic sources the earthquakes with intensity 9 (MSK scale) may occur in its capital. The population of the city is 1 350 000. In order to plan preventive measures and reduce possible social and economic losses due to future events the seismic risk assessment was carried out for the Sofia City territory. The special geographic information system (GIS) developed in the Russian Agency on Monitoring and Forecast of Emergency Situations was implemented. The different input data on seismic hazard level with taking into account secondary processes and different scenario a were used for losses computations (number of fatalities, number of people injured, distribution of different buildings type according to damage states). The existing building stock is not homogenous. The information about different types buildings' distribution was taken from the city territory map (scale 1:10 000). The influence of vulnerability functions for different buildings types on the expected social and economic losses was studied. The parameters of fragility laws were computed for typical buildings and structures in the area under consideration. The maps of damage states distribution caused by scenario earthquakes are compiled for the whole city and its districts. Individual seismic risk computations were carried out with GIS application and the corresponding maps are presented. The output modelled information can be used by decision makers, insurance companies and others. The GIS applied in this study, as well as the input data collected during many years may be integrated into the city information system in order to increase the efficiency of response measures in the case of emergency situations.

ST3/E/17-B5 0945

THE ERZINDZAN EARTHQUAKE AT 1939 - A CASE OF A MULTIDISASTER EVENT

Boyko RANGUELOV (Geophysical Institute, Sofia 1113, Bulgaria, email: bkr@geophys.bas.bg) Arnd Bernaerts (Bordesholmer Str.14a, Hamburg 22143, Germany)

A bad thing never came alone. The famous Erzindzan earthquake (M~8.0) on 30 December 1939 generated many effects - surface ruptures, landslides, macroseismic intensites up to 11 degree, tsunami in the Black see, as well as big destructions and many human deaths (more 30-40 000). There are very clear descriptions from this time (mainly by the newspapers) about the anomalous behaviour of the meteorological weather in the epicentral area - extremely low temperatures, very large snowfalls, freeze winds, big storms. All these events make very difficult all rescue operations. During the following days, very large rains to the south and south east generated very big flooding and mudflous to the southern, eastern and south-eastern parts of Turkey. These negative meteorological events add more than several thousands deaths and many injured accompanied by destruction of the buildings and expected summer harvest. Our hypothesis follows the general possible explanations of the observed negative events: bad, very sensitive meteorological conditions, (the lowest air pressure as a probable influence for the earthquake generation), the strong earthquake itself, generation of tsunami in the Black sea, very probable influence of the mixed sea water to the weather conditions, storms observed on the coast followed by cold air invasion, followed by the snowfalls and freezing weather. Than to the south, generation of the big rainfalls, followed by the floodings and mudflows. The interconnection between all these events brings many tragedies, bad economical consequences and human deaths. To check this hypothesis is very difficult and the problems are under discussion. But the observed events, provide the opportunity to discuss and to try to obtain more reliable information about these very destructive events.

ST3/E/41-B5 1000

SEISMIC RISK ASSESSMENT FOR CATALONIA (SPAIN)

Chavez, J., Fleta, J., GOULA,X., Roca, A., Secanell, R. & Susagna, T. (Institut Cartogràfic de Catalunya, Parc de Montjuic. E08038 Barcelona. Email: xgoula@icc.es)

Following Spanish regulations for Civil Defence, the Civil Defence Agency of the Catalan government has promoted an evaluation of the seismic risk in Catalonia. A new parametric catalogue of seismicity, in terms of macroseismic intensities and a new seismotectonic zonation of the area under study (32000 km2) and surrounding regions (in total about 220 000 km2 surface) are the basis of a hazard analysis. Deterministic and probabilistic approaches with different models of earthquake occurrence have been used; a quasi-stationary behaviour is deduced. Uncertainties of the results are estimated by Montecarlo technique. For return periods of 500 years standard deviations less than half degree of intensity are obtained. A map of seismic zones combining deterministic and probabilistic approaches is proposed for average soil conditions. The final map is modified, for urban areas, considering site effects estimated from geological maps. An estimation of vulnerability of dwelling buildings is carried out together with the assessment of seismic risk for people and of earthquake losses in all municipalities of Catalonia on the basis of the map of seismic zones. The methodology developed is summarised in four steps: 1) Classification of the existing buildings in vulnerability classes according to EMS-92, 2) estimation of damage in buildings, 3) assessment of the human casualties, and 4) evaluation of economical losses.

ST3/E/49-B5 1045

ABOUT THE PROGNOSIS OF SEISMIC INFLUENCES FOR THE CAPITAL OF KYRGYSTAN

Aleksandra Frolova, Institute of Seismology NAS of the Kyrghyz Republic (SI NAS KR), Bishkek, E-mail: kis@imfico.bishkek.su Svetlana Uranova , Kyrghyz Scientific and Design Construction Institute of the ministry of Architecture and Construction of the Kyrghyz Republic KyrghyzNIIPC), Bishkek, E-mail: uran@imfiko.bishkek

The capital of Kyrgyzstan Bishkek is located in the seismic hazardous Chu Depression. The map of maximum accelerations was calculated in isolines for Chu Depression. The most part of this territory may be exposed to shaking more than 600 cm/sec2 (0,6g). Amplitudes of accelerations are in accordance with new facts of strong movements. The possible response spectrum and values of resonance periods and maximum accelerations were calculated for Bishkek from different source zones. The possible amplitude of shaking is 0.6g for Bishkek for average soils. This acceleration corresponds to the intensity 9 according to the MSC-scale.

ST3/E/48-B5 1100

RISK ANALYSIS IN KOLA; SEISMIC LOADS AND WEATHER FACTORS IN SIMULATIONS OF AVALANCHE HAZARDS IN THE KHIBINY MASSIF

Pavel Chernous and Evgeny Mokrov (Centre of Avalanche Safety, 33a, 50-years of October St., Kirovsk, 184230 Russia; email: P.Chernous@apatit.murmansk.su); Yura Fedorenko and Sergey Morozov (INEP, KSC RAS, Fersman str. 14, Apatity, 184200 Russia, email: morozov@inep.ksc.ru); Eystein S. HUSEBYE (IFJ, UoBergen, Allegaten 41,N-5007, Norway, email: eystein.husebye@ifjf.uib.no)

The Khibiny Massif, Kola is well known for many avalanches in winter some of which have caused losses of human life in the past. In order to mitigate this hazard the Avalanche Safety Service (Apatity JSC) monitors weather conditions, estimates snow transport and measures snow depths over slopes close to open pit mines. These data are used for predicting avalanche risk and issue warnings for miners. Occasionally explosives are used for preventive triggering of avalanches which also may cause avalanches elsewhere. However, outside mining areas safety measures are less rigid so tourists and weekend skiers are at risk. Hence, we are undertaking as a first step in risk mitigation to model mathematically avalanches (snow drifts) per se and their potential for being released. The snow slab is modeled as an elastic non-moment shell which parameterization is obtained via field measurements. Critical parameters are snow thickness, shear and tensile properties and friction coefficient. Avalanche initiation is tied to exceedance of a critical stress threshold. For hazard extrapolation to non-mining areas meteodata from the Rassvumchor plateau (1100m height)

were used to evaluate prevailing wind conditions via the Navier-Stokes eqs. Trigger levels were tied to ground accelerations of mining and other explosions as measured at the new NANSEN 3-comp. station within the massif. On this basis we have calculated snow thicknesses in Khibiny and in addition also singled out areas likely to be hazardous. During spring 99 we expect to get observational data on real snow thicknesses and areas where avalanches have taken place thus ensuring direct comparisons to the theoretical predictions made.

ST3/P/4-B5 1115

INTENSITY ESTIMATION USING THE GRAPHIC FORM OF THE EMS-98 SCALE

Peter LABÀK (Geophysical Institute, Slovak Academy of Sciences, Dúbravská cesta 9, 842 28 Bratislava, Slovak Republic); Christa Hammerl (Institute of Meteorology and Geophysics, University of Vienna, UZA II, Althanstrasse 14, A-1090 Vienna, Austria); Jirí Pospísil (Geophysical Institute, Academy of Sciences of the Czech Republic, Bocni II, 141 31 Prague, Czech Republic)

A new graphic form of the EMS-98 scale is presented. The effects on humans, and objects and nature are displayed in the form of tables. The tables include the size of the effects for all intensities. The definition of damage to buildings is displayed in the form of vulnerability class vs. damage grade table for each intensity degree. The tables enable us to identify how the observed effects obtained either from questionnaires and damage data for recent earthquakes or from damage data for historical earthquakes correspond to the defined effects for an intensity degree.
We used the graphic form of the EMS-98 scale for the intensity estimation for two recent and two historical earthquakes - the April 12, 1998 Slovenia, the 1997 Umbria-Marche, the January 15, 1858 2ilina (Slovakia), and February 4, 1794 Leoben (Austria) earthquakes. We used the Slovak and Czech questionnaire data for the Slovenian earthquake, the damage data collected by ESC WG Macroseismology (Stucchi, ed., 1998) for the Umbria-Marche earthquakes and the damage data from the studies by Hammerl & Labák (I999) and Hammerl (I996) for the historical earthquakes. The use of the proposed graphic form of the EMS-98 scale allowed us to identify inconsistencies of the Slovak and Czech questionnaires (originally proposed for the MSK-64 scale) with the new EMS-98 scale. The problems of the intensity estimation for both recent and historical earthquakes under study are also discussed.

ST3/E/14-B5 1130

SEISMIC HAZARD AND MICROZONATION IN CENTRAL AMERICA

LINDHOLM C. D.1, H. Bungum1 and F. Nadim2 1) NORSAR, Box 51, 2007 Kjeller, Norway 2) Norwegian Geotechnical Institute, Box 3939 Ullevel Hageby, Oslo, Norway

Central America has experienced repeated earthquake disasters in this century, and with the current economical growth the vulnerability will increase unless the main urban centers firmly commit themselves to precautions. The first steps in reducing vulnerability is proper mapping of hazards and risks and the engagement of competent scientists on the national level within these fields. As part of a regional project, seismic microzonation for main urban centers in Panama, Costa Rica and Nicaragua have now been undertaken, and seismic hazard evaluations are being made for Honduras, El Salvador and Guatemala. The microzonation studies implies computation of seismic hazard based on a probabilistitic approach, integrated with modelling of ground motion contributions from local, active faults. The hazard results, which are also based on locally developed ground motion relations, were presented both in terms of peak ground acceleration maps and in terms of pseudo-velocity spectra. Geological investigations were undertaken to map the potentials of local faults, applying analysis of air photos and satellite data as well as morphologic evaluation with trenching and fault dating. The geologic investigations were particularly extensive in Panama and Nicaragua and involved extensive regional co-operation. Local soil amplification has been focused on through analytical as well as empirical methods. Data from local strong motion networks that have been used in spectral ratio analysis have been compared with results from analytical analyses (such as through the computer code SHAKE). Finally also Spectral Analysis of Surface Waves (SASW) experiments have been carried out. The societal needs have been attended to in these studies through active participation of city councils and national emergency commissions as users of the microzonation products, and through reporting on city growth perspectives.

ST3/E/47-B5 1145

DETERMINISTIC VS. PROBABILISTIC EARTHQUAKE HAZARDS AND RISKS

ROBIN K. MCGUIRE (Risk Engineering, Inc., 4155 Darley Ave, Suite A, Boulder, Colorado, 80403, USA, email: mcguire@riskeng.com)

Deterministic vs. probabilistic approaches to assessing earthquake hazards and risks have differences, advantages, and disadvantages that often preclude the use of one over the other. Factors that influence the choice include the decision to be made (i.e. the purpose of the hazard or risk assessment), the seismic environment (whether the location is in a high, moderate, or low seismic risk region), and the scope of the assessment (a single-site risk, a multi-site risk, or risk to a region). Decisions coming from earthquake assessments include selection of design or retrofit criteria and levels, financial planning for earthquake losses, and planning for emergency response and long-term recovery. The more quantitative the decision to be made, the more appropriate is probabilistic hazard and risk assessment. For high seismic regions (e.g. California or Japan) where the largest earthquakes occur every 100-300 years), a deterministic scenario for the largest event will allow details to be examined such as ground motion effects caused by rupture propagation. In low seismic regions, extreme deterministic scenarios will have probabilities of occurrence that are too low to be useful for most decision purposes. Specific site analyses generally require a probabilistic approach. Multiple-site analyses (e.g. for a portfolio of exposed or insured properties, or a lifeline) often require a probabilistic analysis because of multiple variables and complexities of the system, and a deterministic check can be misleading. Regional assessments often benefit most from deterministic models.

ST3/E/23-B5 1200

COMPARISON OF SOME MACROSEISMIC EPICENTRE LOCATION METHODS

R.M.W. MUSSON (British Geological Survey, West Mains Road, Edinburgh, EH9 3LA, UK, Email: R.Musson@bgs.ac.uk)

The provision of spatial co-ordinates for historical earthquakes, derived from macroseismic data, can follow one of two objectives. The first is to try to determine, from macroseismic evidence, what point would have been cited as the epicentre in the sense that this term is used in modern instrumental catalogues. The second is to determine some conventional point representing the focus from which the strongest shaking appears to radiate. The term barycentre has been suggested for such a point. It can be argued that the latter approach is more appropriate for seismic hazard studies, in which the aim is to characterise the field of strong shaking of future earthquakes. On the other hand, such an approach, if it is to be pursued consistently, requires one to jettison all instrumental earthquake catalogues, which may not be practical. This paper compares some simple approaches to making automatic epicentre determinations from macroseismic data and examines their accuracy with respect to instrumentally determined epicentres.

ST3/E/28-B5 1215

A COMPARATIVE STUDY OF SEISMIC RISK ASSESSMENT

Zhi-xian YANG (Institute of Crustal Dynamics, CSB, P.O.Box 2855 Beijing 100085, China, email: zhixian@public.bta.net.cn) Pei-zhen Zhang (Institute of Geology, CSB, P.O.Box 634, Beijing 100029, China, email: peizhen@public3.bta.net.cn)

Calculated seismic hazards by different programs are slightly different. Results from programs SEISRISK¢ó (Bernice Bender and David Perkins), FRISK-88M (R. McGuire) and SEISRISK-CH (used for seismic zoning mapping in China) using same attenuation relation and same seismicity parameters are compared in this study. The features of the differences for high seismicity as well as low seismicity region are described. The authors propose that resolution of the calculations is the major factor that affects this difference. Spatial distribution of seismicity is not uniform. In seismic hazard assessment, in order to emphasize the non-uniformity of seismicity appropriate weighting procedures should be used. A procedure of weighting on seismicity parameters before calculating seismic hazard is adopted by Chinese seismologists in the past decade. Recently an alternative procedure of weighting on calculated seismic hazard based on the delineation of seismic sources is adopted by US seismologists. In the later procedure seismic sources include not only the area with high seismicity but also the area with low seismicity historically but potentially prone to major earthquakes known as background zone. We applied these two weighting procedures to the same area and compared the results obtained. We also compare the results from the combined source models with and without background zone. The comparisons indicate that the procedure of weighting on the seismicity parameters is appropriate for emphasis of high seismic hazard in a special seismic zone, while the procedure of weighting on calculated seismic hazard is appropriate for evaluation of seismic hazards in the area with low seismicity.

ST3/P/06-B5 1230

REINTERPRETATION OF THE JANUARY 15, 1858 ZILINA (SLOVAKIA) EARTHQUAKE

Christa HAMMERL (Institute of Meteorology and Geophysics, University of Vienna, UZA 11, Althanstrasse 14, A- 1090 Vienna, Austria); Peter Labák (Geophysical Institute, Slovak Academy of Sciences, Dúbravská cesta 9, 842 28 Bratislava, Slovak Republic)

The January 15, 1858 Zilina earthquake is the first earthquake on the territory of Slovakia for which a systematic collection and analysis of the data was performed by earthquake contemporary researchers. The most recent isoseismal map by Brouek (published in Atlas of Isoseismal Maps for Central and Eastern Europe, Procházková & Kárník, 1978) includes 196 intensity data points. Comparing five detailed earthquake contemporary studies (original documents by Jeitteles, 1858; Jeitteles, 1858; Kornhuber, 1858; Schmidt, 1858- Hunfalvy 1859) we found their supplementary character. In this special case the procedure of comparing different contemporary studies was very fruitful. We identified more than 600 localities (including negative reports). Names of localities are given in Slovak, German and Hungarian languages. We studied their "history" to avoid duplications. Further it should be stressed that Jeitteles used some kind of questionnaires and distributed them in the affected area. The questionnaires were focused on the time, the direction, the number and the duration of the shock(s), the air temperature, the barometer reading, about noise, air- and light phenomena, movement of waters, impression to man and animals, mechanical effects and other consequences. The answers served as a good basis for damage estimation. We used the EMS-98 scale for the estimation of the site intensities (the method of intensity estimation is presented in the contribution by Labák et al. at this conference). Comparison with Kárník's and Broucek's intensity estimations and estimation of the focal parameters is also shown.

GEOINFORMATION SYSTEM FOR OPERATIVE COMPUTATION OF SOCIAL LOSSES DUE TO EARTHQUAKES

Larionov V.I. (1), Aptikaev F.F (2), FROLOVA N.I.(3), Ugarov A.N.(4)
(1) Agency on Monitoring and Forecast of Emergency Situations, Ministry of Emergency Situations of Russian Federation (2)Joint Institute of Physics of the Earth, Russian Academy of Sciences (3)Seismological Center of IGE, Russian Academy of Sciences (4)Extreme Situations Research Center

The extreme estimations of macroseismic effects gained from past strong earthquakes was used in special Geographic Information System (GIS) in order to compute social losses. In the present study 1025 earthquakes with M=3 and above, characterized by anomalous high macroseismic effect from ancient time up to 1998 are analyzed. The relationship between the number of fatalities and people injured and different magnitudes are proposed for the estimation of possible social losses from earthquakes. These relationships are valid for two groups of countries, where the most part of buildings was constructed with or without taking into account earthquake resistant measures. As well as the most probable (median) number of casualities and the ratio of number of fatalities and people injured are estimated as a function of seismic intensity for these two groups of countries. For each group of countries the estimations error was characterized by quantile equal to 0.3 lg (factor 2). These reletionships are very conservative for both groups of countries within last tens years. The GIS contains cartographic base data about the states boundaries and global geographical grid. The obtained statistical relationships are used as the GIS mathematical models. The co-ordinates of earthquake epicenters and their magnitudes are used as input data for losses computations. The output results are presented as tables. The comparison of losses estimations obtained with the help of the GIS and another GIS, which uses simulation models, gives good agreement. For the Northern Caucasian region the divergence does not exceed 15%. The proposed GIS may be easily integrated into INTERNET and used by wide range of end-users in earthquake-prone areas for taking a decision about immediate response in the case of emergency.

ST3/E/42-B5 1415

VULNERABILITY ANALYSIS BASED ON MACROECONOMIC DATA

YONG CHEN, Qi-fu Chen and Ling Chen (No. 63, Fuxing Avenue, China Seismological Bureau, Beijing 100036, P. R. China)

When we employ readily available macroeconomic data -GDP- as the basis for the vulnerability analysis, the vulnerability is defined as the ratio of physical economic loss to the GDP within a given area resulting from the occurrence of earthquakes, which we called as macroscopic vulnerability.
The vulnerability in inventory method varies with the type of buildings. For those buildings with very poor quality, such as the adobe in Costa Rica or the old civil houses in mainland of china, the vulnerabilities of them are almost the same, which represent the vulnerability in the worst cases. On the other hand, for those buildings with high quality and with seismic design, such as the reinforced masonry in Middle East or the reinforced concrete building in China, the vulnerabilities are also the same, which represent the vulnerability in the best cases due to employing the state-of the are design and construction techniques. The same results obtained by different authors are not strange because they represent the two extreme situations under the contemporary conditions: the best one and the worst one.
The plots of macroscopic vulnerabilities vs. seismic intensity just fall in the variation ranges limited by two extreme plots form inventory study. It is easy to understand because the total loss is the sum of different building and facilities loss, therefore, the macroscopic vulnerability should be greater than that of the worst situation in inventory study, and less than the one from the best situation. The use of macroscopic vulnerability in earthquake loss estimate is easy, simple and feasible. Present study provides a possible link between the building vulnerability of inventory method and macroscopic vulnerability.

ST3/W/12-B5 1430

REALISTIC MODELING OF SEISMIC INPUT FOR MEGACITIES AND LARGE URBAN AREAS:THE IUGS-UNESCO IGCP PROJECT 414

Giuliano F. PANZA (Dipartimento di Scienze della Terra – Università di Trieste, Via Weiss, 4 34127 Trieste, Italy and The Abdus Salam International Center for Theoretical Physics, Miramar, Italy, email: panza@geosun0.univ.trieste.it); Fabio Vaccari and Fabio Romanelli (both at Gruppo Nazionale per la Difesa dai Terremoti - CNR, Rome, Italy and Dipartimento di Scienze della Terra –Università di Trieste, Via Weiss, 4 34127 Trieste, Italy, email: vaccari@geosun0.univ.trieste.it, romanel@geosun0.univ.trieste.it)

The project addresses the problem of pre-disaster orientation: hazard prediction, risk assessment, and hazard mapping, in connection with seismic activity and man-induced vibrations. The definition of realistic seismic input can be obtained from the computation of a wide set of time histories and spectral information, corresponding to possible seismotectonic scenarios for different source and structural models. The availability of realistic numerical simulations enables us to estimate the amplification effects in complex structures exploiting the available geotechnical, lithological, geophysical parameters, topography of the medium, tectonic, historical, palaeo-seismological data, and seismotectonic models. The realistic modelling of the ground motion is a very important base of knowledge that can be very fruitfully used by civil engineers in the design of new seismo-resistant constructions and in the reinforcement of the existing built environment, and, therefore, supplies a particularly powerful tool for the prevention aspects of Civil Defense. At present, the project is active in Antananarivo, Bangalore, Beijing, Bucharest, Budapest, Cairo, Catania, Damascus, Delhi, Kathmandu, Ljubljana, Mexicali, Mexico City, Naples, Rome, Santiago de Chile, Santiago de Cuba, Silistra, Sofia, hessaloniki, Tijuana and Zagreb.

ST3/W/38-B5 1445

MAXIMUM POSSIBLE EARTHQUAKES AS THE UPPER THRESHOLD OF SEISMIC POTENTIAL ESTIMATES OF EARTHQUAKE ACTIVE ZONES

Vladimír SCHENK, ZdeHka Schenková and Pavel Kottnauer (all at Institute of RockStructure and Mechanics, Academy of Sciences, CZ-182 09 Praha 8, The Czech Republic, email: schenk@ irsm.cas.cz)

The seismic potential is commonly understood as the upper threshold of an ability of seismogenic zone to originate the maximum earthquake. To test some approaches of statistical evaluations of the seismic potential two earthquake zones, the Gulf of Corinth area (Central Greece) and Kresna region (SW Bulgaria), that belong to seismically high-active European areas, were used. There are several published earthquake catalogues (Makropoulos 1985, Papazachos 1988, Shebalin et al. 1974) and unpublished data on earthquake occurrences monitored by local arrays of the National Observatory of Athens and the Geophysical Institute, Bulgarian Academy of Sciences. Array data were compiled by Drakatos, Kalogeras, Papadopoulos and Ranguelov and were obtained from both organisations within the joint activity in the EC INCO-Copernicus Project ASPELEA. The presentation attempts to extend standard procedures for some additional seismogenic zone quantities as a seismoactive layer thickness, a characteristic earthquake estimate, a linkage of active part of zone to known tectonic data, etc. Obtained seismic potential evaluations will be discussed from the viewpoint of a reliability of an applied methodology. The presented research was realised under the EC INCO-Copernicus ASPELEA Project No ERBIC 15CT97 0200.

MAGNITUDE FROM DOCUMENTARY DATA: CURRENT TOPICS AND OPEN PROBLEMS

DARIO ALBARELLO (Dept. of Earth Sciences, University of Siena, Via Laterina 8, 53100 Siena, email: dario@ibogfs.df.unibo.it)

By following standard statistical approaches, several empirical relationships have been so far proposed in the literature for the macroseismic estimate of magnitude. However, the heterogeneous character of the variables involved in this kind of analysis, and in particular the ordinal and discrete character of Intensity, prevents from the safe use of the usual statistical methods. As an example, it can be shown that, when linear empirical relationships are considered, the uneven sampling of data combined with the peculiar frequency distribution of magnitude values result in biased parameterizations. Suitable distribution-free statistical approaches can be adopted to overcome such kind of problems. These new procedures could help to evaluate the actual constraining power of the explicative variables so far proposed and to allow a more reliable treatment of the involved uncertainties. Furthermore, these methodologies could be useful to better understand the dependence of magnitude-intensity relationships on local seismotectonic features. In fact, despite the critical role of regionalization in the assessment of magnitude-intensity relationships, the development of suitable statistical procedures remains an open problem. To this purpose, a new procedure is discussed and tentatively applied in the Mediterranean region.

ST3/E/22-B5 1515

IN SITU MEASUREMENT OF SITE EFFECTS AND BUILDING DYNAMIC BEHAVIOUR RELATED TO DAMAGE OBSERVED DURING THREE RECENT EARTHQUAKES

MARCO MUCCIARELLI (Universit` della Basilicata, Potenza, Italy); Maria Rosaria Gallipoli (I.M.A.A.A.-C.N.R, Tito Scalo, Italy); Giancarlo Monachesi (O.G.S.M., Macerata, Italy)

After three events (Marche-Umbria, 1997; Slovenia, 1998; Southern Italy, 1998) a series of in-situ meaurements were undertaken. In the aftermath of mainshocks, HVSR were measured using aftershocks,microtremors and man-made excitations. The measurements were performed both on free-field and inside damaged buildings. It was possible to see how the enhancement of damage can be attributed to a double resonance effect observed when a building fundamental mode approaches soil resonance frequency, and how dispacements provide a better relationship with damage rather than accelerations, especially using IDI. Some more interesting effect were observed, namely: 1) the increase of site effect close to fault gauge zones not activated by the event; 2) the coupling of frequency of adjacent building with different characteristics (RC and stone masonry); different damage in buildings that appear to be exactly similar but that show different fundamental frequency.

ST3/W/14-B4 Poster 0930-01

SEISMIC GROUND MOTION MODELLING FOR THE LJUBLJANA BASIN

Andrej GOSAR and Mladen Zivcic (both at Min. of the Environ. and Physical Planning, Geophysical Survey of Slovenia, Pot na Golovec 25, SI-1000 Ljubljana, Slovenia, email: andrej.gosar@gov.si); Peter Suhadolc and Francesco Marrara (both at Dep. of Earth Sciences, University of Trieste, Via Weiss 1, 34127 Trieste, Italy, email: suhadolc@geosun0.univ.trieste.it)

Ljubljana, the capital of Slovenia, is situated in a Plio-Quaternary tectonic basin characterised by almost flat surface and rough bedrock topography. The basin is filled up with lacustrine sediments and carbonate gravel, up to 200 m thick. Site effects can have, therefore, strong influence on seismic ground motion. The strongest earthquake in the history of the city occurred in 1895 (M=6.1, I=VIII-IX MCS). The lack of stronger recent seismic activity and observational data increases the importance of numerical modelling for hazard assessment.
The data from a revised earthquake catalogue and newly determined fault plane solutions were combined with available geological data to determine the parameters of possible seismic sources. These are related mainly to dextral strike-slip faults running south-west of Ljubljana at a distance from 30 to 120 km. The largest historical earthquake in this area was in 1511 with an assessed magnitude of 6.8. A 3D structural model of the Ljubljana basin was built from the results of numerous geophysical investigations and borehole data. From this we extracted a profile towards the active area of Mt. Sneznik, lying 50 km SW of Ljubljana, for which strong motion records of an MLV=4.7 event were recorded both on sediments and on bedrock. The hybrid technique which combines the modal summation and finite-difference methods was used to calculate three-component synthetic seismograms in 2D media. A great influence of bedrock topography on the shape, duration and amplitude of the signal was observed. Comparison with available records shows a good match of the shape and amplitude of the principal phases, but an underestimation of the signal duration.

ST3/W/11-B4 Poster 0930-02

LARGE FLUCTUATION OF WAVE AMPLITUDE PRODUCED BY SMALL FLUCTUATION OF VELOCITY STRUCTURE - FOR CASE OF SPHERICAL WAVE

Mitsuyuki HOSHIBA (Meteorological Research Institute, Tsukuba, 305-0052, Japan, e-mail: mhoshiba@mri-jma.go.jp) Takashi Furumura (Hokkaido University of Education, Iwamizawa, 068-0835, Japan, e-mail: furumura@atson.iwa.hokkyodai.ac.jp)

Seismic velocity structure of the real Earth is described by a combination of deterministic large-scale structure and small-scale fluctuation. When waves propagate in media having the small scale fluctuation, the fluctuation makes the rays bent and introduces focussing and defocusing, and then produces the fluctuation of wave amplitude. To estimate how large fluctuation of the wave amplitude is made due to the velocity fluctuation, the average and the variance of wave amplitudes are evaluated as a function of propagation distance from numerical simulations of scalar wave propagation in 3D random media having Gaussian or exponential autocorrelation functions. Phase screen method and pseudospectral method are used considering Ricker wavelet as source time function. Comparing the cases of point sources with those of plane wave source, the decay rate of maximum amplitude with distance is small for point source because the effect of stochastic dispersion is weak for point source. For small propagation distance the variance for point source is smaller than that for plane wave, and for large distance that for point source is larger than that for plane wave. The variance of maximum amplitude is larger than the square of its average (i.e., large fluctuation of wave amplitude) even for several % of velocity fluctuation. These results suggest how small error and how fine resolution are necessary for velocity structure model for the discussion of wave amplitude.

MODELLING THE AMPLIFICATION OF S-WAVES AT ZUIDLAARDERVEEN

Theo DE CROOK (Royal Netherlands Meteorological Institute, Seismology Division, P.O. Box 201, 3730 AE De Bilt, The Netherlands, email: crookde@knmi.nl)

The aim of this study is to investigate the influence of shallow soil deposits on the amplification of S-waves in the borehole station Zuidlaarderveen (ZLV) and its vicinity. This amplification is important in terms of seismic hazard. The amplification in the borehole station ZLV is observed mainly in the upper 25 meters. The soil deposits are modelled with a one-dimensional model. The records of local earthquakes recorded in the borehole station are used as input motions for the model and to validate the model. Site investigations are carried out in the upper 50 meters to determine accurate soil parameters. The amplification function, calculated with the SHAKE program, approximately matches the measured amplification in the upper 25-meter for frequencies below 15 Hz.
In the vicinity of the station ZLV the soil deposits vary strongly over a few hundred meters and consist of mainly sands with clay and peat layers. In this area representative soil profiles are selected. For these profiles the amplification factors of the m

THE EFFECTS OF SOURCE PARAMETERS ON STRONG GROUND MOTIONS

Midori KAWAHARA and Masatake Ichikawa (both at Tokyo Electric Power Services Co. Ltd., 3-3-3 Higashi-Ueno, Taito-ku, Tokyo, 110-0015 Japan, email: kawahara@aed.tepsco.co.jp); Tomoyoshi Takeda and Hiroyuki Ishikawa (both at Tokyo Electric Power Company, 4-1, Egasaki-Cho, Tsurumi-ku, Yokohama, 230-8510 Japan)

It is an important problem to decide rupture processes in predicting strong ground motions due to future earthquakes. The detailed rupture processes of past earthquakes have been derived by the inversion analysis using waveforms or envelopes of the strong ground motions. Statistically analysing of these rupture processes, slip models for future earthquakes have also been derived. Though the characteristics of asperity sizes have been clarified, it is still difficult to identify locations of starting points of rupture and distributions of asperity. Therefor, it is necessary to know to what extent the simplified source models are applicable, in other words, to investigate which source parameters greatly influence strong ground motions. In this study, using the rupture processes derived from the inversion analysis as the true model, we estimated how the characteristics of strong ground motions are changed by simplifying each source parameter. Using a discrete wave number method for waveform synthesis, we analysed long period seismograms (< 2Hz), which are determined directly by the rupture processes. We assumed two simplified models, one with a constant slip magnitude, and the other with a constant slip direction. We found that in both cases the ratios of maximums of the displacements for the simplified models to those for the true one range from 0.3 to 2.0. Correlation between the waveforms for each simple model and the true one is high, especially in the case of the constant slip magnitude. We will also investigate the effects due to locations of starting points of rupture and distributions of asperity.

PILOT SYSTEM FOR AUTOMATIC DETERMINATION OF EARTHQUAKE SOURCE PARAMETERS USING BROADBAND STRONG-MOTION WAVEFORM DATA

Keiko KUGE (Department of Geophysics, Kyoto University, Kyoto 606-8502 Japan; email: keiko@kugi.kyoto-u.ac.jp) Tomotaka Iwata and Kojiro Irikura (both at DPRI, Kyoto University, Uji 611-0011 Japan)

Strong ground motions in a near-fault region are controlled by earthquake source parameters including geometry and dimension of the fault plane, rupture direction, and locations and sizes of asperities. To estimate the distribution of strong ground motions in a short time, we should rapidly determine the source parameters in an automated method. n order to test ability of the automatic determination, especially with broadband strong-motion waveform data, we have been running a pilot system automated for earthquakes in south-western Japan, using data from K-NET. Finding a new data set in the data center, the system starts to determine the moment tensor solution by modelling the three components of waveform that include P and S waves. Since 1996 the system has determined more than twenty moment tensor solutions of earthquakes with magnitudes from 3.4 to 5.5, distributing the results through the e-mails and home pages. For large earthquakes, we are expanding the system to automatically determine the fault planes and ruptured areas by using aligned-point-source modelling. The ability of the modelling was tested and approved for recent inland earthquakes with magnitudes of 6 to 7, which include the 16 January 1995 Kobe (Mw6.9), 26 March 1997 Kagoshima (Mw6.1), and 25 June 1997 Yamaguchi (Mw5.9) earthquakes, and numerical experiments. With a source of real-time waveform data, the automated system will enable rapid determination of source parameters, leading to quick estimation of ground motions for the obtained source parameters.

RUPTURE DIRECTIVITY EFFECTS ON SOURCE SPECTRA IN NEAR-SOURCE AREA

Hiroe MIYAKE, Tomotaka Iwata, and Kojiro Irikura (Disaster Prevention Research Institute, Kyoto University, Uji, Kyoto, 611-0011, Japan, email: miyake@egmdpri01.dpri.kyoto-u.ac.jp)

Rupture directivity effects on far-field seismic waves have been widely discussed in its azimuthal variation. It is also important to clarify directivity effects in near-source area for studying rupture processes and strong ground motions. We propose a method of determining the rupture area and direction from the directivity effects obtained from seismic spectra. We examined five crustal earthquakes (Mjma5.7~7.2) using K-NET records at more than 20 stations located less than 50km from the epicenter. Source processes of these events were estimated by the waveform inversion in the low frequency range (<1Hz). Based on the inversions results, we classified the observed spectra into those at forward, side-ward, and backward stations. To remove site and propagation effects in observed spectra, we took spectral ratios of main shock to aftershock(Mjma4.0~4.7). We used a frequency range below the aftershock corner frequencies. When the rupture propagated horizontally along strike unilaterally, forward, side-ward, and backward directivity effects were clearly found in the spectral ratios. Source displacement spectra of the main shock at forward stations had higher corner frequencies and steeper high-frequency decays compared with those at side-ward stations. Results at backward stations were contrary to those at forward. When the rupture propagated predominantly up-dip direction, forward directivity effects were observed only in the epicentral area. In case of the bilateral rupture event, forward directivity effects were observed near the rupture end. To examine the directivity effects on the spectra, we made numerical tests in which finite extended fault planes were expressed as a sum of sub-faults. Seismic waves from the sub-faults were calculated using the Boore's stochastic simulations. From the numerical tests, we confirmed that the spatial variations of source spectra are expressed as a function of rupture area and direction.

3-D FDM SIMULATION OF THE 1995 HYOGO-KEN NANBU EARTHQUAKE WITH DISCONTINUOUS GRIDS

Shin Aoi (National Research Institute for Earth Science and Disaster Prevention, 3-1 Tenoudai, Tsukuba-city, Ibaraki 305 Japan, email: aoi@geo.bosai.go.jp); Haruko Sekiguchi (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, email: haru@egmdpri01.dpri.kyoto-u.ac.jp); Tomotaka Iwata (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan; email: iwata@egmdpri01.dpri.kyoto-u.ac.jp); Hiroyuki Fujiwara (National Research Institute for Earth Science and Disaster Prevention, 3-1 Tenoudai, Tsukuba-city, Ibaraki 305 Japan, email: fujiwara@ess.bosai.go.jp)

We use 3-D fourth-order finite-difference method (FDM) using discontinuous grids in order to simulate ground motions in source area during the 1995 Hyogo-ken Nanbu Earthquake. Discontinuous FDM grids adapted to the velocity structure is highly effective when they are used for synthesizing waveforms of large-scale basins (Aoi and Fujiwara, 1998, submitted to BSSA). Most 3-D simulations of Hyogo-ken Nanbu Earthquake employed coarse grids with the spacing of more than 100 m for finite-difference calculations, and hence the models with the S-wave velocity of approximately 600 m/s at the superficial layer, resulting in underestimated amplitude. We use the discontinuous grids, that consist of small grids (50 m spacing) up to the depth of 2.5 km where there exist sedimentary layers and coarse grids (150 m spacing) from that depth up to 25 km that is the lower bound of the fault plane. It is suggested by geophysical explorations that the S-wave velocity of the superficial layer is about 400 m/s. The use of the discontinuous grids enables us to treat a model with such S-wave velocity, with frequency of up to more than 1 Hz. Compared to the case with the S-wave velocity at the superficial layer of 600 m/s, the velocity amplitude of the synthetics at the observation point on the sedimentary layer becomes several dozens percent larger.

EFFECTS OF SURFACE GEOLOGY ON EARTHQUAKE GROUND MOTION IN THE CITY OF BARCELONA, SPAIN

Maria-Jose JIMENEZ, Mariano Garcia-Fernandez (Institute of Earth Sciences "Jaume Almera"/C.S.I.C., Lluis Sole i Sabaris, s/n, E-08028 Barcelona, Spain. email: mjjimenez@ija.csic.es, mgarcia@ija.csic.es); Gaetano Zonno (Istituto di Ricerca sul Rischio Sismico/C.N.R., Via Bassini, 15, I-20133 Milano, Italy. email: zonno@irrs.mi.cnr.it)

This paper presents the results on earthquake hazard scenarios for Barcelona urban area as evaluated through a component of the computer prototype developed within the European project SERGISAI. Maps of soil response for the city of Barcelona have been for the first time obtained through a GIS environment, which integrates the different analysis procedures within a single application. The approach followed in order to obtain the hazard scenarios involves: collection of all data relevant to local geology and soil conditions, implementation of geotechnical models into the GIS, estimation of the level of seismic action, generation of strong-motion time histories and implementation of 1D analytical method for soil response calculations. The resulting predictive hazard maps of predominant periods and amplification ratios delineate potential variations on ground shaking and constitute a first approximation towards an integrated approach to Barcelona urban area microzonation. A comparison with empirical values from ambient noise measurements shows that most of the observed differences can be explained in terms of the physical parameters of subsurface layers. The interpretation of observed differences through a detailed analysis of empirical and analytical results is twofold. First to determine site dependence suitability and reliability of both methodologies, and second to both extract information on at-present inaccessible parameters needed for the characterisation of physical properties of soil and delimit areas where further in-depth survey research is needed for a proper seismic hazard assessment.

SITE EFFECT EVALUATION USING COMBINATION OF SOURCE SACLING MODELS AND GROUND NOTION RECORDS

Vladimir SOKOLOV (National Center for Research on Earthquake Engineering, 200, Sec.3, Hsinhai Rd., Taipei, Taiwan, E-mail: vova@email.ncree.gov.tw)

A set of acceleration records obtained during recent Caucasian earthquakes (the Spitak, Armenia 1988, M=6.8; the Ratchi, Georgia 1991, M=7.1) was used to evaluate the site response. The soil/bedrock spectral ratios (SBSR) (mean values and deviations) were determined within frequency interval 0.6-10 Hz as ratios between spectra of the records and spectra that have been simulated for rock outcrop using w-squared Brune's model. The frequency dependence of amplification clearly exhibits the influence of soil deposits of various thickness, as well as the affect of surface topography. The generalises regional SBSR functions for so-called "reference shallow-soil site" were calculated using accelerograms recorded on various stations. The amplification functions were used for prediction of ground motion parameters expected during future earthquakes.

SOURCE SPECTRA SCALING AND ATTENUATION MODELS FOR DIFFERENT SEISMOGENIC REGIONS

Vladimir SOKOLOV (National Center for Research on Earthquake Engineering, 200, Sec.3, Hsinhai Rd., Taipei, Taiwan, E-mail: vova@email.ncree.gov.tw)

Fourier-amplitude spectrum is one of the most important parameters describing earthquake ground motion, and it is widely used for estimating seismic hazard and strong ground motion prediction. At the present there is no doubt that Fourier spectra source scaling and attenuation models may differ in various seismogenic regions. In this study, relationships between Fourier-acceleration spectra, earthquake magnitude and distance were analysed for different active regions using ground motion recordings of small to moderate (M < 6.5) shallow earthquakes. Two characteristic models are used to describe amplitude spectra as a function of earthquake energy and distance: so-called "w-squared" Brune's source spectra model, and empirical model based on statistical analyses of recorded accelerograms. Stochastic simulation of ground motions (peak ground acceleration and response spectra) using obtained models of source spectra and attenuation shows good agreement with observed data.

LOW VELOCITY LOVE WAVE IN HIGH DENSITY STRONG MOTION SEISMOGRAPH NETWORK DATA: RE-EXAMINATION OF UPPERMOST CRUST MODEL IN SOUTHERN METROPOLITAN AREA OF JAPAN

Yasushi ISHIHARA and Masanori Saito (both at Faculty of Science, Yokohama City University, Seto 22-2, Kanazawa-ku, Yokohama, 236-0027, JAPAN, email: ishihara@yokohama-cu.ac.jp) Masayuki Kikuchi (Earthquake Research Institute, University of Tokyo)

Highly condense seismic array network is a powerful tool to research the details of uppermost crust structure and subsurface characteristics of seismic ground motion. We had constructed the strong motion seismograph network in Yokohama city, southern metropolitan area of

Japan, which consists of 150 observatories in about 400 kilometer square area. This region has sediment layer of 3-4km thick which is estimated by artificial seismic refraction survey and surface wave velocity by other sparse network. The thick sediment layer excites slightly long (5-10 sec) period surface waves. This network observed the Love wave excited by relatively nearby and shallow middle-scale earthquake with strike-slip fault mechanism. As the phase-time mapping and band-passed seismograms aligned by epicentral distance, phase velocity and propagation direction of Love wave is estimated with high accuracy. The group velocity is not resolved well because of local magnification and severe long coda duration. This analysis brings the dispersion curve in 5 - 20 sec period range. The phase velocity at 10 sec period is about 2.0 km/s, which is less than one of previous studies. The phase velocity curve does not indicate strong dispersive character in this range. The theoretical study expects that sediment layer is lower velocity and/or thicker than standard structure model, however the sufficient interpretation is not reached. The phase-time mapping shows the heterogeneous seismic propagation affected by westward high velocity mountain region.

MODELING SUBSURFACE STRUCTURE IN A SEDIMENTARY BASIN USING SEISMIC RECORDS OF VERTICAL ARRAY AND VARIOUS GEOPHYSICAL DATA

Hitoshi MORIKAWA (Graduate School of Civil Engineering, Kyoto University, Yoshida-Hon'machi, Sakyo-ku, Kyoto 606-8501, Japan, E-mail: morika@quake.kuciv.kyoto-u.ac.jp), Junpei Akamatsu (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, E-mail: akamatsu@drs.dpri.kyoto-u.ac.jp), Akito Uchida (Nara National Cultural Properties Research Institute, Nijo, Nara 630-8002, Japan).

We discuss a method to estimate accurately subsurface structure in a deep sedimentary basin with use of seismic observation with vertical array, and to assess reliability of resultant structure model on the basis of cross-check of theoretical horizontal-to-vertical spectral ratios (H/V) for S-waves and phase velocities of Rayleigh waves (CR). Study area is Heijo-Kyo, the northernmost part of Nara basin, Japan. The depth to bedrock is known to be about 600m from a nearby deep-borehole. In addition, we could utilize the other geophysical data such as microseism array data obtained by previous works, which provide information of CR.
3-component seismic observations have been carry out at GL 0m, -20m, -42m, and -100m in a borehole, and 70 local and regional events with magnitude of 3.2 to 7.7 were recorded in 1997 and 1998. We analyzed (1) difference in onset time between S-to-P converted wave and S-wave, (2) surface-to-underground spectral ratios (S/UG), and (3)H/V at each depth. It is noteworthy that, spectral ratios of S/UG peak at depth-dependent frequencies of nearly odd multiples (up to third higher mode), and that H/V from earthquake motions and that from microseisms resemble each other. From the analysis, a model of S-wave velocity structure is proposed. To verify the model, we used both of CR and peak period of H/V for S-waves (Tp) calculated from models. Comparison was made with models obtained from the other data such as CR of microseisms and small-scale refraction survey. Although parameters of each model contain the coefficients of variance of 5 to 10%, theoretical CR and Tp for the models coincide respectively in a range of one standard deviation. This enable us, therefore, to use the least squared method to develop a more reliable model satisfying all the available data.

COMPARISON OF VARIOUS METHODS TO ESTIMATE THE GROUND STRUCTURE

Hitoshi MORIKAWA (Graduate School of Civil Engineering, Kyoto University, Yoshida-Hon'machi, Sakyo-ku, Kyoto 606-8501, Japan, E-mail: morika@quake.kuciv.kyoto-u.ac.jp), Junpei Akamatsu (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, E-mail: akamatsu@drs.dpri.kyoto-u.ac.jp), Akito Uchida (Nara National Cultural Properties Research Institute, Nijyo, Nara 630-8002, Japan).

Various methods have been presented to estimate S-wave velocity structure of sediment which will be a basic information for prevention of earthquake disaster. We discuss a method to estimate accurately ground structure in this study, comparing the structure obtained from vertical array observation records of earthquakes with that from other method. For this purpose, using the velocity type seismometers, we carried out the observation in a borehole at Heijyo-Kyo where is located at north of Nara basin, Japan. The seismometers consist of three components and are set at GL 0m, -20m, -42m, and -100m. In this site, the government plans to construct a large wooden structure, which has long predominant period, to restore the ancient capital of Japan. As a priori information, some data obtained from microseisms observations and deep borehole are available to estimation of ground structure. According to these data, the depth to the bedrock, whose velocity of sheer waves is 3.2km/s, is about 600m and we can model this structure in two sedimentary layers. The observation systems have recorded about 70 events in these two years. Using these records, (1) running time of S-P converted waves, (2) spectral ratio between different depth, and (3) horizontal/vertical spectral ratio (H/V) at each depth are calculated and a model of S-wave velocity structure is developed for this site. To verify the development, we compare the obtained model with various models estimated from other data, that is, deep borehole data, dispersion curves from array observation of microseisms, H/V of microseisms around this site, Bouguer anomalies, small-scale refraction surveys. While the S-wave velocity structures estimated from these various data contain the coefficient of variance, whose value is 5 to 10%, they share the same value in range of mean plus/minus standard deviation. Using the least squared method, therefore, we can develop a more accurate model of ground structure which satisfies the various data.

AZIMUTH VARIATIONS OF THE AVERAGE ATTENUATION COEFFICIENTS

Lenka S. TIMIOVSKA (Institute of Earthquake Engineering and Engineering of Seismology, Salvador Aljende 73, Skopje, Macedonia)

Within the frames of a project for computation of seismic risk in Macedonia, there arose the need of investigating the variation of seismic intensity attenuation. Defined from the isoseismals of some earthquakes were the coefficients of average attenuation, and their azimuth variations. Due to the wide range of attenuation coefficients, the application of complex attenuation laws becomes a necessity in determination of the anisotropy of energy expansion. The obtained relationship shows a fairly good agreement with isoseismals of many large events on the whole investigation region and may therefore be useful in providing realistic estimates of spatial attenuation and hence of design earthquakes for a given site. It can also be sometimes useful in estimating the epicentral intensity for an earthquake whose maximum intensity is not reliably known. In general speaking, the results point to the fact that the use of average attenuation values or approximation of the first order is not sufficient enough for corresponding definition of attenuation, but approximations of a higher order are necessary. Investigation to a greater depth could enable prediction of the possibility of obtaining attenuation laws depending on magnitudes on one hand, while on the other, the possibility to work with revised data.

NUMERICAL SIMULATION OF NONLINEAR SITE-RESPONSE EFFECTS

Olga PAVLENKO (Institute of Physics of the Earth, B.Gruzinskaya 10, Moscow 123810, Russia, e-mail: olga@synapse.ru)

To study nonlinear site-response effects, numerical simulation is performed of propagation of Gaussian white-noise seismic signals of various intensities in horizontally layered sedimentary soils. The behaviour of soils under loading is described by nonlinear hysteretic Iwan model, linear elastic model, or linear visco-elastic model. For these models, nonlinear system identification techniques were applied: the spectra and bispectra of output signals are computed, which characterise in frequency domain the linear and nonlinear (due to quadratic nonlinearity) parts of the medium response to a seismic action. It was shown that, for the nonlinear model, increasing the intensity of the input signal gives rise to the signal distortion in the process of its propagation, the shape of the power spectral density curve transforms, and, for intense input signals (corresponding to acceleration of higher than 0.4g), takes the form E ~ f -k; bispectral amplitudes of the output signals increase in the high-frequency and low-frequency domains due to generation of combinative frequency harmonics. This is in accordance with theoretically predicted shape of spectrum and bispectrum in the case of interaction of a large number of seismic waves, in the approximation of chaotic phases. The inverse problem is solved of estimating coefficients of the power series describing the nonlinear histeretic curve of soil behaviour by spectral and bispectral amplitudes. Power spectral density of the seismic noise Iso decreases with frequency as E ~ f -k, this can indicate the presence of a nonlinear component of the edium response to a seismic action in the seismic noise. Estimates of this component for areas with various eological structure are made by bispectra of seismic noise.

ANOMALOUS (~1G) PEAK ACCELERATIONS RECORDED AT STATION KRUGLYI, KAMCHATKA.

PETUKHIN A.G.(1), Dontsov O.V.(1), Egorov O.N.(2), Melekestsev I.V.(2) and Sinitsyn V.I.(1) (1) Kamchatka Experimental and Methodical Seismological Department; (2) Institute of Volcanic Geology and Geochemistry; 9 Piip Blvd., Petropavlovsk-Kamchatsky, 683006, RUSSIA,
email: gusev@emsd.iks.ru

In 1993yr, during strong earthquakes on June 8 (Mw=7.5) and November 13 (Mw=7.0) near South Kamchatka, at ground strong-motion station Kruglyi accelerograms were recorded with unusually large peak accelerations: Amax =991 gal and 897 gal. Hypocentral distances were R=104 and 60 km, respectively. The both records have high frequency content: amplitude Fourier spectra have broad peaks at 5-10 Hz with maximum amplitudes about 30 times greater than it could be expected on rock in Kamchatka from earthquakes with the same values of Mw and R. To find out the reasons of these anomalies, we investigated the geological environment at the station Kruglyi and estimated the station spectral corrections by two methods: (1) the ratio of Fourier amplitudes of micro-seismic noise at the investigated point and at the base rock point; (2) the ratio of the accelerogram spectrum at station Kruglyi and the average spectrum for Kamchatka on rock for the same magnitude and distance. The both spectral corrections are fitted well, i.e., the source of the spectral anomaly is located near the station, at a distance much shorter than the distance between the investigated and the base points. The most probable candidate for such anomaly is the pocket of hydro-thermally altered rocks (sand + clay, 70 m. width, the distance from the accelerometer to the nearest boundary is 30-40 meters, while the accelerometer itself is located on rock). Died hydrothermal system looks like a soft inclusion in rock with vertical parallel walls and produces a resonator/waveguide; this can lead to the observed phenomenon.

SPATIAL VARIATIONS OF SITE RESPONSE AND RESONANCE SITE EFFECTS IN SOILS

Rufet URDUKHANOV and Olga Pavlenko (both at Institute of Physics of the Earth, B.Gruzinskaya 10, Moscow 123810, Russia)

The medium response to a seismic action is often substantially determined by resonant oscillations of various inhomogeneities in the earth's crust, i.e., separate layers, wave guides, or inclusions, excited by propagating seismic waves. An experiment is carried out at a test-site of the Institute of Physics of the Earth with a vibrator seismic source, aimed at a detailed study of the medium transfer functions within a small area. A 3-component receiver was placed in the center of a circle of the 100 m- radius, and the vibrator moved along the circle and radiated signals at frequencies of 10 Hz, 14 Hz, 16 Hz, 18 Hz, and 20 Hz at points having azimuths of 0o, 30o, 60o, 90o, 120o, 150o, 180o, 210o, 240o, 270o, 300o, and 330o. The upper part of the medium are sand and clay layers up to depths of 1000-1200 m. The results of the experiment show: 1) substantial difference in the transfer functions of the medium for different azimuths; 2) noticeable amplification of seismic amplitudes at some frequencies and some frequency bands; 3) amplification of oscillations at a frequency of 17 Hz for all azimuths and resonant oscillations at 17 Hz for one direction, the Q-value is rather high and testifies to contrast boundaries and contrast impedance properties of the resonant structure. According to the scheme of the experiment, we can conclude that the resonant structure is located near the surface, and its dimensions are about some meters. The numerical simulation is performed of propagating of seismic signals in the medium with the geological structure and physical properties depending on depth, as it was determined for the test-site, and the same medium with slight variations in its parameters, assuming deep and subsurface wave guides; estimates of characteristics of the resonant structure are made based on the whole set of available seismic recordings.

CALCULATION OF LONG-PERIOD GROUND MOTION RESPONSE SPECTRUM BY USING BROAD-BAND DIGITAL RECORD

YU, Yanxiang, WANG, Suyun and HU, Yuxian (Institute of Geophysics, China Seismological Bureau, Beijing100081, China, email: yanxiang@cdsndmc.css.gov)

There is an increasing need to study the characteristic of long-period ground motion with the construction of many large scale structures whose natural period are around 10 sec. Although the digital strong motion accelerographs are used for many years and a number of such high-quality records are obtained, recent studies show that it is still difficult to obtain reliable response spectrum due to the low signal-to-noise ratio when the period exceeds 10 sec. The broadband digital seismographs used by seismologist have many excellent characteristics such as broadband, high-resolution and low-noise, which are also needed in study of earthquake engineering. The seismograms recorded by these seismographs might be used in studying long-period ground motion in certain conditions. In this paper we have a detailed study to these records in the aspects of instrument response, resuming of ground motion, correction, spectrum analysis of signal and noise to demonstrate their feasibility in studying

long-period ground motion. Over 70 broad-band (BB or VBB) or low-gain accelerograph (LG) records of the Chinese Digital Seismograph Network (CDSN) and VBB records of GEOSCOPE in Wushi seismic station are used to calculate the horizontal response spectra in the period range up to 20 sec.
The BB system has a very flat amplitude response in the period range up to about 20 sec. The VBB or LG system of CDSN and VBB system of GEOSCOPE have flat amplitude response in the period up to several hundred sec. So these seismographs can record the long-period ground motion which we concern. The ground motion displacement, velocity or acceleration can be expediently resumed by applying the transfer function of the system to the record. Tests in this study show that, as to one earthquake, the ground motions resumed from records of different seismographs are very similar. The baseline correction and high-pass filtering are required before calculating the response spectrum. The baseline drift is removed and a high-pass filter which the cut-off period is 40 sec is applied. No other correction process is used in order to furthest reserve long-period ground motion information. In order to analyze the signal-to-noise level, noise is extracted from the first 62.5 sec of the pre-event recording while the signal is from the thereafter 125 sec recording. Their Fourier amplitude...

NEW INSTRUMENTATION OF THE UKRAINIAN NATIONAL NETWORK FOR SEISMIC OBSERVATIONS

Yu. LOKSHYN, N. Petrov, V. Baranov (all at State Scientific Industrial Association "Metrology",42 Mironositskaya st., 310002 Kharkov, Ukraine, fax: +380 572 43 61 93)

The possible earthquakes are very strong hazard for population safety and could cause the essential economic disasters and environment catastrophes. The problem of the earthquakes prediction and anti-seismic protection has the most importance in Ukraine, where the large industrial units, in particular, the nuclear power stations, are situated in the seismic active regions near large cities. In this sense, Ukraine needs a modern and broad network of the permanent seismic observations. At present, one of the main directions to improve the national seismic observations network is its re-supplying with new seismic control instruments, in particular, with accelerometers and seismic sensors for low and infra-low frequency. Such re-supplying also foresees to perfect the metrological traceability in the vibration acceleration measurement area. The Complex State Program to develop the national system of the seismic observations and to raise the population safety in the seismic hazardous regions has been worked out in Ukraine. In frame of that program the State Scientific Industrial Association (SSIA) "Metrology" develops, manufactures and tests the various types of tri-axis accelerometers and seismic sensors based on that accelerometers intended for operation at the nuclear power stations in the anti-seismic protection systems. To verify those accelerometers and seismic sensors SSIA "Metrology" also develops the Special Standard consisting of Pendulum and Rotating Calibrators. The Pendulum Calibrator has been already manufactured and tested. To make use new accelerometers, seismic sensors and instruments for their verification allows to upgrade the national seismic observations network, to improve it reliability and trustworthy of observations and to mitigate risk of the nuclear power stations maintenance.

STUDY OF THE SITE EFFECT IN ROME AS INFERRED FROM MACROSEISMIC SURVEYS

Andrea Tertulliani (Istituto Nazionale di Geofisica, Via di Vigna Murata, 605 Roma, Italy, email: tertul@ing750.ingrm.it_); Francesca Funiciello, Stefano Donati and Francesca Cifelli (Dept. of Geology, University of Roma Tre, Largo S. L. Murialdo, 00146 Roma, Italy, email: sdonati@uniroma3.it)

An original methodology has been prepared for high density macroseismic surveys in urban areas by Istituto Nazionale di Geofisica, Department of Geology of University Roma Tre and many high schools of Rome. Such a method was applied to Rome during the seismic sequence started in Central Italy in September 1997, studying two earthquakes largely felt in the city: the October 14, 1997 earthquake (Mw=5.7) and the March 26, 1998 earthquake (Mw=5.3). The two events were different in depth and epicentral distance from Rome. The systematic collection of macroseismic data allowed us to plot 669 and 928 observation points respectively for the two events, all in the roman urban area. The high density of information revealed in a great detail the variation of intensity in the urban frame, showing a very good correlation with local geology. The analysis of the intensity variation has shown, as expected, an amplification of the seismic effects on Holocenic deposits, in particular on the alluvial deposits of Tevere valley, and on the alluvial deposits of the minor tributaries. This last evidence is new, as those areas have been never studied before from a seismological point of view. Recent alluvial sites have in general shown, for both earthquakes, major effects in comparison with sites on pre-holocenic formations (bedrock); the increasing in term of MCS scale has been one degree or more. The whole research provides a good confirmation of the important role of the very local geological variations in the seismic response of the city. Our experimental evidences are in good agreement with numerical simulations and modelling of seismic response, that are available only for the historical centre of Rome. These results can provide a significant contribution to the seismic risk evaluation of Roman area, assessing the correct hazard to the recent alluvial deposits.

EFFECTS OF 12 APRIL 1998 KRN, SLOVENIA, EARTHQUAKE (MWA=5.8) ON NATURAL SURROUNDINGS AND THEIR INTENSITY-RELATED DISTRIBUTION

Andrej GOSAR and Polona Zupancic (both at Min. of the Environ. and Physical Planning, Geophysical Survey of Slovenia, Pot na Golovec 25, SI-1000 Ljubljana, Slovenia, email: andrej.gosar@gov.si)

On Easter day, 1998 at 10:55 UTC the strongest earthquake reported in this century in Slovenia (Mwa=5.8) occurred near the border with Italy. The epicenter was in uninhabited area of Krn mountains (Julian Alps) in a complex built area at the junction of External Dinarides and Southern Alps. Preliminary depth of the hypocenter is about 15 km and the focal mechanism shows almost pure dextral strike-slip (NW-SE). The earthquake caused extensive damage in several villages and in the city of Bovec located 10 km from the epicenter. The maximum intensity VII-VIII EMS-98 was assessed. The earthquake caused several massive rock-falls, few landslides and affected the flow of some springs in epicentral area. Due to the fact that this mountain area was unpopulated during the earthquake (very bad weather and high snow), it was useful to grade the damage to natural surroundings and to study intensity-related distribution. An analysis of these effects was therefore made to assess the reliability of the data and their relation to other macroseismic data. The area of greatest rock-falls as well as the area of aftershocks is elongated in direction of the structures. Attention was needed because rock-falls are not rare events in Julian Alps (two larger occurred in last 10 years), that are built mainly of highly fractured carbonates. The maximum assessed intensity from the damage to buildings corresponds to the lower intensity limit, according to EMS-98, at which the observed effects on nature occur. For the landslip of the Bohinj lake bank (15 km away), there is no evidence of the liquefaction, characteristic for higher intensities. Waves on standing water were observed in wider area as well as substantial changes to the level of ground water. Only small damage for few isolated stone buildings in epicentral mountain area was also reported. None of these effects are sufficient to quantify the higher EMS-98 intensity.

MACROSEISMIC EFFECTS OF 12 APRIL 1998 KRN, SLOVENIA, EARTHQUAKE: AN OVERVIEW

Ina CECIC, Matjaz Godec, Polona Zupancic and David Dolenc (all at Ministry of the Envir. and Physical Planning, Geophysical Survey of Slovenia, Ljubljana, Slovenia, email: ina.cecic@gov.si)

On Easter 1998 at 10:55 UTC (12:55 local time) the strongest earthquake reported in this century in Slovenia (MWA=5.8) occurred near the border with Italy. The epicentre was in uninhabited area of Krn mountains (Julian Alps). The earthquake caused extensive damage in several villages and in the city of Bovec (approx. 10 km NW from the epicentre). The maximum intensity was estimated to be VII-VIII EMS-98. One person in Bovec died of a heart attack. The earthquake was also felt in nine European countries, where the data were collected and evaluated by the institutions in charge. After the main shock the questionnaire forms were distributed by mail to all observers in the Slovene database (more than 4300). Several field trips were made in order to collect the macroseismic data in the wider epicentral area. The collaboration with other governmental teams that were collecting and evaluating the damage was established and their data were made available for our use. More than 1000 houses were examined by civil engineers and the damage was described in detail. Older fieldstone and simple stone objects with wooden floors and bad quality mortar suffered the damage most often. Many of them were already damaged in the 1976 Friuli earthquakes, but the retrofitting and the reinforcement of the buildings were done poorly or not at all. Some recently built buildings were damaged as well, in many cases due to the unfavorable soil conditions. The data on damage and the data from questionnaires were combined into a database which enables us to obtain good quality EMS-98 intensity estimates as well as to study single effect distributions. The earthquake caused many effects on nature (huge rockfalls, landslides, etc.) that were also documented.

SEISMIC RISK IN CENTRAL AMERICA - A SIMPLIFIED APPROACH

YONG CHEN (China Seismological Bureau, 100036 Beijing, China, email: yongchen@public.bta.net.cn) Federico Güendel (Universidad Nacional, Apdo. 86-3000, Heredia, Costa Rica, email: fgu@geofys.uu.se) Ota Kulhánek (University of Uppsala, Villavägen 16, 752-36, Uppsala, Sweden, email: Ota.Kulhanek@seismo.uu.se)

Seismic hazard in Central America (in 50 years, 10% probability of exceedence), is assessed on a 5´x 5´grid by making use of available earthquake catalogs and attenuation formulae. In the simplified seismic risk approach used, the time consuming and costly vulnerability analysis is replaced by macro-economic indicators, such as the Gross Domestic Product and population distribution, which are easy to compile. Calculated losses correlate well with the distribution of seismic hazard and social wealth. In Central America, the largest losses of US $ 2.5 billion are expected in Guatemala (50-year interval, 10% probability of exceedence). For Costa Rica and El Salvador the respective figures are US$ 1.6 and 1.5 billions. In Honduras, Nicaragua and Panama the expected losses are significantly below US$ 1 billion.

1995 NEFTEGORSK EARTHQUAKE STATISTICS OF OIL PIPE LINE SYSTEMS

KOFF G.L (1), Frolova N.I. (2), Zverev L.A. (3)
(1)Institute of Lithosphere, Russian Academy of Sciences Moscow, Russia (2) Seismological Center of IGE, Russian Academy of Sciences, Moscow, Russia (3)VNIPI "Morneftegas", Okha, Russia

The Neftegorsk earthquake (M= 7.1) occurred on May 28, 1995. It resulted in large social and economic losses. The number of fatalities reached 1958 people, about one thousand inhabitants were severely injured. Damage rate of almost all existing buildings was discovered to be 4 (heavy damage) and 5 (total collapse). The earthquake caused more 30 breaks of the oil pile line system in the Northern Sakhalin. Three major oil pipelines Tungur-Sabo, Sabo-Blockpost 3, Okha-Komsomolsk-na-Amure were inspected. The diameter of the damaged pipelines varies from 325 mm up to 426 mm. The main damage to pipe lines occurred due to ground layers displacement and failure. Cracks from 20 to 100 cm wide and offsets up to 30 cm have been measured throughout the observed pipe line routes. The typical damage to pipe lines is cracks in joints, total failure of joints. The detailed description of the inspected pipe line breaks is given. The most severe damage to pipe lines was found at distances from 10-12 km up to 16-20 km from Neftegorsk. Little damage was observed at distance of 35 km. Most of oil pipe line damage during the earthquake were observed in the areas characterized by unfavourable ground conditions and local dislocations, as well as in the vicinity of moving blocks of Verkhne-Pitulsky and Gyrgylaninsky active regional faults. The engineering geological conditions and physical mechanical soil properties were studied in the areas of pipeline breaks. The engineering recommendations for the oil pipeline restoration and future construction are given.

A METHOD OF EARTHQUAKE RISK ASSESSMENT

LUO WEI (Seismological Bureau of Beijing, CSB No.28 Suzhou Street, Haidian District, Beijing, 100080, China, email: weiluo@public,bta.,net.cn)

The violent earthquake activity on a global scale is mainly concentrated in the relatively narrow zones of the plate boundaries. However, there are also violent neotectonic movement and earthquake activity within the plates and continents. The most typical region where intraplate earthquakes happen is a large triangle situated in the continental China and its environs. This is a soecific phenomenon from the action of the strong plate boundary force by the collision between the Indian and Eurasian plates at the Himalayan Arc. On the basis of the theoretical and experimental results, the epicentral distribution, the surfaces rupture belts and focal mechanism solutions, the seismicity framework is suggested. The framework is formed by the two groups of neotectonic slip lines approximate to logarithmic spirals; that is, the zones where the maximum shear stress and shear strain are concentrated. The netlike structure makes a spatial framework dominating over the neotectonic movement and earthquake activity, and provides a new method for studying and predicting strong earthquake risk areas. The spatial distribution of the large earthquakes (M≥7) in the continental China is changed from along the neotectonic slip lines to an area within a plan rectangular co-ordinate. We found out that the earthquakes obviously concentrated on two narrow and interesting zones similar to the X type rupture. It is useful for us to reduce the areas where we attempt to explore the large

earthquake occurrence. According to the dynamic developing process of the moderate events (M≥5) along the neotectonic slip lines in every year since 1900, it is found out that the events increased before a large earthquake with magnitude greater than or equal to 7 occurrence. The moderate events mainly occurred at the special locations on or near the slip lines related to the future large earthquake epicenters. In fact, most of the large earthquakes of the recent years do occur as above descriptions.

INVESTIGATING CONSISTENCY BETWEEN ESTIMATES OF SEISMIC HAZARD: A COMPARATIVE EVALUATION OF THREE METHODOLOGIES

CLAIRE McQUEEN EQE International Ltd, The Genesis Centre, Science Park South, Birchwood, Warrington, UK, WA3 7BH

Raised awareness of the threat posed by natural hazards such as earthquakes has led to an increase in the number of studies attempting to quantify these risks. Several methods are available for this purpose which prompts the question: "What degree of consistency, if any, may be expected between results produced by each method?" This study uses Cornell type, Historical Parametric, and Extreme Value methods to assess the seismic hazard across the South Eastern Caribbean, a region for which a detailed and complete catalogue exists. Hazard levels are displayed as contour maps showing Peak Ground Acceleration (PGA) with a 10% probability of exceedence in any 50 year time period. For each method, a number of sensitivity tests are performed, yielding results that are then are used to produce a suite of maps illustrating the dependency of results on various input variables. Comparisons are also made for modelling scale and attenuation relationships, and inter-methodological consistency is examined.
The results suggest that of all the input variables, the attenuation relationship chosen to model ground motion has the greatest effect on the results. As far as consistency between methods is concerned, providing that a historically complete catalogue is available, the methods produce contour maps with a similar spatial distribution of hazard. However, absolute ground motions are highly dependent upon the attenuation model applied.
Given the importance of hazard continuity, it is recommended that caution be exercised when using composite hazard maps taken from sources that favour different methodologies. For risk assessment purposes, since results from individual studies are often not directly comparable, super-zone hazard maps covering areas that are not delimited by political or national boundaries should be created; thus necessitating further discussion of standardisation of data collection and hazard assessment methodology.

SIGNIFICANCE OF FAULT-RELATED BEDROCK-STRUCTURE IN MICROZONING OF A DEEP SEDIMENTARY BASIN: STUDY ON THE 1996 LIJIANG EARTHQUAKE, YUNNAN, CHINA (IDNDR JOINT-RESEARCH)

J.AKAMATSU(Disas. Prev. Res. Inst., Kyoto Univ., Uji, Kyoto 611-0011, Japan,
e-mail: akamatsu@drs.dpri.kyoto-u.ac.jp), K.Nishimura(Dep. Informatics, Okayama Univ. of Science), H.Morikawa(Graduate School of Civil Eng., Kyoto Univ.), K.Onoue(DPRI, Kyoto Univ.), N.Seto, M.Nakamura(both at Earthq. Res. Inst., Univ. of Tokyo), M.Komazawa(Geological Survey of Japan), L.Jiang(Seismological Bureau of Yunnan Prov.), K.Li(Seismological Bureau of Lijiang Pref.), Q.Luo and Y.Wang(both at Inst. of Structural Theory, Tongji Univ.)

The Lijiang Earthquake of February 3, 1996 (M7.0) brought serious damage to Lijiang basin. Its seismogenic fault is considered to be Xueshan fault lying along the western edge of the basin. There is another large fault, called Lijiang-Jianchuan fault, which crosses the basin in the southern part. What is important to note is that anomalous distribution of damage to wooden houses and RC buildings was observed in the basin. This involves an issue of microzoning. Thus we studied the subsurface structure of the basin, mainly the configuration of bedrock related to the faults, on the basis of array observations of microseisms, large and small scale seismic refraction surveys and gravity survey. The results show that, the depth to bedrock reaches 1,200m or more in the central part, and bedrock subsides steeply by more than 700m along Xueshan fault at the western edge, whereas subsidence of bedrock across Lijiang-Jianchuan fault is not significant. We suggest from these results that the irregular configuration of bedrock related to the faults has played an important role in amplification of ground motions, and consequently the anomalous distribution of damage. In conclusion it is pointed that configuration of bedrock should be taken into account for microzoning study, for which combined analysis of microseisms and Bouguer gravity anomalies is very useful.

DETERMINATION OF THE EPICENTERS, MAGNITUDES AND DEPTHS OF PHILIPPINE HISTORICAL EARTHQUAKES

MA. LEONILA P. BAUTISTA1,2, Bartolome C. Bautista1,2 and Kazuo Oike1(1Dept of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, Sakyoku, Kyoto, Japan, 606-8502; 2Philippine Institute of Volcanology and Seismology, C. P. Garcia Avenue, UP Diliman campus, Diliman, Quezon City 1100, Philippines)

A large volume of Philippine historical earthquake descriptions from 1589 to 1897 is reviewed, evaluated and interpreted in order to estimate their magnitudes, epicenters and depths. Historical earthquake data are obtained, as much as possible, from primary sources in libraries and archives in the Philippines and Spain since the period under study is also the time when Spain started its more than 300-year colonial rule of the Philippines. More than 3000 events consisting of about 6679 intensity reports are catalogued, interpreted and their intensities determined by considering the possible effects of local site conditions, type of construction and the number and locations of existing towns to assess completeness of reporting. Epicenters of 487 historical events are determined based on the resulting generalized isoseismal maps augmented by information on recent seismicity and location of known tectonic structures. Their historical magnitudes are estimated by using previously determined magnitude-felt area equations for recent events. These equations were derived using intensity data of eighty-eight recent, shallow Philippine earthquakes. Meanwhile, depths were calculated using the depth estimation software of Musson (1998) that uses intensity at epicenter (Io) and felt areas at different intensity levels. Results show that about half of the evaluated events have less than 50-km depths while the rest are deeper than 50 km.
The epicenters are found to mostly lie along known tectonic structures. As compared with recent seismicity, however, the eastern Philippine region and Mindanao island showed low seismicity as compared to recent data. The quality of epicenter and magnitude determination was also assessed based on the number of intensity reports. Most earthquakes earlier than 1850 had only 9 or less reports. Good quality reports start to be collected from 1850 probably correlative to an increase in the number of reporting towns. Comparing with the number of recent earthquakes, the results show that there are still a large number of events especially during the pre-1850 period that remains "missing" or unevaluated due to meager historical accounts.

SENSITIVITY ASPECTS OF SEISMIC HAZARD ASSESSMENT – CASE STUDY FOR THE GERA-RONNEBURG REGION (GERMANY)

Dieter KRACKE, Roswitha Heinrich, Diethelm Kaiser Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Burgweg 11, D-07749 Jena, Germany, email: kracke@geo.uni-jena.de

The region Gera-Ronneburg is part of the large Kyffhäuser-Jachymov-fault zone and displays moderate seismicity. But its seismic hazard is significantly higher then that of the surrounding area. The earthquake catalogue of Germany contains for this region, besides the well investigated Central German Earthquak (March 1872, I0=VII-VIII), entries of up to I0=VIII (14th century). Epicentral intensity and coordinates of these earthquakes are considered as uncertain. In seismic hazard analysis historical events which are uncertain are often neglected. But, especially in regions of moderate seismicity, the time window considered should be extended as far as possible. Apart from the necessity to study the historical sources of the strongest 14th century earthquakes we investigate the influence of these events on the seismic hazard, taking into account all uncertainties of their size and location. Macroseismic observations, especially from the Central German Earthquak (1872), show strong lateral variations of local intensities in the epicentral area. These variations correlate with local geology. To verify the influence of site effects we recorded and analysed local events and noise at selected sites. The influence of the local site effects on the seismic hazard is included in the sensitivity analysis.

EARTHQUAKE PREDICTION: PROBLEMS AND RESULTS

Oleg KHAVROSHKIN, Vladislav Tsyplakov and Natalia Vidmont (United Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya 10, 123810 Moscow D242 Russia, Email: khavole@uipe-ras.scgis.ru)

The history of the problem mentioned in the head is full of dramatic collisions. Methods of many branches of modern science are applied for its solving. Thus, we shall invent general aspects of this problem without detail: 1. The monitoring of the energetic state of investigated region. 2. Physical models. 3. The paradigm of the prediction and courses of its deadlock. 4. Nets of seismic stations. 5. What to do: abandonment of the old paradigm, the prediction in the open non-linear system, etc.
The analysis based on the scheme proposed leads to sad prognosis on complete decision of the problem in nearest 10-20 years. The only way is to abandon on the existing paradigm and development of the scheme of operative prediction of individual using (OPIU). We propose the scheme of OPIU that can be realized just now. It is based on the analysis of the emission seismic response of geophysical media in the region learned by the user, to local variations of strained state. We suppose, that the great part of seismological information is contained in the emission seismic noise. Thus, this noise must be recorded in dangerous areas permanently.

NEW PROBABILISTIC HAZARD ASSESSMENT FOR SWITZERLAND

Francesca BAY, Swiss Seismological Service, Institute of Geophysics, ETH-Hoenggerberg HPP, CH-8093 Zuerich, email: bay@seismo.ifg.ethz.ch Souad Sellami, Donat Faeh & Domenico Giardini , Swiss Seismological Service, Institute of Geophysics, ETH-Hoenggerberg HPP, CH-8093 Zuerich Juan José Egozcue, Dep. Mathemática Aplicada III, U. Politécnica de Cataluña, Gran Capitán s/n, E-08034 Barcelona, Spain

Switzerland is a country of moderate seismicity but high economical risk. Probabilistic seismic hazard studies have been conducted for Switzerland in the past in terms of macroseismic intensities, mostly due to the lack of strong motion data. Engineering needs and the international norms require the assessment of the seismic hazard in terms of physical parameters. The classical probabilistic hazard methods do poorly take into account the uncertainties of the input parameters (as location, magnitude, intensities and attenuation). A method to evaluate uncertainties using Bayesian statistics, was developed and applied to estimate the return period for different intensities at different sites (Egozcue and Ruettener, Natural Hazards 14: 91-112,1997). The new earthquake catalogue is a compilation of the macroseismic earthquake catalogue which covers the time period from 1021 to 1997 for intensities 4 to 9 and instrumental data since 1942 for magnitudes ranging from 3.5 to 5.2. Empirical relationships for Switzerland are used to convert magnitudes from Intensities. Seismotectonic investigations and paleo-seismological observations are under studies. Recently acquired attenuation relations (Smit 1996, Ph.D ETH Zuerich) are based on the data of the short period network of the SED which is operated since 1974 and the strong motion network which has been installed in 1992. The attenuation relations are in terms of peak ground- and spectral acceleration with respect to magnitude (ML) and hypocentral distance. The Bayesian method was further developed to deal with the incomplete part of the catalogue and applied at chosen sites in order to compare the hazard. This poster presents new results of seismic hazard assessment in terms of peak ground- and spectral acceleration and sensitivity analyses of the input parameters.

ST3/E/08-B4 Poster **1400-13**

THE PROBABILITY ESTIMATION OF STRONG VRANCEA EARTHQUAKES ON THE BASIS OF MAXIMUM ENTROPY PRINCIPLE

Victoria GINSARI (Institute of Geophysics and Geology Moldavian Academy of Sciences, Academy str. 3, Kishinev, MD-2028, Moldova, email: postmaster@geo.moldova.su)

Some results of seismic hazard assessment, conditioned by vrancean intermediate earthquakes, are presented in this paper. It was used maximum entropy principle (MEP), known by application in many engineering fields. Later, some researchers adopted MER for using in seismic hazard analysis, especially, for the estimation of the strong earthquakes recurrence. MEP indicates an alternative way for the recurrence and probability estimations not rejecting, but supplementing the results, obtained by use of least-squares fit, maximum likelihood method or some other method.
Taking into account the scatter in M max value for Vrancea zone according to the different authors investigations (7.5-8.0), and specificity of method MEP, we have been set apriory by three values of M max: 8.25, 8.0, 7.75. In this case, the recurrence interval of a magnitude 7.5 earthquake, the most realistic estimation of the observed value of the strongest vrancean earthquake during the millennium, is found to be 104, 115 or 159 years, respectively. For three apriory taken M max: 8.0, 7.75, 7.5, the magnitude of an earthquake with a 10% probability of exceedance in 50 years is determined to be 7.84, 7.66, 7,45. It should be noted that computed values of earthquake recurrence with M=7.0 are invariant to M max and are equal to 37 years. The comparison of both recurrence estimations and probability density functions, obtained on the basis of MER and other methods (by using the same data set) shows that recurrence intervals for the earthquakes with M=7.25, computed by MEP, are higher, then that one computed by other method. The difference is increased considerable with increasing of magnitude. Thus, if the results, based on the MEP, were not taking into account, the seismic hazard would have been overestimated.

SEISMIC HAZARD ASSESSMENT IN PORTUGAL, A COMPLEX INTRAPLATE SETTING

Susana P VILANOVA, Joao F B D Fonseca, Alexandra Paula and Carlos A S Oliveira (all at IST, Av. Rovisco Pais, 1, 1049-001 LISBOA, Portugal, email: vilanovs@fisica.ist.utl.pt)

This poster describes an effort towards the assessment of seismic hazard in Portugal, emphasising the problems inherent to most intraplate settings, such as the lack of instrumental data and the uncertainties about the attenuation laws. In Portugal these difficulties are increased by the complexity of the tectonic environment: continental margin under compression on the W, zone of continental convergence on the SE, and a dense network of Late Hercynian faults cutting the basement throughout the region. Strong motion data from intraplate earthquakes in continental regions, both stable and active (excluding the very specific environments), where analysed and used to "calibrate" the existent (but limited) macroseimic database for Portugal. Different assumptions for the attenuation curves for several source zones lead to different scenarios used as input for the Seismic Hazard Analysis. We compare the results obtained in this study with previous hazard estimates.

SEISMIC ZONATION FOR NORWAY

LINDHOLM C. D.1, H. Bungum1, A. Dahle1, F. Nadim2, J. Holme2 and G. Woo3 1) NORSAR, Box 51, 2007 Kjeller, Norway 2) Norwegian Geotechnical Institute, Box 3939 Ullevel Hageby, Oslo, Norway 3) EQE International Ltd., 18 Mansell St., London E18AA, England

Eurocode 8 "Design provisions for resistance structures", comprising earthquake resistant design, is expected soon to be implemented in many European countries. Norway has prepared for adaption to these codes through a National Application Document, which also includes results from a national seismic zonation study. This means that earthquake resistant design can be incorporated without extensive site studies on seismic loading unless strict safety criteria are calling for a site-specific analysis. The basic seismic zonation study was done for Norwegian onshore and offshore regions with a unique international co-operation from the British side. Through this co-operation the seismic hazard results across the national boundaries were prepared in a joint effort. The results were utilizing recent ground motion attenuation models and a newly developed earthquake source zone definition, based on a quality controlled earthquake catalogue where all magnitudes were converted to moment magnitude. The results were presented in terms of peak ground acceleration (PGA) maps for four annual probabilities together with normalized pseudo velocity spectra with corresponding time histories. The smoothed maps were based on computations in a 50 km x 50 km grid, and one normalized spectrum was found representative for all Norwegian regions. Furthermore relations for computation of vertical spectra and duration were presented allowing for flexible application of the results. Soil amplification of earthquake loads were defined for three main onshore categories (rock, moraine and clay, silt and sand) for which response spectra were developed and for typical offshore soil conditions.

SEISMIC HAZARD ASSESSMENT INCORPORATING SITE EFFECT: PROBABILISTIC MICROZONATION

Vladimir SOKOLOV (National Center for Research on Earthquake Engineering, 200, Sec.3, Hsinhai Rd., Taipei, Taiwan, E-mail: vova@email.ncree.gov.tw); Yury Chernov (SK IGC, 185 Dzerzhinsky pr., Stavropol, Russia 355105)

The problem of accounting for local soil effect on earthquake ground motion is especially urgent when assessing of seismic hazard - recent needs of earthquake engineering require for including effects of surface geology into hazard maps. When evaluating of seismic hazard, it is necessary to account dangerous earthquakes of various magnitudes that may occur at different distances and, therefore, to consider soil response on different excitation levels. Recently developed by authors method of seismic hazard calculations allows us to create hazard maps involving influence of local soil conditions using soil/bedrock spectral ratios. Probabilistic microzoning maps may be constructed showing Macroseismic Intensity, Peak Ground Acceleration, Response and Design Spectra, as well as ground motion time series (accelerograms) for various return periods (probability of exceedence), that allow to optimize engineering decisions. The results of the approach utilization are presented.

ST3/E/11-B4 Poster **1400-17**

COMPARISON OF RECENT STRONG EARTHQUAKES EFFECT AND SEISMIC HAZARD MAPS: AN OPPORTUNITY TO EVALUATE HAZARD ASSESSMENT TECHNIQUE

Vladimir SOKOLOV (National Center for Research on Earthquake Engineering, 200, Sec. 3, Hsinhai Rd., Taipei, Taiwan, E-mail: vova@email.ncree.gov.tw); Yury Chernov (SK IGC, 185 Dzerzhinsky pr., Stavropol, Russia 355105)

Results of seismic hazard analysis are used as a basis for engineering decisions, and design ground motion parameters, so-called "basic seismicity", (MMI (MSK) intensity, PGA values and response spectra) are dictated in Building Codes. Recent strong earthquakes, occurred throughout the world, showed that the assessment of seismic hazard in some respective regions must be revised. New assessment of "basic seismicity" in terms of MMI (MSK) intensity, PGA values and response spectra were carried out for some regions of the former USSR (the Caucasus, Central Asia, Sakhalin island) using technique of probabilistic seismic hazard assessment developed by the authors. When employing the method, we used the data on the seismicity that were available before recent strong earthquakes. Therefore, this study may be considered as a test of the approach. The results demonstrate that our assessment of "basic seismicity" (MSK intensity, PGA values and response spectra) for 1000-years return period (0.05 probability of exceedence in 50 years) confirm the observed data, and they may be used as a reliable basis for Building Code provisions.

SUBSURFACE STRUCTURE BELOW OHMI BASIN, SOUTHWEST JAPAN, AS DEDUCED FROM GEOPHYSICAL EXPLORATION AND ITS POSSIBLE EFFECTS ON EARTHQUAKE HAZARD AND RISK

Keiichi Nishimura(Faculty of Informatics, Okayama University of Science, Okayama 700-0005, Japan, email: nisimura@big.ous.ac.jp), Masao Komazawa (Geological Survey of Japan, Tsukuba 305-8567, Japan, email: koma@gsj.go.jp), Tomoki Tsutsui(Aso Volcanological Laboratory, Kyoto University, Kumamoto 869-1404, Japan, email: tom@aso.vgs.kyoto-u.ac.jp) and Masao Takabayashi (Seta Senior High School, Ohtsu 520-2132, Japan, email: setahspc@mx.biwa.or.jp)

Ohmi basin, situated to the east of Lake Biwa, southwest Japan, is a sedimantary basin filled with late Pliocene-to-Pleistocene lacustrine deposits and surrounded by mountains both on the east and on the south. In the basin, anomalously high seismic intensities have been recorded from large historic earthquakes, including fairly distant Nankai-trough events that occurred south off Honshu Island. This involves a issue of microzoning. Thus we studied the subsurface structure below the basin using data of seismic refraction exploration, long-period microtremors and Bouguer gravity anomaly; in addition, well information from two deep drillings, performed inside the Lake and in the eastern part of the basin, was used to constrain structural models to be obtained. The result of analysis shows fairly complicated configuration of bedrock below the basin: the thickness of lacustrine deposits is greatest near along the eastern edge of the basin, possibly implying fault-related subsidence of bedrock; toward the west, after being thinnest in the central part of basin, the deposits are thickened again near the coast of the Lake where they are overlain by reclamation land. It is highly probable that such complicated surface geology has significant effects on seismic ground motion, thereby bringing anomalous distribution of earthquake damages in the basin.

UNCERTAINTY STUDIES IN SEISMIC HAZARD ASSESSMENTS APPLIED TO SELECTED SITES IN CENTRAL EUROPE

Gottfried GRUENTHAL, Rutger Wahlstrom (both at GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany, email: ggrue@gfz-potsdam.de)

An essential element in the current practice of seismic hazard assessments consists in the consideration on uncertainties in the procedure. The presented seismic hazard study is based on a logic tree approach applied to selected sites in seismically most active parts of central Europe. The influence of various input parameters and their combinations is analyzed with respect to resulting mean, median and fractiles of the hazard curves. Emphasis is given to constraints on attenuation relations of peak and spectral accelerations as well as intensities, focal depth distributions, magnitude frequency relations, lower and upper bound magnitudes (the latter being also depth dependent) and the source regionalizations.

THE GSHAP WORLD MAP OF SEISMIC HAZARD

D. GIARDINI (ETH, 8093 Zurich, Switzerland, email: giardini@seismo.ifg.ethz.ch) G. Grunthal (GFZ, Potsdam, Germany), H. Gupta (NGRI, Hyderabad, India), D. Mayer-Rosa and S. Sellami (ETH, Zurich,Switzerland), K. Shedlock (USGS, Boulder, USA), P. Zhang (SSB, Beijing, China), T. Annaka (Tokyo Electric Power Sevices, Japan), M. G.-Ashtiany (IIEES, Tehran, Iran), K. Atakan (Bergen University, Norway), S. Balassanian (NSSP, Yerevan, Armenia), P. Basham (CTBTO, Vienna, Austria), C. Dimate (Ingeominas, Bogota, Colombia), M. Erdik (Kandilli Obs., Istanbul, Turkey), M. Garcia (CSIC, Barcelona, Spain), Giesecke (CERESIS,Lima, Peru), K. McCue (AGSO, Canberra, Australia), R. McGuire (Risk Engineering, Boulder, USA), R. Musson (BGS, Edimburgh, UK), S. Riad (Assiut University, Cairo, Egypt), D. Slejko (OGS, Trieste, Italy), V. Ulomov (JIPE, Moscow, Russia), the Working Groups of the GSHAP regions: Central-North America, Central-Northern Europe, Eastern Asia, Northern Eurasia, Ibero-Maghreb, Adria, the working Groups of the projects: PILOTO, CAUCAS, RELEMR, SESAME, PAIGH-IDRC, EU-QSEZ-CIRPAN.

The Global Seismic Hazard Assessment Program (GSHAP) was launched in 1992 by ILP and ICSU and endorsed as a demonstration program by the UN/IDNDR. The GSHAP promoted a regionally co-ordinated, homogeneous approach to seismic hazard evaluation. Regional activities were concluded in 1992-98; the results have now been compiled in a uniform set of databases and in a world map of seismic hazard expressed in PGA. Support for the GSHAP implementation was provided by ING, Roma, by national and regional institutions, by IASPEI, UNESCO, ICSU, ILP, IDNDR, EU, NATO, INTAS and IGCP. All GSHAP materials (regional report, maps, datasets) can be retrieved on the GSHAP web site at http://seismo.ethz.ch/GSHAP/. The GSHAP world map of seismic hazard will be presented for the first time at the IUGG assembly and will be available for distribution at the assembly.

MEASUREMENTS OF HORIZONTAL CRUSTAL DEFORMATIONS AT THE BAIKAL GEODYNAMIC POLYGON

Vl. KUPKO, V.Strelets (all at Kharkov State Research Institute of Metrology, Ukraine, fax +380 572 43 61 93)

Results of horizontal crustal deformations in the Baikal Lake region will be reported. A high-precision range-finder developed and produced at the Kharkov State Research Inst. Of Metrology is used to detect three-year crustal movements. The used range-finder is based on a double frequency optical laser interferometer and is able to measure a distance from 1m to 5 km with an uncertainty of the order 0.05mm. Yearly variations of +11.7 mm/1.5 km; +12.3 mm/3 km; +6.2 mm/700 m ;-0.3 mm/700 m are detected in various directions. Possible geophysical interpretations will be given.

HIGH PRECISION LASER COMPLEX TO MONITOR LINEAR-ANGULAR MOVEMENTS IN GEOPHYSICS

Vl.KUPKO, S.Kovshov, I.Lukin, V.Sobol, G.Pushkariov(all at Kharkov State Research Institute of Metrology, Ukraine, fax +380 572 43 61 93)

The Kharkov State Research Institute of Metrology has developed a new high precision laser complex for linear-angular measurements in a range 1m to 5 km with an uncertainty of 0.05 mm (linear) and in a range ±180 degrees (horizontal) with an uncertainty of 2" (angular). The complex combines the following main components: a high precision laser range-finder which is heading the state hierarchy scheme; an angular measuring system based on photo-electric transformers; a complex system for measurements various parameters of atmosphere (temperature, pressure, humidity); a special algorithm to take a current air refraction index into account. The developed complex can operate under influence of non-stationary disturbances. Some technical details of the complex and first obtained field measurement results will be given in this presentation.

VERIFICATION COMPLEX FOR GEODETIC LENGTH MEASURING EQUIPMENT

Vl. KUPKO, N.Kravchenko (all at Kharkov State Research Institute of Metrology, Ukraine, fax +380 572 43 61 93)

High precision length measurements in a range from meters to kilometers are of great

importance in geodesy since it is necessary to detect earth crustal deformations as well as to establish reference networks and monitor conditions of great industrial constructions. To verify all the used instrumentation, special laser interferometric comparators are usually created. In this presentation we report on a unique verification complex consisting of length base of 168 m created in Armenia. This base is located in an underground tunnel (depth is 70 m, diameter is 4 m). A complex consists of various retroreflectors, microscopes, half-transparent mirrors, centering devices, railways etc. Performed interferometric measurements show an achieved accuracy of the length of the base of the order of +/- 0.03 mm (standard error). The first obtained results on observations of crustal deformations using the length base will be reported.

MACRO SCALE MODELLING OF CATASTROPHIC NATURAL HAZARDS

ADRIAN STEWART, and Dr Claire McQueen, (both at EQE International Ltd, 500 Longbarn Boulevard, Warrington, WA2 0XF, UK. Tel:- +44 1925 838372, fax =44 121987 654, Email: astewart@eqe.co.uk, cmcqueen@eqe.co.uk.

Economic losses from Natural disasters over the last few decades have been enormous, as demonstrated by Hurricane Andrew in the US. The impact on the global economy can reverberate for years after a single event. Assessing the risk to regions and countries is essential in the context of enabling International Organisations, Governments and International Industry and Commerce to plan, mitigate and manage losses. In terms of risk from damaging earthquake or windstorm events, the risk is a function of the hazard intensity combined with the vulnerability of the properties within any given unit or area. The deterministic results of such studies may also be combined with expected frequencies to obtain probabilistic estimates of risks. In order that the losses expected within an area from an event be estimated accurately, the vulnerability functions and hazard models should be representative of the scale of the are that they are located in. Scale is an important issue. The Hazard Model needs to reflect the reduced risks expected over larger areas. However, the detail needs to remain in order that the spatial resolution of the hazard across an area is accurately represented. The question is whether vulnerability and hazard models can be created for a specific scale, or whether it is possible to calculate losses on a detailed grid and aggregate consistently at any macro scale.

THE S. BALKAN DBANK OF SHALLOW AND INTERMEDIATE DEPTH EARTHQUAKE MACROSEISMIC DATA

B. C. Papazachos, A. A. Savaidis (both at Geophysical Laboratory, University of Thessaloniki, GR-54006 Greece); Ch. A. PAPAIOANNOU, C. B. Papazachos (both at ITSAK, P. O. Box 53 Foinikas, GR-55102 Thessaloniki, Greece, email: chpapai@itsak.gr)

In the present paper information is given on the data bank of macroseismic observation and the basic source parameters of earthquakes in the southern Balkan area starting from the 6th century BC. This data bank includes about 37500 macroseismic observation of 577 strong (M => 6.0) shallow earthquakes for the time interval 550 BC-1996 AD, of 300 shallow earthquakes of the present century with magnitude 4.1<= M <=5.9 and 60 intermediate depth (60km <h <150km) earthquakes of the present century with magnitude 5.5<= M <=7.9. The input data for this data bank were either site-specific intensities or grouped data derived from published macroseismic maps. All the intensity values were converted to the MM scale. For all cases the geographical coordinates are given. The intensities are homogeneous, that is, the different degree of vulnerability of structures through the time periods spanned by the data was also considered.
The data were elaborated using published scaling empirical relations, based on present century data, holding between macroseismic intensities versus distance and instrumental magnitude, in order to determine the macroseismic magnitude. Furthermore based on the macroseismic pattern and the scaling relations, the epicenter and the magnitude of the historical earthquakes were determined. For cases of shallow earthquakes where an adequate number (N>10) of observations was available, synthetic isoseismals were compiled considering anisotropic radiation of the seismic energy at the source.
In the dBank for every populated site in the southern Balkan area there are intensities caused by at least 20 earthquakes. The macroseismic observations for every site and the magnitude and epicentral distance in the data bank were used both for the determination of site specific attenuation relations, which are important for any hazard assessment, as well as a hazard map depicting the distribution of the observed intensities I > VIII for every site. Moreover, a map depicting the maximum observed intensities for the study area was compiled.

EVALUATION OF THERMALLY RELEVANT PROCESSES FOR TEMPERATURE PROGNOSIS IN ALPINE TUNNELS

Thomas KOHL, Andreas Busslinger, Ladislaus Rybach Institute of Geophysics ETH Hönggerberg, CH-8093 Zurich, Switzerland

The present day temperature field results from the complex interplay of several factors and processes. The analyses of the subsurface temperature fields have been performed customarily by treating individually and separately involved mechanisms such as steady-state topography effects, transient palaeoclimatic effects, lateral and vertical heterogeneities, P / T dependency of thermal parameters, forced and free convection, radioactive heat production, erosion / sedimentation. Such treatment neglects the potentially important interplay of these effects and processes. In this paper a combined 3-D analysis is presented for a well studied situation along at a major Alpine Swiss engineering project: the new Gotthard base tunnel project which will cross the mountains at a level of maximum 550 m a.s.l. and below an overburden of up to 2500 m. The design of the tunnel ventilation and climate system during construction and operation requires a sophisticated temperature prognosis which has to account for all possible thermal transport mechanisms.
The basic concept for our numerical (FE) study is the evaluation of the topographical influence on transient temperature signals in mountain areas. In the important depth range, primary thermally relevant effects result from morphological situations and fluid advection. Also important for the alteration of the local temperature fields are the climatic history since the last Ice Age and the combination of uplift and erosion. The results highlight the necessity for topographical correction of temperature data in the areas not affected by fluid movement which yield maximum temperatures above 40°C. In the highly permeable fault zones, however, the fluid advection may wash out any transient effect.

NUMERICAL MODELS OF THE CONDUCTIVE THERMAL REGIME IN LONG VALLEY, CALIFORNIA

S. HURTER and D. Pribnow (all at: Joint Geoscientific Research GGA, Hannover, Germany)

Within the International Continental Drilling Program (ICDP) and Long Valley Coring Project (LVCP), numerical models are applied to explain the lower than expected temperatures down to depths of 3 km and to understand the deeper thermal regime of this active caldera. Conductive and convective heat transport at various rates and timescales are expected. Full advantage is taken from the fact that numerical models allow the effects of several processes to be evaluated separately or jointly. The first step was to set up a background steady state thermal field neglecting fluid flow. The model is based upon knowledge of the regional setting surrounding the caldera so that future and more complete models can distinguish local anomalies due to the caldera itself from the regional thermal field. Long Valley caldera is situated within the transition from Sierra Nevada to Basin and Range, two contrasting physiographic provinces. Sierra Nevada has thicker stable crust, lower heat flow at the surface, while Basin and Range is characterised by volcanism, higher seismicity, normal faulting, higher upper mantle temperatures and higher heat flow. An E-W section was discretized into a 2-D model. The heat conduction equation was solved by a finite difference scheme (SHEMAT) at 500 x 220 gridpoints. The surface temperature was fixed at 8 °C. The side boundaries were insulating. Radioactive heat production in the crust followed an exponential decrease with depth. Model temperatures are lower than those measured in the Long Valley Exploration Well. In a second step, the existence of a long-lived magma chamber at a depth of 7km underneath the eastern half of the caldera was examined by imposing a temperature of 800 °C at each magma chamber node. The resulting model temperatures at 2km depth are 200 °C higher than those measured. Transient models of the cooling of this magma chamber suggest that its thermal signal should still be detected in the present-day, more than 750 000 years since the great Bishop Tuff eruption. However, the conductive background model in the absence of magma at depth matches the measured temperatures much better.

GEOTHERMAL CHARACTERISTICTS OF THE RIES IMPACT STRUCTURE (GERMANY)

Yuri POPOV (Moscow State Geological Prospecting Academy, Miklukho- Maklai str., 39-1-191, Moscow 117485, Russia, email: Yupopov@mgga-sec.msk.ru) Jean Pohl and Heinrich Soffel (Institute of Geophysics, Muenchen Ludwig-Maximilians-University, Theresien str. 41, D-80333 Muenchen, Germany, email: pohl@alice.geophysik.uni-muenchen.de, soffel@magbakt.geophysik.uni-muenchen.de) Raissa Romushkevich (Moscow State Geological Prospecting Academy)

Rock thermal conductivity measurements were carried out on 530 dry and water-saturated cores from the 1206m deep Noerdlingen borehole drilled in 1973 in the Ries impact structure (Bavaria, Germany). It was found that different structural-lithological complexes and different rock types are characterized by essentially different values of both thermal conductivity and thermal inhomogeneity factors. The thermal conductivity data from dry rocks and the porosity, calculated using theoretical models and experimental data, correlate well with other logs, especially with sonic, electric and neutron gamma logs. Thermal anisotropy of gneisses is found to be negligible although significant anisotropy for these rocks is usually observed. Average heat flow density values vary from 117 mW/m2 in the depth interval of 70-250m to 68mW/m2 in the depth interval of 250-500 m, to 72mW/m2 in the depth interval of 500-870m and are predicted to be 77 mW/m2 in the depth interval of 870-1200m, i.e. 33-45% higher for these depths than in previously published data. Significant differences in temporal variations of the temperature gradient determined from the temperature logs measured at different times after termination of drilling (from 1 day up to 10 months) indicate significant variations in strata permeability and fluid activity.

TECTONIC LEAKAGE OF FAULT BOUNDED AQUIFERS SUBJECT TO NON-ISOTHERMAL RECHARGE: A POSSIBLE MECHANISM GENERATING THERMAL PRECURSORS TO SEISMIC EVENTS

Valiya M. HAMZA (Observatório Nacional – CNPq, Rio de Janeiro, Brazil)

The thermal consequences of flow transients generated by deformation induced leakage at fault zones intersecting confined aquifers have been examined using a simple analytical model. The recharge of the aquifer is assumed to take place by vertical infiltration through the confining layers. The energy equation relevant in this case can be derived by evaluating enthalpy fluxes associated with lateral and vertical components of fluid flows as well as that due to volume changes in the permeable layer, generated by deformation induced alterations in the hydraulic head. Results of numerical simulations indicate that thermal transients arise during the stress build-up period as a consequence of mixing of the infiltrating fluids with those in the aquifer. Steady state conditions are attained within relatively short periods of time due to rapid energy exchange. On the other hand, when deformation ceases infiltration is drastically reduced and consequently return to equilibrium thermal conditions is quite rapid. Thus, under favorable conditions, relatively small changes in deformation pattern can easily lead to abrupt and substantial changes in the thermal regime. Model results also indicate that the characteristics of thermal precursors depend on a number of factors such as duration of stress build-up, direction of recharge flux, permeability contrast between the confining layer and the aquifer as well as local geothermal gradient.
Examination of available observational records of temperature variations in bore holes in tectonically active areas indicates that occurrence of transient thermal anomalies with characteristics similar to those predicted by the ‘deformation induced leakage’ model is not uncommon. Examples are presented illustrating model fits to thermal transients, identified as precursors to seismic events, in Firjusa (Turkmenistan) and Izu peninsula (Japan). The results indicate the possibility of obtaining complementary information on processes controlling fluid flow during pre-seismic periods. It appears that the occurrence of thermal anomalies associated with small scale tectonic deformation may be quite widespread, but its detection would require long term monitoring using high precision temperature sensors.

ST4/W/46-B1 1000

THERMAL EVOLUTION, TECTONIC SUBSIDENCE ANALYSES AND DEEP GEOPHYSICAL CHARACTER OF BOHAI BAY BASIN, EAST CHINA

HU Shengbiao and Wang Jiyang (both at Institute of Geology, Chinese Academy of Sciences, Beijing 100029,China, Email: sbhu@mail.igcas.ac.cn)

Heat flow measurements and thermal history reconstruction, using vitrinite reflectance and apatite fission track data, indicate that Bohai Bay Basin is characterized by lower present-day heat flow varying between 50 and 65mW/m2 with a background heat flow value of 63.6mW/m2, and that the basin experienced a much higher heat flow (70-90mW/m2) period prior to 25Ma. Tectonic subsidence analysis shows that the subsidence of Bohai Basin can be divided into two phases: earlier (25-50Ma) initial (rift) and later (Since 25Ma) thermal subsidence. The earlier rift phase is composed of two sub-rift episods with quick subsidence, and the later thermal subsidence was superimposed with rapid subsidence since 12Ma, which can be related to crustal isostasy induced by mantle decoupling as revealed by seismic tomography. The lower present-day heat flow and the higher palaeo-heat flow corresponding to initial subsidence stage as well as the typical rift subsidence style in Bohai Basin support its feature of intraplate, pull-apart rift basin, and provided with some insight to the tectonic-thermal evolution of the basin.

HEAT FLOW IN AND AROUND THE MARGINAL SEAS OF THE NORTHWEST PACIFIC

Lili JIANG (Institute of Geophysics, Chinese Academy of Sciences, 11 Datun Road, Chaoyang District, Beijing 100101)

In this paper, the marginal seas of the northwest Pacific include the Bering Sea, Okhotsk Sea, Japan Sea, East China Sea, South China Sea and Philippine Sea. The adjacent areas comprise the continent around these marginal seas, the islands and the trenches outsides of these seas. Since the first heat flow measurements in the area were taken in 1957 around the Japanese islands and the first marine heat flow measurements were carried in Bering Sea in 1961, more than 4,000 heat flow values have been obtained. The numerical value of the mean heat flow in the area is somewhere between those of the continent and ocean. The results of the heat flow measurements between the east of Eurasia plate and the west of Pacific Ocean Plate imply that the thermal state of the lithosphere in this area is also the thermal transition zone between continent and ocean plate. The thermal anomalies of these marginal seas and their adjacent areas have four characteristics: First, there is no clear borderline among continent, marginal seas and islands in the heat flow anomaly bodies. Second, the low heat flow anomaly boundary gives the outline of the trench system in the northwest Pacific Ocean. Third, in general, the high heat flow anomaly bodies trend towards NE direction, the exceptions being Komandoskaya Basin, the Izo-Ogasawara(Bonin) arc and Marina Trough, they extend towards NW direction. Finally, the area of high heat flow corresponds to strong tectonic activity and the most important is that the local geology structure controls the shapes of local heat flow anomaly bodies.

ST4/W/22-B1 1120

HEAT FLOW PATTERN AND THERMAL STRUCTURE OF LITHOSPHERE IN CONTINENTAL AREA OF CHINA

WANG Ji-Yang (Institute of Geology, Chinese Academy of Sciences, Beijing 100029, China, E-mail: JYWLPX@public3.bta.net.cn)

To date, altogether 730 heat flow values were obtained in continental area of China. The mean heat flow value turns out to be 65.2¡Â6 mW/m2, which is in good accordance with the global continental mean of 65¡Â1.6 mW/m2 (Pollack et al., 1993). Heat flow pattern in continental area of China is characterized by "high in the East & South" and "low in the North & West". The lowest heat flow appears in the NW part of China . For example, the average heat flow in Tarim Basin exhibits to be 50mW/m2 and in Jungar Basin, 45mW/m2. The highest heat flow has been observed in southern Tibet where the mean value may reach up to 80-100mW/m2 and more. There's a good relationship between heat flow and the geological age of the terrain. But there's no good correlation between heat flow and the last tectono-thermal events of the terrain. Generally, relatively high heat flow is observed in old terrain affected by the latter tectonic activity and/or tectono-thermal events. Thermal structure of the lithosphere in continental area of China exhibits that there exists so called "hot crust & cold mantle" thermal structure for the western part of China whereas "cold crust & hot mantle" is inherent for the eastern part of China. The above-mentioned heat flow pattern and thermal structure of lithosphere are resulted from the Pacific plate subduction from the East and continent-continent collision between India and Euroasia plates since Meso-Cenozoic era.

ST4/E/13-B1 1140

UNCERTAINTIES OF LITHOSPHERIC THERMAL MODELS: THE BOUNDARY BETWEEN FACT AND FICTION

Ilmo T. KUKKONEN and Jarkko Jokinen (both at Geological Survey of Finland, P.O. Box 96, FIN-02151 Espoo, Finland, e-mail: ilmo.kukkonen@gsf.fi) Ulf Seipold (GeoForschungsZentrum Potsdam, Post Box 600751, 14407 Potsdam, Germany, e-mail: seip@gfz-potsdam.de)

Any geothermal model used for calculating the lithospheric thermal regime is sensitive to uncertainties in the model parameters, namely, thermal conductivity, its temperature and pressure dependence, heat production rate and applied boundary conditions (surface heat flow, mantle heat flow or mantle temperature). We have investigated the uncertainties of lithospheric conductive models using a random simulation technique with a 4-layer model representative of 155 km thick shield-type lithosphere (50 km thick 3-layer crust). Model parameters were varied according to predetermined probability functions and standard deviations were calculated for lithospheric temperature and heat flow density after 1500 independent simulations. For instance, assuming relative uncertainties of 20-30 % for the individual parameters, the highest variations in Moho temperatures (+- 40-50 K) are due to conductivity and heat production, whereas the temperature and pressure dependencies of conductivity have much smaller effects (< 20 K). When all parameters vary simultaneously, it does not seem possible to estimate the Moho temperature with an uncertainty smaller than +- 100-130 K, and in the mantle the value increases approximately linearly to about +- 220-270 K at the base of the lithosphere. Improving results from these values requires deep temperature and heat flow estimates independent of the model as well as of heat flow measurements in shallow boreholes, which often are disturbed by palaeoclimatic or hydrogeological factors.

ST4/E/16-B1 1200

THERMAL STRUCTURE OF THE LITHOSPHERE SURROUNDING WESTERN MARGIN OF INDIA AND LATE CRETACEOUS GEODYNAMICS

O.P. PANDEY and P.K. Agrawal (National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India email: postmast@csngri.rec.nic.in)

Passive continental margin of western India is an elongated, anomalous, degenerated, seismically active and rifted part of the Indian peninsula. In the present paper, we analyse the available geothermic data to study the sublithospheric thermal structure. The anomalous nature of the lithosphere beneath this region is well reflected in the heat flow and geothermal gradient distribution, the latter varying widely from 15˚C/km to 78˚C/km with an average of over 30˚C/km. The gradients are particularly high in the north Cambay graben, Konkan belt, northern and eastern part of the Bombay offshore and off the Cochin coast. The average gradients in the first three regions herein referred to as West Coast Thermal Anomaly Zone, are of the order of 50 to 60˚C/km. Curie depth analysis using MAGSAT data also indicates a high gradient of about 31˚ C/km within the upper crustal column. As expected, heat flow is quite high in the West Coast Thermal Anomaly Zone averaging over 80mW/m2 . In the major part of this region, gravity anomalies usually have positive bias in an overall low gravaity environment, indicating shallowing of Moho 18 to 30km). The asthenosphere beneath this margin is situated between 30 and 70km. The unusual thermal behaviour of this region could be ascribed to catastrophic and geodynamic events which took place during the last 130 Ma.

ST4/E/26-B1 1220

VARIATIONAL MODELLING OF RADIOGENIC HEAT DISTRIBUTION IN THE CONTINENTAL CRUST

R. N. SINGH (CSIR Centre for Mathematical Modelling and Computer Simulation, Wind Tunnel Road, BANGALORE 560 037, India, email: rnsingh@cmmacs.ernet.in) Ajay Manglik (National Geophysical Research Institute, Uppal Road, HYDERABAD 500 007, India, email: postmast@csngri.ren.nic.in (Attn: AMANGLIK))

The linear surface heat flow-heat generation relationship has been used to quantify the nature of shallow vs. deep source for the surface heat flow.
The radiogenic heat sources are concentrated in the shallow regions in the continental crust and this contributes significantly to the surface heat flow and temperature distribution in the crust. Amongst various models of radiogenic heat sources, the exponential model has been shown as an optimal model using a variational approach to one dimensional steady heat conduction equation by Singh & Negi(1980 a,b). This approach has been extended to include advective heat transport by Bodri & Cermak (1993) who again obtained an exponential model plus a constant term for the radiogenic heat distribution. In the present work, the above studies have been generalised for a stratified model of the crust undergoing both heat conduction and advection transports using a variational approach. The results give a model of the radiogenic heat distribution which is more complex than a simple exponential function. Numerical results show that the concentration of radiogenic sources at various depths would vary with strength of fluid advection for a given set of values of surface heat flow, surface radiogenic heat concentration and reduced heat flow.

HETEROGENEOUS CRUSTAL STRUCTURE IN FOREARC SLOPE OF THE JAPAN TRENCH USING OCEAN BOTTOM SEISMOMETERS

Gou Fujie and Junzo KASAHARA (both at Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi, Bunkyo, Tokyo, Japan, Email: fujie@eri.u-tokyo.ac.jp) Shinobu Ito (Geological Survey of Japan, 1-1-3 Higashi, Tskuba, Ibaraki, Japan, Email: ito@gsj.go.jp) Ryota Hino(Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University, Sendai, Japan, Email: hino@aob.geophys.tohoku.ac.jp) Masanao Shinohara (Faculty of Science, Chiba University, Chiba, Japan, Email: mshino@earth.s.chiba-u.ac.jp) Kiyoshi Suyehiro (Ocean Research Institute, University of Tokyo, 1-15-1 Minamidai, Nakano, Tokyo, Japan, Email: suyehiro@ori.u-tokyo.ac.jp)

A seismic reflection-refraction experiment with Ocean Bottom Seismometers(OBS's) was conducted in 1996 in the Japan Trench in order to clarify the crustal structure in the subduction area. The experiment was conducted along two lines, one was parallel to the trench axis, which is called Line2, and another was perpendicular to the axis, which is called Line1.
To determine the velocity structure beneath the both lines, we applied the tau-p , reflection analysis of multi channel hydrophone streamer data and the iterative non-linear traveltime inversion method, which uses traveltimes of reflections as well as of first arrivals.
Along Line 2, the depth of the plate boundary is not uniform and we found velocity anomaly around there. The seismic activity since 1985 in this area also has not been uniform. According to the observed data along the Line 1, the dipping angle of subducting Pacific Plate becomes steeper toward west of around 143.5E. We observed the oceanic Pn phases at 142.9E station from the trench side shots at distance further than 70km.

WHY ARE THE PALAU AND YAP TRENCHES SO DEEP AND BARE ?

Kazuo KOBAYASHI (Japan Marine Science and Technology Center, 2-15 Natsushima, Yokosuka 237-0061 Japan, email: kobayashik@jamstec.go.jp)

Rates of plate convergence at the Palau and Yap Trenches in the western Pacific are very small. Neither deep-focus earthquakes nor active volcanoes are observed in the arcs adjacent to the trenches. Nevertheless, both trenches are deeper than 8,000 m. In the north-central Yap Trench a deep as great as 8946 m was recently found by R. V. Yokosuka. In spite of large amounts of slope failure deposits collapsed from the steep trench inner (landward) walls identified by visual observation from a manned submersible Shinkai 6500, most of the axial zones of these trenches are kept bare with V-shaped bathymetric cross-section. The Palau and Yap Islands composed of old volcanic and metamorphic rocks fringed with coral-reef limestones are situated in abnormally close proximity of the trench axis and being uplifted, although no evidence of collision is found. I would like to draw your attention to high rates of northwestward horizontal motion of both trenches relative to underlying asthenosphere amounting to about 9 cm/yr. It seems likely that resistance of subducted slab moving on the asthenosphere generates uplifting force in front of the moving slab just like a plow working in the farmyard in addition to enhanced tectonic erosion along the subducting slab.

CRUSTAL STRUCTURE OF ICELAND FROM RECEIVER FUNCTIONS

V. SCHLINDWEIN, G. R. Foulger, Z. J. Du, (Department of Geological Sciences, University of Durham, Science Laboratories, South Road, Durham DH1 3LE, UK)

Despite a wealth of geophysical data available for Iceland, the nature of the crust there is poorly understood. The long-standing debate, whether the Icelandic crust is thin and hot or thick and cold, focusses on a key problem: What and where is the "Moho" underneath Iceland? Some seismic refraction profiles show reflections at 20-35 km depth which are interpreted as the "Moho", but on other profiles a similar reflector is absent. We take a new approach to the problem using teleseismic receiver functions. The HOTSPOT network, a temporary seismic network consisting of 30 broadband seismometers distributed over all Iceland, provided excellent data for this purpose. Receiver functions are sensitive to velocity contrasts beneath the seismometer site, such as the Moho or intracrustal reflectors. However, they do not contain information about absolute seismic velocities. We overcome this problem by incorporating independent geophysical data into the study. Our first results indicate considerable lateral variability of crustal structure. The waveforms of the receiver functions show strong azimuthal dependence. Scattered energy characterizes the receiver functions close to active volcanoes, for example at Askja. In general, seismic velocities increase rapidly in the upper crust. Below about 10 km depth, vertical velocity gradients are small. A velocity inversion occurs in some areas. A strong P-S converted phase stemming from a potential first order discontinuity at depths of 20-35 km is generally not observed.

ST4/W/61-B1 1500

VARIATION IN THE CRUSTAL STRUCTURE BENEATH NORTH-WESTERN ICELAND

DU, Z.J. and Foulger, G.R.

Five broadband seismic stations were operated in northwest Iceland from 1996 - 1998, as part of the Iceland HOTSPOT project of Durham University. Structures beneath these stations were determined by the modelling and the joint inversion of teleseismic P-wave receiver functions and regional surface wave phase velocity data. More than 40 teleseismic events and a few regional events containing high-quality surface wave trains were used. Although the middle period passband of the seismograms contains micro oceanic noise, which prevents us from interpreting some structural details, the inversion reveals major crustal features. P_{s} conversions, appearing about at $3 s$ after the P wave, are observable on nearly all traces of the radial receiver functions. These conversions characterize a reflector at depths greater than about 23 {\it km}. The other common major crustal features are high velocity gradients in the upper crust, and high but nearly constant velocity in the middle crust. The data also clearly indicate azimuthal structural variation. However this could not be verified using tangential arrivals because of high noise contamination.

CRUSTAL THICKNESSES IN SE BRAZILIAN SHIELD BY RECEIVER FUNCTION ANALYSIS: IMPLICATIONS FOR ISOSTATIC COMPENSATION

M. ASSUMPCAO (IAG-USP, Sao Paulo, Brazil, 05508-900, Email: marcelo@iag.usp.br); D. James (Carnegie Institution of Washington) and Arthur Snoke (Virginia Tech, USA).

The Brazilian Lithosphere Seismic Project (a joint project by University of Sao Paulo and Carnegie Institution, 1992-1998) operated 20 temporary broad-band stations (STS-2 with RefTeks) in the SE Brazilian shield. The area, about 1000 km long and 300 km wide, covers different geological provinces: an Archean block in the Sao Francisco craton, the adjacent Brasiliano (700-500 Ma) fold belts, and the Parana basin of Paleozoic origin. Crustal thicknesses were estimated for 16 sites using receiver functions. The P-to-S Moho converted phase was clearly identified at most sites. Crustal thicknesses were estimated using an average crustal P-wave velocity of 6.45 km/s. Vp/Vs ratios of 1.70 were used for the stations in the craton and adjacent fold belt (based on small, local earthquakes), and 1.73 for the other stations. Crustal thicknesses ranged from 35 to 48 km.
Despite a clear correlation between topography and Bouguer gravity anomalies in the area, Moho depths show the opposite pattern from the expected: areas of low topography and less negative Bouguer anomalies, (Parana basin) have thicker crust (40 to 48 km) compared with the high elevation areas of the craton and fold belt (37 to 43 km). Two hypothesis are proposed to explain the data: 1) lower density (contrast of -0.03 to -0.04 g/cm3) in the lithospheric mantle under the Archean block is responsible for maintaining the high elevations in the plateau area: low density and high P-wave velocity are compatible with a depleted (low FeO) composition for the Archean lithosphere; 2) alternatively, if the density contrasts between Archean and Proterozoic lithospheres is smaller than the values above, then the crust beneath the Parana basin must be more dense than that of the craton: higher crustal density and high Poisson's ratio would be consistent with underplating in the lower crust beneath the Parana basin.

SHEAR WAVE VELOCITY STRUCTURE BENEATH EAST AND SOUTHERN AFRICA FROM SURFACE WAVE DISPESION

Vunganai MIDZI, Jens Havskov and Kuvvet Atakan (all at Institute of Solid Earth Physics, University of Bergen, Allegt. 41, N-5007 Bergen, Norway, email: vunganai@ifjf.uib.no, V. Midzi also at Department of Meteorological Services, Goetz Observatory, P.O.Box AC65, Ascot, Bulawayo, Zimbabwe); D.D. Singh (National Geophysical Research Institute, Hyderabad - 500 007, India, email: postmaster@csngri.ren.nic.in)

The fundamental mode Love and Rayleigh waves generated by eight earthquakes, which occurred in central Africa and recorded at BOSA, TSUM, LBTB and SLR seismic stations in southeast Africa, are used to estimate the shear wave velocity structure beneath the region. The observed group velocity of Love and Rayleigh waves are computed using the Multiple Filter Technique (MFT) at the period of 5 to 50 seconds. The inversion of observed dispersion data shows a 33km thick crust with a low velocity layer of 2.5km thickness and shear wave velocity of 3.13 km/sec centred at a depth of 13.2km from the surface. Another low velocity zone (LVZ) of 15km thickness is estimated in the upper mantle beneath a depth of 132.2km from the surface. A shear wave velocity of 3.44km/sec to 3.84km/sec is estimated in the lower part of the crust whilst the upper crustal layers have a shear wave velocity of 3.07km/sec to 3.64 km/sec. The brittle-ductile transition zone may be interpreted as starting at a depth of 15.7km from the surface (the LVZ in the upper crust) which matches with the focal depth of most earthquakes occurring in the region.

ST4/W/49-B1 1640

CRUSTAL DYNAMICS AND ADVECTIVE HEAT TRANSPORT IN CONTINENTAL RIFT ZONES INDICATED BY THERMAL AND HELIUM TRACERS

Christoph CLAUSER, Joint Geoscientific Research Institute, D-30631 Hannover, Germany, Email: c.clauser@gga-hannover.de; Erika Griesshaber (Geological Institute, University of Tübingen, Sigwartstr. 10, D-72076 Tübingen, Germany, Email: erika.griesshaber@uni-tuebingen.de); Horst J. Neugebauer (Geodymics, University of Bonn, Nussallee 8, D-563115 Bonn,Germany, Email: neugbr@geo.uni-bonn.de)

Continental rift zones are characterized by increased permeability due to crustal extension and brittle block faulting of their basement. Numerical simulations of groundwater and heat flow in a two-dimensional type-model of the upper crust show that the dominant mode of heat transport changes from conduction to advection within the permeability range 5E-18 m^2 - 3E-17 m^2, typical values for basement and metamorphic rocks. Depending on the host-rock permeability, faults and fracture zones either serve as preferred conduits for pervasive infiltration or for free convection within these structures. Three characteristic patterns evolve in the temperature and flow fields, depending on the relation of forced to free convection. Inspection of a real continental rift zone, the Rhine graben, shows that these patterns cannot be distinguished only on the basis of thermal data. The ratio 3He/ 4He of the stable helium isotopes provides an additional, independent tracer for transport. Mantle helium varies from 75-50 % in the Eifel volcanic region and 15-25 % at the Miocene Kaiserstuhl volcano in the south to less than 3 % close to the thermal anomalies in the north. Finally, a combination of numerical simulations and a joint interpretation of thermal, helium isotope, and hydro-chemical data shows: (1) The thermal anomalies of the Rhine graben are caused by an E-W groundwater flow system and not directly linked to a mantle intrusion; (2) The 3He/ 4He anomaly in the Eifel volcanic region and around the Kaiserstuhl volcano is not accompanied by a thermal anomaly. The present-day helium signature evidently trails behind the volcanic thermal signal and is not accompanied by thermally efficient mass flow rates.

GEODYNAMIC INVESTIGATIONS OF THE HARZ MOUNTAINS/GERMANY: FINITE LEMENT STUDIES AND INTERPREATIONS

Dr Thomas JAHR (Institute for Geosciences)

The Harz Mountains belong to these geological complexes, which were reinvestigated intensively as one common structure due to the political changes at the beginning of the nineties. The FE modelings are concepted by large scale and subsection modelings: A regional large scale model is developped describing the evolution process of the European Variscides. The results yield to the boundary conditions of the rhenohercynian submodel. The local modeling simulate the geodynamic evolution of the Harz Mountains of the Carboniferous up to Quarternary with characterisics of the geological main epochs. The most important boundary conditions derived from rhenohercynian modelings. The numerical simulation indicates on one side the significant influence of the horizontal stress component: In the case of realistic parameters of the Earths crust this stress field cause a vertical uplift of the Harz Mountains which corresponds to geological aspects and the appearence of the orogenic complex nowadays. On the other side the most important role of the intrusion tectonics, which produced main vertical impulses, is pointed out specially for the evolution of the Harz Mountains. The results show that the introduced method come up to an instrument for the geophysical quantification of geological processes. Keywords Geodynamics, FE-modeling, orogenic processes, tectonics, gravity field.

SEISMIC STRAIN RATES OF THE NORTHERN EURASIAN FOLD BELTS

Sergei YUNGA (Institute of physics of the Earth, Moscow, 123810, B.Gruzinskaya, 10, Email: syunga@uipe-ras.scgis.ru)

A comparative study of focal mechanisms, seismic and structural data from the Northern Eurasian Fold Belts is presented. The method of representation of the focal mechanisms statistics by a cloud of points in a classification diagrams is developed. On the basis of extensive statistics specific features of the regional seismotectonic deformation field are analysed in great detail for the Alpine fold belt, represented here by the Pamir-Tien Shan and Caucasus-Kopet-Dag orogens, where reverse and strike-slip faults are concentrated. The seismotectonic deformation of the Altai-Sayan seismic belt, where strike-slip faulting is widespread, and the Baikal Rift zone, where normal faulting prevails were characterised sufficiently. Farther to the east, in the Olekma-Stanovoi zones of Yakutia, seismotectonic deformation in mainly marked by individual focal mechanisms or by their groups. It is shown that the distribution of seismicity and seismic strain trajectories in the Alpine-Himalayan fold bend are interpreted mainly as the response of a stable Eurasian block to the on-going south-north India - North Eurasia convergence, as well as controlled by the influence of the shape and rheological properties of major structural units. Thus, deformation of the not dominant orientations and types caused by superposition of structural, rheological and others factors acting probably under neotectonic and recent conditions develops in some particular zones at the flanks of reactivated pre-existing structures. This work was partly supported by the RFBR, grant N 98-05-65159.

MULTIFRACTAL HETEROGENEITY IN THE UPPER CRYSTALLINE CRUST

David MARSAN, Chris Bean (both at Geology Dept., University College Dublin, Belfield, Dublin 4, Ireland)

Analyses of the p-sonic velocity and of the gamma log of the Main KTB Borehole indicate the heterogeneous scaling of both logs, which are shown to exhibit multifractal properties. Contrary to their homogeneous, monofractal counterparts, multifractals are characterised by a scaling variability in the local fractal dimensionality, and therefore are more heterogeneous. Consequently, the velocity gradients, a proxy for the seismic reflectivity, follow non-Gaussian distributions, leading to more pronounced scattering of seismic wavelets propagating in such media. While such multifractal properties for the sonic velocity can be linked to a multifractal clustering of fractures as observed for other boreholes, the lithological distribution also appears to be multifractal but with a different scaling, as shown by the gamma log. It can be expected that such properties for the sonic log are related to many different contributions.

TOWARD FULLY SELF-CONSISTENT MODELING OF AVERAGE CONTINENTAL GEOTHERMS

Louis MORESI (Australian Geodynamics CRC, CSIRO Exploration & Mining, PO Box 437, Nedlands, 6008, Western Australia; Adrian Lenardic, Department of Geology and Geophysics, University of California, Berkeley, CA 94720, USA)

The forward modeling of average continental geotherms appears to be a relatively simple task. Given the stability and large lateral extent of the continental crust, one solves a one dimensional conduction equation (in a layered medium) for suitable values of thermal conductivity, internal heat generation and mantle heat flux.
One problem with such a model, however, is that the mantle heat flux is not an independent parameter. Heat from the mantle escapes through convective transport to a surface boundary layer where conduction then dominates. The balance between the convective transport and conduction is a sensitive function of the coupled mechanical and thermal properties of the boundary layer. Furthermore, this balance is inherently not one-dimensional: continual horizontal transport of cooling material along the boundary layer is required to sustain the vertical heat conduction.
In the oceanic case, the lithosphere thermal and mechanical structure is readily modeled (at least when less than ~80Myr old) by a cooling half-space conduction profile attached to a material point in accordance with simple boundary layer theory. However, the presence of buoyant continental crust, and depleted sub-continental mantle lithosphere, prevents convection from determining the thickness of the upper boundary layer. Therefore, the thermal structure of the crust, sub-continental mantle lithosphere, and convecting mantle must be solved as a coupled system in which the convection pattern and associated heat transport is not known in advance. A further complexity is that the continents are finite in extent - the partitioning of mantle heat flow between continents and oceans is another unknown which must be modeled. We present a number of convection simulations in which we incorporate realistic models of the oceanic lithosphere with continental blocks of varying size and shape and with different relative thermal conductivities and heat generation rates. We solve for the velocity and temperature everywhere in the crust and mantle during several mantle overturns. We track geotherms for a number of points within the continental blocks to determine the long-time average profiles, the variance, and the extreme values of the profiles in response to the underlying convection.
As one example we compare geotherms obtained from continental margins with those from the continental interior, and examine the influence of steps in the thickness of the depleted mantle root. Computed geotherms are compared to approximations obtained using 1D conduction modeling to demonstrate the conditions under which the 1D assumption may fail. We also compare the computed geotherms for the continental margin with analytic solutions in 2D for flow under a changing boundary condition.

THE RELATIONSHIP BETWEEN THE RATE OF SUBSIDENCE OF THE OCEANIC LITHOSPHERE AND THE HEIGHT OF THE RIDGE: A CONSEQUENCE OF VARIATIONS IN THE COOLING RATE?

C. DUMOULIN, M.P. Doin and L. Fleitout (Laboratoire de Geologie de l'ENS, 24 rue Lhomond, 75231 Paris cedex 05, France, email: dumoulin@jadeite.ens.fr)

Previous studies on the dependence of seafloor depth on crustal age have shown a linear relationship between subsidence rate and axial depths. The physical models used to interpret this dependence involve lithospheric cooling by conduction with variations of upper mantle's temperature. The lithosphere associated with high ridges and hot mantle subside more. However, some processes, such as crustal thickness variations, deep mantle temperature variations, sea-mounts, crustal faults etc, can perturb the topography and induce a 'random noise' superimposed on the cooling signal.
We show theoreticaly that such a 'noise' could be responsible of a linear relationship between subsidence rate and axial depth with a slope equal to the average of the age's square root. In order to quantify the influence of this 'noise' and understand what can be linked to the cooling of the lithosphere in the ridge-height versus subsidence-rate relationship, we study the bathymetry versus age in the South-East Indian and the South Atlantic oceans. Profiles along flow lines and profiles along an arbitrary direction diagonal to the flow lines are compared.

ST4/W/35-B2 Poster 0930-03

IMAGING THE UPPER MANTLE P-WAVE VELOCITY STRUCTURE OF THE APENNINES (ITALY) BY NONLINEAR INVERSION OF TELESEISMIC TRAVEL TIME RESIDUALS

Giovanni Battista CIMINI (Istituto Nazionale di Geofisica, Via di Vigna Murata 605, 00143 Rome, Italy, email: cimini@nettuno.ingrm.it)

Over 4,000 handpicked arrival times from high-quality teleseismic waveforms digitally recorded by the stations of the National Seismic Network during the past ten years are used to invert for the aspherical velocity structure of the upper mantle beneath the Apenninic chain. The data used in the tomographic reconstruction are the travel time residuals of P, pP, sP, PcP, PKPdf and PKPbc phases computed with respect to the improved global 1-D velocity model ak135. The imaging algorithm applied employs a three-dimensional minimum travel time ray tracing within a standard nonlinear inversion scheme that repeatedly solve the linearized problem and recalculate the ray trajectories after each iteration. The data kernel matrix computed for a weighted damped least square solution of the problem is inverted by using the singular value decomposition (SVD) method to better test the resolution capabilities of the dataset and the reliability of the inversion result. The resulting lateral heterogeneities delineate a very complex pattern, with the anomalies of the P-wave velocity amplitude reaching 10%. A pronounced high velocity anomaly is imaged beneath the internal part of the northern Apenninic arc from the uppermost mantle down to a depth of about 400 km. Below Central and Southern Apennines a low velocity zone is recognized between 0 and 100 km depth. It overlies a complex shape high-velocity region located beneath the belt between 100 and 300 km depth. Velocity contrasts between this feature and the contiguous mantle are less strong than those characterizing the high velocity zone under the Northern Apennines, suggesting a less dense, probably continental, subducted lithosphere.

ST4/W/11-B2 Poster 0930-04

REFLECTION OF MANTLE AND LITHOSPHERIC HETEROGENETIES IN SEISMIC FIELD OF KAMCHATKA REGION

Sergey A. Boldyrev, Victor V. MYACHKIN, Maria S. Solovieva (all - Institute of Physics of yhe Earth, Russian Academy of Sciences, Bolshaya Gruzinskaya, 10, Moscow 123810, Russia, e-mail: sabold@uipe-ras.scgis.ru)

Properties and stuctural organisation of shallow seismicity (H < 50km) in North-West sector of Pacific Ocean in joint region of Kuril-Kammchatka and Aleutian Islands arc are analysed with the use of data of detailed seismological observations during 1962 - 1997. The maps of seismicity paramers distribution, of kinematic and dissipative peculiarities of elastic waves propagation including their azimuthal characteristics were made. At least two hierachic systems of lineaments were distinguished. The main one repeats configuration of the main morphological structures of the region and is represented by interchange of three belts, the distance between extremums varies from 60 - 80km at the south to 40 - 60km at the north. Anomalies intensity decreases towards the ocean. The sub-meridional zones of low viscosity of material (low velocity and high attenuation of elastic waves, predominance of comparatively weak earthquakes etc.) were distinguished with the use of a complex of parameters. Positive relief structures continuing headlands of East Kamchatka, and magnetic anomalies, which are traced on the land and beyond the trench as well, correspond to these zones. Areas where the azimuthal dependence of velocity and attenuation of elastic waves are most obvious coincide with the selected system of lineaments as a whole. Maximum velocity values and increased attenuation of elastic waves are typical for the tracks along Kamchatka (except the region of Kronotsky peninsula), and as a whole they coincide with the extension of the planes of motion in the local earthquakes foci. It allows one to connect the origin of azimuthal dependence of the parameters under study with the tectonic deformations. The monotonous character of the parameters under study alteration through the area and coincidence of the anomalous zones according to different data suggest their connection with lateral variations of the composing substance properties caused by geotectonic development of the region.

ST4/L/04-B2 Poster 0930-05

TRAVEL TIME TOMOGRAPHY FOR UPPER LITOSPHERE VELOCITY STRUCTURE OF THE RUSSIAN FAR EAST

Alexander VOITENOK(Institute of Tectonics and Geophysics Far Eastern, Branch of RAS, Khabarovsk, Voroshilova street, 9-63, Russia,680051 email: u153vaa@rtzi.ru)

During 1975-1990 years on a continental part of Far East of Russia the network of regional seismic stations operated. The data, obtained by them, about seismic waves arrival times are used for specification of upper litosphere velocity structure. I used an iterative two-stage algorithm for definition of 3D velocity model. At the first stage, proceeding from a previously determined velocity model, the specified situations of earthquakes and origin times are determined. Initialy is used the standard velocity model. At the second stage the task of definition of abnormal velocities is solved. Usual methods of linear inversion were used. This sequence repeats up to achievement of a required error. Travel paths are calculated by numerical solution of the eikonal equation for an inhomogeneous medium. For till completion of solution the common error of the computing scheme is estimated. With this objective the initial datas about a situations of hipocenters and origin times are distorted by casual noise according to an error of their definition. The difference of definitions on the source and deformed data characterizes stability of a method. The definition of a model is executed for both P and S- waves, though data about travel times of S-waves is significant less. Therefore for S- waves the simplified scheme is used.

ST4/E/66-B2 Poster 0930-06

SHEAR-WAVE SPLITTING IN THE UPPER MANTLE BENEATH THE AEGEAN AREA

K. MAKROPOULOS, P. Papadimitriou, G. Kaviris, I. Kassaras (all at Department of Geophysics, University of Athens, 157 84 Athens, Greece, email: kmakrop@cc.uoa.gr); D. Hatzfeld (LGIT, UJF, Grenoble, France, email: Denis.Hatzfeld@obs.ujf-grenoble.fr); H. Lyon-Caen (Institut de Physique du Globe de Paris, France, email: lyoncaen@jadeite.ens.fr); A. Kiratzi (Geophysical Laboratory, University of Thessaloniki,Greece, email: kiratzi@geo.auth.gr); L. Vinnik (Institute of Physics of the Earth, Moscow, Russia, email: vinnik@synapse.ru)

The Aegean Sea is a region characterized by subduction and back-arc spreading. In this study, data on the deformations and flow in the upper mantle of the region are presented. These data are obtained from a temporary broadband seismological network installed over the Aegean. The network was in operation for six months (February-July 1997). In spite of the relatively short time span and the high noise level at some stations, we were able to detect teleseismic SKS and SKKS phases coming from different azimuths and with a high signal to noise ratio. The inversion of the recorded particle motions for shear-wave splitting indicates that the dominant direction of polarization of the fast shear wave is close to North-South. This anisotropy indicates an approximately North-South extension in the upper mantle, slightly different from the geodetic data on the deformations in the region. The obtained anisotropy directions are possibly related with the internal deformation of the Aegean. At some stations a complicated pattern of shear-wave splitting was observed, which suggests that anisotropy in the subcrustal lithosphere and asthenosphere could be different.

ST4/E/46-B2 Poster 0930-07

A SEISMIC ANISOTROPY OF THE LITHOSPHERE AROUND THE TRANS-EUROPEAN SUTURE ZONE (TESZ) BASED ON SHEAR-WAVE SPLITTING DATA OF THE TOR EXPERIMENT

J. PLOMEROVA, D. Kouba, L. Vecsey and V. Babuska (Geophysical Institute, Czech Acad. Sci., 14131 Praha 4, Czech Republic, email: jpl@ig.cas.cz) TOR Working Group

The Trans-European Suture Zone (TESZ) is the most prominent tecto-geological boundary within Europe separating mobile Phanerozoic terranes in the western part from the Precambrian East-European Platform in the eastern part. Distinct changes of seismic anisotropy of the mantle lithosphere are related to this intra-continetal suture. The effect is observable in various wavelengths as well as seismic wave types. In the long-periond range, the radial anisotropy of surface waves differs distinctly in the lithosphere on both sides of the TESZ. In the short-period range of body waves, the P residual spheres detected changes in the lithospheric anisotropy related the various blocks around the TESZ as well. A passive teleseismic field experiment -TOR- traversing the northern part of the TESZ in Germany, Denmark and Sweden was conducted during 1996-1997. The array recorded data for teleseismic tomography of the upper mantle with a high lateral resolution, about few tens of km, including data for seismic anisotropy studies. Our analysis of shear-wave data recorded at broad-band stations during the field measurements aims at retrieving a 3D orientation of anisotropy around the TESZ and mapping lateral changes of the 3D orientation of anisotropic structures along the TOR antenna. An interpretation of the observed seismic anisotropy by the

preferred orientation of olivine crystals results in a model of the mantle lithosphere characterized by plunging anisotropic structures. It is evident that different orientations of large-scale olivine fabrics on both sides of this major suture zone extend through the whole lithosphere.

REGIONAL SURFACE - WAVE GROUP VELOCITY INVERSION BY SPHERICAL HARMONIC METHOD

Liangbao ZHU and Qing Xu (Department of Geophysics, Peking University, Beijing 100871,China)

If one complex surface-wave velocity function defined on a regional sphere area is imitated directly by spherical harmonic functions, maybe very high order spherical harmonic coefficients are needed. By conformal mapping in which the surface-wave velocities keep unchanged, a regional area on a sphere surface can be extended to a much larger spherical segment area. Then we extend the spherical segment area to the whole sphere by analytic continuation, and the continuation of the velocity is arbitrary. Imitating the velocities by spherical harmonic expansion on the sphere after transformation can greatly reduce the number of spherical harmonic coefficients needed. The inversion of surface-wave velocities turns into the linear inversion of spherical harmonic coefficients. The resolution kernel and the root square deviation of inversion can be obtained by analyzing the spherical harmonic coefficients. The algorithm has advantages in the sense that: the computing speed is fast, the contours are smooth, and the tectonic boundaries are clear. Theoretically, this method is not only applicable to the surface-wave group velocity inversion, but also to a wide variety of analyses of regional fields.

ST4/W/28-B2 Poster **0930-09**

CAN THE LOVE-RAYLEIGH DISCREPANCY BE CAUSED BY ISOTROPIC LATERAL HETEROGENEITIES?

Valerie MAUPIN (Dept of Geophysics, Univ. of Oslo, PO Box 1022 Blindern, 0315 Olso, Norway; email: valerie.maupin@geofysikk.uio.no)

At global as well as at regional scale, the lithosphere appears faster to Love waves than to Rayleigh waves. This Love-Rayleigh discrepancy can be modelled by introducing transverse isotropy in the upper mantle. In the oceanic lithosphere, transverse isotropy is usually associated with azimuthal anisotropy and can be explained by the orientation of olivine crystals, at least partly. The situation is more complex in the continental lithosphere, where azimuthal anisotropy is not necessarily associated with transverse isotropy. Although a more complex structure of the olivine orientation or horizontal layers of partially molten material could explain this situation, the Love-Rayleigh discrepancy could also partly originate from the presence of isotropic lateral heterogeneities, as noted by Levshin and Ratnikova (1984). Using recent mode-coupling methods for modelling surface wave propagation in 3-D structures, we explore if any kind of isotropic laterally heterogeneous model of the mantle could produce the systematic Love-Rayleigh discrepancy observed in continental regions.

REFINED SEISMIC STRUCTURE OF THE INDIAN LITHOSPHERE-ASTHENOSPHERE

Avadh RAM, Pati Patel (Both at Department of Geophysics, Banares Hindu University, Varanasi-221005, India; Tel: +91 542 317123; Fax: +91 542 317074; email: aram@banares.ernet.in)

The Indian subcontinent is of particular interest to geoscientific community of the world because of the manner it has moved northward and colided with the Eurasian plate. Himalayan mountains to the north and mid-oceanic ridges to the south and earthquake belt surrounding the Indian plate all show that the lithosphere-asthenosphere structure in this region must have some significant lateral and vertical variations. Several scientists have tried to find one dimensional velocity models in the past using the seismic wave data. It has been confirmed by the study of the Gaurribidanur seismic array data from the Indian subcontinent (Ram & Mereu, 1997) that the region has two prominent anomalous zones lying around "400km" and "650km" depths with varying thicknesses. Seismic structures associated with these anomolous zones have also been clearly identified using the other methods.
We have also obtained the variation of P-wave seismic velocity in x-y plane for various depths. These velocity models for continental and oceanic regions have been refined using other imaging techniques for travel-time and slowness data and the uncertainties are demarcated with the help of envelopes. The dynamic interaction and modelling processes are discussed. Anelasticity and scattering effects have also been considered in refinements of the models. Further, an attempt has also been made to map the atructure three dimensionally on the basis of the methodology and computer programs developed by ILP Task Group II-4, where initially; an "I" data set has been prepared. Various linear features have been identified using multimode/multistructure procedures. Finally, a refined seismic structure of the part of Indian lithosphere-asthenosphere has been delineated.

MAPPING THE LITHOSPHERE-ASTTHENOSPHERE SYSTEM IN THE CENTRAL MEDITERRANEAN SEA FROM SN WAVE ATTENUATION

Giuliana MELE (Instituto Nazionale di Geofisica)

The lithosphere-asthenosphere system is mapped over the central Mediterranean area using regional shear wave propagation characteristics. The shear Sn phase in a good indicator of the presence of asthenosphere at shallow depth, i.e., of discontinuies in the lithospheric mantle. A large number of raypaths crossing the study area from different azimuths provided useful information and constraints on the extent of low-strength attenuative zones in the uppermost mantle. A previous study of Sn attenuation in Italy showed that the asthenosphere replaces the lithosphere at shallow depth beneath the northern part of the Apennine chain, and a lithospheric delamination has been hypothesized. A Sn high attenuation zone is also found beneath the southern Tyrrhenian Sea. In this case the uprising of asthenosphere is expected, and it is consistent with other geological and geophysical evidences of a back-arc process. The lateral extent and the continuity at depth of the south Tyrrhenian subduction zone has been also mapped using deep S phases. In the present study the continuity of the mantle lid is investigated over the area of the Ionian Sea, south of Italy, and across the Sicily Channel, between Africa and Sicily.

A PRIMARY STUDY ON LITHOSPHERE STRUCTURE IN EASTERN REGION OF QINGHAI-TIBET PLATEAU

LIU Hongbing, Kong xiangru and Yan yongli(all at Institute of Geophysics, Chinese Academy of Sciences, Beijing, 100101, P. R. China, Email: bliu@mail.c-geos.ac.cn)

In Oct of 1998, A geophysical survey including Magnetotelluric sounding(MT), gravity and geomagnetism was carried out by Institute of Geophysics, Chinese Academy of Sciences in eastern region of Qinghai-Tibet plateau. It is known from tectonic mapping that study area was divided into four blocks by three large sutures, but we have very little information on deep-seated structure which have close relationship with evolution of Tibet plateau, the purpose of research is to find some evidences of deep matters The geophysical study region is located in range of 97-98oE and 35-26oN, the profile with the length of 900km runs through Bayanhar, Qingtang and Gandise block in NS direction, 349 gravity and geomagnetic data were acquired simultaneously , and 31 MT sites are be placed along the profile with about 18km-interval to detect electrical conductive feature , MT recording period (256Hz to 4096s)is long enough to reach the bottom of lithosphere. By data processing, the crustal thickness from gravity data is abou u and Cayu region is only 90km deep, the distribution of the high conductive layers in crust were complicate, most of those is about 25km deep, but near the Banggongco-Nujing and Jingshajing sutures the depth of the layers are only about 20km. Besides, all of geophysical data show that their amplitude of the variation in southern region are stronger than those in northern region. A further integrated study is being conducted, the primary result show that in the southern region of profile the tectonic actii!

RAYLEIGH WAVE GROUP VELOCITY MAPS OF EAST ASIA

Liangbao ZHU and Qing Xu (Department of Geophysics, Peking University, Beijing 100871,China)

Rayleigh waves are used in a tomographic inversion to obtain group velocity maps from 10s to 120s periods of East Asia (70¡ãE-145¡ãE, 10¡ãN-55¡ãN). Due to the dense path coverage and the good azimuthal distribution of paths, we obtain some new results. The Tarim Basin is obviously recognizable in the maps of 10s -15s periods, appearing as a low velocity structure, but it can¡¯t be seen in the maps of 16s-33s periods, and then appears as an area of high velocity in the maps of 36s-85s. This indicates that there is a deep root under the Tarim Basin. With clear demarcation lines to the Indian plate on the south and to the Tarim Basin and Qaidam Basin on the north, Tibetan plateau is the most prominent low velocity block in the maps of 44s--110s, and the velocity in its central and western portion is lower than that in the east. The South-North seismic belt appears to be one with high group velocity gradient, which divides the China continent into eastern part and western part; the velocities in the east are noticeably higher than that in the west. The central South China Sea, the Japan Sea, and Philippine Sea appear as oceanic crust. The image of Philippine Sea is completely consistent with the topography and the seismic zone. Around the Philippine Sea and the Japan Sea, there is a low velocity belt of about 400km wide, and it may be a zone with magmatic activities. In the vicinity of Chiang Mai, Thailand we can see a low velocity zone with scale of 1000km, which may be created as the mass of Tibetan plateau migrates south-east.

UPPER MANTLE SEISMIC STRUCUTRE BENEATH THE PHILIPPINE SEA REGION INFERRED FROM SURFACE WAVE PHASE VELOCITIES

Yasuyuki NAKAMURA and Takuo Shibutani (both at Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto, 611-0011 Japan, Email: saru@rcep.dpri.kyoto-u.ac.jp, shibutan@rcep.dpri.kyoto-u.ac.jp)

The distribution of anisotropic seismic structure in the upper mantle beneath the Philippine Sea region was obtained using surface wave dispersion data both of Rayleigh and Love waves.
About 800 Rayleigh and Love wave phase velocity curves were calculated with the non-linear waveform inversion (Trampert and Woodhouse, 1995) in the periods of 30-100s. The calculated phase velocity curves were inverted for Rayleigh and Love wave phase velocity maps by 2-D tomographic inversion for each period. The block parameterization where the block size was 2.5 degree-times-2.5 degree was adopted in the tomographic inversion.
The Rayleigh and Love wave phase velocities were converted to eigenperiods of the fundamental spheroidal and toroidal modes respectively. The eigenperiods were inverted for the upper mantle seismic structure with transversely isotropic features in each block down to the 220km depth.
In the depth range 80-100km, resultant shear wave velocity structure distributions well correlate with the tectonic evolution history suggested in the Philippine Sea. The older western part of the Philippine Sea has high velocity, and the younger eastern part indicates low velocity. The averaged shear wave velocities for the Philippine Sea is about 4.3km/s in the depths of 50-220km, which is slower than the PREM model. This slow upper mantle is also seen in other back arc basins, for example Lau basin.

MODELLING OF TELESEISMIC WAVES IN DIPPING ANISOTROPIC STRUCTURES

Andrew W. Frederiksen and Michael G. BOSTOCK (both at Department of Earth and Ocean Sciences, U.B.C., Vancouver, B.C., V6T 1Z4, CANADA, Email: andyf@geop.ubc.ca, bostock@geop.ubc.ca)

The existence of seismic discontinuities within the continental upper mantle has long been recognized, with more recent studies often indicating an association with strong elastic anisotropy. Structural relations with surface geology have, in a number of instances, established a correspondence of such features with ancient subducted lithosphere, thereby underlining their importance in understanding the assembly and stabilization of continental lithosphere. The near vertical sampling of teleseismic P, S, and SKS waves provide a convenient means of characterizing mantle discontinuities but computationally efficient methods of calculating synthetic seismograms are required for structures that exhibit lateral variability. We consider mantle lithospheric models consisting of planar, homogeneous anisotropic layers with arbitrary dip. Reflectivity techniques cannot be used to model dipping layers, while fully 3-D ray tracing in anisotropic media is computationally involved owing to its reliance on shooting or bending methods. The travel time equation of Diebold (1987) for dipping layered media is adopted as the basis for a high-frequency asymptotic method that does not require ray tracing. Travel times of plane waves in anisotropic media are calculated from simple analytic formulae involving the depths of layers beneath a station and associatedvertical phase slownesses. Amplitudes are computed using the reflection and transmission matrices for planar interfaces separating anisotropic layers. Preliminary results from simple models indicate that upper-mantle seismic responses depend in a complex fashion on both layer dip and anisotropy, particularly in the case of converted phases.Rotation of energy onto the transverse component from Ps conversions is induced by both dip and

anisotropy, the dip having greater influence on travel time. The S response is further complicated by a marked dependence on the polarization of the incident wave, while the behavior of Sp conversions is strongly influenced by dip. Applications of this method to both P and S data from the Yellowknife broadband seismic array will be presented.

ON CORRELATION AND DE-CORRELATION OF MANTLE TRANSITION ZONE DISCONTINUTIES

D.S.RAMESH (National Geophysical Research Institute, Uppal Road, Hyderabad-500 007, India, email: postmast@csngri.ren.nic.in)

Recent advances in secondary phase identification and recognition of precursor arrivals to major seismic phases (e.g. SS, PP) enable to image the fine structure of the mantle transition zone. As is typical in studies dealing with weak signals, the attendant methods of data processing and analyses besides data quality contribute to variations in the final results. Also, signal enhancement strategies like stacking for a small region with fewer seismograms accompanied by lower signal to noise ratio (SNR) can yield dubious results. Recent studies do indeed present conflicting results both in global scale and for smaller regions as well. The ongoing debate on whether the 410-km and 660-km discontinuities in the mantle transition zone are globally anti-correlated or de-correlated perhaps owes its origin to factors mentioned above. It is also interesting to recognise possible positive correlation of these discontinuities, albeit, locally in regions of active tectonics (e.g. northwest Pacific Ocean). The northwest Pacific Ocean is taken up as a case study with about 1700 broadband seismograms applying simple yet refreshingly innovative strategies to study the nature of the mantle transition zone discontinuities and their disposition. A novelty in the present study involves replacement of the stacking procedure by display of 'time-moveout' corrected seismograms facilitating identification of precursors in individual seismograms. In addition, the seismograms are sorted by bouncepoint longitude. Possible latitudinal variations are also studied, by both viewing the seismogram section in latitude corridors and latitude-wise sorted sections. Also, the bouncepoints are projected on to appropriate direction profiles (eg. NorthWest) to better document signatures of subduction zone. Such a presentation of seismograms hopefully registered narrow zone signatures of smaller wavelength related to subduction. Due to the opposing signs of Clapeyron slopes, the 410-km and 660-km boundaries are excepted to be negatively correlated. However, recent studies based on high-pressure experiments, thermodynamic calculations and numerical simulations suggest that the Clapeyron slope of the spinel-perovskite phase transition at a depth of 660-km changes from negative (dP/dT < 0) to positive (dP/dT > 0) in the triple point temperature region 1700_x_C-2000_x_C for a pyrolite composition mantle. This change in Clapeyron slope to positive (dP/dT (0) would thus enable the 660-km discontinuity to be positively correlated with the overlying 410-km discontinuity which is indeed reflected in our seismological observations for the study region.

WHOLE EARTH STRUCTURE ESTIMATED FROM SEISMIC TRAVEL TIME DATA

L. R. JOHNSON and D. W. Vasco (both at Center for Computational Seismology and Seismological Laboratory, University of California, Berkeley, CA 94720, USA)

Seismic travel time data for a suite of P and S body wave phases are used to infer the three-dimensional velocity structure for the entire earth. Ray tracing in a three-dimensional model is used to relocate the seismic events. The model is described in terms of volumetric cells and a general inverse problem is formulated to determine the P velocity, S velocity, and anisotropy within the cells. The topography on major internal velocity discontinuities is also included in the inversion. The model parameters are estimated using an iterative Lanczos algorithm to obtain a partial singular value decomposition. With such a decomposition, it is possible to also obtain estimates of model resolution and uncertainty. The results are similar to those obtained with other inversions of body wave data, with the uneven sampling of the earth due to the non-uniform distribution of sources and receivers playing a dominant role in the resolution. The crust and uppermost mantle of the model are well resolved under continents, particularly in the northern hemisphere, and the velocity anomalies correlate strongly with surface tectonics. The magnitude of the velocity heterogeneity decreases with depth in the mantle before it increases again in regin D", although the resolution is limited in this region at the bottom of the mantle. There is evidence of lateral variation of the P velocity in the outer core which appears to be resolved. There is also evidence for anisotropy in the P velocity within the inner core, but this feature trades off strongly with velocity heterogeneity.

A WHOLE MANTLE P WAVE ATTENUATIONN STRUCTURE OBTAINED FROM THE ISC AMPLITUDE DATA

Hiroaki NEGISHI (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, JAPAN, email: negi@rcep.dpri.kyoto-u.ac.jp)

The 3-d structure of P-wave attenuation was obtained in the whole mantle by applying the tomographic method to the amplitude data of the Bulletin of the International Seismological Centre (ISC). The 115,418 amplitude data of the 2,721 events occurring from 1984 to 1995, observed at 718 stations, were analyzed after the focal mechanism correction. AK135 velocity model (Kennett et al., GJI, 1995) was used for the ray tracing and the geometrical spreading correction. The simultaneous inversion technique was adopted for determining source amplitude, site amplification factor and 1-D Qp**-1 structure down to 2,720 km depth, and 3-D Qp**-1 perturbation distribution from the 1-D model was obtained. The attenuation at the upper mantle is relatively stronger than that at the lower mantle. Such pattern is also seen in the various earth models that obtained by the Earth's free-oscillation analyses. The lateral variations in long wavelength show a similar pattern to the previous P-wave veloccity studies. Two major high attenuation zones appear to be located at the middle and lower mantle beneath the Central Pacific and norhtern Africa, while low attenuation body is spreading at the upper and middle mantle beneath the Eurasia continental shield. This is the first result that delineates the whole mantle attenuation heterogeneity of the short-period body waves. This new information will become important for investigations of geothermal and geodynamical features of the Earth.

GLOBAL SEISMIC BOUNDARIES AND WEAK ZONES IN THE CRUST AND UPPER MANTLE

Nina PAVLENKOVA (Institute for Physics of the Earth, B.Grusinskaja 10, 123810 Moscow, Russia, email: Ninel@Pavlenkova.msk.ru)

Long range seismic profiling revealed a fine stratification of the crust and upper mantle: high velocity layers alternate with lower velocity ones and strong reflection boundaries often separate the layers. A change of velocity pattern where the block structure is transformed into a subhorizontal layering and a local isostatic equilibrium are typical at the boundaries. These structural features and other geophysical data suggest that the boundaries separates brittle and weak layers. Several such boundariesr layers have a global significance and suggest rheological stratification of the lithosphere. In the continental crust weak zones are determined at depth of 10-20 km and at the Moho level. A rheologically weak layer underlain by the reflection boundary N is distinguished at a depth of 80-100 km. It is located inside the thermal lithosphere beneath old platforms (East-European, Siberian, North-American) and at the bottom of the lithosphere beneath active tectonic areas (West Europe) and in oceans (Angoa-Brazil Geotraverse). The nature of these boundary layers may be explained by changes of mechanical properties of the matter. The velocity inversions which are often characterized by higher electrical conductivity may be a result of fluids or melt concentration at the critical depths. The high velocity boundaries suggest the anisotropic layers formed by the mantle matter flows. Together with deep faults the weak layers form a channel system for the mantle fluids and matter transportation. During tectonic ativation the lithosphere weak layers are transformed by partial melting in asthenolites which are important for the plume tectonics. The crustal weak zones and the plastic flows at the Moho level help the crustal blocks to move at local plate tectonics. (The study is a part of RBRF project 99-05-64799)

BROAD-BAND SEISMIC PROFILE TO IMAGE THE CRUST AND MANTLE STRUCTURE BENEATH THE INDIAN CRATON AND THE HIMALAYAS

K.S.Prakasam and S.S.RAI (both at National Geophysical Research Institute, Uppal Road, Hyderabad-500 007,India, email: postmast@csngri.ren.nic.in)

Seismic structure of the Indian crust and mantle is being investigated using array of broad-band seismic stations. The array of 30 broadband seismic station will operate over 3000 km from the Archean terrains in the south (8 degree North) to the Himalayas (30 degree North). Proposed profile would operate in three phases. Beginning January 1999 first phase of the array is operating over the Dharwar craton (Archean granite gneiss and metamorphic terranes), Proterozoic Cuddapah basin and Deccan Volcanic Province. While the investigation concentrate on the Indian region, it will help answer several global questions like how thick is lithosphere in different geological terranes/ages; structure and composition of the crust; nature of dissimilarity between Archean, Proterozoic and Phanerozoic provinces; crust and lithospheric structure beneath the Ganga basin and the Himalayas. We present initial result from broad-band array focussing the nature of crust and upper mantle in Dharwar Craton.

MANTLE Q AT PERIOD 12.4 HOURS: NEW ESTIMATES FROM SATELLITE TRACKING AND ALTIMETRY

R D RAY (NASA Goddard Space Flight Center, Code 926, Greenbelt MD, USA; email: richard.ray@gsfc.nasa.gov)

The most convincing estimates of mantle Q at periods of many hours have historically come from extrapolating seismic and free-oscillation estimates via some assumed frequency dependence, sometimes contrained by estimates from the Chandler Wobble. At the semidiurnal tidal period, direct estimates of Q have been difficult to obtain because of the dominating signals of the ocean tides, which account for more than 95% of the tidal energy dissipation. But knowledge of the ocean tides has been rapidly improving, primarily owing to satellite altimetry, and in 1996 we reported (NATURE, 381, 595-7) an estimate of solid-earth tidal energy dissipation and mantle Q based on combining satellite altimeter measurements with tracking observations of tidally induced satellite orbit perturbations. Tidal estimates from both reveal a small systematic difference in the quadrature component of the degree-2, order-2 spherical harmonic coefficients, which we attribute to a small lag in the earth's body tide. The formalism accounts for this lag in both the altimeter and tracking solutions and also accounts for a very small contribution from the lunar atmospheric tide. Since this original report, both altimeter and tracking estimates have improved. Recent solutions for the body-tide lag at the M2 period are 0.20 +/- 0.09 degrees, implying an energy dissipation of 100 +/- 50 gigawatts and a solid-earth Q of 300. Further new solutions will be discussed, as will the prospects for significantly reducing error bars and for obtaining estimates from other tides in the diurnal band.

GLOBAL ANOMALIES IN TIDAL GRAVITY AND LOWER MANTLE STRUCTURE

A.KOPAEV (Astronomical Institute of Moscow University, Universitetski prosp. 13, Moscow, 119899, Russia; fax: +7-095-9328841; e-mail: kopaev@sai.msu.su)

Direct modelling of the tidal delta-factors and phase lag anomalies caused by upper and lower mantle heterogeneities has been carried out for M2, O1 and Mf tidal waves using the approach of S.Molodenski (1980) and SH8/U4L8 seismic model. Resulting lateral anomalies of delta-factors are less than 0.1 % and correlate with CMB-topography and should not be observable at the current accuracy level in tidal gravimetry. Nevertheless, highest quality tidal gravity data selected from ICET Data Bank reveal global anomalies that correlate modelled with modelled anomalies although the former ones are one order larger in magnitude (up to 1 %). This discrepance may reflect inapplicability of mantle elastic parameters deduced from seismic data to tidal frequencies (i.e. mantle' elastic parameters for tidal frequencies are higher than for seismic ones) and/or suspected lateral anomalies in lower mantle viscosity.

ST4/E/72-B2 Poster **0930-23**

BIRTH AND DEATH OF A GEOPHYSICAL ANOMALY

U. RAVAL and K. Veeraswamy National Geophysical Research Institute, Hyderabad, India

Most lithospheric geophysical anomalies originate due to (1) Plate (horizontal) and/or (2) Plume (vertical) tectonics. Since these thermomechanical causes are finite in space and time, their geo- physical effects would tend to decay when the sources become weak or inoperative. For example, an asthenospheric upwelling would result in both short- and long-living lithospheric anomalies. Thus, (a) swells/ uplifts, doming, subsidence, long wavelength gravity low and low seismic velocity layers (LVLs) etc. form short period features and (b) high density, seismic velocity (HVLs), electrical conductivity (HCL), magnetic susceptibility etc., frozen in the crust, are long living until a major rejuvenation/ orogeny. Thus, while the cratons have long-living fetures, the mobile belt features have relatively shorter life.The heat and mass transfer during magmatic underplating may result in a gravity high after sufficient cooling and also in high seismic velocity and magnetic susceptibility. From such heating and cooling follows a cycle from low (when hot) to high (when cold) anomalies. The Meso-Cenozoic dynamics of the Indiancontinental lithosphere giving rise to birth and death of certain geophysical anomalies over the subcontinent is discussed.

THE EFFORTS APPLIED ON ALL OF PLATE'S AROUND AND ITS BASE BY GLOBAL MANTLE FLOW

Xunying SUN (Department of Geology, Peking University. Beijing, 100871, P.R.China. email: dzsxy@pubms.pku.edu.cn); Guoping Liang, Yuezhi Sun, Jinzhao Liu and Huai Zhang (Mathematical Institute, Chinese Science Academy, Beijing, 100081, P.R.China. email: ling@public.east.cn.net)

Every Plate or massif is one part of the earth surface. Its tectonic movement as a result of thermal motion of global mantle is driven by the efforts applied not only on all of its around but also on its base by global. So, if the tectonic effect will be studied, the efforts acting on the plates must be studied clearly. The following quastions should be answered: How do acte the efforts on the plate or massif? How do distribute the efforts?
We use 3-D finite element method for Newtonian medum to calculate the global mantle and crust creep flow. The LDDA (Lagrangian Discontinue Deformation Analysis) technique is used to treat the contact problems of plate boundaries such as subduction zones and collision belts. The LDDM (Lagrangian Domain Decomposition Method) and parallel algorithm are emploied to calculate with parallel computer. The CMM (Combinatorial Mesh Method) is emploied to handle the multiscale problem, for example, the problem of differient meshes between global and local plate or massif.
First of all, on the basis of fitting the velocities of divergent and convergent boundaries of the plates,the velocity field is obtained as well as the temperature and the pressure feilds. Than, the stresses acting on preceding boundaries and bases are calcalated. Finally, obtained the efforts applied on the plates or massifs by global.

TECTONIC AND SOLAR CYCLES, MOVEMENT OF CONTINENTS, CLIMATE

D.SADYKOV, I.Levchenko, E.Bukreeva, A.Baimoldaeva (all at Abay University, Almaty, MD Koktem-1, 28-12, 480090 Almaty, Republic of Kazakstan, email: 89284974@public.asdc.kz)

Tectonic and the solar cycles depend on galactic year (220 Ma). At an equatorial part of the Earth the compression is possible for 55-110, 165-330, 385-440, 495-550, 605-660, 715-770, 825-880Ma, and the stretching is possible at high breadthes of the Earth at the same intervals of time. The compression at its polar part is possible for 0-55, 110-165, 220-275, 330-385, 440-495, 550-605, 660-715, 770-825Ma. The change of character of deformational processes happens at the time of transition of solar system through the special points of a galaxy in 55Ma, where the solar system crosses area where the galactic weight is at its flat part. These processes resalt in the change of temperature of ocean and change of climate of the Earth. The increase of a level of ocean and flooding of continents happen basically in 40-60Ma, and reduction of ocean level in 44-60Ma. These intervals of change of a climate will be coordinated to the interval 55Ma. The occurrence of the glacier periods on the Earth depends on places of a place of continents at the given interval of time. All continents were in the area of South Pole at 600Ma and then were drifting to North, under the theory of tectonic plates. In these situations the exact fixing of the glacier periods is complicated. Therefore changes of a climate for 0-600Ma are better correlated with change of a level of ocean for 600Ma and forms 0.00003cm p.a. This parameter characterizes the tendency of reduction of the world ocean level and will be coordinated to amount of weight of water leaving the Earth annually. The given data are a background for an estimation of change of a climate for shorter periods: tens - hundreds years. Thus the role of solar cycles varied within 10Ma-6 years grows.

ENDOGENOUS HEAT SUPPLY FROM THE CMB AND/OR FROM THE ALB VOLCANISM AND HEAT FLOW

Giovanni P. GREGORI (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy; e-mail: gregori@atmos.ifa.rm.cnr.it)

According to a tide-driven dynamo model (Gregori, PEPI, 77, 39, 1993), three main sources of endogenous Joule's heating ought to be recognised corresponding to the ICB, CMB, and ALB, respectively. Their total energy is sufficient for justifying even the e ntire internal energy budget of the Earth. Upward propagation of endogenous energy occurs (1) from the ICB by convection within the fluid outer core, and (2) from the CMB or the ALB by Hamilton's principle at a speed of the order of magnitude of ~10 cm y ear-1 ("electric soldering iron mechanism", ibid.). Allowance ought to be given, however, also for frictional heating from the ALB, consequent to transformation of plate kinetic energy, a process that seems to be typical of island arcs, or that follows e . g. a superswell upheaval originated by the "electric soldering iron". It is possible to estimate the percent vs. time of endogenous energy from different sources, released during the last ~70 Ma, by means of an analysis of the Hawaii - Emperor Seamount c h ain, also considering geomagnetic reversals. Such an entire scheme appears to be significantly supported by several and as yet otherwise unexplained observational features.

SOME CONSIDERATIONS ABOUT THE OLD EARTH DILATATION IDEA: SHOULD IT BE RE-EVALUATED?

Giancarlo SCALERA (Istituto Nazionale di Geofisica, via di Vigna Murata 605, 00143 - Roma, Italy)

The idea of Earth dilatation, more than a century old, has been tested performing computer assisted cartography and paleogeography. After the recognition of a new class of conformities in the Pacific hemisphere, which is strong clues favouring the possibility of a considerable dilatation of the planet, a more complete series of palcogeographical reconstructions has been performed starting from Palaeozoic and using as boundary conditions paleomagnetic data, geocronological data, paleontological data and the same conformities.
The good self-consistency of the set of reconstructions has deserved the tentative elaboration of a tectonic model of evolution of the trench-arc-backarc zones in agreement with a dilatational planet. Some new argument linking the global expanding tectonics to the Earth rotation are presented.

ST4/W/58-B2 Poster **0930-28**

ON SOME ASPECTS OF THE INTERNATIONAL PROJECT "CREATION OF A SOFTWARE FOR THE STUDY OF THE EARTH STRUCTURE EVOLUTION IN THE INTERESTS OF THE EARTH SCIENCES"

E.Ya.SMIRNOV (Interdisciplinary Centre for Advanced Professional Education, St.Petersburg State University, 14th Line 29, St.Petersburg, Russia)

The project is based on an original concept of the Earth structure evolution. According to this concept, the core of the modern Earth is solid and practically wholly consists of a magnetized iron at a temperature close to absolute zero. Between the cold solid core and the hot fluid mantle there is a sort of a thermonuclear reactor processing the substance of the core surface into the mantle substance, thus monotonously increasing the Earth volume. The Earth crust consists of at least two solid layers split into deformed tectonic plates and monotonously rotating relatively to each other, their interaction basically determining the mechanisms of tectonic processes. The proposed concept of the Earth structure evolution, unlike the previous concepts of this kind, does not contradict the presently available information on the processes going on in the Earth. Besides, even without full implementation of the proposed project, it allows to obtain more adequate idea on the Earth core properties on the basis of the presently available seismic measurements and develop more effective methods of the forecast of earthquakes with epicenters located either within the Earth crust or near the boundary between the core and the mantle. There are certain ideas of development of the necessary techniques. They are based on the character of tectonic plates interaction and on the "drift" of seismic waves in the area of the Earth thermonuclear reactor containing powerful flows of particles with their velocities substantially exceeding those of seismic waves. The description of the project is available in Internet at the address http://www.ecosafe.nw.ru/geya/project.htm

THE SNAKE RIVER EXPERIMENT REVISITED. EVIDENCE FOR THE PRESENCE OF FARALLON PLATE FRAGMENT IN THE TRANSITION ZONE

Eric BEUCLER, Sebastien Chevrot and Jean-Paul Montagner, Institut de Physique du Globe de Paris. Laboratoire de Sismologie globale. 4, place Jussieu 75005 PARIS FRANCE

The analysis of the 93 PASSCAL-OREGON SRP experiment data [Dueker & Sheehan, 1997] has been reconsidered. New techniques have been applied in the processing of PdS waves, converted from P to S from seismic discontinuities at depth d in the receiver region. The data set cannot be explained by a one dimension velocity model. Consequently we performed a migration using the linear array distribution, lined up with two great seismic regions (South America on one side, Kuril islands and Aleutians on the other side). The 410-km discontinuity presents a noisy aspect, which prevents from observing the discontinuity topography variations. The 660-km discontinuity is clearly more visible, but it seems to vanish or become largely deflected in a large part of the profile. This anomalous behaviour and the noisy aspect of the transition zone could be associated with the presence of a Farallon plate fragment, already described by van der Lee & Nolet (1997).

ON THE PLATE TECTONIC DYNAMICS AND GIANT METEORITE IMPACT

Wan TIANFENG (Department of Geology and Mineral Resources, China University of Geosciences, Beijing 100083, CHINA, email: wantf@sky.cugb.edu.cn) Yin Yanhong (Institute of Marine Geology, MLR, Qingdao 266071,CHINA)

Depending on the data of rock deformation, the change of stress concentration, the periodicity of plate migration, and the periodicity of giant meteorite impact coincides with that the palaeomagnetic inversion, biotic extinction, change of sea level, the solar system's crossing of the galactic plane (about 33 Ma) or cosmic year(about 280 Ma), we proposed a working hypothesis - the microtektite impact induced the plate motion, the essential of that are as follows: (1) The giant meteorite impact has a periodicity of about 33 Ma, coincident with the time for the solar system to cross the galactic plane, where more intense interstellar material would cause meteorite impacts and induce the motion of plates. (2) The angle and orientation of meteorite impact on the Earth surface will influence the direction of plane motion. (3) The giant meteorite will produce a great crater and induce the partial material debility in the upper lithosphere. (4) Because of the thin oceanic lithosphere(50-60 km), the impact of giant meteorite is most likely to destroy the lithosphere, sea floor spreading and change the orientation of migration of oceanic plates.

THE NATURE OF THE CONTINENTAL LITHOSPHERE: INTERPRETATION OF LATERAL VELOCITY ANOMALIES BENEATH NORTH AMERICA

J. Michael BROWN (Geophysics Program, University of Washington, Seattle, WA 98195, USA, Email: brown@geophys.washington.edu)

New data for the elasticity of upper mantle constituents (single crystal olivines, pyroxenes, and garnets) have been obtained as a function of composition under mantle pressures and elevated temperatures. These experimental constraints for essential derivatives (and cross derivatives) with respect to pressure, temperature, and composition, in conjunction with phase equilibria and elemental partitioning calculations, aid in understanding the seismic structure of the upper mantle. Observed lateral variations in velocity are rationalized through a combination of intrinsic temperature effects and changes in mineral modes and elemental partitioning (caused both by temperature and composition variation). Most of the approximately 9% lateral velocity difference between "cratonic" and "tectonic" North America is so accounted for. The complex velocity structure beneath western North America appears to reflect extremes in compositional and temperature heterogeneity. Although anelastic behavior and melting are expected to further reduce velocities in high temperature regions, pervasive partial melt within the upper mantle is not required. Additional observations of rock fabric will be needed to better link single crystal elasticity to seismic determinations of mantle anisotropy.

MANTLE STRATIGRAPHY AND EVOLUTION OF THE SLAVE PROVINCE

Michael BOSTOCK (Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, V6T 1Z4 Canada, email: bostock@geop.ubc.ca)

A data set of 1033 three-component, P wave seismograms from five broadband stations at the Yellowknife Array is assembled to investigate mantle structure below the southern Slave province in Canada's Northwest Territories. Following wave field decomposition, seismograms are source-normalized through simultaneous deconvolution to estimate the near-receiver impulse response as a function of epicentral distance and back azimuth. Images of impulse response reveal a well-developed mantle stratigraphy, anisotropic in part, extending from the Mohorovicic discontinuity to the transition zone. A layer of depth-localized anisotropy (+/-5%), termed H, is situated between ~70 and 80 km depth with an average shear velocity

comparable to that of the ambient mantle and a sharp upper boundary less than 100 m in transition width. The absence of free surface crustal reverberations on the transverse component affords a window into the upper mantle between 100 and 200 km depth. A sequence of at least two layers between 120-150 km depth, collectively termed X, is most clearly evident to the north and is underlain by a second structure L which dips from 170 km in the west to 230 km into the center of the Slave province. The deepest interface above the transition zone W marks a shear velocity inversion near 350 km depth whose signature is restricted to the SV component signalling a dominantly isotropic response. Consideration of these observations in light of data acquired in a recent Lithoprobe seismic reflection traverse and in petrological studies of kimberlite xenoliths prompts speculation into the role of subduction in craton stabilization. It is suggested that the proto-Slave craton was assembled through processes of shallow subduction resulting in a near-horizontal mantle stratigraphy (i.e., H, X) both compositional and rheological in nature. Interpretation of L as the continuation of dipping reflectors on the seismic reflection profile argues for a final phase of craton assembly involving oblique underplating of subducted lithosphere in the Proterozoic. Subsequent modification of the lithosphere, as manifest by Phanerozoic kimberlite volcanism, may be related to W if an interpretation as the top of a layer containing a dense silicate melt fraction is invoked.

ST4/W/06-B2 1200

TOWARD FULLY SELF-CONSISTENT MODELING OF AVERAGE CONTINENTAL GEOTHERMS

Louis MORESI (Australian Geodynamics CRC, CSIRO Exploration & Mining, PO Box 437, Nedlands, 6008, Western Australia); Adrian Lenardic (Department of Geology and Geophysics, University of California, Berkeley, CA 94720, USA)

The forward modeling of average continental geotherms appears to be a relatively simple task. Given the stability and large lateral extent of the continental crust, one solves a one dimensional conduction equation (in a layered medium) for suitable values of thermal conductivity, internal heat generation and mantle heat flux.
One problem with such a model, however, is that the mantle heat flux is not an independent parameter. Heat from the mantle escapes through convective transport to a surface boundary layer where conduction then dominates. The balance between the convective transport and conduction is a sensitive function of the coupled mechanical and thermal properties of the boundary layer. Furthermore, this balance is inherently not one-dimensional: continual horizontal transport of cooling material along the boundary layer is required to sustain the vertical heat conduction.
In the oceanic case, the lithosphere thermal and mechanical structure is readily modeled (at least when less than ~80Myr old) by a cooling half-space conduction profile attached to a material point in accordance with simple boundary layer theory.
However, the presence of buoyant continental crust, and depleted sub-continental mantle lithosphere, prevents convection from determining the thickness of the upper boundary layer. Therefore, the thermal structure of the crust, sub-continental mantle lithosphere, and convecting mantle must be solved as a coupled system in which the convection pattern and associated heat transport is not known in advance. A further complexity is that the continents are finite in extent - the partitioning of mantle heat flow between continents and oceans is another unknown which must be modeled.
We present a number of convection simulations in which we incorporate realistic models of the oceanic lithosphere with continental blocks of varying size and shape and with different relative thermal conductivities and heat generation rates. We solve for the velocity and temperature everywhere in the crust and mantle during several mantle overturns. We track geotherms for a number of points within the continental blocks to determine the long-time average profiles, the variance, and the extreme values of the profiles in response to the underlying convection.
As one example we compare geotherms obtained from continental margins with those from the continental interior, and examine the influence of steps in the thickness of the depleted mantle root. Computed geotherms are compared to approximations obtained using 1D conduction modeling to demonstrate the conditions under which the 1D assumption may fail. We also compare the computed geotherms for the continental margin with analytic solutions in 2D for flow under a changing boundary condition.

CONNECTION BETWEEN STRUCTURE, DYNAMICS AND INSTABILITY OF THE LITHOSPHERE

Andrei Gabrielov (Departments of Mathematics and Geophysics, Purdue University, W. Lafayette, IN 47907-1395, USA, email: agabriel@math.purdue.edu); Vladimir KEILIS-BOROK (International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Warshavskoye shosse 79 kor.2, Moscow 113556, Russia, email: vkborok@mitp.ru); David Jackson (Department of Earth and Space Sciences, UCLA, Los Angeles, CA 90095-1567, USA, email: jackson@ucla.edu)

Structure of the lithosphere imposes strong limitations on its stationary dynamics. Inconsistency between structure and dynamics leads to instability, expressed in accumulation of stress, deformation, fracturing, and the change of geometry of the system. Two integral measures of such instability are introduced: geometric incompatibility G, depicting instability concentrated near the faults' junctions, and kinematic (Saint Venant's) incompatibility depicting inconsistency between absolute movements of the blocks and relative movement on the faults. The estimates of G and K link together the structure and dynamics of the lithosphere, the driving forces included. An analog of Stokes formula is found, allowing to estimate instability of the structure from observations on its boundary.

IMAGING OF THE LITHOSPHERE AND MANTLE TRANSITION ZONE BENEATH THE TANZANIAN CRATON AND SURROUNDING MOBILE BELTS, EAST AFRICA: IMPLICATIONS FOR CRATONIC STABILITY AND THE ORIGIN OF EAST AFRICAN UPLIFT AND TECTONISM

T.J. OWENS (Department of Geological Sciences, University of South Carolina, Columbia, SC 29208 USA, Email: owens@sc.edu); A.A. Nyblade and C.A. Langston (Department of Geosciences, Penn State University, College Park, PA); H.Gurrola (Department of Geosciences, Texas Tech University,Lubbock, TX); J. Ritsema (Seismological Laboratory,California Technical University, Pasadena, CA)

Results of a 20-station broadband seismic array experiment deployed in and around the Archean Tanzania Craton in1994-95 shed new light on issues of both the stability of cratonic lithosphere and the origin of the East African uplift and tectonism. We utilized crustal and upper mantle receiver function analysis, teleseismic travel-time tomography, and regional earthquake waveform modeling to generate three-dimensional images of the upper 700 km of the earth in this region. Due to the natural distribution of teleseismic earthquakes relative to Tanzania, our resolution is best in the eastern half of the craton, the eastern rift, and the continental margin of Africa. Our derived images help constrain the existence of a seismically fast cratonic keel extending to at least 200km depth beneath the Tanzanian Craton. Beneath this fast zone, anomolously low velocities extend down into the mantle transition zone. On the margins of the craton, low seismic velocities extend from the transition zone up to shallow depths beneath rifted mobile belts. These observations suggest a deep-seated origin for the uplift, rifting and volcanism of East Africa that can be explained most easily by a mantle plume. A process in which this plume rises beneath the cratonic keel and is deflected around the sides of the keel is consistent with our observations. It is also consistent with the uplift of the broad East African Plateau, and focussing of rifting and volcanism in the surrounding mobile belts and suggests that the Archean craton is relatively resistance to thermal erosion during this plume event.

SMALL-SCALE CONVECTION WITHIN UPPER MANTLE BENEATH TIBETAN PLATEAU AND ITS CONTRIBUTION TO THE UPLIFT OF THE PLATEAU

Xiong XIONG , Houtze Hsu (Both at Institute of Geodesy and Geophysics, Chinese Academy of Science, 54 Xudong Road, Wuhan, Hubei 430077, China, email: xxiong@asch.whigg.ac.cn); Rongshan Fu(Department of Earth and Space Science, University of Science and Technology of China, Hefei 230026, China, email: frs@ess.ustc.edu.cn)

Although many mechanisms have been proposed to clarify the uplift of the Tibetan Plateau, the mechanism of mantle dynamics is paid little attention. The evolution of the upper mantle flow under the Tibetan Plateau in the past 206 million years and its contribution to the uplift of the plateau has been investigated by the numerical experiment in the paper. In the experiment the effects of several geological factors, such as a subductive oceanic lithosphere, the Tarim Basin and the moving Indian Plate, are considered. The results show that there is an upper mantle convective system beneath the Tibetan Plateau. The upwelling locates in the central northern part of the plateau, while the downwelling locates in the south and northmost parts. The uplift amount of the Tibetan Plateau includes two parts, mechanical component, which is caused by the boundary stress induced by the small-scale convection within the upper mantle, and the thermal one, which is caused by the heating of the mantle upwelling. At the time scale corresponding to the present, the mechanical component is about 100m, while the thermal one is about 550m. The numerical results suggest that the thermal action is an important factor for the uplift of Tibetan Plateau which can not be ignored.

ST4/W/18-B2 1440

THE STRUCTURE OF THE MANTLE BELOW THE EURO-MEDITERRANEAN REGION

Piromallo C., MORELLI A., Olivieri M. (Istituto Nazionale di Geofisica, 00143 Rome, Italy; email: piromallo@ing750.ingrm.it)

Knowledge of the structure of the upper mantle and transition zone in a region of plate collision, such as the Mediterranean, is a key to understanding the tectonics and dynamics of active and past processes. We have analyzed P-wave delay times from regional and teleseismic earthquakes in our new tomographic study of the Alpine-Mediterranean area. Well defined high velocity structures mark subducted slabs (Alboran, Apenninic-Calabrian arc, Dinaro-Hellenic arc, Carpatian arc) and stable cold lithosphere (Eastern Mediterranean, Adriatic, Western Mediterranean), whereas low velocity regions are connected to high heat flux (Aegean, Tyrrhenian, Pannonian basin, Central Massif, Central Italy volcanic provinces). Seismic fast and slow velocities are usually explained as due to thermal anomalies. In order to calibrate our tomographic results, we also model variations of the depth of mineralogical phase transitions at 410 and 660km -- also affected by temperature – by time-domain inversion of teleseismic P waveforms for transfer functions. We find evidence for small-scale topography of the discontinuities, translating into maximum lateral thermal anomalies of the order of 400K. Recent deployment of seismographs in areas with previously insufficient illumination significantly improved ray coverage for tomography, but the availability of broad-band data outside continental Europe is still limited to few stations.

ST4/E/68-B2 1500

PRELIMINARY RESULTS ON THE STRUCTURE OF THE UPPER MANTLE OF THE AEGEAN AREA, FROM TELESEISMIC SURFACE WAVES MEASUREMENTS

K. MAKROPOULOS, I. Kassaras, P. Papadimitriou (all at Department of Geophysics, University of Athens, 157 84 Athens, Greece, email: kmakrop@cc.uoa.gr); D. Hatzfeld, H. Pedersen (LGIT,UJF, Grenoble, France, email: Denis.Hatzfeld@obs.ujf-grenoble.fr); H. Lyon-Caen (Institut de Physique du Globe de Paris, France, email: lyoncaen@jadeite.ens.fr); Kiratzi (Geophysical Laboratory,University of Thessaloniki,Greece, email: kiratzi@geo.auth.gr)

In 1997, for a period of six months, we deployed a temporary broadband array of 30 digital seismological stations over the Aegean area. About 110 teleseismic events with magnitude greater than 5.5 were recorded, comprising a unique database for the northeastern Mediterranean region. Seismograms of 12 long-period instruments of the network, are analyzed to determine the dispersion of Rayleigh and Love waves, by the two station method. Phase velocities from fundamental and higher-mode data are obtained over the period range 10-100s, along selected paths. Furthermore, the calculated phase velocities are inverted with the linear approach, providing constraints on the upper mantle shear velocity structure, along the propagation paths. In this study, we will present the first preliminary results on the structure of the lower lithosphere and the upper mantle beneath the Aegean, focusing on the possible effect-relation of the defined structure to the observed complex geodynamics of the area.

ST4/E/65-B2 1520

UPPER MANTLE SEISMIC VELOCITY STRUCTURE BENEATH SE BRAZIL

M. SCHIMMEL, M. Assumpcao (both at Dept of Geophysics, University of Sao Paulo, Rua do Matao 1226, 05508-900 Sao Paulo - SP, Brazil); and J. VanDecar (Carnegie Institution of Washington, 5241 Broad Branch Road, NW, Washington DC 20015, USA)

We present preliminary results from teleseismic travel-time inversions for P- and S-wave data mainly recorded at portable broad band stations in SE Brazil. The stations have been employed at more than 25 sites within an area of about 500km x 1000 km during the years 1992 - 1998. Most stations are from a joint project (BLSP92) of the Carnegie Institution of Washington and the University of Sao Paulo (USP) and from a continuation of this project by

the USP (BLSP95). The P and S data base consists of relative travel times (P, PKP and S, ScS, SKS, SKKS-waves) which we obtained from the wave forms by a multi-channel cross-correlation technique (VanDecar and Crosson, 1990) using a new coherence functional (Schimmel, in prep.). The inversion follows the approach described by (VanDecar, James, and Assumpcao; 1995). Our results confirm the main features revealed by VanDecar et al. (1995): a shallow high-velocity region beneath the Sao Francisco craton, deep high velocities to the southwest, and a low-velocity cylindrical structure in the upper mantle to a depth of at least 500 - 600km. The cylindrical structure has been interpreted as the fossil conduit through which the initial Tristan da Cunha plume head traveled to generate the Parana flood basalts. This structure continues to lie beneath the Parana basin indicating that the upper mantle has been in coupled motion with the overlying plate since the opening of the South Atlantic Ocean. The increased aperture of the seismic network, amount of station sites, and data permit a more detailed separation of geological structures such as the Sao Francisco craton and an extension of the study to larger depth. The greater resolution at depth is important for determining the base of the inferred conduit and therefore for characterizing the coupling between upper and lower mantle beneath SE Brazil.

ST4/E/55-B2 1620

SEISMIC BODY WAVE ATTENUATION IN THE UPPER MANTLE

H.X. CHENG, B.L.N. Kennett (Both at Research School of Earth Sciences, Australian National University, ACT 0200, Australia, email:chx@rses.anu.edu.au)

The main challenge in measuring and developing models for attenuation structure in the Earth is the separation of anelastic effects from both propagation and source effects. The slope of logarithm of the spectral ratio between P and S wave arrivals on the same record can be used to determine the t* (differential attenuation) between P and S because the frequency dependent factors common to the two wave types are canceled through the spectral ratio. The use of the logarithmic slope also minimises the influence of absolute amplitude variations. Tests on noise treatment show that the noise spectrum can be represented by a mean base line. The noise can then be removed from signal based on the assumption that noises are same in both signal and noise spectral windows. Tests using synthetic seismograms show that the t* can be recovered quite well but also that the influence of surface reflected phases within the P and S wave spectral windows can be important.
The systematic application of the spectral ratio approach to the estimation of the t* between P and S to the broadband data from Australian stations provides a measurements along nearly 2000 refracted raypaths mostly sampling the northern part of the continent. The measurements also clearly delineate major variations in attenuation between the cratonic structures in the centre and west and the eastern part of Australia.
With our knowledge of the variations in velocity structure, the t* along the different paths can begin to be interpreted in terms of attenuation structure in 3-D. In central and western Australia strong attenuation of S waves is required in the asthenosphere beneath a lithosphere with comparatively low attenuation. In the east the zone of high attenuation is shallower.

ST4/W/44-B2 1640

RESOLVING UPPER-MANTLE ATTENUATION STRUCTURE BY ANALYZING HIGH-FREQUENCY P AND PP SPECTRA

Linda M. WARREN and Peter M. Shearer (Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA, 92037-0225; email: lwarren@ucsd.edu)

We study the P-wave attenuation structure in the upper mantle by computing the spectra for more than 22,000 P and 4000 PP waves using selected seismograms from the global seismic networks between 1988 and 1997. Each spectrum is the product of source, propagation, and receiver response functions. Since there are multiple receivers for each source and multiple sources for each receiver, we can approximate the source and receiver responses by stacking the appropriate P spectra. The resulting source-specific response functions include both the source spectra and the effect of near-source attenuation in the upper mantle; the receiver stacks include the instrument and site responses and near-receiver Q structure. Next, we correct the PP spectra using the source and receiver stacks found from the P waves. For each PP path, the remaining spectrum, which represents the propagation response, is used to estimate t* at frequencies between 0.55 and 1.95 Hz. Since we have accounted for the source- and receiver-side effects and attenuation in the lower mantle is small, most of the residual t* is accumulated in the upper mantle at the PP bounce point. Maps of our t* measurements plotted at their surface bounce points show remarkably coherent patterns. Eurasia is less attenuating while the northeast Pacific is more attenuating than the global average. The patterns of more and less attenuating regions that we see are similar to those in the S-wave attenuation model QR19 [Romanowicz, 1995]. Our t* measurements for oceanic bounce points demonstrate a good correlation between the age of the ocean floor and the amount of attenuation.

ST4/W/14-B2 1700

ANISOTROPY, MANTLE FLOW AND SCATTERED SURFACE WAVES IN THE KAMCHATKA REGION

Jeffrey PARK, Vadim Levin, Valerie Peyton, Jonathan Lees, Mark Brandon (all at Dept of Geology and Geophysics, Yale University, POB 208109, New Haven CT 06520 USA; email: park@hess.geology.yale.edu); Evgenii Gordeev, Victor Chebrov (OMSP, Petropavlovsk-Kamchatsky, Kamchatka, Russia) and Alexei Ozerov (Institute of Volcanology, Petropavlovsk-Kamchatsky, Kamchatka, Russia)

Active subduction of the Pacific plate beneath the Kamchatka peninsula appears to terminate at its intersection with the Aleutian Island chain, where a transform plate boundary forms a "corner" with the subduction zone. The near-absence of seismicity north of the Aleutian junction suggests that the subducting Pacific plate terminates at this point, dangling a slab edge into the ambient upper mantle flow. By analogy with the Lau Basin in the Tonga region, slab rollback at the Aleutian corner would lead to east-west extension in the upper mantle beneath central Kamchatka, slab-parallel flow on the seaward side of the trench, and possibly transport of fore-arc asthenosphere eastward to the back-arc side. In an alternative scenario a contiguous slab that is currently aseismic might extend north of the Aleutian junction, forming a barrier for the east-west asthenospheric flow. Mantle flow leads to peridotite deformation, preferred alignment of mantle minerals, and elastic anisotropy. Sharp lateral gradients of anisotropy would be developed in likely models for mantle flow in the Kamchatka region. These would induce quasi-Love waves (Love-to-Rayleigh surface-wave scattering) at periods longer than 50 seconds. Preliminary analyses of data from the GSN station PET in Kamchatka and ADK at Adak Is. in the Aleutians show strong quasi-Love waves, presumably associated with mantle flow near the local plate boundaries. In August 1998 a joint team of US and Russian investigators installed a network of 15 broadband portable seismometers on the Kamchatka peninsula. Initial data records from selected stations in the portable network display long-period quasi-Love waves, similar to those seen at PET. We will report on attempts to combine data from the Kamchatka network and Aleutian-Island stations to infer mantle flow in this region.

ANISOTROPIC TOMOGRAPHY OF THE ATLANTIC OCEAN

Graca SILVEIRA (Centro de Geofisica da Universidade de Lisboa,Rua da Escola Politecnica, 58, P-1250 LISBOA) , Eleonore Stutzmann, Jean-Paul Montagner (both at Departement de Sismologie, Institut de Physique du Globe, 4 place Jusseu, 75252 PARIS-CEDEX 05, France.) and Luis Mendes Victor (Centro de Geofisica da Universidade de Lisboa)

The depth extent of the Mid Atlantic Ridge and the role of hotspots in the Atlantic opening are still a matter of debate. In order to constrain the structure and the geodynamic processes below the Atlantic Ocean, we provide the first anisotropic phase velocity and S-wave velocity maps of this area, obtained at a regional scale. We have determined Rayleigh wave phase velocities along 1311 direct epicentre-to-station paths. After shallow layer corrections, the phase velocities are inverted, without a priori constraints, to obtain anisotropic phase velocity lateral variations in the period range 50 - 250s. In a second step, the inversion versus depth enables to retrieve S-wave velocity structures. The ridge axis corresponds to a low velocity anomaly visible down to 150km in the North Atlantic and down to 200km in the South Atlantic. A good correlation between hotspot locations and low velocity anomalies is obtained down to the deepest depth inverted. Furthermore, a low velocity anomaly elongated along a North-South direction is visible at every depth and seems to be correlated with hotspot positions. On average, the North Atlantic is associated with higher velocities than the South Atlantic. The maps of phase velocity anisotropy under the Atlantic Ocean are interpreted in the Mid-Atlantic area where we have the best resolution. Close to the ridge, the fast axis of Rayleigh wave phase velocity is found perpendicular to the ridge axis. A comparison of anisotropy directions and plate motion shows that seismic anisotropy integrates also deeper phenomena such as mantle convection.

ST4/W/51-B2 1740

DEPTH DISTRIBUTION OF ANISOTROPY USING CONVERTED WAVES

Takashi IIDAKA and Fenglin Niu (both at Earthquake Research Institute, the University of Tokyo, 1-1-1 Yayoi, Bunkyo-ku, Tokyo 113, Japan, Email: iidaka@eri.u-tokyo.ac.jp, niu@eri.u-tokyo.ac.jp)

Depth distribution of the anisotropy inside the earth has been an important problem to be solved.The shear-wave splitting analysis using converted waves makes it possible to estimate the anisotropy at each layer; i.e. crust, upper mantle, lower mantle, and D" layers, if the clear converted waves caused by each boundary are observed. We researched shear-wave splitting in the east China region to know the depth distribution of the anisotropy by comparing the waveform splitting by the use of SKS, P-SmS(P-S converted at the free surface and reflected Moho discontinuity) and P660s(P-S converted waves at the `660km' discontinuity) waves. However, 660s and P-SmS waves were only observed at HIA and three stations (ENH, MDJ and SSE), respectively. We can not restrict which parts of the anisotropic region should be attributed. The analysis of P-SmS wave indicates crustal anisotropy is estimated to be less than 0.05 sec at the most eastern China region.
The time-lag values of the shear-wave splitting caused by the lower mantle and upper mantle including crustal anisotropy are about 0.4 sec and 0.2 sec beneath the HIA station, respectively.The shear-wave splitting analysis of the converted waves makes it possible to reveal the depth distribution of anisotropy.

MANTLE STRUCTURE AND DYNAMICS 3

ST4/W/20-B3 0840

A SMALL DENSITY JUMP ACROSS THE 660KM DISCONTINUITY INFERRED FROM PP AND SS PRECURSOR AMPLITUDES

Peter M. SHEARER and Megan P. Flanagan (University of California, San Diego, La Jolla, California 92093-0225, USA, e-mail: pshearer@ucsd.edu)

Globally averaged depths to the 410- and 660-km discontinuities are now constrained rather precisely from studies of seismic reflections off these boundaries. However, the amplitudes of the velocity and density jumps at the interfaces are known much more poorly, and results from different studies show scatter of a factor of two or more. The density jumps, critical parameters for modeling of mantle dynamics, are particularly hard to measure and are often based on velocity versus density scaling relationships rather than direct observational constraints. Seismic reflections at near-vertical incidence are sensitive to the impedance changes at the interfaces and cannot separately resolve the velocity and density jumps. However, at shallower ray angles the reflection coefficients respond differently to the velocity and density changes. Thus, in principle, by studying the behavior of reflection coefficients as a function of ray angle, the velocity and density jumps can be separately resolved. We adopt this approach to modeling the range dependence in the amplitude of long-period SS and PP precursors resulting from underside reflections off the 410 and 660km discontinuities. We stack over 20,000 long-period seismograms to obtain measures of the range dependence in PdP and SdS amplitudes. We estimate error bounds on our observed amplitudes using a bootstrap resampling approach. Using synthetic seismogram modeling, we then compute confidence ellipses within the three-parameter model space of changes in P velocity, S velocity and density across each interface. Our results show that the PREM model is within the 95% confidence ellipse for the 410km discontinuity but well outside the allowed jumps across the 660km discontinuity. In particular, the density jump across the 660km discontinuity is constrained to lie between 4 and 6%, substantially below the PREM value of 9.3%. Many convection models have assumed the PREM density jump at 660km in computing the barrior to mantle flow caused by a negative 660km Clapeyron slope. Our results suggest that these studies may be overestimating the influence of the 660km discontinuity on mantle flow.

ST4/E/02-B3 0900

MANTLE DISCONTINUITIES BENEATH NORTHEAST OF CHINA AND ITS GEODYNAMIC IMPLICATION

Shaoxian ZANG and Yuanze Zhou(both at Department of Geophysics, Peking University, Beijing 100871, China, email: sxzang@ibmstone.pku.edu.cn, zyz@www.geophy.pku.edu.cn)

In this study we investigate the mantle discontinuities beneath the northeast part of China where the Japan sea subducting slab reached and try to find some clues for interaction between subducting slab and discontinuities.The converted waves of P-SV were used to study the discontinuities. The seismological records from eight stations were used. The three directions of record UD, NS and EW were transformed to P, SV and SH coordinate system.

The polarization filter was applied to the three components P, SV and SH in time domain, then the P-SV phases were picked out from the time window of 15 -110seconds after P arrival by comparison the P and SV components. The methods of cross-correlation and waveform analysis were also applied to select the converted wave phases. According to the converted phases, the converted points were obtained basing on the PREM velocity model and concentrated nearly on the depths of 150km, 220km, 400km, 520km, 660km, 900km and 1100km respectively. There are obvious velocity contrasts. It was also noted that some converted points are distributed between 220km and 400km as well as 660km and 900km. The reason for that was analysed. The big attention has been paid to the 660km discontinuity. The depth of the discontinuity from the east part of the region to west part along the subducting direction is slightly changed. It may imply that the subducting slab does not penetrate through the 660km discontinuity, but is bended and extended horizontally from east to west.

ST4/E/49-B3 0920

MAPPING LOWER MANTLE TOPOGRAPHY USING A HIGH RESOLUTION MIGRATION TECHNIQUE

Aoife O'MONGAIN (British Geological Survey, Murchison House, West Mains Road, Edinburgh EH9 3LA, UK, email: aom@mail.nmh.ac.uk) Jurgen Neuberg (School of Earth Sciences, University of Leeds, Leeds LS2 9JT, UK, email: j.neuberg@earth.leeds.ac.uk)

P-waves recorded on the Northern California Seismic Network provide the high resolution required to investigate the heterogeneity in the lower mantle which is associated with the intermittent detection of a D" discontinuity. The overlapping Fresnel zones of the bounce points in the lower mantle facilitates the development of models which are significantly more consistent than previous models created using data from single stations or sparse arrays. An advanced processing scheme which involved the use of the vespagram, FK and matched filter methods, was developed to enhance anomalous lower mantle P phases and retrieve all possible parameters which could be used to determine their origin and character. Analysis of the effect of reflector topography on the lower mantle phases led to the development of a migration scheme. Differential travel times, slowness and azimuth values obtained from the array processing techniques were used in the migration scheme, which does not constrain the positioning of the scatterers to one depth, but accounts for reflector topography or for the occurrence of lower mantle scattering bodies. Realistic structures could be inferred from the migration results; D'' structures larger than the effective Fresnel zone size were observed. Mountainous D" topography with a height of 300km above a base level of 3616km is suggested for the bounce point region south of the Aleutian Island Arc. The central Pacific region shows evidence for a D" discontinuity with considerable topography (150km topography above a base level of 3766km) and also the presence of a low velocity layer at the base of the mantle. In contrast, distinctive scattering bodies, which are all greater than effective Fresnel zone size, are observed in the bounce point region off the coast of Central America. For the first time the size of the scattering bodies responsible for the observed transverse isotropy beneath Central America is constrained.

A COMPLETE P WAVEFORM MIGRATION IN THE LOWERMOST MANTLE BENEATH NORTHERN SIBERIA

Marion FREYBOURGER (email: marion@quake.mit.edu), Sebastien Chevrot (both at EAPS, MIT, Cambridge, MA02139, USA), Frank Krueger (Institut fuer Geowissenschaften, Potsdam, 14415, Germany) and Ulrich Achauer (EOST, UMR 7516 CNRS-ULP, Strasbourg, 67084, France)

More than 15 years of PcP and ScS precursor studies failed to give enough constraints for an appropriate explanation of the origin of the highly variable discontinuity on top of D" (2 to 3% velocity contrast, 150 to 400 km above the core-mantle boundary). Whether there indeed exists a discontinuity with topography or rapidly varying velocity contrast, or scatterers non uniformly distributed within D" is still debated. Classical 1D or 2D forward modelling appear unsatisfactory. The larger amount of high quality broadband data now available has thus recently stimulated the development of migration techniques in order to take into account potential non great circle paths resulting from 3D effects and to extract the information from larger datasets. A new migration scheme is here introduced to address the issue of the origin of PcP precursors. This is to our knowledge the first complete waveform migration scheme for the investigation of the lowermost mantle. The method is tested on synthetics and then applied to a dense dataset of Kuril events recorded in Western Europe which samples D" beneath Northern Siberia. The migration reveals the existence of a finite size scatterer with highly anisotropic scattering diagram, some 2600-2650km beneath the Tajmyr peninsula (around 70 deg N, 80 deg E).

LOW SOUTHERN HEMISPHERE CORE-MANTLE BOUNDARY P WAVESPEEDS DERIVED BY PKP A-POINT LOCATION AND DIFFRACTED PKP(AB) SLOWNESS

George HELFFRICH (Earth Sciences, U. of Bristol, Bristol UK), Paul Silver (DTM/Carnegie Institution of Washington, Washington DC USA)

Records from a portable array of broadband seismometers deployed in South America contain near-antipodal P wave arrivals through the core (PKP). The 50-100 km instrument spacing permits the waveforms and distance decay of PKP frequency content of PKP to be analyzed in detail to establish the A-point position in the PKP travel time curve, which at 184 degrees, is farther than specified in contemporary radial earth models (PREM, IASP91, SP6, AK135). The A-point position and array analysis of slowness anomalies of the major arc branch of PKP(AB) reveal ~5% slower CMB wavespeeds under the south Atlantic and Indian Ocean, locations not previously recognized as anomalous. Wave speeds 5% slower than ambient must exist at both the source- and receiver-side of the CMB. While the southern Atlantic site lies below the Tristan hotspot, there is no similar feature above the CMB interaction point at the source side.

ST4/W/01-B3 1100

DYNAMIC CONSTRAINTS ON THE STRUCTURE AT THE BASE OF THE MANTLE

Igor Sidorin, Michael GURNIS, and Donald V. Helmberger (all at Seismological Laboratory,Caltech, Pasadena, CA 91125 USA, email: gurnis@caltech.edu)

The lowermost mantle, D", contains substantial variations in seismic velocity both radially and laterally on ~10 km to >1,000 km scales. Seismic phases related to D" are widely used to study the structure at the base of the mantle. We use dynamic forward modeling (thermo-chemical models of mantle convection with imposed plate tectonics) to predict the seismic structure in the deep mantle. By computing synthetic waveforms and comparing them with data, we select dynamic models consistent with seismological observations. Thermal anomalies from slabs alone do not give rise to a sufficiently strong triplication. The geographical patterns of the triplication caused by a basal phase change agree with seismic observations better than those caused by a chemical layer. By comparing the predicted trends in amplitude and travel time distributions with regional data, we obtain constraints on the (P,T) conditions and the value of Clapeyron slope of such a phase change that yield best agreement with seismological data. We geographically predict the elevation of the discontinuity above the core-mantle boundary using thermal anomalies inferred from tomographic inversions. The discontinuity is imposed on the large-scale structure predicted by tomographic models with an appropriate compensation for the added velocity increase. Synthetic waveforms are computed for many 2-D sections of this composite seismic structure. We find that the strength of D" (Scd) is strongest beneath seismically fast regions (like the Caribbean) and weakest in slow regions, such as the mid Pacific, consistent with observed waveforms.

ST4/W/08-B3 1120

A MODEL OF WHOLE-MANTLE HETEROGENEITY DERIVED FROM WAVEFORM DATA

Charles MEGNIN, Barbara Romanowicz & Ludovic Breger (Berkeley Seismological Laboratory, U.C. Berkeley, 94720)

We present a new mantle model of VSH heterogeneity calculated from the inversion of handpicked waveforms of Love waves, body waves and first and second orbit higher mode arrivals. Our model is developed laterally up to spherical harmonic degree 18 and radially on 16 cubic spline knots spaced according to the depth sampling. The waveform modeling is done with the mode coupling formalism 'NACT' of Li & Romanowicz (1995) that is appropriate for the modeling of both surface and body wave energy. We invert iteratively for mantle heterogeneity and for CMTs until a stable solution is obtained. The set of a priori is determined by performing an inversion for the set of damping parameters that optimizes the retrieval of the 3D convection model GEMLAB1 of Bunge et al (1998). This model incorporates the effects of phase transitions at 410 km & 670 km, partial bottom heating, viscosity contrast between upper and lower mantle and the history of plate motions since the mid-Mesozoic.
Cross-sections across subduction zones such as Tonga-Kermadec, Farallon, Peru-Chile show continuous fast structure penetrating the lower mantle, although the depth of penetration fluctuates from one region to the next. In contrast, fast anomaly appears to accumulate at the 670 km discontinuity under the Kurile, Japan trench and Izu-Bonin arc, with no penetration in the lower mantle, in agreement with the results of Fukao et al (1992). Continuity across the whole mantle of the slow anomaly below the African continent is observed, suggesting a deep origin to the African superswell.
To test the model in the lowermost mantle, we selected S-SKS differential traveltimes for narrow azimuthal corridors between the Fiji Islands region and North American stations and compared them with synthetic ones. The trends observed in the data are compatible with those predicted by the model.
Finally, we separate the model into its positive and negative parts. In the lower mantle, the spectral image of the "slow" model shows wavelengths that increase progressively with radius, from a degree two peak near the CMB to a degree six maximum at 700km. In contrast, the "fast" part exhibits little variation with depth with spectral peaks at degrees two and three throughout the lower mantle. This image suggests that upwellings become increasingly diffuse as they ascend, while the downwellings remain comparatively coherent.

EVIDENCE FOR RADIAL ANISOTROPY IN THE EARTH'S MANTLE

Lapo BOSCHI and Adam M. Dziewonski (both at Department of Earth and Planetary Sciences, Harvard University, 20 Oxford street, Cambridge MA 02138, U.S.A.) Email: boschi@seismology.harvard.edu

In the last twenty years or so, numerous authors have used the techniques of global tomography to obtain three-dimensional images of the laterally heterogeneous structure of the Earth. During this time, the number of available seismic measurements was increased enormously, and the inversion methods were constantly refined. Today, velocity models obtained with different datasets and very different approaches often show an encouraging consistency between each other. Nevertheless, recent results suggest that seismic tomography might be capable of constraining geophysical observables that were not accounted for by earlier studies; Ekstrom and Dziewonski (1998), for example, were able to find a robust regional anomaly in elastic anisotropy, located in the Pacific upper mantle. Vasco and Johnson (1998) suggested that the travel-time measurements associated with phases traveling through the Earth's core are best explained by allowing the outer core to be laterally heterogeneous. In general, such results seem to indicate that the many seismic data that are now available probably contain some valuable information that we might as yet have neglected. Our research focuses on the possibility of radial anisotropy throughout the mantle. We perform joint inversions for lateral anomalies in horizontal and radial P-velocity (the "A" and "C" parameters) in the Earth's mantle, and in the topography of the CMB, using P, PKP, and PcP travel-time data and a block-parameterization of high nominal resolution. We interpret our results in the framework of the above mentioned recent studies; in particular, radial anisotropy of the mantle can be an alternative way, without requiring outer-core lateral heterogeneities, to fit the travel-time data associated with core-phases. Furthermore, an anisotropic map of the mantle can provide new constraints on our geophysical interpretation of tomographic images.

SEISMIC TOMOGRAPHY, 3D SPHERICAL MANTLE CONVECTION, AND GEODYNAMICS: THE MUTUAL BENEFITS

J. Huw DAVIES (Dept. of Earth Sci., Univ. of Liverpool, L69 3BX, UK, email: davies@liv.ac.uk); H.-P. Bunge (Dept. of Geological Sciences, Princeton Univ., Princeton, NJ, USA)

The best way to demonstrate understanding of the dynamics of the mantle is by developing successful mantle circulation models that explain a wide body of data. Spatially, the most testing data come from seismic tomography. We have started on the road of directly testing realistic 3D high Rayleigh number (node spacing down to 25km) spherical mantle circulation models which incorporate recent subduction history. The lateral temperature variations are converted to seismic velocity perturbations then, using exactly the same 2.5D ray-set as used in our tomography we predict the travel-time residuals. These are then inverted using exactly the same joint structurer location inversion algorithm i.e. the model data go through exactly the same 'filter' as he actual data. These results can be compared directly with the P body-wave data inversions implemented using a 3D a-priori model constructed with geodynamical constraints. The circulation models predict well the downwellings but as expected do not match the locations of the hot upwelling plumes found crossing from the lower to upper mantle in the tomography. The mantle circulation and a-priori seismic models provide excellent realistic synthetic models with which to investigate the practice of global seismic tomography. For example one can quantify: the trade-off between relocation and structure, the optimum damping parameters, the best model parameterization, and the degree of aliasing. For example we find that the histogram of the synthetic travel time residuals is never Gaussian, rarely unimodal, and not centred around zero. This for example brings into question

procedures (e.g. L2 norm, source relocation) that theoretically assume such a distribution. The non-zero mean questions using 'true' global reference earth models constrained by free oscillations as initial models for body-wave inversions.

SUBDUCTION PROCESSES AND FLUID/ROCK INTERACTIONS IN THE CENTRAL ANDES IMAGINAGED BY GEOPHYSICAL OBSERVATIONS

Günther Asch, Christian. Haberland, Frank Schilling, Xiaohui Yuan, Henry Brasse, PETER GIESE, Stefan Lueth, Peter Wigger

The lithosphere of the Central Andes (21° and 24°S) has been investigated by the interdisciplinary research program "Deformation processes in the Andes" carried out by geoscientists of the Freie Universitaet Berlin, Technische Universitaet Berlin, the GeoForschungsZentrum Potsdam and the Universitaet Potsdam in co-operation with institutions in Southern America. Here geophysical studies are presented which monitor fluid/rock interactions in the downgoing slab and the overlying slab. The pattern of intermediate depth seismicity as double seismic zone portrays the shape of the isotherns in the temperature range 500°-700°C. Tomographic sections of the parameters vp/vs and Q display regions of hydration and melting in the upper plate. Extreme low velocity regions indicate the distribution of partly molten rocks in the uppermost crust Sections derived from receiver functions reveal the transition from basalt to eclogite in the downgoing slab.. There are welll expressed changes in the petrophysical structure of the lithosphere in the upper plate in N-S direction, which may be correlated the recent volcanic activities in the magmatic arc.

SEISMIC STRUCTURE OF SUBDUCTION ZONES: IMPLICATIONS FOR ARC MAGMATISM, SEISMOTECTONICS AND GEODYNAMICS

Dapeng ZHAO (Department of Earth Sciences, Ehime University, Matsuyama 790-8577, JAPAN; E-mail: zhao@sci.ehime-u.ac.jp)

High-resolution 3-D seismic structure of several subduction regions including Japan, Alaska, and Tonga is determined down to 700 km depth by using high-quality data recorded by regional seismic networks. Major findings are summarized as follows. (1) The subducting Pacific slab is imaged as a high-velocity zone with a thickness of 50-90 km and a P-wave velocity 4-6 percent faster than the normal mantle. (2) The subducting Philippine Sea slab in west Japan is also detected. It has a thickness of 30-35 km and a P-wave velocity 3-5 percent faster. (3) In the crust and mantle wedge, low seismic velocities are visible beneath active volcanoes. The mantle wedge low-velocity zones are related to the arc magmatism caused by the convective circulation process in the mantle wedge and dehydration reactions in the subducting slab. (4) The hypocenter of the 1995 Kobe earthquake (M 7.2) in west Japan was located in a distinctive zone characterized by low seismic velocity and high Poisson's ratio. This anomaly may represent a fluid-filled, fractured rock matrix that contributed to the initiation of the Kobe earthquake. Evidence shows that the fluids mainly due to the dehydration of the subducting Philippine Sea slab. (5) Large crustal earthquakes (M 5.7-8.0) from 1885 to 1998 in Japan occurred in or around crustal low-velocity zones which may represent weak sections of the seismogenic crust and be caused by active volcanoes and/or magma chambers in volcanic areas and by fluids in fault zones in non-volcanic areas. The weak sections of the crust are subject to the tectonic stress and prone to large earthquakes. These results indicate that large earthquakes do not strike anywhere, but only anomalous areas which may be detected with geophysical methods.

LABORATORY EXPERIMENTS ON SUBDUCTION AND BACKARC EXTENSION

Francesca FUNICIELLO (Dip. Scienze Geologiche, Univ. Roma Tre, Largo S. L. Murialdo 1, 00146, Roma Italy. Institute of Geophysics, ETH, 8093 Zurich Switzerland e-mail: ffunicie@geo.uniroma3.it), Claudio Faccenna, (Dip. Scienze Geologiche, Univ. Roma Tre, Largo S. L. Murialdo 1, 00146, Roma Italy, e-mail: faccenna@uniroma3.it), Domenico Giardini (Institute of Geophysics, ETH, 8093 Zurich Switzerland)

We have performed 2D and 3D laboratory experiments to investigate the way the oceanic lithosphere sink into the mantle. Models have been performed with silicone putty, simulating the viscous behaviour of an oceanic lithosphere subjected to long term deformation and glucose syrup, simulating the mantle. We tested the influence of two parameters on the style of mantle convection: (1) lateral boundary conditions, i.e. box width, (2) deep discontinuity in the mantle resemblming the 670km transition. We expressed the results in terms of: rate of trench retreat, rate of subduction, dip of subduction and state of strain of the upper plate. Our results show how the slab trajectory into the mantle is influenced by the presence/absence of deep discontinuity.

THERMAL MODELING IN TORN, SUBDUCTED PLATE EDGES

Jonathan M. LEES (Department of Geology and Geophysics, Yale University, New Haven, CT, 06511 email: lees@love.geology.yale.edu); Anne Davaille (Universite Paris 7, Institut Physique du Globe, Paris, France email: davaille@ipgp.jussieu.fr)

In this paper we investigate the implications for a tear in the Pacific plate at the northern limit of the Kamchatka volcanic arc. The Kamchatka-Bering juncture is characterized by unusual volcanic products and distribution of heat flow below the Komandorsky basin, and shallowing of seismicity along the subduction zone from Southern Kamchatka (600 km) to relatively shallow seismicity near the Kamchatka-Bering Fault intersection (100-200 km). If the Pacific plate is torn below the Bering fault, a slab window will be present through which mantle material can flow around the exposed Pacific plate edge, below the northern extent of active volcanism in Kamchatka. The exposed edge and subsequent mantle flow have a significant effect on internal structure of the subducting slab, as seen, to first order, by the shallowing seismicity. To investigate this model, we use a combination of laboratory experiments, numerical and theoretical modeling.
A subducting slab with three sides exposed to the mantle will heat up faster than a semi-infinite slab. Analytical solutions for the thermal evolution of a torn slab with high Peclet number (fast subduction) show that conduction alone cannot explain the shallowing seismicity. On the other hand, numerical solutions of the thermal evolution of a slab thinned toward the edge simulates the seismological data: minimum temperature isotherms inside the slab shift inward, producing a lack of deep seismicity near the edge. Older plates are thinned and fragilized on their edge by small-scale convection. Preliminary laboratory experiments show that in this case, applying a mantle flow around the fragilized edge is sufficient to produce, in a few Myr, the necessary amount of thinning.

ST4/W/15-B3 1500

HUNTING BIG SLAB IN KAMCHATKA

Jeffrey PARK, Vadim Levin, Valerie Peyton, Jonathan Lees, Mark Brandon (all at Dept of Geology and Geophysics, Yale University, POB 208109, New Haven CT 06520 USA; email: park@hess.geology.yale.edu); Evgenii Gordeev, Victor Chebrov (OMSP, Petropavlovsk-Kamchatsky, Kamchatka, Russia) and Alexei Ozerov (Institute of Volcanology, Petropavlovsk-Kamchatsky, Kamchatka, Russia).

The Pacific-North America plate boundary takes a sharp turn where the Aleutian Islands meet the Kamchatka Peninsula, changing from strike-slip to convergent motion. Active subduction of the Pacific plate beneath the Eurasian landmass appears to terminate here, though past plate convergence farther north can be inferred from the continuity of accreted terranes across the Aleutian intersection. The history of subduction in this region should be reflected in thegeometry of high-velocity slab material in the upper mantle. Hypotheses include (1) a dangling slab edge that ablates down-dip as it warms in the upper mantle; (2) a "tablecloth bulge" if a contiguous slab drapes over the boundary corner; and (3) a contiguous slab that parallels the full coastline of Kamchatka. Option (3) would imply that subduction of the Bering Sea plate fragment is still proceeding north of the Aleutians, but has been quiescent in historical times. We investigate the Kamchatka slab with broadband receiver functions. From P-coda this method reconstructs P-to-S converted phases from velocity interfaces beneath a seismic station. Preliminary analysis of data from the GSN station PET at Petropavlovsk-Kamchatsky shows a strong P-to-S converted phase from the upper surface of the slab, including a splendid lowpassed conversion from the large P-diffracted arrival from the 9 June 1994 deep-Bolivia event. In August 1998 a joint team of US and Russian investigators installed a network of 15 broadband portable seismometers on the Kamchatka peninsula, both north and south of the Aleutian junction. Initial data records from stations in the portable network have quality sufficient to detect similar conversions from elsewhere on the slab's upper surface. We will report on attempts to map the existence, location and strength of P-to-S converted phases, to distinguish between models for mantle flow in this region.

ST4/E/04-B3 1550

ANTI-CORRELATION OF THE 410 AND 660KM DISCONTINUITIES AND SUBDUCTION ZONE STRUCTURE

Jonathan COLLIER and George Helffrich (Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queens Road, Bristol, BS8 1RJ, UK, email: jonathan@gly.bris.ac.uk)

Seismic mantle discontinuities at global average depths of 410 and 660km are believed to arise from pressure induced phase changes. Thermodynamically refined Clapeyron slopes suggest elevation of the 410km discontinuity and depression of the 660 in cool regions of the mantle. We test this hypothesis by investigating the response of these discontinuities to cold downwelling material in subduction zones. A slant stacking technique with regional seismic network data is used to enhance weak arrivals in the time window between P and sP for teleseismic events in the northwest Pacific and South America. In stacked data arrivals resulting from interactions with the 410 and 660km discontinuity are enhanced above the background noise level. Use of networks in the western US and the UK coupled with the location of the largest number of source earthquakes provides the best data coverage in the Izu-Bonin region. Here we clearly image elevation of the 410km discontinuity of up to 60km in the core of the subducting slab and a broad depression of the 660km discontinuity by up to 40km consistent with expected Clapeyron slopes. The observations of the 410km discontinuity are incompatible with the presence of a significant metastable wedge. In the Kurile Islands region elevation of the 410 in the slab is also seen whereas under the Japan Sea a more regional elevation is observed. Beneath Chile little deflection of the 410 is seen indicating either absence of subducting slab in the aseismic region or the weak cooling effect of a relatively young slab on the mantle.

ST4/E/32-B3 1610

410KM DISCONTINUITY UPLIFT IN SLAB INCOMPATIBLE WITH METASTABLE WEDGE

Jonathan Collier, George HELFFRICH (Earth Sciences, Univ. Bristol, Bristol BS8 1RJ, UK)

Deep earthquakes occur at temperatures and pressures where the brittle failure associated with shallow earthquakes cannot occur. The transformational faulting hypothesis for deep earthquakes holds that when olivine is in a metastable state due to the kinetically hindered transition to a denser phase, and is nonhydrostatically deformed, planar faulting is possible when the olivine transforms. The hypothesis requires a metastable wedge of untransformed olivine in the slab. We test this hypothesis by seeking the position of the 410 km discontinuity inside a slab where deep earthquakes occur. Using short-period regional network data from Europe and North America, we located the 410 in the Izu-Bonin deep seismic zone using underside pP- and sP-like reflections from the discontinuity. The discontinuity topography that we observe is consistent with the maximum elevation expected from numerical modelling and Clapeyron slope estimates, up to 60 km relative to the 410 depth outside the slab. We see uplift on both the oceanward and the trenchward sides of the seismicity, ruling out the uplift as being an artifact of the velocity contrast at the formerly oceanic crust side of the slab/mantle interface. Thus a crucial element of the transformational faulting model for deep earthquakes is missing in one deep seismic zone. Whatever the mechanism of deep earthquakes, it must operate when the olivine transformation progresses under essentially equilibrium conditions.

ST4/W/03-B3 1630

A TELESEISMIC TOMOGRAPHIC IMAGE OF THE ICELAND MANTLE PLUME

G.R. FOULGER, M.J. Pritchard (Both at Dept. Geological Sciences, University of Durham, Durham, DH1 3LE, Email: g.r.foulger@durham.ac.uk); B. R. Julian (U. S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025, U.S.A., Email: julian@usgs.gov), G. Nolet, W.J. Morgan, R. M. Allen (All at Dept. Geosciences, Princeton University, Princeton, NJ, U.S.A., Email: guust@weasel.princeton.edu), B.H. Bergsson, P. Erlendsson, S. Jakobsdottir, S. Ragnarsson and R. Stefansson (All at Vedurstofa Islands, Reykjavik, Iceland, Email: ragnar@vedur.is).

A major passive seismic experiment is currently underway to map the structure of the crust and upper mantle over the whole of the Iceland hotspot. Thirty-four broadband seismic stations, distributed over the whole of Iceland, were operated for the two-year period 1996 - 1998. An extremely rich dataset that includes teleseismic, regional and local earthquakes was collected. The data have been used to obtain a teleseismic tomography image of the Iceland plume from the surface down to about 600km. For this study we also used data from 8 stations

of the permanent Icelandic network, and thus a total of 42 seismic stations contributed data. About 120 earthquakes were used with a good azimuthal distribution around Iceland. The data included about 4500 P-wave arrival times, including the phases P, pP, PP, PcP and PKiKP, and about 2000 S-wave arrival times, including the phases S, sS, SS and SKS. We performed many inversions, varying the initial starting model, damping and the inversion program used. Our final results will be presented for the first time in this talk.

ST4/W/10-B3 **1650**

PLUME-RIDGE-INTERACTION: THE INFLUENCE OF STRONGLY TEMPERATURE DEPENDENT VISCOSITY

Michael ALBERS and Ulrich Christensen (both at Institute of Geophysics, University of Goettingen, Herzberger Landstr. 180, 37075 Goettingen, Germany, email: mab@geo.physik.uni-goettingen.de)

Many hotspots of the Earth are located on or nearby mid-ocean ridges. Geophysical as well as geochemical observations indicate that abnormal plume material may interact over long distances with ridges. These observations are often explained by flow of plume material from the hotspot along the ridge axis. However, in previous numerical models no significant channeling of plume material has been found. We investigate the interaction of mantle plumes with mid-ocean ridges in 3-D numerical convection models. Using a multigrid technique with local grid refinements, we are able to incorporate a much stronger temperature-dependence of viscosity than was possible in previous models. This allows lateral viscosity variations of more than 6 orders of magnitude, which is realistic in a ridge situation. Results for ridge-centered plumes are presented. The maximum extent of plume material along the ridge is systematically determined in dependence on various model parameters, like the heat flux of the plume, the spreading rate of the ridge and the viscosity contrast between plume and ambient mantle. It turns out that a plume viscosity in the order of 10E-17 Pas and a slow spreading rate are necessary for significant flow of plume material along the ridge axis.

ST4/E/64-B3 **1710**

DYNAMICAL EFFECTS OF MELTING IN THE HAWAIIAN PLUME

Neil Ribe (Dept. of Geology and Geophysics, Yale University) Laszlo Cserepes (Eotvos University, Budapest) Ulrich CHRISTENSEN (University of Goettingen)

We use a 3D variable viscosity convection model to study the effect of the reduced density (depletion buoyancy) of the residuum after melt extraction and the loading of the surface by melt deposition on the geoid and topographic anomalies produced by the Hawaiian plume. In addition, we study the spatial distribution of melting in the plume and compare with the temporal evolution of individual Hawaiian volcanoes. We use the melting parameterization of McKenzie & Bickle (1988) and assume rapid extraction to the surface. From a set a model calculations, we derive scaling laws for melt production rate and topographic uplift depending on the plumes's thermal flux and excess temperature and the lithospheric thickness. The observed topography is well matched by models with about 250 K excess temperature and 4000 kg/sec buoyancy flux. The effects of surface loading reduce the apparent geoid-to-topography ratio obtained by applying standard spatial filtering procedures to the "observed" range of 4-6 m/km. All the melt is drawn from the hottest part of the plume, implying no direct melting of asthenosphere or lithosphere. 99% of the melt is erupted in a region within 200 km of the plume center with a distribution that is skewed downstream. We also find a secondary melting region about 400 km downstream from the plume that is separated from the main region. This provides an explanation for the late-stage "rejuvenated" volcanism of the Hawaiian islands.

A COMPARISON OF THE GEOPHYSICAL SIGNATURES BETWEEN GREECE AND ITALY AS DERIVED BY GEODETIC DATA

M.G. Doufexopoulou & V.N. PAGOUNIS (Dept. Rural and Surveying Eng. NTU Athens, Heroon Politechniou 9, Zografos – Athens, Greece, email: vassilios.pagounis@survey.ntua.gr)

The difference between GPS geometric height and leveled or trigonometric heights gives point undulations of the geoid that have an estimated accuracy of +-/0.10 cm. By subtracking from these local signals, the model values at the same points computed with the EGM96 and OSU91a coefficients at various truncation degrees and lag intervals various residual point field undulations are produced. These signals are rich in geophysical information without biased assumptions on the analytic structure of the local gravity field, or the used density values. Several statistical procedures enable to eliminate the global model gravity field contribution and to trace tectonic signatures in geographical sense. On the other hand the numerical computation of raw variance and variability spectra provides a simple method to draw conclusions on the relative difference in the depth of the main sources above each tectonic block. We present results of this methodology using GPS and leveled data from Greece and Italy.

3D REFLECTION IMAGING OF THE PUGET LOWLANDS, CASCADIA, USA

L.A. PRESTON (Geophysics Program, Box 351650, University of Washington, Seattle, WA, 98195-1650; email: preston@geophys.washington.edu), K.C. Creager, R.S. Crosson (Geophysics Program, Box 351650, University of Washington, Seattle, WA, 98195-1650), T.L. Pratt, C. Weaver (U.S. Geological Survey, PO Box 351650, University of Washington, Seattle, WA, 98195), M.A. Fisher, T. Parsons, T.M. Brocher (U.S. Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025)

The 1998 Seismic Hazards in Puget Sound (SHIPS) experiment used closely spaced airgun sources and uniformly distributed seismometers to gain a better understanding of the crustal structure of the densely populated Puget Sound region, Washington. The Seattle Basin is an area of low-velocity sediments up to 10km thick underlying the metropolitan area and Puget Sound. Evidence for large earthquakes on the Cascadia subduction zone and on regional fault systems underscores the need to know the 3D structure of the Seattle Basin to assess the hazards due to reverberation and seismic focusing. 3D tomography and borehole sonic logs have shown that the compressional-wave velocities within the Seattle Basin are as low as 2-3 km/s. 2D reflection profiles, collected along the waterways of Puget Sound, have provided a high resolution image of the shape of this basin along a north-south section. During the SHIPS experiment, 6500 airgun shots within Lake Washington, Puget Sound, and Hood Canal were recorded at an array of 150 onshore seismometers spaced about 10km apart in the Puget Lowlands. We are using a 3D seismic reflection software package to produce a high resolution image of discontinuities within the Puget Lowlands crust. These low-fold 3D reflection images will improve and extend the lateral and vertical resolution of the Seattle Basin and other crustal features previously studied using 3D seismic tomography and 2D seismic reflection.

INTERPRETATION OF LINE TEST-02 AROUND GANOS VAULT FROM THE SEA OF MARMARA

AKKARGAN Sahin (The University of Istanbul, Faculty of Engineering, Turkey. email: sahin@istanbul.edu.tr)

The control of Geophyscist on sesimic data has increased due to developments of digital seismic receording and analyzing technology. Thus, seismic data processing techniques have been applying more efficently with saving time to analyse data. In this study I present a seismic section (line TEST-02) which constitutes part of the data acquired by R/V MTA Sismik-1 on the Sea of Marmara under TUBITAK's National Marine Geological and Geophysical Program. Line TEST-02 is a stacked and migrated seismic section recruited from 302 shots. My preliminary interpretations of line TEST-02 reveal a polarity reversal between CDP's 1150 and 1500 most probably caused by an antithetic fault surrounded by some other minor faults indicating a potential hydrocarbon (gas) trap. This interpretation, however, must be justified by additional seismic line shoots in the vicinity of the region under construction.

STRUCTURAL MODEL OF THE ERZURUM BASIN (EASTERN TURKEY) BASED ON THE GEOPHYSICAL PROFILES

M.Salih BAYRAKTUTAN (Earthquake Res. Centre, Atatürk Univ,Erzurum Turkey, Fax +90 442 2187140, email: msalih @ rocketmail.com) Azer Kadirov (E R C , Ataturk University, Erzurum, Turkey) Ali Aliyev (Geological Survey, Huseyn Cahid Prospekt, Bakü, Azerbaycan)

The Erzurum Basin (EB) is located in the centralsegment of almost E-W striking active Erzurum Faults,between Erzincan and Igd›r Basins, in East Anatolian Convergence Zone. EB is bounded along both northern and southern margins, by sinistral strike slip faults with large reverse components and thrusts. Geophysical data obtained from four gravity-magnetic and one seismic profile have been analized for structural features. Basin floor topograhpy has rough relief with two major trough shaped depressions extending in NE-SW and NNW-SSE. One positive structural feature seperates the north western segment (Daphan Plain) from the main depression (Karasu Plain). This treshold at about 800m depth and the thicknesses of clastic deposits (Late Pliocene-Quaternary) on both sides reaches abouth 1.2 and 1.6 km, respectively.The secondary depression to the NW of Il›ca with 4x16 km dimensions reflect the deepest part of the Pliocene lacustrine area in which fan delta deposits emerged from continental high at NW. Basin floor deepens southwards (and east). Basement folds in volcanic units with ENE-WSW extending axis are cut by two sets of active faults striking at NNE-SSW and NNW-SSE. Gravity map displayed +10 (to +30) mGal positive and -14 (to -16) mGal anomaly differences. All magnetic profiles showed sharp changes along N and S margins which are well coincided with gravity anomalies. Consequently, geophysical data revealed three main stages of structural deformation in the history of basin inversion.

DYNAMIC RESTORATION OF CROSS-SECTIONS WITH DIAPIRIC STRUCTURES

Alik ISMAIL-ZADEH (International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Warshavskoye shosse 79, kor. 2, Moscow 113556, Russia, email: aismail@mitp.ru) Christopher Talbot (Institute of Earth Sciences, Uppsala University, Villavagen 16, SE-752 36 Uppsala, Sweden) Yuri Volozh (Institute of Geology, Russian Academy of Sciences, Pyzhevsky per. 7, Moscow 109017, Russia)

The backstripping method widely used in basin analysis sometimes fails in studying salt-bearing basins, because salt greatly affects the deformation of salt overburden. We present a numerical approach for dynamic restoration of cross-sections to their earlier depositional stages in regions of salt tectonics where deformation is confined to salt and its overburden. The technique combines the Galerkin-spline finite-element method with interface tracking and a backstripping method. We formulate a model concept where a viscous material filling a model rectangular box is divided into layers by advected boundaries (horizons), across which physical parameters (density and viscosity) change discontinuously. The model approximates a stratified geological cross-section. The evolution of salt-affected structures is restored by using backstripping and decompaction of sediments. We demonstrate the applicability of the suggested technique by reconstructions of upbuilt and downbuilt diapirs. The technique is applied to restore a depth converted cross-section through the south-eastern margin of the Pricaspian salt basin. The section is characterised by mature downbuilt salt diapirs and a remnant salt sheet, which are shown to emerge from an originally continuous salt sheet modified by differential sedimentary loading. The numerical approach is well suited for restoration of cross-sections with ductile overburdens.

MOSAIC AND CRUSTAL STRUCTURE OF THE DEFORMED BLOCKS IN THE CENTRAL INDIAN OCEAN BASIN FROM SEISMIC AND GRAVITY INVESTIGATIONS

D. Goapala RAO, K.S. Krishna (National Institute of Oceanography, Dona Paula, Goa-403004, India, email: gopalrao@csnio.ren.nic.in, krishna@csnio.ren.nic.in); Yu.P. Neprochnov, B.N. Grinko (P.P. Shirshov Institute of Oceanology, 36 Nakhimovsky prospect, Moscow-117851, Russia, email: ypn@geo.sio.rssi.ru, gas@sio.rssi.ru)

Seismic reflection and refraction, free-air gravity (shipborne and satellite derived) and bathymetric data of the Central Indian Ocean Basin are analysed to map the mosaic of all the deformed crustal blocks and to determine crustal structure beneath some of the blocks. The deformed blocks in the form of anticlinal basement rises, zones of high angle faults, low amplitude broad basement rises associated with high angle faults and reactivated pre-existing structures are trending in NE-SW direction. The deformation zone comprises of 22 such blocks originated at different ages. Besides, linear chain of circular gravity anomalies that are identified near parallel to 82 degrees 30 minutes E longitude might be due to volcanic constructs. The seismic sequence stratigrphic studies have revealed 2 to 3 km thick sediments consisting of five seismic sequences H1 to H5 separated by Oligocene (?), upper Miocene, lower Pliocene and upper Pleistocene unconformities and underlain by mid-Cretaceous oceanic basement. Model studies of the Ocean Bottom Seismic refraction and free-air gravity (satellite derived) data across the three deformed blocks and in between troughs in the north (along 81.5 degrees E longitude) have revealed structure of the crust and deformation occurs within the crust only. The NE-SW deformed crustal blocks can be accounted due to the NW-SE compression, anti-clockwise rotational forces and different mechanical stregnth of the

rocks in the area. Serpentinites, low velocity layer possibly occur at sub-crustal depths and appear to facilitate the deformation of the crust from time to time.

SEDIMENTARY DYNAMICS OF KASHI DEPRESSION IN TARIM BASIN

LI Tie-Jun and Luo Xiao-rong (Inst. Of Geology, Chinese Academy of Sciences, Beijing, China, 100029)

Kashi Depression is a secondary depression of Tarim Basin in north-western China. On its south and north sides, there are Kunlun Shan and Tian Shan orogenic belts. Influenced by the India-Asia collision, the western Kunlun Shan and the southern Tian Shan were reactivated during Neogene and Quaternary. And these two orogenic belts have overthrusted to Kashi depression during this period. Controlled by the thrust activities and Airy isostatic adjustments, the crust thickness of Kashi depression has been significantly increased, and the present crust thickness ranges between 52 and 54 km.
Accompanied with the emplacement of the foreland thrust- fold belts, the lithosphere in the area was deflected greatly and foreland basins were formed before the western Kunlun Shan and the southern Tian Shan. But it is because the interval between the two orogenic belts was not long enough and the foreland basins couldn't be distinguished effectively. Different from the typical foreland basins, Kashi depression was a composite symmetric foreland basin which was controlled by the two orogenic belts on its southern and northern sides, and the subsidence amount was the sum of the subsidence amounts before the two mountains. According to the studies of seismic data, gravity and magnetotellurics, the Cenozoic sedimentary thickness in Kashi depression are more than 12,000 m and the maximum of Quaternary conglomerate thickness is more than 8,000m, which corresponds to the most intense tectonic activity stage.

HIGH RESOLUTION TOMOGRAPHIC LMAGING IN SOUTH CHINA SEA

ZHU Jieshou, Yan Zhongqun, Cao Jamin, Cao Xiaolin, and Zhang Xuemi (Dept. of Geophysics) Chengdu University of Technology, Chengdu 610059, China, email: zhujs@cdit.edu)

The most of west Pacific marginal basins showed that they were spreading in 32-15 Ma and ended the opening turned to compressible closure after 17-15 Ma. Recently, due to the setting and observing of the global observation system of geophysics and geodesy, it became possible to do seismic tomography in detail to view the three-dimensional structure of the deep interior of the Earth. The high resolution seismic surface wave tomographic imaging for the South China sea and other surrounding marginal basins, such as Sulu sea, Celebes basin and Andaman sea, west Philippine basin. We have collected about more than 500 long period digital seismic records from 7 stations of GSN and CDSN, which located at China, Thailand, Indonesia. The high resolution tomographic inversion had been conducted by processing these surface wave data. The three-dimensional velocity image from earth's surface to 6 00 km depth, ranges from - 1O°S to 3 O°N in latitude and from 94°E to 136°E in longitude.
The image mainly reflects the lithosphere/asthensphere system of the spreading marginal basins. South China sea had a thinning lithosphere (60~70km) and thickened asthenosphere. The very low v@ty also appears in the asthenosphere beneath the basin, which is related with upwelling plume in the upper mantle in west Pacific marginal sea. In contrast the continents and islands go around the South China sea, such as south China block, Indochina block, Sumatra, Java, Philippine, show the high velocity in the lithosphere.

ANOMALIES OF ELECTRICAL CONDUCTIVITY AND ELASTIC PROPETIES OF THE CRUST IN THE SAYAN-BAIKAL PROVINCE THEIR RELATIONS AND NATURE

POPOV A.M.(Institute of the Earth's Crust, Siberian Branch of the Russian Academy of Sciences. E-mail:popov@earth.crust.irk.ru)

There exists a hypothesis that layers of enhanced electrical conductivity in the crust physical and spatially coincide with waveguides. However, detailed analysis of spatial relationship between the two anomalies on the example of the Sayan-Baikal province showed inconsistency of this hypothesis. The crustal conductor observed within the province is evident both beneath the craton and in its tectonically active surroundings between 11 and 55 km below the surface, shallowing up toward the active areas. It is 15-20 km thick and has a conductivity ranging from 100 to 2000 S. The waveguide is absent within the stable Siberian craton but occurs beneath activated areas at depths between 11 and 22 km. It is 5 km thick and laterally discontinuous showing tectonic layering of the medium and a velocity deficit of -0.2-0.3 km/s. Therefore, the two anomalous layers are spatially discordant. It is suggested that the behaviour of elastic and conductive properties of the medium depends on its rheology, fluids playing an active part. Electrical conductivity increases in the brittle-ductile medium favourable for origination of interconnected fluid-filled microcracks whereas seismic velocities there either remain the same (Berge et al.,1995) or likewise increase (Nur, 1974; Petkevich, 1965). Seismic velocities decrease producing a waveguide in the brittle medium (uppermost crust) where cracks are isolated and not, at least fully, filled with fluids. Such a relationship between elastic and conductive properties implies that fractured medium is favourable for origination of the anomalies in point.

ST4/E/60-B1 Poster **0830-10**

KAMCHATKA: DEEP STRUCTURE OF THE AVACHA -KORYAKSKY GROUP OF ACTIVE VOLCANOES BY THE GEOPHYSICAL DATA

MOROZ Yu.F. (Gontovaya L.I., Institute of Volcanic Geology and Geochemistry, FED RAS. Petropavlovsk-Kamchatsky, 683006. Russia (4150058293); e-mail: ivgg@svyaz.Kamchatka.su)

Two 3D models for lithosphere of the area of Avacha-Koryaksky group of volcanoes were developed based on the data of seismology, gravimetry and magnetotelluric sounding; a model of elastic and density properties and a geoelectrical one. It is shown that active volcanoes are confined to the boundary of the lithosphere blocks with various values of P-wave velocity, density and electric conductivity. The first block involves crustal layer of increased electric conductivity at the depth of 25-40km. This layer rises to the depth of (10km in the area of volcanoes. The second block is characterised by the velocity inversion in the middle crust and by the absence of the crustal layer of increased electric conductivity. By seismic data obtained from the explosive source and from the earthquakes beneath active volcanoes two zones are distinguished: zone of increased velocity in the middle crust at a depth of 10-25km and zone of anomalous absorption of the seismic waves under the cone of Avachinsky volcano. A wave guide is fixed in the basement of Avachinsky graben; here zone of anomalously increased values of electric conductivity is also present. Based on the analysis of distribution of the physical parameters in the studied volume of lithosphere, areas of magmatic chambers are revealed: crustal at the depth of 10-20km and peripherical at the depth of 0-2km. The latter is probably connected with the zone of geophysical anomalies in the basement of Avachinsky graben either. Considering pecularities of distribution of the physical parameters in the studied volume of lithosphere a possible mechanism of magma feeding for the volcanoes is suggested. Recent dynamic processes and formation of magmatic chambers are mainly determined by the geothermal solutions penetrating to the upper part of the crust from the depth of 25-40km.

AVERAGE CRUSTAL STRUCTURE OF THE WESTERN BRANCH OF THE EAST AFRICAN RIFT AND RELOCATION OF EARTHQUAKES BETWEEN 1° N AND 12° S

Richard W. FERDINAND (Department of Earth Sciences, Seismology, Uppsala University, Villavagen 16, S-752 36, Uppsala Sweden, email: rf@ geofys.uu.se Thierry Camelbeeck (Royal Observatory of Belgium, Avenue Circulaire, 3, 1180 Brussels, Belgium, email: Thierry.Camelbeeck@mailserv.oma.be)

Arrival time data from 56 regional events recorded by 21 stations of the East and Southern African network and a local network in south-western Tanzania were used in estimation of average crustal model for the region bounding the western branch of East African rift system, between I° N and 12°S. The model is characterised by 38 km crust thickness, with an average velocity of 6.32 km/sec and 3.61 km/sec for P and S waves respectively. Upper mantle velocities for Pn and Sn phases are 8.11 km/sec and 4.67 km/sec respectively. These velocities are not different from those obtained for the African shield. Relocated regional earthquakes using our model show low epicenter errors of less than 10 km. Good agreement between locations of these events and those corresponding and reported by ISC bulletines, demonstrate the importance of these networks to locate regional earthquakes and hence improvement in event location capability in eastern Africa.

INVESTIGATING THE LIGURIAN SEA (WESTERN MEDITERRANEAN SEA) BY MEANS OF LOCAL EARTHQUAKE TOMOGRAPHY

EVA E, Spallarossa D. (Dipteris, Universita' di Genova, Viale Benedetto XV,5, 16132 Genova, Italy, email: elena@dister.unige.it) Solarino S. (Institute of Geophysics, ETH-Hoenggerberg, Zuerich, CH-8093, Switzerland, email: stefano@tomo.ig.erdw.ethz.ch) EVA C. (Dipteris, Universita' di Genova, Viale Benedetto XV,5, 16132 Genova, Italy, email: elena@dister.unige.it)

In the last decade the knowledge and quality of seismological data for the Ligurian Sea greatly improved due to several seismic surveys conducted both off and on shore and especially due to the installation and running of a permanent seismic network equipped with 1C and 3C stations. The revision of the seismic catalogue, completed by waveforms and phase picking provided by the surrounding networks, and a quite restrictive selection on the data yielded a high quality dataset that has been used to improve the knowledge of the role of the Ligurian Sea in the Mediterranean region. Computation of a reference velocity model and tomographic inversion of local earthquakes data lead to a detailed frame of the distribution of velocity structure. As a consequence, reliable three dimensional locations constrained the map of seismicity for the area. Computation of focal mechanisms using 3D velocity models outlined the distribution of forces acting on this puzzling area. Basically, it turns out that seismicity affects the foot of the continental slope in correspondence with some crustal faults while another seismicity band seems to delimit the northern side of the Corsica block. Tomographic images outline a very shallow Moho in the center of the Ligurian Seadeepening down to 25 km beneath the coastal regions.

ST5/E27-B1 Poster **0830-13**

VELOCITY HETEROGENEITIES OF EARTH CRUST AND SEISMICITY (TIEN-SHAN)

Tamara SABITOVA and Albina Adamova (both at Institute of Seismology, National Academy of Science, Asanbai 52/1, Bishkek 720060, Kyrgyz Republic, email: kis@imfiko.bishkek.su) Oksana Lesik (Experiment-Methodical Expedition of IVTRAN RAS, 720049, Bishkek 720049, Kyrgyz Republic, email: olesik@gdirc.ru)

Complex analysis of deep structure data has been carried out for the kyrgyz part of Tien-Shan. based on results of tomography imaging (P- and S- wave velocity variations maps for each of the crustal and uppermost mantle layers, velocity sections) and subsequent zoning of region under investigation on type of velocity sections. Epicenters map considering the earthquake intensity shows the seismic activity over period from 0001 till 1998.
It is shown that there are some differences in velocity variations which are characteristic for crust structure of strong (M>6.5) and moderate (M=5-6) earthquakes focal zones. Strong earthquakes originate, as a rule, in layered crust, for which were revealed following features: high gradient zones with low velocity layer at different depth levels, and mainly in lower crust (35-50km) and subvertical weakened channels. Focal zones of moderate events also confined to contacts of different velocity blocks in upper crust (0-20km). These contacts sometime are zones of known faults, dividing different geological blocks. In that reducing of velocity and existence of subvertical weakened channels can not be observed. Background seismicity (M<5) apparently connected with less marked velocity heterogeneities.
Mentioned patterns allow to account for difference in observed source location for strong and moderate events: few strong earthquakes look as if they contour the region under study reflecting by it the presence of low velocity zone over most part of Northern and several areas of Southern Tien-Shan; high seismic activity zone (and epicenters density) being located in Southern Tien-Shan, indicates strongly marked mozaic structure of upper crust of this region.

3-D VELOCITY TOMOGRAPHY OF THE CRUST AND THE UPPER MANTLE IN THE CENTRAL KOREAN PENINSULA AND ITS VICINITY

So Gu KIM (The Seismological Institute, Hanyang University, Ahnsan, Kyonggi-do, 427-791, South Korea; Tel: +82-345-400-5532; Fax:+82-345-400-5830, email sogukim@mail.hanyang.ac.kr) Qinghe Li(Lanzhou Seismological Institute, SSB, Lanzhou, 73000, China)

Pg, Sg, PmP, SmS, Pn, and Sn arrival times of 32 events with 404 seismic rays are inverted for location and crustal structure. 5 (1? along the latitude)* 6 (0.5? along the longitude)* 8 block (4 km each layer) model was inverted. 3-D seismic crustal velocity tomography including eight sections from the surface to the Moho, thirteen profiles (but only eight presented here) along latitude and longitude, the Moho depth disribution was determined. (1) the average velocity and thickness of sediment are 5.15 km/sec and 3-4 km, and the velocity of the basement is 6.12 km/sec. (2) the velocities fluctuate strongly in the upper crust and those of the lower crust under Conrad appear horizontal. (3) the average depth and velocity of the Moho are 29.8 km and 7.97 km/sec. (4) the Chugaryong Rift Zone can be located from the cross section profiles. (5) we note that there are big anisotropy bodies near Hongsung and north of Seoul in the upper crust, implying that they may be related to the Chugaryong Rift Zone and deep fault systems, respectively.

From 3-D velocity tomography in the upper mantle, we found that the Benioff-Wadati subduction zones are dipping about 30 degree up to 700km in the east side of the Korean Peninsula, and there are low velocity anomalies in the upper mantle, especially near Mt. Paektu indicating that they may be related to the low velocity bodies of partial melting. 660km- and 410km discontinuities are also found to be in the inner continental side and in the outer continental side of the the East Sea(Japan Sea), respectively.

SEISMIC TOMOGRAPHY IMAGES OF THE QINLING-DABIE OROGENIC BELT

SUN Ruomei, LIU Futian, LIU Jianhua, Xu Peifen (all in the Institute of Geophysics, Science Academy of China, 100101 Beijing, CHINA, email: sunrm@sun.ihep.ac.cn)

The Qinling orogen of central China between the Sino-Korea craton and the Yangtze craton began in late Mesozoic. Ultra-High Pressure (UHP) metamorphic rock belt, found in Dabie mountain, is the largest one in the world. We did the P, S wave and Vp/Vs tomographic inversion of North China craton, Qinling-Dabie orogenic belt and Yangtze craton in central China. The results are as follows: 1. The image of the upper crust has a close correlation with surface geology. The North China basin shows obviously low velocity, whereas the orogenic belt expresses high velocity with E-W trend, reflecting old tectonism. However the velocity anomalies at depths 80-110km display a trend in N-S direction, a feature possibly controlled by recent tectonism. 2. The velocity image at depth of 40+ km beneath the Moho shows that the orogenic belt is divided into three sections. West of 108E, the West Qinling displays low velocity anomaly, the crust is thicker than 40km with indications of a mountain root. Between 1080E and 1040E, in the East Qinling, the velocities are high with no indication of mountain root, and the crustal thickness is less than 40km. East of 1040E in the Dabie Mountains, velocities are obviously low, the crustal thickness is not less than 40km. 3.The image in a profile across the Dabie mountain shows a slab-like high velocity anomaly dipping from south to north, that may be remain of ancient subducted block, which break off around 130-170km. The slab breakoff seems the mechanism of recurvature of UHP metamorphic rock.

A MODEL OF LITHOSPHERIC STRENGTH WITH A MINIMUM FOR SEISMOGENIC ZONE

Mitsuhiko SHIMADA (Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University, Uji, Kyoto 611-0011, Japan, email: shimada@rcep.dpri.kyoto-u.ac.jp)

The brittle-ductile hypothesis for seismogenic zones in the intraplate crust (e.g., Meissner & Strehlau, 1982; Sibson, 1984; Ito, 1990, 1993) is principally based on the strength envelope of the lithosphere (Goetze & Evans, 1979; Brace & Kohlstedt, 1980) inferred from laboratory experiments on frictional strength and steady-state creep strength. The hypothesis is also based on the similarity between the strength envelope and the frequency-depth distribution of earthquakes, which implies that the possibility of earthquake occurrence is higher at the depth where the strength of the crust is higher, or that the stronger part of the crust has the ability to generate more earthquakes.
Here, we show a modified model of lithospheric strength inferred from our laboratory experiments indicating that strength values of a granite are unusually low between 200_$Bo__(Band 280_$Bo__(BC with a minimum at around 250_Bo_(B in the high-pressure type fracture regime (Shimada et al, 1983: Shimada & Cho, 1990: Shimada, 1992) that occurs when the compressive strength equals the frictional strength. The lithospheric strength inferred from these experimental results and our previous assumption that the high-pressure type fracture occurs in the crust considering the size effect of rock strength, suggests a low-strength zone between 8 and 12 km depth. This suggestion could provide an alternative explanation for the brittle-ductile hypothesis: earthquakes could occur or nucleate more easily where the strength is low. A similar suggestion has been proposed by a model for the frictional strength profile with a minimum, assuming high (near lithostatic) pore fluid pressure (Streit, 1997). Our model could be applicable to the moderate pore pressure or even dry condition.

ST4/W/59-B1 Poster **0830-17**

USE OF CODA OF LOCAL EARTQUAKES AND SEISMIC NOISE FOR STUDY OF THE EARTH'S STRUCTURE AND MONITORING OF GEODINAMIC PROCESSES

Irina J.TCHEBOTAREVA(Inst. Earth Physics RAS,B.Gruzinskaya 10,Moscow 117234, Russia, email: chari@synapse.ru) Haruo Sato(Dept.Geoph.,Tohoku Un., Aoba-ku, Sendai, 980-8578, Japan, email: sato@zisin.geophys.tohoku.ac.jp)

Conventional methods of study of the structure of the Earth's crust and mantle consider only passive reradiation of seismic energy by structural heterogeneities. They do not consider the seismic component connected with emission from the active volumes of the energy-saturated medium. Our study of coda of local earthquakes and seismic noise shows that both noise and coda contain the emission component from the deep active sources. Method of emission tomography was applied for analysis of the data obtained by "The 1993 Joint Seismic Observation Group in and around the Nikko area"; the dense seismic array composed from 3-component stations was set in the volcanic area in northern Kanto, Japan. Analysis of seismic noise before P wave of earthquakes reveals active volumes emitting a weak seismic signal, the largest of them are connected with the mid-crust magma body and area of large earthquakes. The study of records after the direct S waves shows that coda waves are composed from both a scattered component and emission one induced by the direct waves from earthquake, moreover the scattered component decreases with time and the induced component increases. The volumes of induced emission received from the 'late coda' differ from the scattering structure received from the 'early coda' and are the same as the active volumes detected from seismic noise. The emission radiation from the active volumes is a response to the change in the stress field and can be used for seismic monitoring of geodynamic processes. By means of choice of a suitable frequency band and array aperture we can make study in different scales, from the crustal to the global one.

BASIN FORMING PROCESS AND FAULT DISTRIBUTION AT THE TERMINATION OF THE RIGHT-LATERAL LEFT-STEPPING FAULTS: A CASE STUDY OF OSAKA BAY BASIN, KINKI DISTRICT IN JAPAN

Shigekazu KUSUMOTO (Department of Geophysics, Graduate School of Science, Kyoto University, Kitashirakawa oiwake-cho, Sakyo-ku, Kyoto 606- 8502, Japan. E-mail: kusu@kugi.kyoto-u.ac.jp), Yoichi Fukuda, Keiji Takemura and Shuzo Takemoto (Department of Geophysics, Graduate School of Science, Kyoto University, Kitashirakawa oiwake- cho, Sakyo-ku, Kyoto 606-8502, Japan.)

Osaka Bay basin, Kinki district in Japan, is a sedimentary basin that is filled with Quaternary sediments. This basin is sandwiched between the Median Tectonic Line (MTL) and Arima-Takatsuki Tectonic Line (ATL). These tectonic lines are right-lateral strike-slip faults with reverse component and form a left-stepping en echelon arrangement. Although the right-lateral left- stepping en echelon faults generally develop an upheaval structure at the termination, the Osaka Bay does not fit in the case. In addition, the MTL and ATL have more than one fault at their end with reverse and lateral motion components.
In order to understand the formation of a sedimentary basin at the termination of the right-lateral left-stepping faults, we numerically simulated the behavior and distribution of secondary faults caused by the strike-slip motion. The results of simulations show that 1) the depression structure can be formed only when the secondary fault is reverse and its displacement is larger than 20 % of the lateral motion, 2) faults at the end of the MTL and ATL are developed by the secondary ruptures due to strike-slip motion and 3) distribution of the secondary faults indicates the change of the past maximum compressive stress in Kinki district. We thus conclude that Osaka Bay basin was formed by the evolution of the secondary reverse faults due to the same strike-slip motions.

NUMERICAL MODELING OF A COLLISION STAGE OF CONTINENTAL CRUST FORMATION IN KOLA SUPERDEEP REGION (THE BALTIC SHIELD)

PARPHENUK Olga (Institute of Physics of the Earth RAS, 10 B. Gruzinskaya, Moscow, 123 810, Russia, email: olg@uipe-ras.scgis.ru)

Thermal-mechanical model of continental collision including brittle overthrusting in the upper crust and lower crustal viscous flow is developed and applied to the modeling of the Northern Pechenga formation in the vicinity of the Kola Superdeep borehole along the Luchlompolsky thrust fault (the Baltic Shield). The uniqueness of the Baltic Shield data is defined by the Kola Superdeep drilling results, which give an exellent opportunity to evaluate all the results including seismic interpretation. Finite-element 2- D modeling was used to examine the conditions under which ductile flow of the rheologically layered lower crust and upper mantle can produce the structure with crustal roots and surface uplift as a result of shortening, loading and erosion. The numerical calculations of shortening and overthrusting along the Luchlompolsky thrust fault for the rate of 1 cm/yr during 60 Myrs and erosion rate 0.1 cm/yr demonstrated the possibility of the structural formation with thickened upper crust and progressively increasing level of erosion, which reflects the exhumation of the rocks from different depths to the surface. The shape of the crustal root for the initial deep angle of fault assumed for the structure has the wavelength of topography which can lead to its relaxation by viscous flow.

RELATIVE DISPLACEMENT ACROSS THE FRACTURE ZONE

Keisuke TANIGUCHI (Kyoto University of Education, Fushimi-ku, Kyoto, 612-8255, JAPAN, Email: taniguti@wsml.kyokyo-u.ac.jp)

Geodetic survey and continuous observation of crustal deformation across faults or fracture zones have led to many evidences that crust was consisted of loosely coupled blocks mostly bounded by faults or fracture zones. In order to study the relative movement of two crustal blocks bounded by the fracture zone in the tunnel of Hokuriku observatory of Kyoto University in Japan, three dimensional relative displacement meters were designed and has been set up across that fracture zone since 1986. They have measured tidal and seismic relative displacements between two fixed points in three orthogonal directions. Results are as follows, 1) Tidal strain across the fracture zone was about four times as large as the theoretical, whereas the observed near the fracture zone was only half of the theoretical. Strain seismograms across the fracture zone are from 5 to 15 times as large as at the neighborhood and larger than the calculated strain seismograms with STS type seismographs set up in the same tunnel. 2) The vector of each tidal and seismic relative displacement across the fracture zone is almost fixed at any term. This may be caused by the existence of plane-like fracture zone. 3) Amplification factor is related to propagation azimuth of each earthquake. And dip angle of propagation is smaller, the amplification factor is larger. These results indicate that the change of fracture zone width, in other words, compress- extension motion at the fracture zone causes the amplification of seismic waves. 4) It was confirmed that block bounded by that fracture zone spreads in horizontal. And calculation with FFT indicates that fracture zone extends to several km in dip direction. 5) Seismic waves which frequency are larger than 1Hz only cause the amplification.

THERMAL REGIME AND DYNAMICS OF COLLISION ZONE: RESULTS OF MODELING

Vladimir S.ZAKHAROV (Moscow State University, Geological Depth, Dynamic Geology Chair, Vorobiovy Gory, Moscow, 119899, Russia. Email: zakharov@dynamo.geol.msu.ru)

This paper will report on a quantitative model of mechanical and thermal processes under collisions in rheologically stratified lithosphere (upper elastic crust, lower plastic crust, elastic mantle lithosphere). In the area of collision delamination and subduction of the mantle lithosphere of undermoving plate takes place resulted in the development of plastic deformation in the lower crust. Results of modeling indicate significant (up to 65 km in 20 m.y.) increase of the crust thickness in the collisions area. Though formation of orogen occurs in the condition of general compression, in the central part of orogen on late stages of collisions and in postcollision phase an area of extension arise, connected with gravitational spreading of the formed raising. The dissipative heat generation originates in the process of the lower crust material viscous flow . It brings about heating both the crust and undercrust mantles as well. Simulation of heat regime shows that the area of significant temperature rise on the base of crust (50 - 200oC in 20 m.y.) has a thickness of about 10 km and hundreds of kilometers in other dimensions. Substantially heated (up to 100 oC) an upper part of the mantle lithosphere (near 10 km thick). Temperature of the crust base under wide range of parameters reaches the wet granite liquidus point. The partial melting of the lower crust material has been made possible. Thus, premise conditions for origin of the postcollision granitoid magmatism are formed. This mechanism of dissipative heat generation can also explain the existence of deep metamorphism.

PHASE TRANSITIONS IN THE GROWTH OF CONTINENTAL CRUST

Carlo GIUNCHI (Istituto Nazionale di Geofisica, Via di Vigna Murata 605, 00143 Roma, Italy, Email: carlo@gea.df.unibo.it); Yanick Ricard (ENS Lyon, 46 Allee'd'Italie, 69364 Lyon Cedex 07, France)

We investigate the thermal and petrological behaviour of the continental crust and its growth due to events of continental collision. The evolution of the thermal profile and of an univariant phase transition in the lower crust, during the thickening and the following relaxation and erosion, is computed by a numerical model. In case of fast collision events, the rise of the topography is isostatically favoured, but it is counteracted by a fast transition to the dense

phase. Depending on the density contrast, this may cause even a topographic collapse. The thermal relaxation following the collision is able to trigger the re-transformation of the dense phase, but this time the topographic rise may be affected by erosion rate. We study the interplay between these factors trying to model and to put constraints on the evolution of the topography of mountain belts.

DYNAMIC PROCESSES OF THE STRESS CHANGES IN CENTRAL KYUSHU, JAPAN

Shigekazu KUSUMOTO (Department of Geophysics, Graduate School of Science, Kyoto University, Kitashirakawa oiwake-cho, Sakyo-ku, Kyoto 606-8502, Japan. E-mail: kusu@kugi.kyoto-u.ac.jp), Yoichi Fukuda, Shuzo Takemoto and Keiji Takemura (Department of Geophysics, Graduate School of Science, Kyoto University, Kitashirakawa oiwake-cho, Sakyo-ku, Kyoto 606-8502, Japan.)

The eastern part of central Kyushu is a key area for understanding the tectonic history of Southwest Japan because the region is located at an intersection of tectonic lines and is near an inflection point of the subducting Philippine Sea plate margin. This region is also characterized by gravity lows which are caused by the tectonic and volcanic depression structures. All tectonic depression structures and gravity lows in this region can be restored by considering the following two mechanical processes; 1) the formation of the half-graben under the N-S extension before 1.5 Ma, 2) the formation of the pull-apart basins under the W-E compression after 1.5 Ma.
In order to explain the source of the regional stress field and of its variation, the effects of the convergence direction of the subducting Philippine Sea plate, interplate coupling between the Eurasian and Philippine Sea plates and upwelling flow were evaluated by means of the finite element analyses. The results show; 1) the extension in central Kyushu before 1.5 Ma is not the passive extension but the active extension caused by the upwelling flow, 2) the upwelling flow gives the maximum shear stress of 5 - 6 MPa on the base of the lithosphere and 3) the W-E compression field required in central Kyushu after 1.5 Ma can be explained by the change of the convergence direction of the Philippine Sea plate and the decrease of the maximum shear stress on the base of the lithosphere.

THE CONJECTURAL GEODYNAMIC MODEL OF MODERN DEVELOPMENT OF THE CENTRAL ASIAN REGION

Leonid Bogomolov, Vitaly BRAGIN and Yuri Trapeznikov (all at International Research Center - Geodynamic Proving Ground in Bishkek, 720049, Bishkek, Kyrgyz Republic, E-mail: bragin@laurel.gdirc.ru)

For the Central Asian region, including Gindukush, the distribution of 9-13 class earthquakes was reviewed for 25 years. A choice of energy diapason for earthquakes to be investigated is determined, from the bottom, by their statistic importance for the whole region and from the top, by the sufficiency of quantity of earthquakes for the comparative analysis of their number from year to year on 1œ _ 1œ cells. Spatial time analysis of these seismic events showed, that normalized frequency of origin of earthquakes has a natural spatial distribution in the region remaining from year to year. This is determined, that frequency changing of these classes earthquakes origin occurs in synchronism within the territory under consideration. The calculations made and compared with pattern of earthquakes distribution under observation demonstrate, that it impossible to explain the given picture by transmission of horizontal stresses in resilient plastic substance. The detailed distribution of earthquake origin frequency and earthquake synchronous on time changing within the region can be explained by presence of substance flow in quasi-plastic layer at depths of middle crust - upper mantle and by exposure of this flow to the above-laying levels of crust. The supposition of substance flow presence in quasi-plastic level with roof laying at a depth of 20 and more kilometers is bored out by quantities and directions of the earth's surface movement on the Tien Shan territory ascertained with the aid of GPS measuring and by data about the presence of indivisible conducting horizon received by means of magnetotellurics. The main component of flow has a radial character and a center situated in the Gindukush area and direction outgoing from it.

WEIGHTED STATISTICAL ANALYSIS OF THE OBSERVED GLOBAL STRESS ORIENTATIONS

WEI, Dongping (Graduate School at Beijing, University of Science and Technology of China, P.O.BOX 3908, Beijing, 100039, P.R. China, email: dongping@earth.gsbustc.ac.cn) SENO, Tetsuzo (Earthquake Research Institute, University of Tokyo, Yayoi 1-1-1, Bunkyo-ku, Tokyo 113-0032, Japan, email: seno@eri.u-tokyo.ac.jp)

Over 7000 global stress indicators have been compiled in a digital database in the World Stress Map Project (WSMP). Five qualities from highest quality A to lowest E were defined in WSMP database in ranking the data. Previous study (Coblentz and Richardson, 1995) has presented a statistical analysis of the WSMP stress indicators with the aim of quantifying trends in both the SHmax orientations and stress regimes. The analyses was carried out with 5x5 degree bins which provide a resolution of several hundred kilometres by using 4537 high-quality WSMP indicators with the rating A to C.
In the present study, we mainly deal with the SHmax orientation with the weighted statistical analysis. The WSMP datum with an error of SHmax orientation within 10-15 degree is quality A, within 15-20 degree is B, with 25 degree is C, bigger than 25 degree is quality D, and that with no useful SHmax orientation information is quality E. So here we exclude E type data, and assign different weight coefficients to A-D data on the basis of their qualities of SHmax orientations, i.e. 1/12.5 (12.5 is the mean of 10 and 15), 1/17.5, 1/25 and 1/75 to each A,B,C and D quality indicators, respectively. For simplicity, we convert all these weight coefficients to integers, so here the weight coefficients of 6,4,3 and 1 are assigned to A,B,C, and D quality data, respectively.
We apply a Rayleigh test, a standard statistical method in the analysis of directional data, to check whether the distribution of SHmax orientation in the defined bin is random. An important aspect of this study is the choice of different weight coefficients drawn from quantitative inspection of the WSMP database. We also compare our result with previous study which assigned the same weighted coefficient 1 to quality data A to C. The mean SHmax orientations within the bins are slightly different between the weighted coefficient and equal weight coefficient cases. The average deviation of the average SHmax orientations for all the global plates between these two cases is about 4.8 degrees. However, some continental regions and convergent boundary regions, for example, Baikal rift, Iran plateau, and Aegean Sea regions etc., have relatively large difference up to about 12 degrees for the above two cases. Our analyses also indicate that more bins are rejected as sampling a random distribution at each confidence level. This is because the weighted coefficients strengthen the importance of the stress indicator with a higher orientation accuracy, thus decrease a possibility of random distribution.

REFLECTION AND TRANSMISSION OF LOVE WAVE IN PRESENCE OF SUDDEN CHANGE IN CRUSTAL THICKNESS

A.ROY and R.K.Bhattacharyya (Department of Applied Mathematics, Calcutta University, 92. A.P.C.Road, Calcutta 700009, India. e-mail: aroy@cucc.ernet.in)

In order to investigate the transmission of Love wave through laterally varying structure, we consider the mode conversion of Love wave in presence a sudden change in the layer thickness. The integral equation that arises in the problem is solved by means of Wiener Hopf technique combined with mode matching method. In the limiting case of change when the layer thickness is small, some numerical computation both for transmission and reflection coefficient are given. As a special case we also derive the results for laterally varying structure and also discuss the reflection and transmission of Love wave across a vertical discontinuity between two welded media.

DETERMINATION OF GREEN'S TENSOR FOR A GRANULAR ELASTIC MEDIUM AND APPLICATION TO WAVE PROPAGATION IN A RANDOM MEDIUM

Gayatri Chattopadhyay (Department of Mathematics, Surendranath College, Calcutta 700009, India) and R.K.Bhattacharyya (DST Project, Department of Applied Mathematics, Calcutta University, 92. A.P.C.Road, Calcutta 700009, India. e-mail: aroy@cucc.ernet.in)

Green's tensor for a granular elastic medium is computed and used to study the wave propagation in a random granular elastic medium by employing J.B.Keller's perturbation technique. Four different types of body waves are shown to propagate through the medium. The propagation is affected by random inhomogeneities of the medium. The effects have been calculated in terms of correlation functions. Particular forms of correlation functions are assumed to show that the waves attenuate as they propagate. Numerical results are obtained.

ON WAVE PROPAGATION IN A RANDOM CONDUCTING MAGNETO-VISCOELASTIC MEDIUM

Gayatri Chattopadhyay (Department of Mathematics, Surendranath College, Calcutta 700009, India); Rabindra Kumar BHATTACHARYYA (DST Project, Department of Applied Mathematics, Calcutta University, Science College, Calcutta 700009, India.)

The problem of wave propagation in arandom conducting magneto-viscoelastic medium is investigated by employing perturbation technique. The appropriate Green's matrix has been evaluated and used to obtain the wave velocity equation.It has been shown that the propagation of body waves depends upon the random inhomogeneities of the medium. The expressions measuring deviations resulting from random fluctuations of the material properties have been derived in terms correlation functions between parameters of the medium. The body waves attenuate due to randomness as they propagate through the medium. A numerical solution is being attempted on the assumption of particular forms of correlation functions.

TWO DIMENSIONAL INTERPRETATION OF DIRECT CURRENT RESISTIVITY TRVERSING DATA FOR STUDYING SHEAR ZONE, EASTERN INDIA

K.K.ROY (Department of Geology and Geophysics, Indian Institute of Technology, Kharagpur - 721 302, West Bengal, India, Email: kkroy@gg.iikgp.ernet.in) L.K.Das and K.K. Mukherjee (both at Geological Survey of India, Ratnakar Building, 4, Chowringhee Lane, Calcutta - 700 016) P.S. Routh (Department of Geophysics and Astronomy, University of British Columbia, Vancouver, Cauoda) M.K. Sen and R. Chunduru (both at Institute of Geophysics and Department of Geological Sciences, The University of Texas at Austin, 8701 Mopae Express way, Texas 78759-8397, USA)

Direct current resistivity traversing was done across the Singhbhum shear zone near Ghatshila - Mosabani, Eastern India using the collinear dipole dipole configuration with dipole length of 500m and dipole separation varied from 500m to 6kms. Two-dimensional forward modeling was done using finite difference method and the inversion was done using Very Fast Simulated Annealing and Ridge Regression. The same data were inverted by three different institutions with different software and common features of these three interpretations are accepted with certain degree of confidence. It is observed that important geological signatures along this traverse are reflected in all the models but the geometrical shapes of the high and low resistive zone came different in different interpretations. Singhbhum shear zone is 1.5km thick and dip increases with depth. The shear zone is vertical at a depth of 1km from the surface. The north Singhbhum fold belt composed of Garnet, Kyanite, Silliminate, Staraulite schist is highly resistive and running parallel to Singhbhum shear zone for about 150km. Since the level of nonuniqueness in 2-D inversion is much higher than in 1-D inversion, the same data should preferably be inverted using different software based one different techniques.

TWO DIMENSIONAL DIRECT CURRENT INVERSE PROBLEM USING GENETIC ALGORITHM AND SIMULATED ANNEALING

K.K. ROY and N.S.R. Murthy (both at Department of Geology and Geophysics, Indian Institute of Technology, Kharagpur - 721 302, India, Email: kkroy@gg.iitkgp.ernet.in) B.K. Kumar (MBT, Pune, India) D. Sarkar (School of Geology and Geophysics, University of Oklahoma Norman, USA)

Two dimensional direct current resistivity forward problem was solved developing the source codes in finite difference and finite element modeling. Global optimization methods were used for 2-D inversion. Source codes for Genetic Algorithm (GA) and Very Fast Simulated Annealing (VFSA) are developed by the authors and the programs are tested for simpler structures.
Resistivity traversing data collected across the Singhbhum shear zone near Rajkharswan Singhbhum Archaeon Craton, Eastern India were inverted using both GA and VFSA. The results show that the shear zone is highly conducting and is about 2km thick. Just north of the shear zone highly resistive Proterozoic north Singhbhum fold belt is the prominent feature in the model. 2D resistivity modeling for cultural studies with dipole length of 500m and total electrode separation of 6 to 7km is possible. There are some common features in both GA and VFSA interpretations. Global optimization tools appear to be powerful in 2D inversion. About 50% of the model features may reflect the subsurface.

THE EXCITEMENT OF WAVES IN THE EARTH ATMOSPHERE CAUSED BY A WIND FIELD

A.Pataraya, Z.khvedelidze, A.Chitaladze (Tbilisi State University, Chavchavadze Ave 3, Nanking, Taipei, Tbilisi 380028, Georgia. Email: sciteco@access.sanet.ge)

The experiment of the gravitational and acoustic waves in the Earth atmosphere is investigated in work. The atmosphere is assumed to be an ideally isothermally stratified and the waves excite by the inhomogeneous wind.
The amplitude reaches its maximal value on certain moment. The maximal amplitude of the gravitational wave is larger than that of the acoustic waves. These results can explain the perturbation of the ionosphere before and after the earthquake.

DISCUSSION OF METHOD FOR JOINT INVERSION OF SEISMIC SURFACE WAVES AND GRAVITY DATA FOR THREE-DIMENSIONAL DENSITY STRUCTURE

Chongbing LIU and Jinsheng Ning(both at Department of Geodesy,Wuhan Technical University of Surveying and Mapping,Wuhan,430079,P.R.China, e-mail: cbliu@dns.wtusm.edu.cn), Yushen Zhang (at Institute of Geophysics, Academia Sinica, Beijing,100101,P.R.China)

Seismic surface waves have been a very useful tool to study the Earth's upper mantle. But as a geophysical inverse problem, inversion of seismic surface waves can only reach a non-unique solution.In order to reduce the nonuniqueness, one important approach is to increase the data set, namely, include data of other disciplines into the inversion.In this paper,a method for joint inversion of seismic surface waves and gravity data,is proposed and formulated to investigate three-dimensional density structure of the upper mantle.The results of simulation experiment indicate that (1)the inclusion of gravity data can reduce the number of relatively small singular values of the kernel coefficient matrix,(2)the trade-off curve of joint inversion is located left-down to that of inversion using seismic data only, and both the variance and resolution of the solution estimation of joint inversion are improved, and(3) the resulting three-dimensional density structure of joint inversion approach to the theoritical density model closer than do that of inversion using seismic data only, especially within the depth range of 0~300km. Using this method, a three-dimensional density structure of upper mantle in North China is constructed,and the result is of interesting tectonic implication.

HEAT FLOW AND THERMAL HISTORY OF YINGGEHAI BASIN, SOUTH CHINA SEA

XIONG Liang-Ping , He Li-juan and Wang Ji-yang (Institute of Geology, Chinese Academy of Sciences, Beijing 100029, China, E-mail: JYWLPX@public3.bta.net.cn)

Yinggehai Basin is a shearing-extensional basin in South China sea. Based on temperature measurements in 56 wells and thermal conductivity determinations on 68 rock samples, mean heat flow value has been calculated and it turns out to be 84.1 mW/m2. This is the highest value so far observed in oil-gas bearing basins in China. The high heat flow is the results of three-phase extension of the basin since Cenozoic era. The first-phase extension occurred during 50-45 Ma followed by thermal subsidence till 28 Ma. The second-phase extension happened during 28-22 Ma and the third-phase extension, 5.2-1.9 Ma After every extension, the basal heat flow at the bottom of the basin has been raised, starting from 60 mW/m2 and reaching the highest value of 72 mw/m2 at 1.9 Ma. If the radiogenic heat from the thick sediments is added, the surface heat flow may reach up to about 80 mW/m2 which is consistent with the observations. Another words, the Yinggehai basin is becoming hotter and hotter after every extension and the highest value is observed nowadays.

TEMPERATURE REGIME IN THE SURFACE RUPTURE ZONE OF THE 1993 LATUR EARTHQUAKE, INDIA : RESULTS FROM DRILLING

Sukanta ROY and R U M Rao (National Geophysical Research Institute, PO Bag 724, Uppal Road, Hyderabad 500 007, India, email: postmast@csngri.ren.nic.in)

Faults associated with shallow focus earthquakes are often associated with a complex configuration of fractures in the near surface zone. Drilling in such zones may connect two previously unconnected fractures causing vertical movement of water (and heat) inside the borehole. Precise temperature measurements made in boreholes clearly reveal zones of entry and/or exit of water causing characteristic perturbations in the temperature field over the affected depth sections. The 1993 Mw 6.1 Latur earthquake had a centroid depth of 2.6 km and was associated with a surface rupture zone (SRZ) near Kilari. Detailed seismological, soil-gas helium and drilling investigations in the area confirmed the existence of a thrust fault dipping SSW at 50 degrees. Two boreholes, KLR-1 and KLR-3, on the hanging wall, penetrated the entire 338 m flood basalt cover and KLR-1 was deepened into the Archaean granite-gneiss basement up to 617 m. KLR-2 was drilled up to 270 m on the footwall. Heavy loss of drilling fluids, poor core recovery and slickensides characterised the depths where the fault was met with in the holes. The temperature profiles for all the holes revealed a "constant temperature zone (CTZ)" up to a depth of ~262 m after which they tend to return to normal formational temperatures. This is attributable to entry of water in the holes at shallow depths and its exit through a major fracture zone around 262 m. The basaltic section below 300 m and the granite-gneiss basement section yielded undisturbed temperature profiles and identical heat flow values. Three other holes located outside the SR in the Killari area yielded undisturbed temperature profiles pointing to the uniqueness of the perturbations in the SRZ.

HYDROGEOLOGY OF THE UPPER CRUST NEAR KOLA HOLE - GEOTHERMAL ASPECTS

MILANOVSKY Svet (Institute of Physics of the Earth, Moscow, email: svet@uipe- ras.scgis.ru, Moscow,) L. V. Borevsky (HYDEC Research Company, Moscow), V. I. Morgachev and V.N.Orlov (both Pechenganickel Kombinat, Nickel)

The paper presents data about hydro-geothermal field in crystalline rocks of the upper crust. These data were obtained during long term field observation in prospecting holes drilled on the territory of copper- nickel ore deposit which belongs to Pechenga Structure of Baltic Shield. Our interest to this study was stimulated by results of Kola superdeep drilling project. In the area of Kola hole we have the unique opportunity to investigate in details relationship between space peculiarities of thermal field, hydrogeology, fracturing of crystalline rocks and stress-field . In many prospecting holes situated near Kola hole we analyzed thermal field, hydrogeodynamics and geochemistry of groundwater. The zone of exogenous fissuring about 800m (up to 2000m) depth was established by hydrogeological study on Pechenga and Kola Peninsula as well. The observed thermal field seems to be closely connected with permeability (cracked-tie) of metamorphic rocks belonging to this zone. For the upper, fractured crust we observe: increasing with depth thermal gradient and heat flow, neg- correlation between filtration coefficient and geothermal gradient, space inhomogenity of geothermal and filtration parameters, reflecting anisotropy of transport properties of fracture system. The permeability of this zone depends on tectonic and lithological factors. The result of the study of space peculiarities of permeability in the upper crust gives us an opportunity to take out realistic parameters for numerical model of heat- mass transfer.

JOULE HEAT DISTRIBUTION AND GEOTHERMAL ZONES

Xiaoqing GAO(Lanzhou Institute of Plateau Atmospheric Physics,CAS, 730000 Lanzhou, P.R.China, email: xqgao@lzu.edu.cn); Giovanni P Gregori(Istituto di Fisica dell'Atmosfera, CNR, 00133 Rome, Italy, email: gregori@atmos.ifa.rm.cnr.it)

According to the Geodynamo Theory, electric current exists in the Earth. It can produce heat because of the resistance of the material of the Earth.This electric current can be derived from geomagnetic field data or model. Till now, the best geomagnetic field model(MAGSAT) was gotten by satellite global observation in 1979-1980. By this model, the global distribution of Joule Heat on ALB(Asthenosphere-Lithosphere Boundary) (direct proprotion to electric current square) had been gotten.It is surprisingly found that the distribution of Joule Heat on ALB matches the global geothermal zones very well.And the strongest Joule's Heating is located below Tibet Plateau, the youngest and the highest plateau on the Earth. It seems that the geothermal heat mostly comes from ALB, it is contralled by Joule's Heating process.

GEOTHERMAL GRADIENT VARIATIONS IN SOUTHERN IRAN AND ITS EFFECTS ON HYDROCARBON MATURATION

JAMSHID HASSANZADEH (Institute of Geophysics, Tehran University, P.O. Box 14155-6466, Tehran, Iran, email: jhassan@chamran.ut.ac.ir); Minoo Kosarian (Institute of Geophysics, Tehran University, P.O. Box, 14155-6466, Tehran, Iran, email: minoo@iman.ut.ac.ir)

A preliminary geothermal gradient map of Iran is constructed using all bottom hole temperatures previously measured in drill holes for oil, gas, and coal explorations. Data from few geothermal fields in N and NW Iran are also included in this map. With the exception of Zagros simply folded belt and the Persian Gulf, the geothermal data are generally sparse for the rest of the country. The range and pattern of gradient variations in Iran is far more complicated than inferred from the global heat flow map. Geothermal gradient contours in the Zagros generally run parallel to the folding axes and values increase to the south (from ~ 10 C/km in the northern folded Zagros to ~ 40 C/km in the southeastern part of the Persian Gulf). Moho depth decrease in the same direction. The Qatar-Kazeroon lineament divides the Zagros-Persian Gulf area into two zones with different thermal gradients. To the east of this divide, average gradient is remarkably higher than in the western Zagros. The regional thermal anomaly in the east is due to the Infracambrian Hormoz salt series intruding the overlying strata. Salt, in general, is a very effective heat conductor; however, the Hormoz salt has also a great potential of radioactive heat generation due to its abundant uranium-rich rock fragments. The abnormal heat flow explains the dominance of gaseous hydrocarbons in the eastern Zagros-Persian Gulf region. This is an example of shallow source for surface heat flow on the edge of a cold continental shield.

HEAT FLOW IN THE ALGARVE BASIN, SOUTH PORTUGAL

M. Rosa DUQUE (Departamento de Fisica, Universidade de Evora, Rua Romão Ramalho 59, 7000 Evora, Portugal, email: mrad@uevora.pt)

The Algarve Basin is a Mesozoic-Cenozoic sedimentary basin located in the South of Portugal, with an East-West axis extending mainly in the offshore areas. This basin evolved in a constrictive compressive stress field during the Quaternary but its positive and negative vertical movements are mainly flexural, possibly associated with deep located lithospheric mechanisms.Two heat flow values were obtained in boreholes Ruivo 1 and Algarve 1. This values were obtained using BHT values and thermal conductivity data from thermal conductivity tables. In this work, the heat flow in this basin is analysed using data from five boreholes drilled for oil prospecting. Temperature data were obtained from BHT measurements. Gamma-ray logs were used to obtain heat production from radioactive elements in the region. Samples from one borehole were used to obtain thermal conductivity data in laboratory. Information about porosity was obtained from sonic and formation density logs.An estimation of the heat flow and temperature values at the bottom of the basin was found from heat flow values obtained in the holes and heat generated in the basin.

THE NUMERICAL SIMULATION OF COUPLED FLUID FLOW, TEMPERTURE AND PRESSURE IN YINGEHAI BASIN

XU Hehua, Zhang Jian, Xiong Liangping (Institute of Geology , Chinese Academy of Sciences, Beijing)

The numerical simulation is a useful method in quantitative analysis of sedimentary basin. During basin evolution, all kind of observed variables interplay and influence each other. It is very important to couple temperature, pressure and flow in basin modeling. In this paper£¬the nonlinear numerical modeling method to couple temperature, pressure and flow is introduced. Yingehai Basin in South China Sea is rich in oil and gas with high temperature and high over-pressure, so temperature, pressure and flow is of nonlinear relation. We apply this numerical model to simulate fluid migration in Yingehai basin. Finite element method is adopted in solving control equation. Results of calculation indicated that this numerical modeling is applicable in Yingehai basin. In Dong-Fang 1-1 structure, there exits large-scale movement of hot liquid with high temperature and high over-pressure. The movement of hot liquid is either horizontal or vertical. The fluid passage of hot liquid is at depth of 1250m to 1550m along fratures caused by mud dipire. We simulated the effect of seepage to thermal evolution and the results indicated that the flux of liquid is an important factor to the temperature distribution.

THERMAL HISTORY OF TARIM BASIN DERIVED FROM FISSION TRACK ANALYSIS

WANG shejiao(Research Institute of Petroleum Exploration and Development Xue Yuan Road 20 Beijing 100083,P. R. China, email: sbhu@mail.igcas.ac.cn)

Thermal history and timing of hydrocarbon generation of the Tarim Basin are evaluated by fission track analyses. The results show that the temperature-gradient during late Paleozoic is very high which is caused by igneous activities in the basin. Cooling from elevated palaeotemperature was caused by late Permian and late Triassic uplift and erosion of 0.8¡À0.2km and 1.0¡À0.2km respectively. The increase of temperature during Cenozoic was due to the rapid depression corresponding to foreland basin. The timing of hydrocarbon generation can be determined. The main source rocks of Cambrian and Ordovician passed into the oil generation window during the middle Paleozoic and into the zone of gas production during the middle Mesozoic. At present, most of these source rocks are still in the zone of gas production but part of them are in the zone of dry gas production. As another important source rocks, Triassic and Jurassic have not been heated enough to be mature at present time, only in the Kuche depression, north part of the Tarim Basin, the source rocks passed into oil window. by fission track analyses. The results show that the temperature-gradient during late Paleozoic is very high which is caused by igneous activities in the basin. LITHOSPHERIC THERMAL STRUCTURE AND EVOLUTION OF THE TRANSYLVANIAN DEPRESSION - INSIGHTS FROM NEW GEOTHERMAL MEASUREMENTS AND MODELING RESULTS

Crisan DEMETRESCU (Institute of Geodynamics, 19-21 J.L.Calderon Str.,R-70201, Bucharest, Romania) Soren Bom Nielsen (Department of Earth Sciences, Geophysical Laboratory, The University of Aarhus, Finlandsgade 8, DK-8200 Aarhus N, Denmark) Mirel Ene, Delia Zemira Serban, Gabriela Polonic, Maria Andreescu (all at The Institute of Geodynamics, 19-21 J.L.Calderon Str., R-70201, Bucharest, Romania) Aurel Pop (ROMGAZ-SA Medias, Romania) Niels Balling (Department of Earth Sciences, The University of Aarhus)

The surface heat flow density pattern of the Transylvanian Depression (TD) represents a marked high amplitude short wavelength low in a region of generally elevated heat flow. Detailed temperature-depth profiles obtained by continuous temperature logging in 24 thermally stabilized wells to a maximum depth of 1400 m, combined with a finite element modeling of topographic and fluid flow effects support the conclusion that the observed thermal gradient in the TD truly represents the rate of heat loss of the subsurface. Modeling results show that the transient effects of sedimentation and erosion mean an overall 5-7 mW/m2 reduction in heat flow compared to the steady state value and that a low mantle heat flow and a low crustal heat production rate in the TD are necessary to explain the heat flow anomaly. The shape of the Neogene depression is roughly circular with radius 60 km with sediment thickness increasing toward the centre where it reaches more than 4000 m. A system of roughly circular faults borders the basin. The TD has a length scale in all directions which is similar to the thickness of the lithosphere and calls for three-dimensional modeling. As a first approach we invoke a rheological lithosphere model of alternate radial compression and extension to model the Neogene subsidence. The compressional phases are related to the Old Styrian (20-17 Ma), Young Styrian (16-15 Ma) and Moldavian (13-11.5 Ma) tectogeneses active in the Carpathians, while weak extensional phases account for the uplift of the basin in Pannonian (5.5-0 Ma).

DEEP-SEATED GEOTHERMAL RESOURCES SURVEY PROJECT IN THE KAKKONDA GEOTHERMAL FIELD, JAPAN

Takao OHMINATO, Yasukuni Okubo, and Kouhei Akaku (New Energy and Industrial Technology Development Organization, Sunshine-60, 3-1-1 Higashi-Ikebukuro, Toshima-ku, Tokyo, Japan, email: ominatotko@nedo.go.jp, okuboysk@nedo.go.jp, akakukhi@nedo.go.jp)Nobuo Doi (Japan Metals and Chemicals Co. Ltd., 72 Sasamori, Ukai-aza, Takizawa, Iwate-gun, Iwate, Japan, email: doi@geothermal.co.jp)

The New Energy and Industrial Technology Development Organization (NEDO) has been conducting a research project named "Deep-Seated Geothermal Resources Survey" since 1992 in order to establish a desired direction for development of deep geothermal resources which exist beneath the already-developed shallow reservoirs. Deep wells WD-1a (3729m) and WD-1b (2963m, side tracked from WD-1a) were drilled in the Kakkonda geothermal field, north-eastern Japan, for this project. WD-1a penetrated Quaternary granite body named Kakkonda Granite for about 870m and reached the temperature over 500C. WD-1b encountered highly permeable fracture zone, which WD-1a missed.
Various types of survey methods, including well geological survey, well loggins, electro-magnetic survey, and micro-earthquake monitoring have been conducted and new results have been obtained; (1) Highly permeable fracture system is not observed in the region hotter than 400C, suggesting that this temperature corresponds to the limit of the productive geothermal reservoir, (2) Beneath the swarms of micro-earthquake hypocenters, deep drillholes, including Wd-1b, often encounter lost circulation which indicates the existence of productive zone,(3) Hypocenter distribution of micro-earthquakes has a lower limit which corresponds to the temperature range of 320-350C.At the well WD-1b, production tests were also conducted and geochemical samples have been obtained, as well. More detailed analyses are now going on and the series of results of this project will be used to make guidelines for the development of deep-seated geothermal resources all over Japan.

GEOTHERMAL GRADIENTS AND ESTIMATES OF THERMAL STRUCTURE OF THE JAPANESE ISLANDS

Yasukuni OKUBO, Akiko Tanaka and Yusaku Yano (Geological Survey of Japan, 1-1-3 Higashi Tsukuba Japan 305, email: okubo@gsj.go.jp)

Geothermal gradients have been estimated from temperature logging data of 1809 drillholes and heat flow data of 108 sites in the Japanese Islands. Most of the geothermal gradients in volcanic areas are greater than 100 K/km. Non-volcanic areas, on the other hand, represent values less than 30 K/km. A spatial mesh data set of geothermal gradient is created by the two-dimensional interpolation of spline fit from the measured geothermal gradients. Although the measured data include errors, the high density data coverage allows one to delineate the regional geothermal structures of the Japanese Islands. Then the depths of 350 deg. and 580 deg. isotherms are mapped based on the following assumptions: (1) 10 deg. at the ground level; (2) a one-dimensional and steady state model; (3) constant thermal conductivities of 2.5 W/m K for the upper crust and 2.0 W/m K for the lower crust; (4) constant heat productions of 1.5 mW/m3 for the upper crust and 0.15 mW/m3 for the lower crust. Comparison with the thermal structure indicates that the Curie point depths deduced from magnetic analysis represent the 580 deg. isotherm. The map of 350 deg. isotherm, which could correspond to the cutoff depth of seismic activity, marks shallow depths in the volcanic areas and varied depths in the surrounding areas.

HEAT- AND FLUID-FLOW AT THE SOULTZ HOT-DRY-ROCK SYSTEM IN THE RHINE GRABEN

D PRIBNOW and C Clauser (both at: Joint Geoscientific Research Institute GGA, Stilleweg 2, 30655 Hannover, Germany, Email: dan.pribnow@gga-hannover.de)

Hot-Dry-Rock (HDR) is a concept for using Earth's heat as an energy resource. An artificial underground heat exchanger at a depth of 3.0 to 3.5 km has been created in the granitic basement of the Rhine Graben, close to the town of Soultz in France, by hydraulically connecting two deep boreholes over a horizontal distance of 500 m with the hydrofrac-technique. During a 4-month circulation test, over 240,000 m3 of water have been injected and produced at flow rates of 20 to 25 l/s and with outflow temperatures above 140 degC. The net output of thermal power exceeded 10 MW. The experiments indicate that the circulation system in the underground is hydraulically open.Numerical models of coupled heat- and fluid-flow help to understand the observations. At the regional scale, previous models suggested deep fluid circulation from East to West through a sandstone aquifer across the Rhine Graben causing a heat flow anomaly at Soultz. This is in contradiction to recent geochemical analyses of pore fluids. Models of the regional flow-system that agree with the pore-fluid chemistry include deep flow through the granitic basement. These models show that in the area of the HDR heat exchanger fluids generally move upwards. The results of the regional simulations are incorporated as boundary conditions in a local 3-D model of the underground heat exchanger at Soultz. This model is based on flow of two kinds: (1) Darcy-flow in the artificially fractured (stimulated) areas of the granite and (2) channeled flow on natural faults. The stimulated volume is a heat exchanger in the classical HDR concept: it is the hydraulic connection between injection and production hole and it provides the surface for heat absorption of the fluid flowing through the fractured rock. Additionally, the hydraulic fracturing of the granite created a connection with the regional fault system of the graben. Although not part of the HDR concept, this extension of the involved hydraulic system improves the long-term heat extraction process because the regional fault system acts as a buffer for temperature and pressure. The numerical models are used to predict the performance of a pilot plant that is planned to utilize an underground heat exchanger at 200 degC.

INFLUENCE OF WATER AND DRILLING FLUID ON THE STRUCTURE AND PERMEABILITY PROPERTIES OF METAMORPHIC ROCKS AT THE DEPTH 7-12 KM IN KOLA WELL

Abdrakhimov M.Z. (RIC "GERS", Tver), MILANOVSKY Svet (Institute of Physics of the Earth RAS, Moscow, email: svet@uipe-ras.scgis.ru) and M.Z.Traskin (Moscow State University)

A number of data obtained at the Kola Superdeep well give the evidence of rock volume discompaction in-situ below 7-8 km: low seismic velocities, high porosity, increasing drilling rate and hole cavity, core disking, etc... The series of experiments connected with thermo-barotest of rocks for in-situ conditions at various depths of Kola well has confirmed the assumption that on depth 10-12 km, rocks in environment of water or drilling liquid, can tend to discompaction of rocks. We observed pronounced fluid-induced embrittlement effects on amphibolite and gneiss specimens strength was reduced to about a half of the initial value. It enabled us to estimate surface energy decrease and adsorption on the basis of Griffith brittle fracture criterion and Gibbs adsorption isotherm. Microstructure researches of core have shown, that that its specific features in particular the frequent occurrence of intergranular microcracks increasing with depth from 9 to 12 km are consistent with the hypothesis about the Rehbinder effect or stress corrosion as the mechanism of spontaneous penetration of drilling fluid along grain boundaries under Gibbs-Smith condition. Our study have demonstrated that the surface activity of water as the principal constituent part of the drilling fluid, combined with elevated temperatures and differential stresses, contributes to the development of intergranular micricracks under conditions for the lower part of superdeep well.

LONG-TERM TEMPERATURE MEASUREMENTS IN THE VOROTILOVO DEEP GEOLABORATORY

Yuri POPOV (Moscow State Geological Prospecting Academy, Miklukho- Maklai str., 39-1-191, Moscow 117485, Russia, email: Yupopov@mgga- sec.msk.ru) Lev Pevzner ("NEDRA", State Scientific and Industrial Enterprise on Superdeep Drilling, Svoboda str. 8/38, Yaroslavl 150000,Russia, email: root@nedra.yar.ru)

Data on spatial and temporal variations of temperature and temperature gradient in the Vorotilovo deep borehole (5374m in depth, without a casing tube, drilled in 1989-1992 in the Puchezh- Katunk impact structure, Russia) were inferred from 28 temperature logs obtained in 1992-1998. At present the thermal regime of the strata can be considered to be close to equilibrium. The maximum temperature value is about 98 C. Different rate of thermal equilibrium restoration for various depth intervals of the strata was observed. Regular temporal variations in temperature gradient within the depth interval of 3700-4800m are negligible inspite of a monotonous increase in temperature (by 4-6%). Significant systematic changes in temperature gradient value are being observed within the depth interval of 0-1700 m although there are short depth intervals with insignificant temporal variations in temperature gradient.
Basically a degree of temporal changes of temperature gradient decreases with depth and corresponds to a decrease in rock porosity values. Dependence of vertical variations in temperature gradient on borehole diameter changes and some technological factors are found out.

USING HELIUM ISOTOPE RATIO TO ESTIMATE CRUST AND MANTLE COMPONENTS OF SURFACE HEAT FLOW

Yang WANG (Lab. for Geothermics, Institute of Geology, Chinese Academy of Sciences, P.O.Box 9825, Beijng 100029, China, email: thalassa@263.net)

The ratio between crust and mantle heat flow component(Qc/Qm) can be estimated by helium isotope ratio (He3/He4). He4 is the product from decay of uranium and thorium; and He3 comes from mantle by degassing. Because U and Th (and K) mainly concentrate in crust, so He4 is approximately proportional to the heat flux of crust. He3 is associated with mantle heat flux. However, the specific relations between heat flux and He3 or He4 flux may be considerably modified by transport processes. But the He3/He4 ratio can be used to constrain the Qc/Qm ratio. Using the He3/He4 ratio and Qc/Qm data in basins of North China and Eastern China, and that of MORB, which He3/He4 ratio is 8 RA(atmospheric He3/He4 value) and Qc/Qm approximately equals zero, we obtain the relation between He3/He4 and Qc/Qm:Qc/Qm=0.87-0.39*log(He3/He4) (1) in which the unit of He3/He4 is RA. Furthermore, the crust and mantle heat flow components can be taken from surface heat flow and Qc/Qm value. We had used formula (1) to estimate the crust heat flow(Qc) and the mantle heat flow(Qm) for some terrains in China. The Qc and Qm are ~70 and ~30 mW/m/m in South Tibet; and in Tarim Basin they are ~30 and ~14 mW/m/m respectively; and in Sichuan Basin, Qc equals ~39 mW/m/m, Qm is ~16 mW/m/m; but they are ~31 and ~39 mW/m/m respectively in Songliao Basin, NE China. Our results were confirmed by previous geothermal studies. Helium isotope ratio(He3/He4) may be a useful parameter for separating crust and mantle components from surface heat flux.

SEPARATING SHALLOW AND DEEP COMPONENTS OF SURFACE HEAT FLOW BY WAVELET TRANSFORM

Yang WANG (Lab. for Geothermics, Institute of Geology, Chinese Academy of Sciences, P.O.Box 9825, Beijing 100029, China, email: thalassa@263.net)

The surface heat flow are superposition of some components which correspond to different sources within the Earth. The large scale feature of surface heat flow field corresponds to deep source (i.e. mantle) because lithosphere is a low-pass filter for conductive heat; and the small scale feature of the field is related to shallow processes due to the heterogeneity of thermal properties in crust. It is necessary to decompose the heat flow field into different scales in order to separate shallow and deep heat flux components. Wavelet analysis is a powerful tool for field decomposition, because of the local feature of wavelet functions; and it was tested by numerical experiment. Based on Mallat's pyramidal algorithm, we developed the code for 1-D multiscale analysis which are then applied to decompose the heat flow profile along East European Geotraverse 5 (EEGT5) and the profile along 115 degree E in China. The decomposition produces a series of heat flux component profile related to different scales. Among these results, the high order details of the wavelet transform (e.g. D6) correspond to the heat flux of 60 km depth; the low order details (e.g. D3) is related to crustal heat flux; and the base function of wavelet transform (e.g. A6) reflects the trend of heat flux change along the profile. The decomposition result of EEGT5 profile shows that, the main component of heat flow in Pannonian Basin comes from mantle, and mantle heat flow decreases toward east and west; the relative high surface heat flow in Saxothuringicum and Eastern Carpathians are due to high crustal heat flux which corresponds to the thick crust or high heat production in crust. The decomposition on 115 degree E in China demonstrates that, the mantle heat flow beneath Northern China is higher than that beneath Southern China; but the crustal heat flow of Southern China is much higher than Northern China. Previous studies on EEGT5 and China confirmed our results (Shen et al.,1990, Wang J. et al.,1996).

HEAT FLOW, SEISMICITY AND CRUSTAL STRUCTURE IN SOUTH PORTUGAL

M. ROSA DUQUE, José F. Borges and Maria João Costa (Physics Department, University of Evora, Rua Romao Ramalho 59, 7000 Evora, Portugal, email: mrad@uevora.pt)

The Variscan Fold Belt SW suture zone in Iberia involves several different units. From South to North we find: the South Portuguese Zone (SPZ), the Pulo de Lobo Formation (PLF), the Beja-Acebuches Ophiolitic Complex (BAOC), the Beja Igneous Complex (BIC) and the Ossa Morena zone (OMZ).
Aeromagnetic data suggest the existence of continental crust under the OMZ and SPZ forming a thin plate over a décollement zone. The SPZ corresponds to an accretionay prism that evolved to a typical foreland thrust belt with décollement of Carboniferous to Upper Devonian sediments above a Pre-Upper Devonian Paleozoic sedimentary sequence resting on a Precambrian basement. A Variscan suture that evolved to a continent-continent collision exists between the OMZ and SPZ. Flake tectonics in the Lower Devonian produced obduction to the North folowed by a subduction in the same sense.Several heat flow data obtained in boreholes drilled for mineral prospecting were used in this work. Seismicity and hypocenter location in the area were studied and compared with heat flow density values. Temperature values at the surface, estimated from boreholes, were compared with surface temperature values obtained from other sources of data. Crustal structure in the region was obtained from seismic and MT data. Geotherms for the region were calculated and a preliminary rheological model for the SPZ was obtained.

CONTACT METAMORPHISM OF SEDIMENTARY STRATA BY A BASALTIC SILL: COMPUTER SIMULATIONS AND GEOLOGICAL EVIDENCE

J. Safanda (Geophysical Institute, CZ-14131 Praha, Bocni II/1401, Czech Republic, email: jsa@ig.cas.cz); V. Suchy and K.Melka (Geological Institute, CZ-16500 Praha, Rozvojova 135, email: suchy@gli.cas.cz); I. Sykorova (Inst. of Rock Structure and Mechanics, CZ-18209, email: sykorova@alpha.irsm.cas.cz); P. Dobes (Czech Geological Survey, CZ-11821 Praha, Klarov 3/131, P.O.B. 85); M. Stejskal (Chemical Univ., Dept. of Oil Technology and Petrochemistry, CZ-16628 Praha)

Thermal influence of a 4 m-thick basaltic sill on adjacent organic matter-rich shale has been studied in detail at Kosov Quarry, the Barrandian basin (Silurian and Devonian), Czech Republic. Computer simulation of the thermal effect was based on the finite-difference transient solution of the heat conduction equation in 3-D axially symmetric geothermal model of the sill and its surroundings taking into account the heat of the magma crystallization. A different extent of the fluid convection, the initial magma temperature and the depth of the intrusion were considered. The results predict the thermal effect of hundreds of degrees C limited to the close surroundings (of a few metres) of the sill. The common feature of all the versions was a short duration of the heat pulse - a few years at most, during which the contact metamorphism of sediments had to occur. A range of independent geological thermometers (organic matter reflectance, illite and chlorite "crystallinity", analysis of fluid inclusions and isoprenoid distribution) have been employed to compare these predicted values with actual geological evidence. All the thermal indicators generally show an appreciable increase of paleotemperatures toward the contact of the sill with enclosing sediments. A thermometer based on graptolite reflectance confirms relatively short-lived heating at maximum temperatures of about 500 C that were attained in a narrow (about 1 m thick) zone adjacent to the intrusion. Aqueous and hydrocarbon fluid inclusions in secondary calcite and quartz cements evidence substantially lower temperatures (from 60 to 150 C) that dominated within the igneous body upon cooling.

HEAT FLOW ANOMALIES AND GEODYNAMIC IN THE NORTH-WESTERN PART OF THE BLACK SEA

Roman Kutas, Vladimir KOBOLEV and Vladimir Tsvyaschenko (Institute of Geophysics Acad. of Scinces, av. Palladin 32, 252142 Kyiv, Ukraine)

More than 500 heat flow measurements were performed in the Central part of the Black Sea.Low values (20-40 mW/m2) are now predominant. However last years geothermal anomaly has been revealed in the north-western part of the Black Sea (south-westwards from the Crimean peninsula). Within the anomaly heat flows are 70-90 mW/m2 being increased up to 130-150 mW/m2 on the local areas. Geothermal anomaly is situated on the continental slope in the zone of the deep Odessa-Sinop fault. In this area a masif of igneous rocks (from basic to pacidic) was found on the continental slope. Their age varies from 135 to 26 Ma.In Pliocene-Quaternary the north-eastern part of the Black Sea adjiacent to Crimea subsided. Along the Odessa-Sinop fault shear movements was evolved. Mutual movements of plates are expressed in the modern intensive seismic activity along Crimean peninsula. Interpretation of the geothermal data shows that the heat flow anomaly is due to the young tectonic and magmatic processes. Significant differentiation of thermal field and intensive local anomalies which are situated along the fault at the foot of the slope are created by hydrothermal processes. In this zone many water and gas expultion have been revealed.

THERMAL LITHOSPHERIC STRUCTURE AND GEOTHERMAL MODELING ALONG AND ACROSS THE GULF OF SUEZ

Sherif EL-HADY (email: Srozza@frcu.eun.eg); Imam Marzouk and Mohamed Dessoky (all at National Research Institute of Astronomy and Geophysics, Helwan ,Cairo, Egypt)

One- and two-dimensional geothermal modeling were per- formed along and across the Gulf of Suez basin to study the thermal regime of the basin and its relation to the lithospheric structure. The FINITEG computer Program (Lee et al., 1980) was used for managing one- and two- dimensional geothermal modeling along the studied areas. Many modifications were made by the present authors in the FINITEG program to agree with the recent techniques used for temperature modeling. Most of these modifications were concentrated on the way of calculation of thermo-physical parameters (heat production, thermal conductivity and thermal diffuvisity), which used for solving the geothermal modeling problem in the studied areas. It is found from the results of one-dimensional thermal lithospheric structure that, the average lithosphere thickness of Northern Egypt is ranged from 107 Km to 122 km. The last lithosphere thickness value is considered to represent the initial lithosphere thickness at the beginning of the Gulf of Suez rifting. Two- dimensional thermal lithosphere structure for the Gulf of Suez is performed through two profiles. The two profiles are chosen to pass through the new estimated heat flow areas in the Gulf of Suez. The first profile (A) is about 100 km in length and passes through Shadwan seismically active area and Esh El-Mellaha area towards the Eastern Desert. The second profile (B) is about 110 km in length and passes through the Gulf of Suez Basin, started from Shadwan area and end to Ramadan oil field. In each profile, the thermal lithospheric structure is calculated by a time step of one million year from the beginning of rifting (24 My) till the present situation. The thermal lithosphere structure of each time step is considered to represent the initial thermal lithospheric structure of the next time step. It is found from the results of the two dimensional geothermal modeling in the Gulf of Suez that, the lithosphere/ asthenosphere boundary is very shallow (32-33 km) just below Shadwan seismically active area, while it reached to about 50 km just below Ramadan Field. It is found also that, the shallow hot swelled lithosphere /asthenosphere boundary could be only the sufficient factor which governs the observed geothermal anomaly along the Gulf of Suez.

GEOTHERMAL EVOLUTION OF A MIOCENE SUBDUCTION AREA: THE EASTERN CARPATHIANS

Serban VELICIU (Geological Institute of Romania, Caransebes, 1; 78344 Bucharest, Romania, e-mail veliciu@igr.sfos.ro)

The geological structure of the Carpathians is now viewed as a collection of effects of the plate tectonics; on the other hand it is possible to construct various geothermal models that provide some insight into the tectonic history. These models must be reconciled with the knowledge of the structure of the lithosphere, petrphysical properties of rocks and the thermal regime of the Earth as inferred from the observations at its surface. The Eastern Carpathians area is relatively young and it is characterised by less than 25 m.y. since the last thermo-tectonic event; consequently, a dynamic model should be adopted. In order to explain the high heat flow (73-126 mW/m2) observed at the inner part of the Eastern Carpathians, a 2-D model which takes into account the radiogenic heat generation and the descent of a lithospheric plate has been elaborated. Calculated geotherms by finite element method indicate the presence of a high temperature anomaly (exceeding 1000 deg.C) localised in the upper mantle. The geothermal data suggest that both the high heat flow and the building up of the Pliocene-Quaternary volcanic chain are consequences of the lithospheric Miocene subduction in the Carpathians area.

THE RELATIONSHIP BETWEEN GEOTHERMAL VORTEX AND EARTHQUAKE

Maocang Tang and Xiaoqing GAO (both in Lanzhou Institute of Plateau Atmospheric Physics,CAS, Lanzhou 730000, P.R.China, email: xqgao@lzu.edu.cn)

Earthquake always companied by thermal process. The change of soil temperature at different depths shows the underground thermal process.The data of soil temperature observed in more than 180 meteorological observatories in China for the period of 1980-1993 have been analyzed.And the concept of Geothermal Vortex was proposed and defined. The result shows that there are close relationship between geothermal vortex and earthquake.Earthquake always happened at the edge, with high gradient, of geothermal vortex.The stronger the geothermal vortex, the stronger the earthquake. It is possible to predict dangerous areas of earthquake by following the movement of geothermal vortexes.Based on the statistical facts, a thermal-dynamic process linking geothermal vortex and earthquake has been proposed.

TIDE GRAVITY NEAR MT. ELBRUS - NO EVIDENCE FOR HEAT FLOW INFLUENCE

A.KOPAEV, V.Yushkin (both at Astronomical Institute of Moscow University, Universitetski prosp. 13, Moscow, 119899, Russia; fax: +7-095-9328841; e-mail: kopaev@sai.msu.su)

We chose tectonically active region of Central Caucasus to check independently the famous hypothesis of prof. Melchior concerning the correlation between the tide gravity anomalies and heat flow, as well-known tests (i.e. Baker et al, 1989) covered the area of Central Europe where loading tides may affect the 'purity of experiment' generally. Tide gravity observations have been carried out at the Baksan station located 15 km apart from the highest top of Europe, sleeping volcano Mt. Elbrus, using quartz tide gravimeter DELTA-1 (modernized from Sodin-209 with addition of CCD, special tilting device for absolute in-situ calibration, etc) after its attestation at the ORB, Brussels. Elaborate processing of available gravity data (7 months altogether) gives delta-factors for M2 and O1 that agree with model values 'Wahr-Dehant 'plus' Schwiderski) within the error bars of 0.3 % resp. 0.5 %. So, there are no serious discrepancies (larger than 0.3 %) between the tide gravity observations and models in 'geophysically hot' areas even at the distance of 3300 km from the nearest ocean.

RHEOLOGY AND DEFORMATION OF THE TYRRHENIAN PLATE

Carlo GIUNCHI (Istituto Nazionale di Geofisica, Via di Vigna Murata 605, 00143 Roma, Italy, Email: carlo@gea.df.unibo.it). Spina Cianetti e Paolo Gasperini (Dipartimento di Fisica, Settore Geofisica, Universita' di Bologna, Viale B. Pichat 8, 40127 Bologna, Italy)

The deformation of the Tyrrhenian plate is investigated by a thin plate model with realistic rheology for the crust/lithosphere system. The Tyrrhenian and peri-Tyrrhenian basins are trapped between the convergence of the two major African and Eurasian plates, resulting in the subduction of the african lithosphere underneath the Calabrian arc and the formation of the Alpine and Apenninic belts. We try to include in the model forces acting at the plate boundaries that better represent the observed deformation. The work focus on the interplay between the push of the African plate, the roll-back of the Tyrrhenian plate and other potential sources of intraplate deformation. It is found that the rheological eterogeneities in the Tyrrehian plate are needed to describe the partitioning of the deformation in the Apenninic and Calabrian arc, and in the plate itself.

TIME-DEPENDENT DYNAMICS OF THE TONGA-KERMADEC SUBDUCTION ZONE

Lijie Han, Michael GURNIS, and Hendrik van Heijst (all at Seismological Laboratory, Caltech, Pasadena, CA 91125, USA, email: gurnis@caltech.edu;); Carmen Gaina and R. Dietmar Mueller (Department of Geology and Geophysics, University of Sydney, Sydney, NSW 2006, Australia, e-mail: dietmar@es.su.oz.au)

We formulate regional, time-dependent dynamic models of the Tonga-Kermadec subduction system from 40 Ma to the present. The goal of our approach is to explore the sensitivity of outcomes to both uncertainties in plate tectonic reconstructions and lateral and radial variations in mantle properties. The regional models have a spherical geometry, but the flow is solved only within the area of interest. The full convection problem within a viscously dominated fluid is solved with the coupled momentum and energy equations. The rheology is linear, but highly pressure and temperature dependent. Plate kinematics are imposed as velocity boundary conditions with weak plate margins at the inferred evolving position of trenches. The plate tectonic model is characterized by the initiation of subduction at about 40 Ma at the Norfolk ridge and with subsequent opening of the Norfolk, South Fiji, and Lau basins. Moreover, the New Hebridestrench sweeps southwest from the Late Miocene to the present. The dynamics of the slab are influenced by the rapid motion of the trench both along strike and oceanward. The shape of the slab in the dynamic models are compared with relocated hypocenters within the upper mantle. In global seismic tomographic inversions, the Tonga-Kermedec system is characterized by strong fast anomalies within the transition zone and top of the lower mantle but does not appear to extend below ~1000 to ~1200 km depth. This is consistent with the Eocene initiation of subduction. The conclusion is quantified by comparing the outcomes of dynamic models with seismic tomography.

THE PARAMETERIZED MIXED MANTLE CONVECTION MODELS OF CONTINENT AND OCEAN

ZHANG Jian, (Institute of Geology, Chinese Academy of Sciences, Beijing, 100029, China); Shi Yaolin (Graduate School, University of Science and Technology of China, Academia Sinica, Beijing 100039, China. E-mail: shiyl@sun.ihep.ac.cn)

Recent studies reveal that mantle convection could be mixed, that is, convection penetrates the 670km boundary and involves whole mantle in some places, while convection is layered in some other places. Therefore, we carry out the parameterized mixed mantle convection model to modeling the penetrative mantle convecting beneath Oceanic and Continental lithosphere. In model, we introduce a time-dependent penetration parameter F, which denotes the ratio of mantle material involved in whole mantle convection over the entire mantle. Completely whole mantle convection is achieved if F approaches 1, and convection is completely layered if F approaches 0. When layered convection dominates, the temperature difference between upper mantle and lower mantle, until the thermal driving force can overcome the phase barrier to slab penetration. With the parameter F, thermal evolution of mantle convection state can be calculated, temperatures and heat losses can also calculate respectively. It is found that there is a nonsynchronou of the overturn between oceanic and continental mantle. This nonsynchronou can cause the tectonic activity and geothermal anomaly in the marginal zone between Oceanic and Continental lithosphere. Such results offer a physical interpretation of the observed geothermal anomaly in South China Sea. For example, Yingehai basin which lies in the marginal zone of Pacific and Euroasian plate has elevated temperature and pressure background that could be created by the nonsynchronou of the overturn between oceanic and continental mantle.

APPLICATION OF CONTINUUM PLASTICITY MODELING TO 2D SIMULATIONS OF PLATE TECTONICS

Louis MORESI and Hans Muhlhaus (Australian Geodynamics CRC, CSIRO Exploration & Mining, PO Box 437, Nedlands, 6008, Western Australia)

We use a Lagrangian Particle Finite Element code to study the problem of convection in a fluid with material properties which are a strong function of composition and strain history. The method is applied to the study of the manner in which the Earth's lithosphere is mobilized and subducted. The lithosphere is treated as the cool thermal boundary layer of a convecting fluid with strongly temperature dependent viscosity. In such a system, the lithosphere will be entirely stagnant unless the boundary layer yields under relatively high stresses. This yielding, mimicking pervasive brittle failure of the lithosphere, has been demonstrated to produce convection with plate-like surface motions and a boundary layer structure similar to the cooling oceanic lithosphere. In the Earth, plate boundaries are strongly localized along narrow zones dominated by major fault systems and can easily be picked out in maps of global seismicity. Several studies have shown that it is important to consider the history dependence of the yielding of the lithosphere in order to reproduce well-defined, narrow plate boundaries in convection models (i.e. to consider the fact that plate boundaries which have accumulated significant slip appear to be weaker than newly yielding lithosphere). Such modeling requires that the strain history of a particular parcel of material must be tracked for at least the period of time it remains part of the brittle lithosphere. At the same time, the large-scale convecting system must be modeled for a number of overturns. Together these requirements make the problem difficult to solve - requiring the tracking of a highly deforming lagrangian reference frame while also retaining computational efficiency so that an enormous number of timesteps can be completed. Lagrangian Particle methods give us a simple way to track history variables in a highly deforming fluid while retaining the computational efficiency of a multigrid fluid-dynamics finite element code. Our model uses a strain-softening yield criterion for each material parcel in the convecting system to study the influence of history dependent rheology on the form taken by the structures which allow the thermal boundary layer to founder. The introduction of this history dependence immediately induces a strong localization of deformation in converging regions into narrow shear bands. The development of these shear bands tends to stabilize the convection …

DIFFERENTIAL CORE-MANTLE ROTATION AS A SOURCE OFADDITIONAL HEATING AND ORIGINATING OF DEEP PLUMES

Natasha Petrova, Alexander Gusev (Department of Astronomy and GRG, Kazan University, Kremljevskaja Str., 18, Kazan, 420008, Russia, E-mail: petrova@astro.ksu.ras.ru)

Modern tectonophysics of plumes determines the region of plume origin in ultra-low velocity zone of the core-mantle boundary (D" zone) being a power heat source.
On evidence derived from seismotomography the earth core has a very rough surface that has ledges and depressions with the amplitude up to 5--6~km. The thickness of intermediate layer is varied from 100 to 300~km according to different data.
Dissipative effects, arising from the different core-mantle rotation, are of particular interest as the source of additional heating of the Earth interior. The friction power extracted from differential core-mantle rotational kinetic energy of the Earth depends on the flattening of the core, size and viscosity of D" layer. It may be transformed into heat and then create instability of the D" thermal layer, leading to the generation of upwelling vortical plume.
According to the theory of differential rotation for two-layer Earth (rigid mantle and liquid core)(Getino, Fernandiz, 1995; M.Greff, H.Legros, 1998; Petrova, Gusev, 1997), which predict two eigen-modes: Chandler Wobble and Free-Core Nutation, we estimated frictional dissipative power that is approximately equal to 10\% from the total Earth' heat flow.

EXPERIMENTAL INVESTIGATION OF WAVE PROPAGATION IN THERMAL PLUMES

Nils LAUDENBACH / Ulrich R. Christensen, (Institute of Geophysics Goettingen)

In laboratory experiments thermal plumes are created by injecting hot corn syrup into a column of cold syrup. The viscosity contrast is up to a factor of 1000.The experimental apparatus is able to generate laboratory plumes with well defined volume fluxes. Solitary waves, that propagate upwards in the plume conduit, are generated by enhancing the injection rate for a few seconds. For the measurement of the thermal structure of the plume we have implemented a method based on the deflection of a laser beam passing through the plume. Continuous scanning provides a new radial temperature profile each second, which allows detailed studies of the thermal structure of solitary waves. Because of thermal diffusion, the conduit widens with height, while its central temperature decreases. The solitary waves start with the same temperature as the unperturbed conduit, however, we find that the temperature in the waves decreases less rapide with rising height. This can be explained by the faster upward propagation and the trapping of fluid within the soliton. If solitary waves exists in mantle plumes, this would imply that they arrive at the bottom of the lithosphere with a larger excess temperature than what the plumes normally exhibits, which could explain strong variations of melt generation with time.

VORTEX VOLGA-KAMA'S PLUME UNDER RUSSIAN CRATON

Alexander GUSEV, Natasha Petrova, Dpt. of Astronomy and GRG, Kazan University, Kremljevskaja Str., 18, Kazan, 420008, Russia, E-mail: gusev@astro.ksu.ras.ru

Tectonophysics of plumes is based on the modern jet-theory of viscose matter including and adapting convective structure of ascending and descending flows of mantle matter. The plume source is located at ULVZ, which is characterised by large contrast in density, viscosity, material flow rates, chemistry and thermodynamical parameters.
The vortex plume penetrating lower and upper mantle is considered as plausible pattern. Such vortex plume is more stable under influence of different motions in the mantle, under cross-section of various phase transition zones: spinel $\to$ oxides, perovskite (670km), olivine $\to$ spinel (410km). The vortex plume increases an additional pressure on the crust, causing notable elevation of Moho boundary ($\sim$ 4--5 km) and sedimentary cover ($\sim$ 2--3 km), such as the South-Tatar Crest in the Volga-Kama's region. The top of vortex plume pins to the Earth's crust, melting the matter and creating local intensive heat flow (74 mW) at the surface. It discretely moves under the plate, conserving mushroom-like pluto-bodies (30-50km) in crust and causing the gravitational anomalies.
By this means, under motion of the plates the plume's top remain its track ("hot-spot" track) at the plate surface in the form of volcanic islands archipelago in ocean region or in the form of pluto-like bodies, dome-shaped uplifts and arch lineaments chains in the thick continental plates such as Euro-Asian one. Investigating the "hot -spot" tracks we can conclude about

velocity and direction of plate motion like Russian craton (12 ± 3mm/year, south-western line) in the hot-spot reference frame. This value is confirmed by the method of zero kinetic plate moment (Euler's theorem for the sphere) and by analytical extension of velocity of neighboring plates.

LABORATORY EXPERIMENTS ON SUBDUCTION AND BACKARC EXTENSION

Francesca FUNICIELLO (Dip. Scienze Geologiche, Univ. Roma Tre, Largo S. L. Murialdo 1, 00146, Roma Italy. Institute of Geophysics, ETH, 8093 Zurich Switzerland e-mail: ffunicie@geo.uniroma3.it), Claudio Faccenna, (Dip. Scienze Geologiche, Univ. Roma Tre, Largo S. L. Murialdo 1, 00146, Roma Italy, e-mail: faccenna@uniroma3.it), Domenico Giardini (Institute of Geophysics, ETH, 8093 Zurich Switzerland)

We have performed 2D and 3D laboratory experiments to investigate the way the oceanic lithosphere sink into the mantle. Models have been performed with silicone putty, simulating the viscous behaviour of an oceanic lithosphere subjected to long term deformation and glucose syrup, simulating the mantle. We tested the influence of two parameters on the style of mantle convection: (1) lateral boundary conditions, i.e. box width, (2) deep discontinuity in the mantle resemblming the 670km transition. We expressed the results in terms of: rate of trench retreat, rate of subduction, dip of subduction and state of strain of the upper plate. Our results show how the slab trajectory into the mantle is influenced by the presence/absence of deep discontinuity.

A NEW BROAD-BAND SEISMIC NETWORK WITH SATELLITE TRANSMISSION IN CATALONIA (SPAIN)

Figueras, S.; Fleta, J.; GOULA, X.; Olivera, C.; Olmedillas, J.C.; Roca, A. and Susagna, T. Institut Cartogràfic de Catalunya, Parc de Montjuïc, E-08038 Barcelona. email: xarxasismica@icc.es; http://www.icc.es

Technological advances in the field of telecommunications make possible now to use continuous satellite data transmission for geophysical applications at a very affordable economical cost compared to other transmission systems. The use of low consumption VSAT platforms gives more freedom to choose stations sites, in particular in mountainous areas as the Pyrenees. The capacity and flexibility of available systems make possible the installation of multisensor field stations that can send data to different reception and acquisition centres simultaneously. The project of the Institut Cartogràfic de Catalunya includes the installation of 20 broadband, high dynamic range seismic stations in our territory (aprox. 32000 km2)with continuous transmission to the recording centre at Barcelona. Some of this stations will also contain dual frequency continuous transmission GPS receivers. The recording centre and 3 first field stations will be installed on April 1999 and it is expected that an operative network of 10 stations with fast automatic location and early warning systems will be ready on January 2000. High importance will be given to the automatic data distribution which should include: 1) data interchange among centres responsible for data acquisition and dissemination of information; 2) early warning with information to various agencies, in particular to responsible for civil defence and 3) good quality data dissemination to the scientific community.

ST5/W/17-B3 **0850**

A NEW MEXICAN NATIONAL SEISMOGRAPHIC NETWORK

D.A. Novelo-Casanova, S.K. Singh, and J. Pacheco (all at Instituto de Geofisica, Universidad Nacional Autonoma de Mexico, Ciudad Universitaria, Mexico, email: david@ollin.igeofcu.unam.mx)

The new Mexican National Seismographic Network (MNSN) will have great impact in regional advanced seismic research and in local seismic mitigation programs. At present, 18 broadband observatories in south-central Mexico are operating. Each remote station has a STS-2 seismometer, a FBA-23 accelerometer, a Quanterra processor Q680/LT-G and a GPS clock. In addition to the broadband network, MNSN operates other seismic networks located at strategic sites (Mexican Valley, Guerrero, Popocatepetl). All this instrumentation, together with the national short-period network, provides the means for: (1) detailed studies of the Mexican seismicity; (2) rapid response to earthquake disaster prevention measures; and (3) earthquake engineering research.

THE ALERT SYSTEM OF THE SIL NETWORK AND EARLY WARNINGS OF EARTHQUAKES AND VOLCANIC ERUPTIONS

Steinunn S. JAKOBSDÓTTIR and Ragnar Stefánsson (both at Department of Geophysics, The Icelandic Meteorological Office, Bústa_avegi 9, IS-150 Reykjavík, Iceland, email: ssj@vedur.is, ragnar@vedur.is)

The SIL system is an advanced seismic network in Iceland, automatically locating earthquakes, estimating moment magnitudes and "local" magnitudes and calculating fault plain solutions. It has facilities to monitor on routine basis active faults with a relative accuracy of tens of meters, to monitor on routine basis the orientation of individual fault plains and comparing direction of fault planes to direction of the active fault. An automatic alert system is in continuous development in the SIL system. The alert system is two-fold, a central alert based on the automatic bulletin and a station alert that reports directly on ground motion at the site stations. For the central alert Iceland is divided into alert regions. The size of each region and its preset thresholds for expected number and magnitude of events, depend on the seismicity in the area and the station spacing. The station alert reports on big amplitudes and on increase in the background noise. Alerts given by the automatic system are evaluated by seismologists, which then decide if warnings should be forwarded to The Civil Defence and local authorities. To do that they use the facilities of the SIL system to carry out what might be called a real-time research to find out what is really happening. The aim is to include all new understanding, as gained from earthquake prediction research, directly into the system to improve it. The alert system was started in september 1992. Since then there have been two eruptions in Iceland, both within the glacier Vatnajökull, and two periods of earthquake swarms, with earthquakes reaching magnitude 5. Both eruptions where predicted and warnings issued to The Civil Defence and aviation authorities before the eruption. The alert system issued automatic warnings both few days and few hours before the big events. An overview over automatic alerts and warnings issued by seismologist before these events will be given in the talk.

UPDATING THE ISC BULLETIN

Raymond J WILLEMANN and Dmitry Storchak (International Seismological Centre, Pipers Lane, Thatcham, Berkshire RG19 4NS, UK, email: ray@isc.ac.uk)

Internationally funded to publish the definitive global seismicity bulletin, the ISC has avoided changes that might alter the fundamental content of the Bulletin. This conservative approach has been mandated by the need for hypocentres, magnitudes and other earthquake parameters that are as uniform as possible. It is now possible, however, to compute new locations and magnitudes for the ISC's entire Bulletin back to 1964 and to provide data more flexibly, for example giving users residuals with respect to their own choice of location or earth model. Thus, the ISC could now change models or procedures occasionally as required to best serve seismologists, and compute new parameters of past events according to the updated practices.Over more than 30 years of operation, possibilities for many types of changes have arisen. Seismologists might be well-served by adding new features to the Bulletin as soon as they are ready, but most would probably prefer a single change of all procedures for computing earthquake location and size. Changes that the ISC may consider over the next few years include

- Using updated travel times, based on a modern homogenous earth model such as IASP91 or PREM, a 3-dimensional or anisotropic model, or regional models.
- Computing locations from more phases (S or PKP) and more readings (vector slowness).
- Using station travel time and amplitude corrections, either static or source-dependent.
- Implementing alternative location algorithms, e.g., epicentres from only differences of arrival time, depths from waveform fits, or relative locations using JHD.
- Computing magnitude on alternative scales, such as ML or MW.

REAL-TIME SEISMIC INFORMATION SYSTEM BY FREESIA PROJECT

Mizuho ISHIDA (National Research Institute for Earth Science and Disaster Prevention, 3-1 Tennodai, Tsukuba-shi, Ibaraki-ken 305-0006, Japan, email: ishida@geo.bosai.go.jp)

FREESIA (Fundamental Research on Earthquakes and Earth Interior'S Anomalies) project started in 1994. The major objectives of the project are; to develop abroad-band network for real-time earthquake monitoring and subsequent data analysis; to co-install strong motion seismographs to record large earthquakes; to open, in quasi-real time basis, the information about source mechanism and ground motion for earthquakes with magnitudes down to around 3.0 in and around Japan. The Freesia network now consists of twenty stations covering whole Japan. Each station is equipped with three-component broad band seismometers and strong motion sensors, with 24-bit digital data recording at a sampling rate of 80 Hz. Data from eleven stations are transmitted to NIED (National Research Institute for Earth Science and Disaster Prevention) through continuous telemetry, continuously stored in the data mass storage and are available through internet. Data from the remaining data from nine stations by a dial-up telephone link. We develop a software of automated moment tensor determination by using on-line broadband seismic waveforms from the FREESIA networks. The location and origin time which are broadcasted by Japan Meteorological Agency by e-mail are used. The moment tensor solution determined by using long period waveforms (from 20 to 50 seconds) of 3 stations are automatically displayed on the World Wide Web within five minutes after the e-mail information was received. The FREESIA program is cooperative project between NIED and several universities and is supported by NIED.

CLOSE-RANGE SEISMIC MONITORING OF THE MINING AREA NEAR APATITY, KOLA

Yura V. Fedorenko (IFJ/UoBergen and Inst. North Ecology Problems, Kola Science Centre, RAS, Fersman Str. 14, Apatity, 184200 Murmansk Reg., Russia; Email: yura.fedorenko@ifjf.uib.no) Lena Beketova (Geological Inst., Kola Science Centre, RAS, Fersman Str. 14, Apatity, 184200 Murmansk Reg., Russia) Eystein S. HUSEBYE (IFJ, UoBergen, Allegaten 41,N-5007, Norway, email: eystein.husebye@ifjf.uib.no)

A truly nuisance in monitoring CTBT compliance is small areas of high mining activities like that near Apatity, Kola. The numerous chemical explosions here are occasionally recorded at teleseismic distances but very frequently at local and regional ranges. Since every signal recorded would necessitate some processing and possibly analyst inspections these explosions constitute a significant extra workload to seismic monitoring tasks on any data center level. Our approach to resolve this problem was to install on an experimental basis a 3-component seismic station NANSEN (NKK;33.84N,67.60E) in the Apatity mining district. The self-constructed data logger is flexible with respect to sampling rates, detector design, data storage and transfer to a local center. Timing is via GPS-clock and the station operation is remotely controlled and calibrated. In the initial stages of NKK-operations the emphasis is aimed at automatically to identify explosion signals and the associated mine locations. Here we are using the algorithms for explosion site recognition presented elsewhere (Husebye & Fedorenko, IUGG99 Abstract). There are many mines in the Apatity area but today only 5 are in operation. The explosion signals from these mines were always correctly 'recognized' as such. We are also expanding this aspect of NKK-operation that is to recognize other mines on Kola on the basis of signals recorded. The hardware cost of the NANSEN station was less than US $ 2000. which we rate a modest investment for significantly reducing analysis at data centers at local/regional distances from Apatity. This aspect of 'explosion' monitoring is easily transportable to other areas with numerous mining and/or quarry explosions. There is also an environmental aspect of the NANSEN station operation namely to monitor seismic loading on the free surface which may trigger snow avalanches (Chernous et al.; IUGG99 Abstract).

CALIXTO'99: STATUS QUO OF AN ONGOING HIGH RESOLUTION TOMOGRAPHICAL EXPERIMENT IN ROMANIA.

FRANK P. LORENZ, M. Martin, F. Wenzel, (Geophysical Institute, University of Karlsruhe, Germany, email: Frank.Lorenz@phys.uni-karlsruhe.de) and the CALIXTO Group (National Institute for Earth Physics, Bucharest, Romania; Faculty of Geology and Geophysics, University Bucharest, Romania; Institute of Geophysics, ETH Hoenggerberg, Zuerich, Switzerland; Ecole et Observatoire des Sciences de la Terre, Strasbourg, France; Istituo Ricerca Rischio Sismico, Milano, Italy; Department of Geological Sciences, Northwestern University, Evanston, ILL, USA; GeoForschungsZentrum Potsdam, Germany).

A status report of the Carpathian Arc Lithosphere X-Tomography (CALIXTO) seismic experiment is given. An international group is operating a large scale high resolution passive seismic experiment between 1999 and end of May 2000. Over 150 mobile acquisition systems, with a large number of broadband sensors is deployed in an area between 24E-28E and 44N-47N investigating the Vrancea Zone, an extraordinary earthquake area with very high seismic activity in intermediate-depth range. We show the results of extended synthetical numerical calculations for optimizing the station distribution and give a proof for distinct Moho-topography within the epicentral area. Our studies include teleseismic and local earthquake data. We give better constraints for seismic hazard assessment for this former subduction zone, by revealing the dimensions of a high-velocity body, which embeds all intermediate-depth seismicity. The P-wave velocity perturbation is about 3%, and we reach an accuracy of about 10km x 10km blocksize with satisfying resolution down to a depth of about 400km.

ST5/E/19-B3 1205

SOURCES OF SEISMIC NOISE AT AUSTRALIAN STATIONS

Mark Leonard (Australian Geological Survey Organisation, PO Box 378, Canberra City, ACT 2601, Australia, email: mleonard@agso.gov.au)

The source of microseismic noise has long been accepted as standing waves in the ocean which are generated by the interaction of two sets of oceans waves travelling in approximately opposite directions. Various authors have suggested the phenomena is due to fast moving storms at sea over-riding themselves, others have suggested it is due to ocean waves interacting with their own reflection of off a coastline.
Data from a regional array of three component broadband seismometers and the Skippy deployment of three component broadband seismometers across Australia has provided a unique set of data for studying the seismological properties of the Australian region. In this study the deployments are used to study the nature and sources of microseismic noise in Australia. Results will be presented showing the correlation of noise peaks with storms in the surrounding oceans and periods of high seas impacting on the Australian coast.

ST5/W/61-B3 1225

OCEANIC WAVEHEIGHT MODELS AND MICROSEISMS

David A. McCormack (Geological Survey of Canada, 1 Observatory Crescent, Ottawa, Ontario K1S 2H1,Canada email: cormack@seismo.nrcan.gc.ca)

Waveheight maps covering the world's oceans have recently become available to the scientific community. Such maps permit direct comparison between observed microseismic wavefields and microseisms predicted by source generation models. This presentation examines the correlation between observed microseisms and the microseismic signals predicted from measured waveheights. In addition to waveheight maps, simple physical models permit forecasting of waveheights up to seven days in advance. The reliability of such waveheight forecasts for prediction of microseismic noise amplitudes is examined.

SYNTACTIC PATTERN RECOGNITION FOR WARNING SYSTEMS AND SUPPORTING DATA BASES

M.N. ZHIZHIN, A.D. Gvishiani, A.A. Burtsev CGDS, Molodezhnaya Str. 3, GC, Moscow, 117296, Russia; +7-095-1334339; Email: jjn@wdcb.rssi.ru J. Bonnin, D. Rouland, EOPGS, 5 rue Descartes, F-67084 Strasbourg Cedex, France; +33-88416368; Email: bonnin@selene.u-strasbg.fr

Syntactic Pattern Recognition Scheme (SPARS) has been applied to classify seismograms from different seismic source zones (Fiji, Tonga and Vanuatu) in New Caledonia region. Several GEOSCOPE stations based in that region provided with the initial data set. The supporting relational database contains a large number of broad-band waveforms of local and regional seismic events. The result of SPARS application to the database analysis is a set of algorithms and software tools for pattern recognition and classification of seismic records in quasi real time.

ST5/W/03-B3 1420

AUTOMATIC S-PHASE PICKING IN BROAD-BAND SEISMOGRAMS USING THE DISCRETE WAVELET TRANSFORM

Reinoud SLEEMAN, Torild van Eck (Royal Netherlands Meteorological Institute, P.O. Box 201, 3730 AE, De Bilt, Netherlands, email: sleeman@knmi.nl) Patrick J. Oonincx (Centre for Mathematics and Computer Science, P.O. Box 94079, 1090 GB, Amsterdam, Netherlands)

We present an algorithm for the automatic picking of seismic S-phases at a single three component broad-band station, in which the discrete wavelet transfrom (DWT) and classical polarization techniques are combined.
A common strategy to detect and pick seismic phases in seismic recordings is the construction of characteristic functions. These functions describe specific properties of the seismic signal. For the detection of S-phases the following functions are used from polarization analysis: (1) ratio of energy in the Q,T-plane and total energy, (2) deflection angle and (3) degree of polarization.
This strategy can be improved by applying DWT prior to the polarization analysis. DWT decomposes the three components of the seismogram at different scales. In this way, different seismic phases are separated at different scales. At each scale the signal is de-noised using the wavelet coefficients prior to the P-phase. Then, the polarization technique is applied at those scales where the S-phase dominates. Results of this algorithm on a large data-set are compared with results based on classical polarization analysis, and show an improvement in performance.

ST5/W/05-B3 1440

IMPROVING PRECISION OF FREQUENCY-TIME ANALYSIS OF SURFACE WAVES

Helle PEDERSEN (1)Laboratoire de Geophysique Interne et Tectonophysique, BP 53x, F-38041 Grenoble Cedex, email: Helle.Pedersen@obs.ujf-grenoble.fr) Jerome Mars, Pierre-Olivier Amblard (2)Laboratoire des Images et des Signaux, ENSIEG, BP 46, 38402 Saint Martin d'Heres, FRANCE Anne-Lise Bard (1 and 2)

Group velocity dispersion curves of seismic surface waves are either directly inverted to obtain earth models, or used to apply frequency-time ('phase-match') filtering prior to further data processing. Unfortunately, the multiple filter analysis commonly used for the estimation of group velocities is not very precise due to the trade-off of precision between the time and frequency domains. To avoid this problem and to improve the measurement of the group velocities, we suggest to develop from the multiple filter analysis, a treatment based on the temporal and spectral reallocation of the energy map. This process, called reassignment multiple filter analysis, is included in the process of the multiple filter analysis, and reassigns the energy attributed to the centre of a time and frequency window to the gravitational energy centre calculated for the same window. This reallocation that concentrates the energy for the width of the band-pass filters applied, allows us a significant gain in terms of resolution and therefore significantly reduces the uncertainty of the group velocity measurement. We test the method on synthetic seismograms for plane layered models, with and without noise, and we apply the method to improve frequency-time filtering on a data set from the TOR experiment from northern Europe. The method is stable, and makes it possible to significantly improve the signal to noise ratio of fundamental mode Rayleigh waves prior to phase velocity measurements.

ST5/W/12-B3 1500

AUTOMATIC ASSOCIATION AT THE ISC

Noureddine BEGHOUL, Raymond J Willemann and Dmitry A Storchak, (all at International Seismological Centre, Pipers Lane, Thatcham, Berkshire RG19 4NS, UK, email: nour@isc.ac.uk)

Each year, the ISC receives two million readings from more than 2000 stations and nearly 200,000 preliminary event locations from dozens of agencies. The number of data in the Bulletin has increased many-fold since the ISC began operations, and programs now in use produce at least one misassociation in most events. The common causes for misassociations include readings from unreported events, gross errors in preliminary hypocentres, large lateral velocity variations, and readings with initial phases excluded from the Jeffreys-Bullen tables. Sometimes a reading simply fits the expected arrival time from a small distant earthquake better than the expected time from an approximately located nearby hypocentre.
We plan to change the association process used at the ISC. We want to reduce the number of misassociations, use more data reported to the ISC, be flexible, rank alternative associations, and not associate a reading when no fit is good. We will define misassociations as departures from associations made by ISC seismologists preparing past Bulletins. Additional data to consider include reported associations and phase identifications, reporting patterns (e.g., some stations report readings only from local earthquakes), and measurements such as S-P time, slowness and azimuth. Flexibility will allow us to improve the performance of the association algorithm, for example by changing the weight given to each type of data, perhaps on a station-by-station basis. When a seismologist finds a misassociation, ranked alternatives could be used to suggest other possibilities.

ST5/W/43-B3 1520

A TEST FOR DISTINGUISHING CONVERTED PHASES FROM UPPER MANTLE DISCONTINUITIES USING COMPONENT COMPOSITION, NON-LINEAR STACKING AND POLARISATION ANALYSIS FOR DATA FROM AN ARRAY OF PORTABLE BROAD BAND INSTRUMENTS

Huilan Zhou* and B.L.N. Kennett (Research School of Earth Sciences, Australian National University, GPO Box,Canberra ACT 2601,Australia); * permanent address: Department of Earth Science, Graduate School at Beijing, University of Science and Technology of China, P.R.China

In this work, we have tried to combine the stacking procedures with other signal enhancement tools with the aim of isolating weak converted arrivals from the upper mantle transitions. As a test, only 6 events and their broadband seismic records at Kimba Array in the Northwestern Australia were used. We introduce the resultant vector U formed by the composition of the R and Z components in R-Z plane, and have then applied the phase weighted stack (PWS) method to these U traces of each event, with comparison to analysis using the R and Z components. The synthetics examination and real data treatment show that the converted phases at U from P to SV or from SV to P at the discontinuities in the upper mantle, such as near 410km and 660km, could be much clearer than at R and Z. From the data analyses, we have had a clear impression that the composite component U is more effective to search the weak phases after non-linear stacking, although this effectiveness is different from data to data, as well as other methods.
The polarization analysis method used to be applied to distinguish the converted phases at single seismic trace. However, this method was combined with linear and non-linear stacking in our work, and a comparison was made between them. The results show that it could become more effective after combined with other procedures. Pre- and post-stack polarization analysis were also tested, and were fund which can also help with the identification of weak arrivals. More tests are worth to do.

ST5/W/13-B3 1640

UTILIZATION OF WAVEFORM CORRELATION IN REAL-TIME SEISMOLOGICAL NETWORK OPERATION

REYNIR BODVARSSON, Dep. of Earth Sciences, Uppsala University Sigurdur Th. Rognvaldsson, Icelandic Meteorological Office Ragnar Slunga, Dep. of Earth Sciences, Uppsala University Einar Kjartansson, National Energy Authority, Iceland

It is well established that accurate measurements of the arrival time difference between similar earthquakes can be used to constrain the relative locations of the earthquakes. The arrival time differences are measured through cross-correlation of the similar seismograms. This method is used routinely in the South Iceland Lowland (SIL) seismic network to accurately map active subsurface faults. Based on the positive results of the correlation techniques used in the relative location algorithm a new approach is being taken regarding the automatic operation of the SIL network. Experience shows that a substantial fraction of the events occurring within a given area belongs to a few clusters or families of earthquakes,

characterized by highly similar waveforms. The cross correlation of seismograms at individual stations can be used to identify such clusters. We are currently working on a method for using cross correlation of neighboring events to automatically determine the onsets of P and S phases with accuracy comparable to or better than achieved in the interactive analysis. The aim is to reduce the need for manual inspection of seismograms from local and regional earthquakes and to improve the quality of the readings in the icro earthquake database. The objective is to create a Geographically Indexed Database (GID) where different classes of earthquakes will be stored. When creating the GID, each event within a given cell is correlated with all other earthquakes in the cell. The results of the correlation are used to group the earthquakes into classes. A few events of each class are stored in the GID. As new earthquakes are recorded by the network, the system automatically looks for similar waveforms in the GID and if found takes the onset picks from there. For events not found in the GID the onsets are estimated through interactive analysis.

ST5/W/18-B3 1700

NEAR-REAL-TIME AND AUTOMATED ESTIMATION OF SOURCE PROCESS USING TELESEISMIC P-WAVE

Yoshiko YAMANAKA and Masayuki Kikuchi (both at Earthquake Research Institute, University of Tokyo, Tokyo 113-0032, Japan, e-mail: sanchu@eri.u-tokyo.ac.jp)

Recently we can get CMT solutions within several hours after earthquakes via E-mail or WWW. Some of these solutions are determined automatically using the long-period surface and body wave data of the global broadband seismograph network. From the viewpoint of disaster mitigation, we need more detailed and earlier information.
For this we have developed automated analysis system to obtain the information such as the direction and duration of rupture propagation. Our analysis is based on Kikuchi and Kanamori (1991) to use teleseismic broadband body waves filtered 0.5-250sec. We assume a triangular source time function, whose pulse width, t, is calculated from QED magnitude with the help of an empirical relation between M and t.
As compared with the long-period surface wave analysis, uncertainty of arrival time with even a few seconds results in timing error causes a serious change in the solution. It is also important to check the quality of used waveform data automatically. We attempt to resolve these difficulties to obtain more reliable information about the direction of rupture propagation. Currently we aim to determine the above source parameters automatically within half an hour for large events occurred in Japan.

WAVEFORM INVERSION VIA ENSEMBLE INFERENCE

Malcolm Sambridge (Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia; email: malcolm@rses.anu.edu.au.)

Over the past decade the availability of digital broad band seismic data has led to extensive use of body and surface waveforms to constrain earth structure. Inversion methods have been developed and applied to a wide range of problems, from the 1m - 1km distance scales of reflection and refraction studies, to regional and global studies using surface and body waveforms. In most cases the objective is to find a single earth model, which provides the best fit to the observations, and from this make inferences on earth structure.
In this work an alternative approach is examined where inferences are based on an ensemble of seismic earth models, with a range of data fits. The inverse problem then falls into two parts (1) generate an ensemble of earth models which preferentially sample regions of model space with high data fit. (2) draw quantitative inferences on the earth from this ensemble. A new Monte Carlo algorithm is presented which can be used for both stages of the problem. The algorithm will be illustrated with an application to the inversion of crustal receiver functions. With the new approach all earth models contribute to the information measures retrieved from the data. In some cases models which fit the observations poorly may tell us just as much as those that fit it well.

FINITE DIFFERENCE MODELING OF PATH EFFECTS IN WESTERN CHINA

L. E. JONES and C. R. Bradley, Geoanalysis, MS-F665 Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Robust velocity models are imperative for full- waveform modeling of structure and for determination of source mechanism and depth. While a carefully determined one-dimensional model may be adequate on a local to regional scale and at longer periods, complexity introduced by lateral heterogeneity may require two or three- dimensional modeling. Surface waves are often the only phases recorded for small magnitude events at regional distances, since they are, in general, much larger in amplitude than body waves. Thus, for moderately-sized (M_b 4.5-5.5) earthquakes in the Lop Nor region (China) we obtain near-regional to regional distance group velocity measurements and use these to contruct a family of simple one- dimensional velocity structures for crustal, lithospheric and uppermost mantle structure in Western China and Tibet, for stations AAK, MAK, LSA and LZH. The initial models are determined either via forward modeling of group velocities, or by inversion of combined group and phase velocity measurements. We then test the validity of the one-dimensional models by full waveform (forward) modeling and comparison to data. Results obtained from dispersion measurements are thus incorporated into existing models for full- waveform [Finite Difference] modeling, and used as initial models for iterative foward modeling. We then compare results from these simple one- dimensional models with two-dimensional composite models incorporating basin structure and moho topography into the original one-dimensional velocity structures.

SEISMOLOGICAL OBSERVATION AND INTERPRETATION: THEORY

ST5/W/24-B4 0930

ENVELOPE BROADENING OF OUTGOING WAVES IN RANDOM MEDIA: A COMPARISON BETWEEN THE MARKOV APPROXIMATION AND THE FINITE DIFFERENCE SIMULATION IN 2D

Haruo SATO (Dept. of Geophysics, Graduate School of Science, Tohoku University, Aoba-ku, Sendai-shi, 980-8578, Japan, email: sato@zisin.geophys.tohoku.ac.jp) Mike Fehler (Los Alamos National Laboratory, Los Alamos, New Mexico, USA, email: fehler@muktinath.lanl.gov)

The envelope broadening of seismic waves after traveling a long distance is one of the most prominent pieces of evidence for the existence of random heterogeneity in the earth medium. It can be interpreted to be a result of multiple forward scattering of waves. By using the Markov approximation for the parabolic wave equation, Sato [1989] directly simulated the envelope and quantitatively explained the observed envelope broadening. However, his model was applicable only for plane-wave propagation. Here, we introduce a method for the direct simulation of envelopes of outgoing waves radiated from a point source in a random media in 3D according to Shishov [1974], and extend it to 2D. The resultant envelope is broadened and the maximum amplitude decreases with the reciprocal of travel distance times the amount attributed to simple geometrical spreading. For the evaluation of this simulation, we compare the envelope derived with waveforms that are numerically simulated by the finite difference method in 2D. There is a good coincidence between them around the maximum peak. But the coda level of the finite difference method is a little larger than that of the Markov approximation since the large angle scattering is accurately modeled only in the finite difference method. We may use the envelope broadening as a quantitative measure of randomness from forward scattering, where we note the coda excitation is a measure of back-scattering strength.

THE 'GAP' BETWEEN SEISMIC RAY THEORY AND ``FULL'' WAVEFIELD EXTRAPOLATION

C. J. THOMSON, Geological Sciences, Queen's University, Kingston, ON K7L 3N6, Canada. 613--533 6178, email: thomson@geol.queensu.ca

A new derivation is given of the factorization of the anisotropic, elastic body--wave equation into two operators which are 1st--order wrt to a preferred direction of propagation. The solution to one of these gives the waves propagating in theforward direction. A 3 by 3 matrix notation is used which emphasizes the role of the Christoffel equation (or what might be called its ``projection'' onto the preferred direction) familiar from ray theory. To see this it helps first to obtain an exact factorization of the wave equation for homogeneous elastic media. When inhomogeneities exist it is necessary to use a Fourier representation for differential operators wrt the transverse coordinates, but still the Christoffel equation is the key. The so—called ``square root operator'' required in the factorization becomes more correctly the ``root of an operator quadratic equation'' intimately connected to the Christoffel equation.The factorization does not assume narrow—angle propagation or involve an a priori reference phase. It includes the P and two S waves and forward coupling between them. It remains valid at slowness--surface singularities (e.g. conical points, a.k.a. acoustic axes --- a most stringent test) and for folded wavefronts.
The one--way equation can be solved ``analytically'' by using ``Path Integrals''. These in turn may be reduced by stationary—phase arguments to standard ray theory, Maslov theory and Kirchhoff representations. In this sense the ``gap'' between ray theory and the numerical solution of the full wave equation is bridged or filled out.
Alternatively, the one--way pseudodifferential wave equation can be solved by numerical ``forward--stepping'' algorithms and here again a number of choices are available. Some of these are intimately related to (in fact, effectively reduce to) the ``phase screen'' approach of Wu and others.

SYNTHETIC SEISMOGRAMS IN COMPLEX CRUSTAL WAVEGUIDES WITH SURFACE TOPOGRAPHY USING HALF-SPACE SCREEN PROPAGATORS

Ru-Shan WU and Xiao-Bi Xie (both at Institute of Tectonics, Univ. of California, Santa Cruz, CA 95064, USA, email: wrs@es.ucsc.edu, xie@es.ucsc.edu)

The half-space GSP (generalized screen propagator) is a variation of GSP with free surface taken into the formulation. The method is based on the one-way wave equation theory and has a fast dual domain implementation. The GSP method is several orders of magnitude faster than finite-difference methods with a similar accuracy for certain problems. It has been used for the simulation of wave propagation for high-frequency waves (1 – 20 Hz) to a regional distance (greater than 1000 km). In this study, we extend the GSP method by incorporating a coordinate transform into the method for the surface topography problems. Comparsion with other methods, such as the boundary element method, through numerical simulations showed that the extended method worked well for mild topographies. Accuracy improvement for rough topography has be en also discussed. Numerical simulations have been conducted for various crustal waveguide structures, including both deterministic structures and small-scale random heterogeneities and random rough surfaces. Influence of random heterogeneities and rough surfaces on Lg amplitude attenuation and Lg coda formation are shown to be significant.

FREQUENCY DEPENDENT SEISMIC Q IN FRAGMENTED CRUST: SCALING ABSORPTION BY SQUEEZE-FLOW FROM MICRO TO MACRO SCALE

Pierre ROULEAU (Department of Physics, Sir Wilfred Grenfell College, Memorial University of Newfoundland, NF, CANADA, A2H 6P9, email: prouleau@beothuk.swgc.mun.ca)

Preferentially localised squeeze-flow of interstitial viscous fluid in rock samples produces significant frequency-dependent absorption of elastic energy in the kHz range. When transposed to the pore space of natural rough-walled fractures, this microscopic absorption mechanism can produce significant, frequency-dependent absorption in the crustal seismic band (i. e. 0.08 to 20 Hz). In the modelling which yields this result, the dimensions of absorption loci are constrained by the critical slip distance of seismic faulting and by crustal permeability estimates from reservoir induced seismicity observations. A characteristic absorption locus is idealised by a narrow gap of cylindrical shape surrounded by a deformable permeable ring, which leads to analytical solutions of the squeeze-flow governing equation in terms of a complex stiffness. The real and imaginary parts of this micromechanical stiffness form the basis for defining a macroscopic quality factor, appropriate for a fractured medium modelled as a tight packing of randomly ordered spheres whose surfaces are rough (fractal) and lubricated. For given thermodynamic conditions, upward scaling of the microscopic absorption requires estimating: 1) the macroscopic stiffnesses of rough fractures (normal and tangential); 2) the microscopic (ring) and macroscopic (crustal) porosity and permeability;and 3) packing parameters (coordination number and fragment dimensions), all of which can be inferred from field-based geological and geophysical observations. Macroscopic Q results for a generic crustal model composed of fractured layers show that in-situ absorption by squeeze-flow can be significant, with peak values remaining well within the crustal seismic band down to midcrustal depths.

ST5/W/08-B4 1145

WAVE SCATTERING ON FLUCTUATIONS OF ELASTIC CONSTANTS AND DENSITIES

Evgeni M. CHESNOKOV, Yuri A. Kukharenko (both at the Institute of Physics of the Earth, Russian Academy of Sciences, email: e.chesnokov@ucl.ac.uk, echesn@uipe-ras.scgis.ru), John Quenn (Conoco

Inc., Seismic Imaging Technology Center, 1000 S.Pine, P.O.Box 1267, 4487 RW, Ponca City, OK - 74602-1267, USA) and Peter Yu. Kukharenko (at the Institute of Physics of the Earth, Russian Academy of Sciences, email: e.chesnokov@ucl.ac.uk, echesn@uipe-ras.scgis.ru)

The fluctuating wavefields generated by scattering of elastic waves from randomly distributed inhomogeneities arising from fluctuations of elastic constants and densities is investigated. The average dynamic Green function and scattering cross section are calculated using a Feynman diagram technique. A relation between the scattering cross section and the spatial correlation functions of densities and elastic constants is obtained. The scattering cross section is calculated without any assumptions on the size of the inhomogeneities relative to the wavelength. The cases of random and correlated spatial locations of inclusions are considered. The dependence of scattering cross section on inclusion shape, correlation radius, and wavelength are investigated. Limited cases are studied analytically, while general cases are studied numerically.

ST5/E/01-B4 1205

LONG WAVE IN AN ARBITRARY IRREGULAR MULTI-LAYERED MEDIUM (2)

Xiaofei CHEN (Department of Geophysics, Peking University, Beijing 100871,P.R.China, email: xfchen@pku.edu.cn)

The classic theory of seismic surface waves was established upon the laterally homogeneous earth model. However, the laterally homogeneous model is only an approximate and idealized medium model. In many actual problems, the lateral heterogeneity of media cannot be ignored, thus new theories for surface waves in laterally heterogeneous medium is needed. So-far, the most of theories for seismic surface waves in laterally heterogeneous medium is established upon the hypothesis of "localization", i.e. the classic surface theory can be applied to each local "quasi 1-D"(quasi-stratified medium) structure by ignoring the interactions among different normal modes. Obviously, this hypothesis is appropriate for week lateral variation and it is questionable for strong lateral heterogeneity. However, there is little study to devote systematically discussing the appropriateness of such hypothesis. As presented in part 1 of this series study we have derived an analytic theory of Love in an irregular multi-layered medium by using the global generalized reflection/transmission matrix method without making "localization" hypothesis. As the part 2 of this series study, we shall use this accurate theory of Love in an arbitrarily irregular multi-layered medium to investigate the appropriateness of "localization" in laterally heterogeneous media. According to our preliminary study, we find that "localization" hypothesis is generally applicable at lower frequency case or weaker lateral variation of the medium, and it is inappropriate for higher frequency case or stronger lateral variation.

ST5/W/11-B4 1225

CAUSAL CONSTRAINT ON THE SCATTERING ATTENUATION IN ACOUSTIC RANDOM MEDIA

Jun KAWAHARA (Department of Environmental Sciences, Ibaraki University, Mito 310-8512, Japan, email: joker@mito.ipc.ibaraki.ac.jp)

The observed nature of seismic attenuation is successfully explained by a well-known theory of scattering attenuation established by Wu (1982) and Sato (1982). The theory deals with the scattering in randomly inhomogeneous media based on the Born approximation, neglecting multiple scattering as well as diffraction. The key is to eliminate the contribution of forward scattering within a cutoff scattering angle (CSA) (or equivalently, to correct the travel-time fluctuations caused by long-scale velocity fluctuations) when evaluating the scattering attenuation. This is essential to avoid the overestimation of attenuation at high frequencies. However, the value of the CSA is not objectively determined in the theory. Although several researchers evaluated the CSA by numerical and laboratory experiments, their results disagreed with each other's. Hence the choice of the CSA remained unsolved until recently.
In this study, we investigate the constraint by causality on the choice of the CSA in cases of acoustic random media. The densities are assumed to be constant for simplicity. Based on the Kramers-Kronig relation, we derive simple relations among the phase velocities in the high- and low-frequency limits and the CSA, in both three- and two-dimensional cases. After some consideration on the phase velocities, we further show that the CSA is uniquely determined as 60 (about 65) degrees in three- (two-) dimensional cases. It is surprising that these values are independent of the types of inhomogeneity.

SEISMOLOGICAL OBSERVATION AND INTERPRETATION EARTHQUAKES

ST5/W/15-B4 1400

SEISMIC PARAMETERS OF STRONG EARTHQUAKES IN BULGARIA AND SPAIN FROM HISTORICAL SEISMOGRAMS

S.Dineva, D.Mihaylov (both at Geophysical Institute, BAS, Acad. G. Bonchev Str. bl.3, 1113 Sofia, Bulgaria. Email: dgm-sid@geophys.bas.bg) J.BATLLO (Escola Universitaria de Ciencies Empresarials Dr. Manya, E-43500 Tortosa, Spain. Email: jbo@tinet.fut.es), T. van Eck (Seismological Division, KNMI, PO Box 201, 3730 AE De Bilt, Netherlands. Email: vaneck@knmi.nl).

All available instrumental data about earthquakes within the territory of Bulgaria and Spain with magnitude larger than 6 from 1904 to 1928 have been collected and analysed. This data include - arrival times and amplitudes from station- and international- bulletins and historical seismograms from the whole world.
New hypocenter locations and magnitude estimations are obtained on the basis of collected arrival times and amplitudes from the bulletins and seismogram readings. The seismograms are digitised and are corrected for the curvature and for the instrument response. The estimated ground motion records are used to obtain spectra of P and S waves and determination of the seismic moment and Mw.
The obtained results are useful for seismic hazard estimations and seismotectonic interpretations in both countries.

ST5/E/11-B4 1420

THE SPACIAL EVOLUTION OF SEISMIC SERIES IN THE BETIC RANGE

Daniel Stich, Gerardo Alguacil (Instituto Andaluz de Geofísica, Universidad de Granada, Spain, email: daniel@iag.ugr.es)

One characteristic of the seismic activity in the Betic Range (Andalucia, Spain) is the spatial and temporal clustering of the vast majority of events. Subject of this research is especially an area on the coast around the towns of Adra and Berja. In Dec. 23. 1993 an earthquake of magnitude 5.0 occurred there and, eleven days later, there was a second earthquake of the same magnitude with epicentre some 20 km apart. Both main shocks were followed by high seismic activity in the area, apparently as two series, spatially separated and close to the main shock locations. Increased activity continued, including further maxima in 1995 and 1996. Altogether, our local network has recorded more than 700 events in the area.
The clustering of events results in the occurrence of similar earthquakes. Similarity is quantified as the maximum cross-correlation value of wave-arrivals of two events. Using this criterion, we detect groups of similar events among our data. For events of sufficient similarity, the interpolated time shift of the cross-correlation maximum, just as well as the slope of the cross-spectrum phase, indicate the time difference of the arrivals. From the relative delay times at various stations, high-precision relative hypocenter locations of the similar events are calculated. Several authors have described these techniques during the recent years. By applying to our data, we want to obtain information on the location, shape and behaviour of the active fault zones, using the spatial distribution of the relocated events as well as the clustering properties and the temporal development of the seismicity. The extensions and potential connections of the seismic zones touch seismic hazard estimation, the area has been affected by destructive historical earthquakes, the last one (Magnitude 6.4) in 1910.

ST 5/E/04-B4 1440

NOVEMBER 6TH 1990, FORK (DARAB-IRAN) EARTHQUAKE

M. RAEESI (Geophysics Institute, Univ. Of Tehran, Tehran, Iran. email: mraeesi@iman.ut.ac.ir) M. R. Gheitanchi and Z. Zarifi (Raeesi) (Both at the above address, email: mrghchee@chamran. ut.ac.ir and zarifi@iman.ut.ac.ir) and A. Zamani (Dept. of Geology, Shiraz Univ., Shiraz, Iran.)

Southeastern part of Zagros continent-continent collision zone is the most active part of this seismogenic belt. On Nov. 6th 1990 at 18:45:53 GMT a destructive earthquake (Ms 6.9) shook Fork region in this part of Zagros. Twenty-two victims, 100 injuries, 300 buildings with total destruction and 2000 structures with partial damage resulted from this event. A reverse surface rupture about 15.1km in length, 273 degrees in azimuth and dipping toward north, two collapse structures and several landslides accompanied the quake. The greater collapse structure is 60m in diameter and 80m in depth. What discriminates this event from thousands recorded-earthquakes in Zagros seismic belt, is the occurrence of surface rupture. There have been only three earthquakes with reported surface rupture inside and along the limits of Zagros belt before the happening of Fork event. The one inside the belt (July 2nd 1972, 12:56:06, mb 5.4) has a normal fault, while the other two quakes (23 Jan. 1909, 02:48:18, M 7.4 and 16 Aug. 1958, 19:13:43, M 6.6) at northern contact of the belt with neighboring zone have thrust faults with strike-slip components. Then it can be said that the Fork earthquake has the first reported reverse surface rupture inside Zagros belt. Zagros is a sequence of folded marginal sediments with thickness about 12-15km and rarely 18km. About 6 to 7km of these, are competent sediments which are surrounded by incompetent layers. Lower incompetent layer is highly plastic and has a thickness about 1000m and plays a very important role in tectonics of Zagros, especially in separating sedimentary cover from bedrock which prevents from reaching of bedrock breaks to earth surface. Causes of reaching the rupture of Fork quake to surface and seismological aspects of the event with especial concern to aftershock distribution and waveform modeling are discussed.

ST5/E/16-B4 1500

DETERMINATION OF SOURCE PARAMETERS OF 1940'S DESTRUCTIVE EARTHQUAKES IN JAPAN USING SMOKED PAPER SEISMOGRAMS

Masayuki KIKUCHI (Earthquake Research Institute, University of Tokyo, Tokyo 113-0032 Japan, email: kikuchi@eri.u-tokyo.ac.jp), Misao Nakamura (NGP, Tokyo 143-0027 Japan, email: misao@ba2.so-net.or.jp) Makoto Yamada (Waseda University, Tokyo 162-0044 Japan, email: yamadamk@mn.waseda.ac.jp)

In 1940's there occurred several destructive earthquakes in western Japan.Seismograms in this period were usually recorded on smoked paper. Owing to the recent developement of photocopy and image processing techniques, we can reconstruct feasible waveform data by tracing, digitizing, and correcting the arc effect due to inclined lever. In the waveform inversion we consider the uncertainty of instrumental constants (pendulum period, magnification and damping constant), timing, and chart speed. Thus we allow a certain deviation of these constants from the face values given in literatures, and determine the source parameters in the least-squares manner.
So far examined are the Fukui earthquake (M 7.1) of June 28, 1948, and the Tonankai earthquake (M 7.9) of December 7, 1944. We used low gain strong motion data at several observatories of Japan Meteorological Agency, with epicentral distance shorter than about 150 km. In both earthquakes a few subevents were identified including a small introducory rupture with a source duration of several seconds. Another destructive earthquake: the Mikawa earthquake (M 6.8) of January 13, 1945 is also being examined.

ST 5/E/37-B4 1520

AN INVERSION TECHNIQUE FOR THE TEMPO-SPATIAL DISTRIBUTION OF SLIP ON THE FAULT PLANE AND ITS APPLICATION TO THREE RECENT LARGE EARTHQUAKES IN QINGHAI-XIZANG (TIBETAN) PLATEAU OF CHINA

Li-sheng XU and Yun-tai Chen (both at Institute of Geophysics, China Seismological Bureau, Beijing 100081, People's Republic of China; email: chenyt@public.bta.net.cn)

A time domain inversion technique is developed to invert the azimuth dependent source time function (STF) for the tempo-spatial distribution of slip on the fault plane. In this technique we begin by using the moment tensor inversion technique to invert for the focal mechanism of the earthquake. Then we use the de-convolution technique to retrieve the azimuth dependent STF. Finally we translate the azimuth dependence of the STFs of the earthquake into the tempo-spatial pattern of the slip distribution on the fault plane. To stabilize the inversion an inequality constraint that no reverse slip occur, is imposed. Using the data from the China Digital Seismograph Network (CDSN), this technique is applied to study the source processes of recent large earthquakes occurred in the Qinghai-Xizang (Tibetan) plateau of China. Among these earthquakes are the April 26, 1990 Gonghe Ms=6.9, the February 3, 1996 Ms=7.0 and the November 8,1997 Mani MS=7.9 earthquakes. It is demonstrated that the inversion technique is efficient in retrieving the tempo-spatial complexities of earthquake rupture process, even in the case that the available data only come from a few stations.

FULL MOMENT TENSOR RETRIEVAL FROM WAVEFORM INVERSION: AN APPLICATION TO THE BOVEC EVENT (SLOVENIA) AND ITS SWARM

Stefano KRAVANJA, Giovanni Costa (Dipartimento di Scienze della Terra, Universita' degli Studi di Trieste, via E. Weiss 4, 34142 Trieste, Italy) Giuliano Francesco Panza, Peter Suhadolc (Dipartimento

di Scienze della Terra, Universita' degli Studi di Trieste, via E. Weiss 4, 34142 Trieste, Italy and International Centre for Theorethical Physics, SAND Group, Miramare, 34100 Trieste, Italy)

The destructive event occurred in Slovenia on April 12, 1998 and the swarm associated to the main event has been studied by applying the waveform inversion algorithm developed by Sileny et al (1992). The algorithm is a two-step procedure; the first step is the waveform inversion for moment tensor rate functions retrieval; the second step is the factorization of the moment tensor rate functions to obtain a moment tensor and a source time function for total, deviatoric and volumetric components. Using only the waveforms recorded by the Friuli accelerometric network, operated by the Department of Earth Sciences of the University of Trieste, for the main shock we get a source mechanism in agreement with the CMT solution retrieved by Harvard and a smooth source time function. The processed aftershocks have their fault plane solutions characterized by a nodal plane oriented NW-SE, in agreement with the fault plane of the main shock.

ST5/E/22-B4 1700

VARIATIONS IN WORLD SEISMICITY: REAL OR IMAGINARY?

A. Douglas (1), J. B. YOUNG (2), M. A. Chinnery (3), email: alan@blacknest.gov.uk (1and 2) AWE Blacknest, Brimpton, Reading, RG7 4RS, UK (3) NGDC, NOAA, Boulder, USA. (Retired)

Studies of earthquakes with magnitudes over mb 5.0 reported by the International Seismological Centre (ISC) show an apparent variation in world seismicity occurring over the 33 year period 1964 - 1996. Part of this variation appears to be roughly periodic. Initial thoughts suggested links to the solar cycle and sun-spots or to meteorological effects such as El Nino. However, studies using maximum-likelihood methods to recompute magnitudes show that the network of stations used has a far greater effect than any geophysical agents. The ISC has no fixed station network for computing magnitudes and contributing stations can change month by month. For example, it can be shown that an increase in the number of contributing stations actually decreases the number of earthquakes over mb 5.0. By using maximum likelihood methods to re-compute magnitudes with a fixed network of stations which report to the ISC it is shown there is little variation with time in world seismicity.

ST5/P/04-B4 1720

SOME ASPECTS OF SEISMOLOGICAL STUDIES OF JABALPUR EARTHQUAKE 1997 THROUGH GSN BROAD BAND DATA

H.N. SRIVASTAVA (India Meteorological Department, New Delhi-110003, India,
e-mail: snb@imd.ernet-in)

Jabalpur earthquake of magnitude 6.1 on 22 May, 1997, caused the loss of about 45 human lives and major damage to property in the city and neigbouring regions.
The focal depth of the main earthquake was reported as about 30 km. through a depth phase from GSN data by India Meteorological Department and other agencies. However, Sg phases identified on seismograms suggest that the focal depth of the earthquake could be shallower than 30 km as the crustal structure close to Jabalpur based on deep seismic sounding explosion data showed the thickness of granitic layer as 20 km. only.
Based on synthetic seismograms using Broad band GSN long period data, the best crustal velocity giving least errors was seen to fit with a Pn velocity of 7.9 km/sec. This is in contrast with the local crustal velocity model based on deep seismic sounding explosion data wherein Pn velocity was found to be 8.1 km/sec. The results suggest the need for developing improved methodology for utilisation of broad band seismological data.

ST5/E/38-B4 1740

ON THE GLOBAL COMPONENT IN THE SEISMIC ACTIVITY AND ITS CONNECTION WITH OBSERVED PECULIARITIES ON THE EARTH'S SPIN

Alexey Fridman (Institute of Astronomy, Russian Academy of Sciences, 10917, Moscow, Pjatnitskaja ulitsa, 48,Email: flexa@glas.apc.org).Nikolay Gor'kavyi (The Crimea Astrophysical Observatory: email: gorkav@catpeak.crimea.ua) Yuri.TRAPEZNIKOV (International Research Center - Geodynamic ProvingGround in Bishkek, email: tua@laurel.gdirc.ru)

Analysis of the data from the catalog of the National Earthquake Information Center (1964-1988) U.S. Geological Survey shows the possibility to identify three components in the seismic activity of the Earth: (1) the global, or T component, which is a general feature for all the hemispheres and large regions of the Earth's globe; (2) the mirror symmetrical, or M component for the submeridional and sublatitudinal seismogenerating structures which is characterized by reducing activity in the first at the time when seismicity in the second is intensified (and vice versa). This is particular clearly showed within the Pacific Ocean region; and (3) the linear, or R component, characterized by a durable drop or, conversely, growth of seismic activity. Using also the Morrison's year-mean data on the variations in the Earth's spin, we prove the connection of the global component of the seismic process with observed peculiarities in the Earth's spin. We calculated the coefficients of correlation of the Earth's angular speed W (t) and the modulus of its time derivative |dW (t)/dt| with the earthquake number N(t). These correlations depend qualitatively on the value of magnitude. The correlation coefficient between N(t) and W (t) is great for earthquakes with M>4.0, but its value systematically decreases with increasing magnitude. The correlation between N(t) and W (t) entirely absent for Earth quakes with M>5.5. An opposite dependence is demonstrated by the correlation between N(t) and |dW (t)/dt|. There is no correlation for earthquakes of M>4.0, but the correlationcoefficient systematically increases with magnitude and reaches a significant value at M>5.5. Also the analysis of changing these correlation coefficients depending on the depth distribution of hypocenters of earthquakes was carried out. Spreading and subduction zones were studied specially. Furthermore, a high value of the coefficient of correlation between N(t) and |dW (t)/dt| was found on averaging the two graphs over several years and shifting the graph N(t) to the past time. The latter fact may be indicative of change in the Earth's angular velocity as one of the causes of increasing seismic activity or the both things are connected with some third cause.

SEISMOLOGICAL OBSERVATION AND INTERPRETATION: APPLICATIONS

ST5/E/35-B5 0830

ANISOTROPY STUDY IN THE GULF OF CORINTH (GREECE) USING MICROEARTHQUAKES RECORDED BY THE CORNET NETWORK

P. Papadimitriou, G. Kaviris and K. Makropoulos (all at Department of Geophysics, University of Athens, 157 84 Athens, Greece, email: ppapadim@cc.uoa.gr)

The analysis of local earthquakes recorded by the Cornet network and located in the Gulf of Corinth (Greece) has revealed the existence of shear-wave splitting. The visual inspection technique is used to estimate the polarization direction of the fast shear wave and the time delay between the two split shear waves. The selected earthquakes are located close to one of the Cornet stations. Most of these earthquakes are recorded by only one station and their azimuth and angle of incidence are estimated using the covariance matrix decomposition method combined with the P-wave polarization direction. Polarigrams plotted for the horizontal components present a clear linear and almost constant polarization for each station, independent of the azimuth of the earthquake, except for one station where different Sfast polarization directions are observed. The mean direction of the fast shear wave polarization at Paradeisi station is N146˚, at Sofiko station N104˚ and at Villia station N142°. At Desfina station two different main Sfast polarization directions were observed, one N143° and the other N55˚. The calculated time delays between the two split shear waves are higher for the stations located in the eastern part of the Gulf. Comparing the mean Sfast polarization direction with the direction of local faulting, we observe that they are approximately parallel at Sofiko station, while at Villia station they are almost perpendicular. In general, the obtained mean Sfast polarization directions at the CORNET stations are perpendicular to the direction of the extension of the Gulf which is NNE-SSW and consistent with the extensive dilatancy anisotropy model.

STUDY ON MANTLE DISCONTINUITIES USING THE P-SV CONVERTED PHASES

Shaoxian ZANG and Yuanze Zhou (both at Department of Geophysics, Peking University, Beijing 100871, China, email: sxzang@ibmstone.pku.edu.cn, zyz@www.geophy.pku.edu.cn) Y. L. Chen (Department of geological sciences, University of South California, U.S.A.)

The discontinuities were studied using P-SV converted phases. The earthquake, which were recorded at CN2, YNB, BNX, NZN, MIH, MDJ and HIA stations, with epicenter distances from 40!cto 90!cand mb 5.8 were selected to study the discontinuities. The records are different in the eight stations. The records are digital and broadband recording in MDJ and HIA, optical analog recording (by SK instrument) and mechanical analog recording(by DK-1 instrument) in CN2 and YBN, mechanical analog recording(by DK-1) in BNX, YLN, NZN and MIH. The analog records were digitized and selected. Both the analog and digital data in MDJ station were used for comparison of the two kinds of data. Both optical and mechanical analog data in CN2 and YNB stations were also used. The method for picking out the P-SV converted phases was studied. The filter of rectilinearity, direction analysis and phase comparison were applied to determine the P-SV converted phases. The discontinuities near the depth of 520km and 660km were found by the different kinds of records. There are two things needed to mention from the results. Firstly, it was found that the analog records, even the mechanical analog records can been used to study the discontinuities.
Secondly, the discontinuities are not as simple as single interface, they may have certain structure and there may be some anomalous bodies in different depth between the discontinuities.

ST5/W/39-B5 0910

AN EXAMINATION OF LINEAR AND NON-LINEAR EARTHQUAKE LOCATIONS USING SYNTHETIC TRAVEL TIMES FROM A 3D MODEL

Anthony LOMAX and Jean Virieux (both at Géosciences-Azur, Universtiy of Nice - Sophia Antipolis, 250 Rue Albert Einstein, 06560 Valbonne, France, email: lomax@faille.unice.fr)Philippe Volant and Catherine Berge-Thierry (both at IPSN , BP6 92265 Fontenay-aux-Roses, France)

We generate synthetic P and S travel-times in a 3D velocity model for known sources at various depths on a vertical plane passing through a station network with the geometry of the IPSN-Durance micro-seismic network in southern France. With these times we "locate" the sources using non-linear grid and Metropolis-Gibbs searches (valid in 3D models) to obtain a probability density function and equivalent Gaussian uncertainty statistics, and we use the linear method Hypoellipse (Lahr, 1989; valid for layered models) to obtain hypocentres and associated Gaussian uncertainties. We also obtain estimates of the known focal mechanisms using synthetic P wave first motions. To validate the non-linear algorithms and to study a near ideal, but unrealizable location scenario, we examine the locations and uncertainties obtained from the 3D synthetic times using the correct 3D velocity model.
To investigate a more realistic location scenario, we use the 3D travel times with added station static shifts, and locate with a 1D layered model. We compare the locations, uncertainties, and focal mechanisms obtained with the linear and non-linear location methods. We find that with both methods the locations can be strongly biased with respect to the "true" locations of the known sources. For events inside of the network, the linear and non-linear locations and uncertainties are similar, but they can differ significantly (particularly in depth) outside of the network. These differences reflect the limitations of linear inversion in the presence of irregular, highly non-gaussian location uncertainties.

ST5/W/46-B5 0930

REASONS FOR PIDC MISLOCATIONS: A VIEW FROM THE ISC

DMITRY A STORCHAK (International Seismological Centre, Pipers lane, Thatcham, Berkshire, RG19 4NS, UK, email: dmitry@isc.ac.uk)

The prototype IDC (Arlington,USA) provides a rapid first determination of seismic events to aid in the swift identification of suspected non-natural events and publishes the Revised Event Bulletin (REB). The REB is also of great value to non-explosion seismology, including it's contribution to the ISC Bulletin. Although the pIDC network was incomplete, discrepancies between ISC and REB locations provide insight into the utility of data from the higher density of stations reporting to the ISC.
Nearly two years of the ISC Bulletin are now available for comparison with the REB. Differences greater than 1 degree are rare. They occur most often when an REB epicentre is supported by only a few stations in a limited azimuth range. Another common cause of large

discrepancies is identification of depth phases as primary waves in the REB, resulting in phantom events quickly following some deep earthquakes. Both of these problems could be excluded based on a careful selection from the REB alone. Another cause of discrepancies is REB locations computed from phases that additional data available to the ISC show to come from two different origins. Mislocations of this type might be especially difficult to spot based on even the most careful review of REB data alone.

ST5/W/48-B5 0950

HYPOSAT - AN SEISMIC EVENT LOCATION PROGRAM

Johannes Schweitzer (NORSAR, P.O.Box 51, N-2007 Kjeller, Norway)

Since summer 1996 a program package to locate seismic sources was developed that attempts to use as much of the available information as possible to invert the parameters of the hypocenter. The following input parameters are used: travel times, travel-time differences between different phases observed at the same station, backazimuth, and ray parameter. The weighting of all input parameters follows the observed standard deviations and the inversion is done with a generalized matrix inversion code. All partial derivatives are internally recalculated for each iteration. A starting solution with 'a priori' uncertainties can be given or calculated as the intersection of all backazimuth observations. If S observations are available, a source time is estimated using the Wadati formula. Observations of all seismic phases as defined in the IASP91 software can be used for the inversion. Implemented global Earth models are Jeffreys-Bullen, PREM, IASP91, SP6 and AK135. In addition, self defined horizontally layered local or regional models, or the crustal structure of Mooney et al. (1998), can be used to localize seismic events. The observed travel times are corrected for the ellipticity of the Earth, and corrections for the elevation of the seismic stations are calculated using the local P and S velocities below the stations. The global crustal model can also be used to correct reflections at the Earth's surface (e.g. pP, sP, PP, SS, P'P',) at their reflection points.
The program package can be copied via anonymous ftp from ftp.norsar.no under /pub/outgoing/johannes/hyposat.

2-D SEISMIC RAY TRACING AND ARRIVAL TIME INVERSION USING A SPECTRAL DECOMPOSED PROPAGATION MEDIUM

R. DE MATTEIS (Universita' del Sannio, Via Caio Ponzio Telesino, 82100 Benevento, Italy: e-mail: raffa@sungea03.na.infn.it), A. Zollo (Dipartimento di Scienze Fisiche, Universita' di Napoli "Federico II", Mostra d'Oltremare pad. 16, 80125 Napoli, Italy: e-mail: aldo@sungea03.na.infn.it) L. D'Auria (Dipartimento di Scienze Fisiche, Universita' di Napoli "Federico II", Mostra d'Oltremare pad. 16, 80125 Napoli, Italy: e-mail: luca@sungea03.na.infn.it), J. Virieux (Geoscience Azur, CNRS-UNR, Universite' de Nice-Sophia Antipolis, Valbonne, France; e-mail: viri@seisme.unice.fr)

We propose a new method for exact 2-D ray-tracing and body arrival time computation based on series expansion representation of medium velocities. The velocity field is represented by the sum of a polynomial and wavenumber spectral Fourier decomposed functions which accounts for the long wavelength velocity variations and short wavelength anomalies. In this case the ray vector equation is resolved locally by setting the initial conditions for ray position and parameter. We provide the iterative analytic expression for computing ray coordinates in a heterogeneous elastic 2-D medium. Synthetic examples show the effect of medium spectral features on the arrival times and ray paths and they allow us to suggest a criterion to estimate the higher wavenumber corners for a given acquisition geometry and arrival time uncertainty. This spectral approach turns to be very efficient for applications to seismic tomography problems where the medium spectral content and the minimum resolved wavelength are generally unknown. In fact, a medium description through a Fourier series enables one to estimate by arrival time data inversion both the medium properties and the minimum resolvable wavelength. We further developed a method for a non linear inversion of Tau-p curves based on travel time computation in a 2-D spectral decomposed propagation medium. This method is based on a global optimization technique (SIMPLEX and Montecarlo methods) which explore the whole parameter space i.e. the coefficients of the polynomial and spectral Fourier functions. Preliminary applications to synthetic and real data from an active seismic experiment will be presented.

ST5/W/04-B5 1145

ADAPTIVE AUTOMATIC PHASE REPICKING FOR HIGH-PRECISION HYPOCENTER RELOCATION IN LARGE SEISMIC DATA SETS

Charlotte ROWE and Richard Aster (both at Dept. of Earth and Environmental Science, New Mexico Tech, Socorro, New Mexico, U.S.A., email: char@dutchman.nmt.edu), Michael Fehler and W. Scott Phillips (both at Los Alamos National Laboratory, Los Alamos, New Mexico, U.S.A, email: fehler@muktinath.lanl.gov)

We report on the development of an efficient algorithm to adjust inconsistent phase picks and produce high-precision hypocenter estimates for large data sets with preliminary phase picks. The technique first estimates a large number of lag constraints for appropriate seismogram pairs by invoking a combination of adaptive coherency-driven prefiltering for coarse alignment and robust coherency-weighted evaluation of the minimum L-1 norm cross-spectral phase slope. Additional correlation processing which may significantly improve repicking and relocation of events in some data sets includes correlation of signal envelopes and adaptive band-rejection of coherent energy in pre-pick time windows. Pre-pick-based filtering is expected to be especially important for data sets exhibiting coherent background noise such as oceanic microseisms or harmonic volcanic tremor, and in improving the consistent picking of S-waves, which may be superimposed on significant coherent energy from the P-wave coda. Events are assigned to similarity classes based on a weighted function of median waveform and/or envelope crosscorrelation maxima. Within each similarity class, pick adjustments from interevent lag constraints are independently estimated using a memory-conservative conjugate gradient approach which minimizes the L-1 norm misfit. We demonstrate the technique using a collection of induced microearthquakes from the Soultz, France hot dry rock geothermal reservoir. This data set is especially well suited for a demonstration of the technique because of its finely detailed seismogenic features corresponding to intersecting joint structures, and because of a large previously-existing data set of manually-estimated consistent picks against which to gauge the success of the algorithm.

ST5/E/33-B5 1205

MOMENT TENSOR INVERSION OF REGIONAL WAVEFORMS : STUDY OF THE SIGNIFICANCE OF THE ISOTROPIC COMPONENT

Valerie TEYSSONEYRE and Bruno Feignier (both at Laboratoire de Detection et de Geophysique, CEA, BP12, 91680 Bruyeres le Chatel, France, email: teyssone@ldg.bruyeres.cea.fr)

The aim of our study consists of discriminating between isotropic and deviatoric sources, particularly to study the significance of the isotropic component in the results from moment tensor inversion using data recorded at regional distances. At such distances, high frequencies are still observed in the waveforms, therefore requiring the use of complex propagation models to compute the Green's functions. In a first step, we have tested our inversion program on a synthetic case. This was done by generating "real" seismograms with the reflectivity method in a flat layered medium and the same model was used to calculate the corresponding Green's functions. We successfully retrieved the correct moment tensor and were able to reconstruct the original signals. This set-up was also used to estimate the influence of the azimuthal station coverage and the number of stations used in the inversion on the resulting moment tensor. Results showing the significance of the obtained isotropic component will be presented. In a second step, we apply our method to an event which occurred near the town of Halle in Germany and was due to a mine collapse. Thus, the nature, location, and geometry of this source is known. Therefore, we were able to test the influence of inadequate Green's functions and measure their impact on the moment tensor obtained, particularly concerning the isotropic component.

OBSERVATIONS OF T-WAVES IN SEISMIC STATIONS IN SOUTHERN SPAIN FROM EARTHQUAKES OF THE NORTH COAST OF MOROCCO

J.M. IBÁÑEZ (1,2), E. Carmona (1) and G. Alguacil (1,2). (1) Instituto Andaluz de Geofisica, Universidad de Granada, Campus Universitario de Cartuja s/n, 18071 Granada, Spain.; (2) Departamento de Física Teórica y del Cosmos. Facultad de Ciencias.Universidad de Granada. 18071 Granada. Spain.

In the present work we show observations of the arrival in short-period vertical seismic stations, placed in southern Spain, of converted T-waves from earthquakes located in the North coast of Morocco. The observation of this type of waves is common for big earthquakes and oceanic paths in which the presence of a SOFAR channel is well known. The novelty of this study is the appearance of this type of wave for earthquakes with moderate and low magnitude (m<4.0) in a short sea path (less than 180 km) and with the presence of strong sea streams (this area is close to the Strait of Gibraltar).
The main characteristics of the converted T-waves are:
• They are observed only in the stations placed close to the coast. For stations located more than 40 km from the coast line there are no observations of them.
• They are observed for earthquakes located in a few areas of the coast of North of Morocco. Not all the seismogenetic sources of this region show these arrivals.
• The spectral contain of these converted T-waves is different to the coda spectral form on which they are overlapped. The spectral shape is reicher in high frequencies and very similar to the P or S waves packet.
• By assuming that the T-waves have been originated in the same area as the earthquakes, their average propagation speed is around 1024 m/s, the same as the sound speed in water. We have calculated the attenuation factor of these converted T-waves by comparing the spectral level of the signal among stations located near the coast line and inland. The Q-value is very low and different to the coda-Q of the area, and similar to the expected surface Q-value. This observation, among others, permits us to infer that these converted T-waves are basically Rayleigh waves. Measuring the time delay among these seismic stations we could establish the possible area in which the T-waves are converted to Rayleigh waves. This zone is located around 1 km inside the sea in the Spanish coast.

AUTOREGRESSIVE ESTIMATION OF SPLITTING MATRICES AND THE ROTATION OF THE INNER CORE.

G. Laske, G. Masters, and F. Gilbert (IGPP, Scripps Inst. of Oceanography, U.C. San Diego SIO-0225, La Jolla, CA 92093; ph. 619-534-2470; e-mail: fgilbert@ucsd.edu)

Recent large earthquakes, recorded by the rapidly growing global seismic networks, have produced a vast amount of high quality data. This new datasetallows us to re-evaluate the techniques used to determine the coupling and splitting characteristics of modes, and hence the three dimensional structure of the earth. Current techniques tend to be computationally intensive and require detailed models of earthquake sources (which may be unavailable for the large and often complicated events used in free-oscillation research). Here, we introduce a new technique that allows us to solve for the most general form of the splitting matrix without knowledge of the earthquake sources. This technique is based on the autoregressive property of combinations of seismograms for each event allowing the splitting matrix to be estimated in a non-iterative, one-step process. We apply this technique to anomalously split modes which are sensitive to the inner core and get extremely reliable estimates of their splitting matrices. These splitting matrices can be used to compute theoretical splitting matrices for past earthquakes assuming different relative rotation rates for the inner core. We find that very small relative rotation rates (less than 0.3 degrees per year) are consistent with our data which is in agreement with new analyses of body-wave data.

ST5/E/12-B5 1420

THE EMERGENCE OF NEW NORMAL MODE CONSTRAINTS ON LONG-WAVELENGTH 3-D DENSITY STRUCTURE

Joseph Resovsky and Michael Ritzwoller (Department of Physics, University of Colorado, Boulder, Campus Box 390, Boulder, CO, 80301, email: resovsky@abdu.colorado.edu)

The acquisition of new normal mode constraints on mantle structure from the 3-6 mHz frequency band should prove to be one of the key components to the development of reliable models of long-wavelength density structure. We have developed an approximate method of modeling the along-branch coupling of the fundamental modes that are the dominant signal in this frequency domain. Modeling of these surface-wave fundamentals enables precise measurements of important lower mantle sensitive modes that are otherwise obscured by the fundamentals, as well as the acquisition of new constraints on upper mantle structures, including anelastic heterogeneity. We show the results of tests which confirm the accuracy of our approximation, and present examples of the new structure coefficients that have been estimated through the application of this technique to a much larger database of long-duration seismograms than that employed in any previous normal mode inversions.

ON SUPER CONDUCTING GRAVIMETER OBSERVATIONS IN SEISMIC SPECTRAL BAND AT THE METSAHOVI STATION, FINLAND

Heikki VIRTANEN (Finnish Geodetic Institute, Geodeetinrinne 2, PL 15, FIN-02431 Masala, Finland)

The summary of four years observations from lowest spheroidal normal mode 0S2 with the GWR T020 superconducting gravimeter, participating Global Geodynamics Project at the Metsahovi station, Finland, are given. Big earthquakes cause excitation of free oscillation of the Earth; modes decaying during few days, except the mode 0S0, which is observable in weeks after some major events at nanogal level. The main attention, however, is paid to find evidences for excitations of normal modes without quaking at the level near to noise limit. The causes of excitation could be slow or silent earthquakes, or the atmospheric-solid earth interaction. Some examples of the excitation are given in seismically silent periods. In addition, the seismic background noise at the site, in the region of microseismicity up to 300 mHz is reviewed.

OBSERVATIONS OF ULF SEISMIC ACTIVITY AND INTERNAL WAVES IN THE SHELF ZONE OF SEA

Vadim V. NAVROTSKY, Vadim V. Novotryasov, Grigoriy I. Dolguikh (Pacific Oceanological Institute, 43 Baltiyskaya Str., Vladivostok, 690041, Russia, email: navr@online.vladivostok.ru)

The laser interferometer (LI) of the Pacific Oceanological Institute with measuring base of 52.5 m has linear frequency response in the 0-300 Hz range and can detect relative displacements of the Earth crust with the accuracy of 1 picometer. It is important to identify different mechanisms of ultra-low frequency vibrations of the Earth crust. The spectral analysis of LI and water temperature records was made in the range from tidal till short internal wave frequencies. The amplitudes of the registered seismic deformations were 7.0 microns for the 24-hour tide and 8.7 microns for the half-day tide. Comparisons of the registered deformations with theoretical calculations for litosphere were made. Basing on model calculations and observational results we can maintain that internal waves in the shelf zone of sea can be the cause of rather stable maximum in the spectra of near-shore litosphere deformations. We suppose that basing on these results a new method of remote sensing of important hydrophysical processes in the shelf zone of sea can be developed.

DIRECT CALCULATION OF EIGENFUNCTIONS AND EIGENFREQUENCIES OF FREE OSCILLATIONS OF THE ROTATING ELLIPTIC EARTH

Vladimir GORBUNOV (Vavilov State Optical Institute, Birzhevaya 12, St.-Petersburg, 199034, Russia, E-mail: gorbunov@neva.spb.ru) Polina Serebryanaya (SPbF IZMIRAN, Muchnoi 2, St.-Petersburg, 191023, Russia, Email: gorbunov@neva.spb.ru)

The earth's rotation and ellipticity of figure cause the splitting of seismic normal modes that is commonly evaluated by perturbation theory. We present here the results of numerical computations of normal modes of rotating, elliptical and oceanless earth model obtained by another way. Our numerical procedure is direct integration of linearized equations of motion by using expansions in vector spherical harmonics to reduce the problem to infinite set of coupled ordinary differential equations over radius. This approach has been already used by M.Smith in the study of the Slichter triplet of inner core translational oscillations, by J.Wahrtidal response. The motivation for the present work is the idea that it is more simple way then perturbation theory to obtain the eigenfunctions of a multiplet because a good accuracy is reached with a truncated system by taking a few neighboring terms in the expansion of the displacement field. The scheme we use to convert vector equations with boundaryconditions to scalar equations is considerably modified. Among other things it does not require the ellipticity to be small. In this report we examine the multiplets of lower spheroidal mode of degree 2 and its overtones by taking only three terms: spheroidal displacement of degree 2and toroidal displacements of degree 1 and 3. In particular, we have found that the center member of the fundamental multiplet is shifted in period by 2.27 s to corresponding degenerate eigenfrequency (perturbation theory gives 0.88 s). This method is convenient for investigation of near-resonance multiplet coupling that has strong effect oneigenfunctions. The study of such quasi-degenerate multiplets (when two eigenfrequencies are close together) offers a possibility in evaluation of asymmetry in the Earth's model of the odd degree.

USE OF A PORTABLE DENSE SEISMIC ANTENNA TO STUDY VERY LOCAL MICROEARTHQUAKES: APPLICATION TO SEVERAL VOLCANIC AREAS

G. ALGUACIL (1,2), R. Ortiz (3), E. Del Pezzo (4), J.M. Ibáñez (1), J. Almendros (1) , J. Morales (1,2), G. Saccorotti (5,4), E. Carmona (1), S. Petrosino (4), M. Abril (1), M. La Rocca (5), F. Bianco (4) and M. Castellano (4).; (1) Instituto Andaluz de Geofisica, Universidad de Granada, Campus Universitario de Cartuja s/n, 18071 Granada, Spain; (2) Departamento de Física Teórica y del Cosmos. Facultad de Ciencias. Universidad de Granada. 18071 Granada. Spain.(3) Departamento de Volcanología. Museo Nacional de Ciencias Naturales. CSIC. C/ J. Gutiérrez Abascal, 2, 28006 Madrid, Spain; (4) Osservatorio Vesuviano - Via Manzoni 249, 80123 Napoli, Italy; (5) Universita' degli Studi di Salerno, Dipartimento di Fisica, Via S.Allende, 84081 Baronissi, Salerno, Italy

The present work shows: the design of a digital portable dense short-period seismic antenna, thought out to study very local microearthquakes; some techniques developed to determine the position of the seismic source; and its application to several volcanic areas.
The seismic antenna is composed of several eight channels modules. Each module has 8 seismometers with preamplifiers close to them that permits to send the signal via cable to the data logger, a data acquisition system and a GPS time receiver. The seismometers used in the experiments were Mark L15 and L25, with natural frequency in 4.5 Hz and electronically extended to 1 Hz, or Mark L4C, with natural frequency in 1 Hz, that sometimes was extended to 0.1 Hz. The data acquisition system is composed of an eight channel anti-alias Butterwoth multipole filter at 48 Hz, a multiplexer that samples the channels every 5 ms and a 16 bits A/D converter. The internal clock is synchronised by GPS time every second and the sampling rate used was 200 sps. The control of the whole system and the storage of the data are done by a portable PC. The triggering algorithm is based on the STA/LTA ratio and with the possibility of a continuous registration.
Two techniques were used to locate the position of the seismic sources: in the time domain we used the named Zero Lag Cross Correlation, and in the frequency domain the called MUSIC algorithm. Parallel to that we improved the ZLCC method introducing the approximation of a circular wave-front incoming to the seismic antenna. Also, a probabilistic approach for the estimate of the slowness vector from these data was used.
Since 1994 these instruments and techniques have been deployed and applied to several volcanic areas: Teide volcano (Spain), Deception island (Antarctica), Stromboli and Vesuvius (Italy) and Llaima (Chile). In some of them (Deception, Vesuvius or Llaima) only one dense antenna was deployed. In others (Teide, Stromboli and also Deception) two dense seismic antennas were deployed in order to obtain a joint location of the seismic source. These and other applications of the seismic antennas are presented in the sessions ST5, JSS46 and JSV47.

THE SWISS EARTHQUAKE MONITORING SYSTEM (CH-NET)

M. BAER, D. Giardini, U. Kradolfer, E. Spuehler and P. Zweifel, Swiss Seismological Service, ETH, CH-8053 Zurich, Switzerland (email: sed@seismo.ifg.ethz.ch)

The Swiss Seismological Service (SED) is responsible for earthquake monitoring in Switzerland and is upgrading the existing seismic networks and individual instruments to establish a modern, integrated monitoring system to serve the earthquake surveillance needs of Switzerland. The new Swiss Earthquake Monitoring System (CH-NET) will replace in the year 2000 the former analog national seismic network and upgrade the existing strong-motion instrumentation. The upgrade will be completed in the 1997-1999 period and is supported by ETHZ. The new CH-NET includes four modules: 1.the Swiss Digital Seismographic Network: 29 broad-band digital stations (Streckeisen STS-2 sensors, Nanometrics HRD 24-bit digitizers) with homogeneous coverage of the Swiss territory and continuous digital data transmission through a protected federal computer network; six BB stations and the central acquisition system are now in operation; 1.the Swiss digital Strong-Motion Network: five arrays (34 stations) monitoring large dams and 63 free-field stations, with concentrations in areas of expected higher strong motions (Basel, Wallis, E. Rhine Valley), equipped with wide-band sensor, DCF-radio clock, and phone connection for automatic data retrieval; 2. the Data Management Center unifies the acquisition, storage and distribution of waveforms from the seismographic and strong-motion networks and fulfills the SED duties of earthquake monitoring; 3.the portable seismographic and strong-motion networks.

INVESTIGATION OF THE PHYSICAL ORIGIN OF THE LONG-PERIOD VERTICAL SEISMIC NOISE

Yuri Starovoit, IIEP RAN, Warshavskoye sh. 79, k1, Moscow, Russia. email: yuri.starovoit@ctbto.org.

Combination facilities of colocated broad band seismometer STS-1 in OBN (Russia) and microbarometer is en effective tool for observation of coupling effects in the boundary between atmosphere and the Earth surface. Even vertical instrument, whose protection against influence of pressure changes much better than horizontal one, sometimes in good agreement with ambient pressure variations in the range 0.8mHz<f<40mHz. The mechanism of this residual correlation was a subject for investigations. Despite uncertainty in absolute values of thermal sensitivity of seismometer's spring and time constants of temperature penetration through the chain of cases, the spectrum of apparent displacement caused by temperature variations was estimated. As a result, an observational spectrum of vertical seismic noise reduced to the pressure variations could be explained as a combination of two effects, which dominate in different passband. First effect, in the range 0.8mHz<f<1.5mHz, could be a result of direct influence on the pendilum by temperature changes in the vault, caused by pressure variations. For computations it was used the values of thermoelastic constant of the leaf spring in the range 3*10^-6 - 3*10^-7 1/K. Ground movements induced by pressure variations dominate in the frequency range f>3mHz. For computations of the transfer function between pressure changes and ground movements it was considered a model of changeble load applied to the elastic halfspace. The spatial correlation of the pressure field was chosen as a variable. Playing with a parameter a good agreement with experimental curve was obtained for reasonable values of spatial correlation of the pressure variations.

SUPERPLUME PROJECT: SOUTH PACIFIC BROAD BAND SEISMIC NETWORK (SPANET)

Mizuho ISHIDA (National Research Institute for Earth Science and Disaster Prevention, 3-1 Tennodai, Tsukuba-shi, Ibaraki-ken 305-0006, Japan, email: ishida@geo.bosai.go.jp)

The "Super Plume" project is to examine the recent working hypothesis of "super plume tectonics" in the light of newly obtained from a broad range of earth sciences; seismology, geology, high-pressure experiments, geodesy, and numerical simulation of mantle convection. The seismological part of this project includes construction of three seismic networks: JISNET (Japan-Indonesia Seismic NETwork: temporal array of broadband seismic stations in Indonesia), GARNET (Global Alliance of Regional NETworks: integrated digital data base from local networks) and SPANET (explanation follows) under the generic name of PANSY (Pacific Networks for Seismology). The main objective of SPANET (South Pacific Broadband Seismic NETwork) is to resolve the mantle structures beneath the South Pacific where a large scale slow anomaly in global tomographic image has been considered to represent a superplume ascending from the core-mantle boundary. Fir this purpose we will deploy, by the end of 2000, sixteen broad-band seismographic stations in and around the relevant region, including ten stations in collaboration with IRIS Incorporated Research Institutions for Seismology). We have already established six CMG-3T stations by cooperation with Australia, Fiji, Tonga, Niue and Cook Islands. All the data from the above three networks are archived at DMC (Data Management Center) of NIED (National Research Institute for Earth Science and Disaster Prevention) in cooperative with IRIS and the collaborated countries. The program is financially supported by STA (Science and Technology Agency), which is started in 1996 and is scheduled to be completed in 2000 (First period:1996_$B!A_(B1998, Second period:1999_$B!A_(B2000).

DATA PROCESSING AND DISSEMINATION IN THE CANADIAN NATIONAL SEISMOGRAPH NETWORK

Jim Lyons, Philip Munro, John Adams, and David MCCORMACK (Geological Survey of Canada, 7 Observatory Crescent, Ottawa, Ontario, K1A 0Y3, CANADA, email: lyons@seismo.nrcan.gc.ca)

The Canadian National Seismograph Network (CNSN) comprises about 100 automatic, unattended digital seismographs installed across Canada. Continuous data from each site are formatted into 6-second packets and transmitted to dual (for redundancy) network centres located in Ottawa, Ontario and Sidney, BC. Data telemetry employs a variety of dedicated full- and half-duplex links over domestic VSAT satellite, terrestrial telephone, and UHF radio. At the

National Seismology Data Centre (NSDC) in Ottawa, almost a gigabyte of continuous, compressed data from 150 seismic components and a 4-element infrasound array are acquired, quality controlled, processed, and archived on a daily basis. For significant local and regional events, automatic event detection, event location, and e-mail alerts are accomplished within minutes. Automatic processing of Yellowknife Array (YKA) data allows global events to be detected, locations refined, and e-mail alerts issued to national and international subscribers within three minutes of p-wave arrival. The National Earthquake Database (NEDB) provides the national repository/index for all phase measurements, and derived parameters. The National Waveform Archive (NWA) holds all digital waveform data. The NSDC acts as Canada's National Data Centre for the CTBT International Monitoring System, forwarding continuous data in near real-time from YKA and 3 other primary seismic stations, a hydroacoustic station, the Infrasound Array, and eventually 4 radionuclide stations, to both the Vienna International Data Centre (IDC) and the prototype IDC in Arlington, VA. The IDC regularly requests additional data from 6 secondary seismic stations via AutoDRM. Continuous data from 10 broad band sites designated "Federation" (FDSN) stations are supplied to the IRIS DMC within weeks of real time for archive. Event-related digital waveforms since 1975 are available from regional networks in Eastern and Western Canada, as are continuous CNSN data since 1992. AutoDRM provides convenient access to on-line waveform data plus selected bulletins, etc. from the NEDB. Once the NWA has been transcribed to a new automated library system (hopefully next year), our entire digital waveform data holdings will be available online. Our Web server, active since April 1995, provides ready dissemination of data to both the scientific community and the general public.

HOT SPOT OBSERVATORY ON ICELAND - A PROPOSAL ON MULTINATIONAL EFFORT

REYNIR BODVARSSON Dep. of Earth Sciences, Uppsala University Ragnar Stefansson Icelandic Meteorological Office Freysteinn Sigmundsson Nordic Volcanological Institute, Iceland Axel Bjornsson Nordic Volcanological Institute, Iceland

The Iceland Hot Spot is a large scale feature on Earth, a plume located beneath the Mid-Atlantic Ridge showing effects over an area of several hundreds thousands square kilometers (gravity). The role of the plume in the deformation processes acting on thecrust is poorly understood. There are indications that the plume up-flow and rifting of the adjacent parts of the Mid-Atlantic ridge have observable influence on the crustal stress in the continents of northern Europe and America. Flow of basaltic fluids into the crust and stresses exerted by the plume cause large variations in the seismicity rate as well as the rate of volcanic activity in Iceland.
The intensified monitoring in Iceland related to seismic risk mitigation has indicated that strain waves related to intrusive episodes can be monitored over large distances (several hundreds of kilometers). The aimof this poster is to put forward an idea of a multinational effort regarding design and construction of a multidisciplinary multistation geophysical observatory for monitoring various geophysical signals from the plume. Continuous geodetic measurements using GPS, gravity, volume strain-meters in bore-holes, long period MT measurements, radioactive gases and microearthquakes are among the observations suggested. The challenge is not only of scientific nature, but also technical as an unmanned observatory with good communication facilities is to be constructed in a mountain area at a latitude of 65 deg N. In this poster we also demonstrate the existing monitoring facilities.

GEOSCOPE 2000

Genevieve ROULT, Jean-Paul MONTAGNER,Jean-Francois KARCZEWSKI and Eleonore STUTZMANN (Departement de Sismologie, Institut de Physique du Globe, 4 place Jussieu, 75252 PARIS-Cedex 05, France)

The GEOSCOPE program corresponds to 28 stations (25 permanent stations and three contributing stations) well distributed. All of them are in the VBB configuration (144db, 24bits), except two of them which have to be transformed. Four channels are recorded, VH and LH channels continuously with respectively a sampling rate of 0.1sps and 1sps, MH which is triggered with a sampling rate of 5sps, and BH which is triggered in 14 stations and continuously recorded in 14 stations. The scientific and technical staffs of GEOSCOPE are defining a new digitizer (144db, 24bits, BH continuously recorded at 20sps for a STS1 sensor, and triggered at 80sps for a STS2 sensor). All stations of the GEOSCOPE program will be equipped in the next future, not only with seismometers, but also with magnetometers, a set of microbarometers, a set of microthermometers, inclinometers, GPS..., in order to transform each station in a multi-parameter observatory. GEOSCOPE 2000 is coordinating with OFM program (Ocean Bottom Observatory) in order to fill the instrumental geographical desert of the oceanic regions, and to install new multi-parameters observatories.
In the future ten GEOSCOPE stations will be teletransmitted by commercial satellite in real time, in cooperation with the french agency CEA/LDG.

ORFEUS: STATUS AND RECENT DEVELOPMENTS

TORILD VAN ECK, Bernard Dost, Reinoud Sleeman and Laslo Evers ORFEUS, c/o Seismological Division, Royal Netherlands Meteorological Institute, PO Box 201, 3730 AE De Bilt, The Netherlands. http://orfeus.knmi.nl, E-mail: vaneck@knmi.nl.

ORFEUS is rapidly developing. Crucial is the exponential growth of the number of installed and operating broad-band seismograph stations in the European-Mediterranean area, rapid developments in data exchange and internet facilities and extended interests from research institutes. This last factor is obvious in the increased activities within ORFEUS four working groups (Station siting, Technical assistance, Mobile equipment and Seismological Software). The Orfeus Data Center (ODC), the core activity of the organisation, is taking advantage of the improved data exchange and internet facilities, with 1) its Near Real Time (NRT) data base and EuroSpyder and 2) extended use of AutoDRM and NetDC. In 1998 the ODC has produced 15 CD-ROM's (10 GB data from 1992 and 1993) and continued providing on-line Spyder(R) and SEED data. The challenge in 1999 will be to continue providing an increasing amount of data from an increasing diversity of sources in a user friendly way. Within the Orfeus working groups activities continue with, among others, the EuroMed stationbook, technical overviews, developing lecture notes, equipment and project overviews, the ORFEUS Seismological Software Library. Further, two workshops: 'Installing, operating and data processing of mobile seismograph station deployments' and 'Java in seismology' are planned for the autumn 1999. Information on new developments and on-going activities will be reported in the ORFEUS Electronic Newsletter.

ACCESSING DATA FROM THE ISC

Anna SURGUY and Raymond J Willemann (International Seismological Centre, Pipers Lane, Thatcham, Berkshire RG19 4NS, UK, email: anna@isc.ac.uk)

The ISC has distributed its data in print, as the Bulletin and Catalogue, since its inception. We have provided data in digital format on custom-written tapes and other media since early in the Centre's history and we continue to provide outcomes from specialised searches of our data. During this period, the Centre established a policy of distribution at a price just sufficient to cover the cost of reproduction. Starting in 1995, we released a series of CDs that now provide our complete data set in computer-readable form, at lower cost than custom products. Since 1997, we have made all of our analysed data freely available on the Internet from our web site. In the future we plan to continue improving the accessibility of our data and the ease of integrating it with other data. New query tools on our web site will provide greater flexibility in selecting data. We have implemented mechanisms to generate focused links to other Internet nodes and insert them in our on-line Bulletin. The objective is not to merely tell users of other data sources, but to link them directly to a moment tensor, waveform collection or velocity model needed for further analysis of the event they have found in the Bulletin. We are working with other seismic data centres to help define more widely useful standards for data exchange and CORBA-compliant object classes. We are evaluating the possibility of distributing functions written in Fortran, C and other languages to allow users to more easily access our data from within their own programs.

NETWORK BROADBAND SEISMOGRAM DATABASE BASED ON JAVA

Seiji TSUBOI (Department of Geoscience, National Defense Academy, Yokosuka 238-8686, Japan, email: tsuboi@cc.nda.ac.jp) Shingo Watada and Yoshio Fukao (both at earthquake Research Institute, University of Tokyo, Tokyo 113, Japan, email: watada@eri.u-tokyo.ac.jp)

We have developed Network Data Center software by using Java-RMI so that users can retrieve, in a standardized format, the data from different data centers in different format, through a common web site without connecting each data center. Java-RMI(Remote Method Invocation) realizes a CORBA-like Object Oriented environment. We have defined several classes based on Java-RMI to retrieve both continuous and event seismograms from remote data centers. We put RMI diapatcher and RMI server at each data center which provides broadband seismograms. The requests received at local RMI dispatcher are delivered to corresponding RMI server at remote data center. When the requested data is found, then the data are sent back to local dispatcher. Users can download the data thorugh the brouser such as Netscape. Currently, prototype system is actually running at Ocean Hemisphere Network Data Center at Earthquake Research Insitute of University of Tokyo. This Network Data Center software will be quite useful if there are several data centers that provide seismograms from different network in different format, such as in the case of PACIFIC21 which is a generic name of the integrated broadband seismogram database in Japan.

SEISMIC NOISE LEVEL IN THE GEOSCOPE STATIONS

El\'eonore STUTZMANN, Genevi\`eve Roult (both at D\'epartement de Sismologie, Institut de Physique du Globe, 4 place Jussieu, 75252 PARIS- CEDEX 05, France.) and Luciana Astiz (at IGPP-SIO, 9500 Gilman Dr, La Jolla, CA 92093-0225, USA)

The seismic noise level of GEOSCOPE stations has been studied for the year 1995 to quantify the station quality. On the horizontal components, the seismic noise varies in most stations as a function of local time for periods greater than 20 seconds. It is higher during the day than during the night. Only stations located in cold areas with little daily temperature variations and stations installed on a long tunnel do not display these daily noise variations.
There is no seasonal variation of short period seismic noise (periods less than 7 sec). On some continental stations, we observe variations of the amplitude of the 7 sec microseismic peak during the year. On all 3 components, the peak amplitude is higher and shifted toward longer periods in fall and winter than in spring and summer. This phenomenum can be explained by an increase of the number and the amplitude of oceanic storms in autumn and winter. For some stations, long period seismic noise (periods greater than 30 seconds) also varies as a function of the season but no systematic characteristic has been observed.
The seismic noise level is lowest at continental stations. Island stations have a similar low noise level at long period but a high noise level for periods shorter than 10 seconds, in particular at the period range of the microseismic peak. Finally, some coastal stations have a low noise level similar to the level at continental stations.
The systematic installation of thermometers and microbarometers at future GEOSCOPE stations will allow the quantification of the environmental influence on seismic noise. These data will be used to reduce the noise level of seismic data.

ST5/W/L/03-B3 Poster 0900-12

RESULTS FROM THE HAWAIIAN SWELL EXPERIMENT

G. Laske, J. Phipps Morgan and J. Orcutt (IGPP, Scripps Inst. of Oceanography, U.C. San Diego SIO-0225, La Jolla, CA 92093; ph. 619-534-8774; e-mail: glaske@ucsd.edu)

The SWELL experiment (Seismic Wave Exploration in the Lower Lithosphere) is designed to map the 3-dimensional seismic structure of the lithosphere and upper asthenosphere beneath the Hawaiian Swell, using intermediate-period Rayleigh waves. The experiment is a multiple-deployment experiment where we use 8 ocean bottom differential pressure gauges in a hexagonal array, with station spacing of about 200km. In successive redeployments, this array will be placed in a leap-frog manner around the Hawaiian Island Chain. Our low-cost seafloor dataloggers (L-CHEAPOs) enable us to conduct sea-going experiments on a reasonable financial level. This experiment provides a genuine alternative to land-based seismic studies where the resolution power is either too low (global studies) or the station coverage is insufficient (regional studies) to map the fine-scale structure of the entire swell.
We recently recovered the instruments of the 12-month pilot deployment which was co-located with the pilot OSN borehole experiment to the southwest of the Hawaiian Islands. We have analyzed waveforms for more than 65 events and are able to obtain stable estimates of Rayleigh wave dispersion at periods between 15 and 70s. In this period range, the recorded waveforms are remarkably consistent with the recordings of the global broad-band station KIP on Oahu. The good azimuthal data coverage allows us to obtain an unbiased estimate of the average structure beneath the array which corresponds to that of lithosphere between 50 and 100~Myr of age. We therefore conclude that the generation of the Hawaiian Swell is inconsistent with thermal rejuvenation in its pure form. While there is little lateral heterogeneity across the array, we find evidence for significantly lower phase velocities under stations which are closest to the islands. The low velocities, which are in concordance with the results of other recent land-based studies, imply a rather narrow channel of hot plume asthenosphere which

has been dragged along the Hawaiian Island Chain. The good data coverage also allows us to study the azimuthal dependence of phase velocity, hence lets us constrain flow patterns in the mantle.
The results of the pilot experiment, together with those of the re-deployments will allow us to explore to which extend each of the proposed mechanisms are involved in the generation of the Hawaiian Swell: (1) thermal rejuvenation, (2) compositional underplating, (3) dragging of hot plume asthenosphere.

MODERN, DIGITAL MULTI-FUNCTIONAL REAL-TIME SEISMOGRAPHIC NETWORK FOR SOUTHERN CALIFORNIA, US: TRINET

Jones, L. M., D. Given, D. Wald (USGS, 525 S. Wilson Ave., Pasadena, CA 91106), and Hauksson, E., R. Clayton, K. Hafner, T. Heaton, K. Hutton, H. Kanamori, P. Maechling, J. Goltz (Seismo. Lab. 252-21, Calif. Insti. Tech., Pasadena, CA 91125);

The United States Geologi-cal Survey, the California Institute of Technology, and the California Department of Conservation are deploying a new generation of seismographic network in southern California. The purpose of this network, called TriNet, is to record and analyze earthquake ground motions in southern California, and distribute that information quickly, to improve our understanding of earthquakes and their effects, to contribute to improving building codes and structural design, and to facilitate emergency response in cooperation with other agencies. TriNet has two elements with the California Department of Conservation element concentrating on engineering applications and the Caltech/USGS element (SCSN/ TriNet) concentrating on seismological and emergency response aspects.
To fulfill its part of the mission, SCSN/TriNet must have capabilities beyond what has previously been designed into any seismographic network. Rapid acquisition and processing of digital data streams exceeding 2 Mbytes/second, realtime ground motion estimations and hardened data distribution channels are some of the new requirements. We have prepared system specifications for SCSN/ TriNet to ensure achievement of five goals: First, operate a hardened seismographic network, that is sufficiently dense to document the true distribution of ground motions at kilometer resolution and robust enough to operate successfully in even the largest possible earthquakes. Second, coop-erate with other agencies working to mitigate the earthquake hazard in southern California in the recording, analysis and distribution of information, Third, create an easily accessible database of earth-quake information in southern California for seismological and engineering research. Fourth, distribute information about an earthquake rapidly after occurrence to save lives and property, by facilitating decision making and mitigating actions such as search and rescue, fire prevention, and deployment of engi-neers and inspectors for building inspection. Fifth, develop a pilot early warning system that would allow us to know that an earthquake has begun before damaging shaking arrives at more distant sites and conduct social science research on the use of such data to be ready to implement once funds for future SCSN/TriNet enhancements, including sufficient stations, are obtained.

DYNAMICAL CHARACTERISTICS OF SEISMIC NOISE LEVEL OF STATIONS OF KAZAKHSTANI SEISMOLOGICAL NETWORK

ZLATA I. SINYOVA, Natalia N. Mikhailova, Igor I. Komarov (email: igr@kaskelen.almaty.kz)

Data of eight seismic stations, located in the northern, eastern and south-eastern parts of Kazakhstan were used in the present study of seismic noise level. These are the following stations, belonging to the National Nuclear Center of Kazakhstan Republic: Kurchatov, Borovoye, Vostochnoye, Zerenda, Chkalov, Aktiybinsk, Makanchi; and Talgar. Starting from 1994, all of these stations are equipped with STS-2 and CMG-3 seismometers. The spectral and dynamical characteristics of seismic noise were studied for all three components (vertical and two horizontal), covering frequency diapason from 20 Hz to 0,001 Hz.All seismometers are installed on bedrock foundation. The spectral density of seismic noise was computed in acceleration domain. For each component the following parameters were computed: median, variance, and histogram of distribution of seismic noise level for a number of frequencies (5 Hz, 1 Hz, 0,1 Hz). The shapes of curves of median values of spectral density on all stations are rather similar. However, there exist a clear difference between curves of spectral density for short-period seismic noise (for frequencies high than 0,2 Hz). At frequency 10 Hz a variation of noise level between quietest and nosiest stations reaches 20 dB; at frequency 1 Hz - accordingly, 7 dB; and there is no statistically significant difference between noise level of different stations at frequencies lower than 0,2 Hz. The low level of seismic noise, as well as a small daily variations of seismic noise, allows to consider the Kazakhstani network as a very effective for monitoring of nuclear explosions and earthquakes, especially for regions of Central and Southern Asia.

A PROBABILISTIC APPROACH FOR THE ESTIMATE OF THE SLOWNESS VECTOR FROM SEISMIC ARRAY DATA

G. SACCOROTTI, Università di Salerno, Via Salvador Allende 84081 Baronissi (SA), e-mail: gilberto@osve.unina.it; E. Del Pezzo, Università di Salerno, Via Salvador Allende 84081 Baronissi (SA), Osservatorio Vesuviano, Via Manzoni 249, 80123 Napoli; e-mail: delpezzo@osve.unina.it.

Array analyses in volcano seismology is the main tool for detecting and quantifying the complex wave-field associated to the volcanic activity, mainly the volcanic tremor and the long period events. The methods based on the analysis of the signal in the frequency domain, or spectral methods (MUSIC algorithm), take the main vantage of both resolving closely-spaced sources and computer speed, but severely fail in the analysis of short duration signals . Conversely, the time domain methods, based on the cross-correlation estimate of signal pairs, can be applied even for short pulses. Both for time and frequency domain techniques, an exhaustive view of the errors associated to the slowness vector estimate does not exist. The estimate of the error is important in the inversion of the slowness vector for source location. In the present work we develop a method based on a probabilistic formalism, which allows for a complete definition of the uncertainties in the estimate of frequency-slowness spectrum based on the measure of the zero-lag cross-correlation. The method is based on the estimation of the theoretical frequency-slowness power spectrum, which can be expressed as the convolution of the true signal with the array response pattern. The application of the Bayes theorem allows for the final estimate of the data probability density function. The method is tested with synthetics using waveforms resembling the most common volcanic earthquakes, and applied to real data as an example.

WHY THE ISC CONTINUES TO SEARCH FOR "UNREPORTED" EVENTS

Since 1974 the International Seismological Centre has searched its unassociated phase readings to find events not reported by other agencies. About 100 to 200 such events are found each month, and while the number of events published by the ISC has risen dramatically over the decades, the number of "new" events has remained steady. Many are genuine new events located in remote areas, such as oceanic ridges, where instrumental coverage by national agencies is poor, or situated near national boundaries, where no single country can obtain a solution with its own stations alone.
One example of a new event was the first earthquake to be confirmed as occurring in continental Antarctica, in 1982. Many new events are already known to local agencies, but their origins are not reported to ISC because they are too small, or are known to be of non-seismic origin, such as mining explosions. In early years the distribution of new events was widespread, but recent improved global location capability of agencies such as the Prototype International Data Center has greatly reduced their number in remote areas. A few are still found, however, in Hindu Kush, Myanmar, and around the Pacific Rim. Many more events are now being found in areas with good local coverage, such as Alaska, Mexico, Andean South America and New Zealand, where for various reasons not all locally determined origins are reported to ISC. Also, the new events seldom have teleseismic amplitude and period readings for ISC to determine a magnitude, and locally determined values of ML are rarely available. Reviewing these events takes a considerable proportion of ISC's analysis effort, and ISC plans to reviewthe procedure to ensure that genuine new events, particularly in remote areas, continue to be discovered without devoting undue effort to rediscovering events already known. We report on regional variation in the proportion of new events not in local catalogues, particularly those requiring data from two or more networks.

HIGH FREQUENCY WAVEFORM INVERSION OF CROSSWELL DATA

Henk Keers, Lane Johnson, Don Vasco (Dept of Geology and Geophysics, Lawrence Berkeley National Lab, UC Berkeley, Berkeley CA 94720, email: henk@ccs.lbl.gov)

Seismic waveforms are inverted using an asymptotic method. The asymptotic method provides an efficient way of computing partial derivatives of the data with respect to the model. The partial derivatives enable the formulation of a waveform inversion algorithm, which is applied to a laboratory crosswell experiment. The goal of the laboratory experiment was the detection of a non-aqueous phase liquid (NAPL) in water saturated sand. The sand was imaged before and afterinjection of the NAPL. Using the waveform inversion method, low velocity anomalies wereimaged that correlate well with post-experiment determination of NAPL concentrations. The low velocity anomaly defocuses the seismic energy. However the observed amplitude reduction due to the low velocity anomaly is not enough to explain the observed low amplitudes. We suggest that other mechanisms (such as multiple scattering, scattering on pore scale), not included in the waveform modeling, play an important role in decreasing the amplitude.

COMPARISON OF MANUAL AND AUTOMATIC ONSET TIME PICKS

Mark Leonard (Australian Geological Survey Organisation, PO Box 378, Canberra City, ACT 2601, Australia, email: mleonard@agso.gov.au)

A data set consisting of analyst onset picks from 60 teleseismic waveforms recorded at an array was used to test the accuracy of automatically generated arrival times from two onset picking algorithms. The 60 picks are picks which an analyst considered could be picked to within 0.2 seconds. They have small to moderate SNRs. Four comparisons were made: the single trace with the beam for the four analysts; the four analysts with each other; the analysts with the ES method (Earl, P. and Shearer, P. (1994) and an AR method similar to Kvaerna, T. (1995).
On average an event manually read on a beam was picked 0.125 seconds earlier than the single trace, with a standard deviation (std) of 0.18 seconds. For the single trace the analysts picks differed on average by 0.1 seconds with a std of 0.15 seconds (0.05 and 0.11 for the beam). The ES method produced similar times to the analysts for large events but performed poorly for small amplitude events. The AR onset time picker typically picked 0.1 seconds after the analyst with a std of 0.2 seconds (0.8 and 0.15 for the beam. There were three events which the AR picker picked more than 0.2 seconds before an analyst but there was no single event where the AR picker differed significantly. Generally the AR picker picks at the same time or slightly later than an analyst.
These findings suggest that for modest sized iP phases the AR onset time picker can pick events with a similar accuracy as an experienced seismic analyst.

WAVELET TRANSFORM BASED S PHASE PICKER

Bojan Uran (Geophysical Survey of Slovenia, Kersnikova 3, 1000 Ljubljana, Slovenia, email: bojan.uran@gov.si)

Single-station three-component seismogram processing in the nearly real time is important for automatic location of earthquakes, distributed data processing and early warning systems. There exist many successful algorithms for P phase arrival picking, but picking of S phase is more difficult. Wavelet transform is used for interscale analysis of polarisation data of the three-component seismograms. Tests have been done with standard wavelet basis functions for a typical set of local and regional seismograms. Newer techniques, like wavelet packets, Malvar wavelets, lifting scheme and matching pursuit were also used to best match the S wave recording and obtain the best estimate for the S phase arrival.

DETERMINATION OF UPPER MANTLE S-WAVE STRUCTURE BENEATH CENTRAL EUROPE USING WAVEFORM TOMOGRAPHY

T. Meier, P.G. Malischewsky, U. Walzer, (Institute for Geosciences, Friedrich Schiller University Jena, Burgweg 11, D-07749 Jena, Germany, email: meier@geo.uni-jena.de)

A regional upper mantle S-wave velocity model for Central Europe is obtained by inversion of longperiod waveforms. Synthetic waveforms for the vertical component are matched to measured waveforms in a frequency range between 6 mHz and 40 mHz. The synthetics are calculated by summation of Rayleigh modes. While the fundamental mode gives resolution in depths between the Moho and about 300 km higher modes allow to map heterogeneity between about 300 km and 660 km depth. The model is interpreted tectonically. For selected paths one-dimensional models for the vertical component obtained by summation of Rayleigh

modes are compared to one-dimensional models based on the inversion of the transverse component and summation of Love modes.

ANNUAL CHANGING RATE OF THE CRUSTAL STRAIN-ENERGY DENSITY AND ACTIVITYOF STRONG EARTHQUAKES IN CHINESE MAINLAND

ZHANG Dongning and XU Zhonghuai

The annual changing rates of the crustal strain-energy density in Chinese mainland are calculated by using the finite element method, and the calculation is constrained with the tectonic stress field and the GPS results of the crust motion. The numerical model is constructed with 3-D elasto-viscous body, and some large-scale active faults are involved. Gravity and buoyancy forces in Tibetan Plateau are considered. Some boundary loading is applied as convergence of Eurasia plate with Pacific plate and Indian plate.
The calculation results are compared with the distribution map of strong earthquakes in China. The transitional zones of the positive and negative strain-energy changing rate areas are just corresponding to Longmenshan fault, Yanshan-Yinshan E-W tectonic zone, Tianshan tectonic zone, Xianshuihe-Xiaojiang fault, Honghe fault and faults around Erdos block, which are all the strong earthquake zones in history. The average recurrence interval of the strong earthquakes is evaluated with the calcualtion results of the changing rates of the crustal strain-energy density. The average recurrence interval in western China should be 250 years or so, and it may be longer in eastern China.

CRUSTAL STRUCTURE IN NORTH MARGIN OF TIANSHAN MOUNTAINS, CHINA

Chun-Yong

The fine crustal structure in the area of 1906 Manas (M=7.7) earthquake, the north margin of Tianshan mountains, is obtained from a deep seismic reflection profile, which stretches across the northern Tianshan piedmont and has a nearly north-south trend. The CDP stack section is characterized by a thin-skinned piggyback structure of crust. The profile is divided into two parts and bounded by the Manas reverse fault. The south part of the profile is transition zone of the Tianshan block and the Junggar block. There are anticlines (Qingshuihe anticline and Manas anticline) and detachments in upper crust. A detachment at depth of 8(10km relates the Manas anticline to the Qingshuihe reverse fault. The north part of the profile belongs in the Junggar block. There exits a 12(14km thick sedimentary cover in the depression. The Moho discontinuity beneath the basin is located at the depth of about 45km and deepens southwards.
The hypocenter of 1906 Manas earthquake is inferred at the junction of the Qingshuihe reverse fault and the detachment, and the epicenter is about 40km far from the Manas reverse fault, where the surface rupture of the Manas earthquake was discovered. It is implicated that the seismotectonics of the earthquake is a fault system constituted by the Qingshuihe reverse fault, detachment and shallow ramp.

NUMERICAL STUDY OF ENVELOPE BROADENING IN RANDOM MEDIA

M.FEHLER and Lian-Jie Huang

Observed long duration of S-waves from earthquakes at depths between 100 and 200 km beneath Japan can be explained as being caused by multiple forward scattering between the source and receiver. For the study of multiple forward scattering effects, we calculated wavefields using two numerical methods: (1) the local Rytov Fourier method, which models forward scattering effects more reliably than the split-step Fourier method and is computationally fast and (2) finite difference solution of the acoustic wave equation, which gives complete wavefields. In addition, we compare envelopes calculated using the Markov approximation, which allows the direct calculation of seismogram envelopes in statistically characterized random media. We calculate the time trace of the RMS envelope averaged over 65 simulations at a distance of 200 km from a point source, where the source waveform is a 2 Hz Ricker wavelet. We used a 2D random media characterized by a correlation distance of 5 km, a RMS fractional fluctuation of 5%, and an average velocity of 4 km/s. The delay between the first arrival and the time that the envelope reaches its peak amplitude is slightly greater and the amplitude of the later portion of envelope is slightly larger for the finite difference solutions than the local Rytov solutions. The envelope calculated using the local Rytov approximation is nearly identical to that calculated analytically using the Markov approximation. Our results show that the local Rytov simulation and the Markov approximation provide reliable information about envelope shapes for forward scattered wavefields but that the influence of wide-angle scattering and backscattering have some influence on envelope shapes and should be considered when analyzing data using random media models.

SIMULATION OF COMPLETE WAVE FIELD PROPAGATION IN VOLCANIC STRUCTURES

Guido Russo, Aldo Zollo (both at Dipartimento di Scienze Fisiche, Universita' di Napoli "Federico II", Mostra d'Oltremare, Pad. 16, 80125 Naples, Italy, Email: russog@na.infn.it, aldo@sungea03.na.infn.it), Mario Mango Furnari and Alberto Imparato (both at Istituto di Cibernetica, C.N.R., via Toiano 6, 70082 Arco Felice (Naples), Italy, Email: mf@cib.na.cnr.it, a.imparato@cib.na.cnr.it)

We have implemented a finite difference (FD) code as part of the interpretation tools developed in the framework of TomoVes project that is aimed at reconstructing the crustal structures underneath Mt. Vesuvius (Italy) by active and passive seismics. The FD code is based on stress-velocity approach implemented by an explicit method on a staggered grid with fourth order spatial operators. It can handle 2D elastic heterogeneous models. To simulate the effect of topography (an essential feature in almost every volcanic area) we adopted a technique consisting in gradually reducing the stress components to zero. The code undergoes a constant upgrading of its performaces by hardware and software improvements. Also, we are developing the code to include anelastic attenuation. We extensively used the FD code to simulate the complete wavefield propagation in heterogeneous volcan modelsobtained by tomographic inversion of first arrival times. Synthetic and observed seismic sections recorded along the main profiles of TomoVes96 experiment are compeared in order to validate arrival times models and verify their consistency with the observed waveform amplitudes.

MODELLING SEISMIC WAVE PROPAGATION IN 2-D CYLINDRICAL WHOLE EARTH MODEL BY PSEUDOSPECTRAL METHOD

Yanbin WANG, Hiroshi Takenaka (both at Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, Hakozaki 6-10-1, Higashi-ku, Fukuoka 812-8581, Japan, Email: wang@geo.kyushu-u.ac.jp, takenaka@geo.kyushu-u.ac.jp) and Takashi Furumura (Faculty of Education, Hokkaido University of Education, Midorigaoka 2-34-1, Iwamizawa 068-0835, Japan, Email: furumura@atson.iwa.hokkyodai.ac.jp)

We present a method for solving the elastodynamic equations in 2-D cylindrical coordinates using the pseudospectral method (PSM). The model and the wavefield are defined in the angular and radial directions, and the derivatives of wavefield are approximated by using the fast Fourier transform in both of the directions.
To solve the 2-D cylindrical elastodynamic equations for whole earth, singularity arises at the center (r=0) of the earth. To avoid this singularity, we develop a scheme that uses extension of field variables in the radial direction. Wavefield at the center and the wave propagation through the center can be calculated by this scheme.The time interval used in the calculation is chosen according to the smallest grid spacing in the grid. In cylindrical coordinate system, the smallest grid spacing is located around the center in the angular direction that is much smaller than the grid spacing in radial direction. Generally, the smallest angular grid spacing around center is so small that the calculation is too time consuming to be carried out. We adopt a multidomain scheme (Takenaka & Wang, 1999) to increase the smallest angular spacing and increase the time interval that is large enough to make the calculation for the whole earth model to be implemented on a general computation resource.
We apply the algorithm to the PREM model in a 2-D slice of the whole earth firstly, and then apply it in the forward modelling of wave propagation in more complex models considering subduction, mantle convection.

LASTIC MODELLING BY A MULTIDOMAIN APPROACH OF THE FOURIER PSEUDOSPECTRAL METHOD USING DISCONTINUOUS GRIDS

Hiroshi TAKENAKA and Yanbin Wang (both at Dept. Earth & Planetary Sciences, Kyushu Univ., Hakozki 6-10-1, Fukuoka 812-8581, Japan, email: takenaka@geo.kyushu-u.ac.jp)

The pseudospectral method is a high-accuracy numerical modelling technique that requires less computer memory and computation time than the traditional techniques such as the finite-difference method. These advantages of the pseudospectral method have enabled us to practically apply this method to modelling seismic wavefields in realistic models that have complex structures such as a sedimentary basin. However, if the sedimentary layers are included in the model, high velocity contrasts arise because of the very low S-wave velocities of the sediments as compared with the bedrock. The grid spacing then has to be very small, which leads to a spatial oversampling in regions with higher velocities. As a result, we also have to use very small time interval for time marching so that the computation requires much CPU time. A breakthrough of this problem is use of a multidomain approach that can employ different grid spacing in different regions, i.e. ``discontinuous grids''. In this study we propose a scheme of the Fourier pseudospectral method for discontinuous grids, which uses an interpolation by the FFT. This scheme can reduce the computation time as compared with the conventional one. In the presentation we also show the accuracy and efficiency of our approach.

NUMERICAL CALCULATIONS OF SEISMIC WAVES BASED ON SOME NONLINEAR VISCOELASTIC MODEL

Dmitry N. Mikhailov, Institute of Physics of the Earth, Russian Academy of Sciences. B. Gruzinskaya 10, Moscow, 123810, Russia, email: dmikch@uipe-ras.scgis.ru.

Effects of nonlinear propagation of seismic waves in the Earth crust are actively studied recently. The estimates of nonlinear parameters of real rocks show that these media have coefficient of nonlinearity, which exceeds coefficient of nonlinearity of homogeneous solid on 2 - 3 order. Such high value of nonlinearity can be related with a mesastructural heterogeneity of geological media, that is with presence in such media of pores, cracks, grains, blocks, etc. The experimental study of features of seismic waves in the Earth crust have shown, that this process generates oscillations of higher or combinative harmonic, distorting a basic seismic wave. The nonlinear attenuation, formation of solitons and other nonlinear effects were observed in experiments.
The generalized viscoelastic rheology model, including an interior linear scale of a media and nonlinear parameter, was suggested for theoretical study of seismic wave propagation. This model consist of equations of mass and impulse balances and rheology equation (relation between strain and stress). The rheology equation was built on base of combination of some mass and viscoelastic rheological elements. Some type of nonlinear relationships between strain and stress were used.
It was shown that in a long wavelength approximation and at a small period of a spreading wave compare with a relaxation time, the resulting equations are reduced asymptotically to the Burgers equation. The numerical calculations of seismic wave propagation were performed on the base of this model. The results were compared with the data of physical experiments. The dependencies of attenuation and velocity of seismic waves on frequencies were found.
These results may be useful for study and constraction of real models of seismoactive zones and for development of new types of prediction of earthquakes based on usage of nonlinear effects (for example, variation of higher harmonic intensity).

SYNTHETIC SEISMOGRAMS OF BODY WAVES IN MULTILAYERED ANISOTROPIC MEDIA

EVGENI M. CHESNOKOV, Alexander A. Vikhorev, and Sergey S. Abaseev (all at the Institute of Physics of the Earth, Russian Academy of Sciences, ul. Bol'shaya Gruzinskaya 10, Moscow, 123810 Russia, email: echesn@uipe-ras.scgis.ru, e.chesnokov@ucl.ac.uk)

For seismology, of importance is to develop the methods for efficient solving the general wave equation, which describe the dynamics of inhomogeneities in arbitrary anisotropic medium. In this work , we present a technique for calculating the Green function of the general wave equation, which is based on summing the normal modes of natural oscillations of the medium. The technique allows one (1) to avoid the pole integrals unacceptable in numerical modelling and (2) to modify the problem of calculating the Green function for inhomogeneous anisotropic medium, successively introducing of inhomogeneities varying from horizontal layers to finite

three-dimensional inclusions. The time needed for numerical calculus also decreases, since the solution is found for relatively great observation times: t >> w(min), where w(min) is the lower bound for signal frequency recorded. The Green function of the layered anisotropic medium with finite three-dimensional inclusions of arbitrary shape is represented as definite integral over two-dimensional sphere, whose integrand is regular function. Attention is paid to the difference between the Green function and theoretical seismogram, obtained as a result of filtering the Green function by the model filter being an analog of receiving apparatus.

INFLUENCE OF SHAPE AND SIZE OF MICROINHOMOGENEOITIES ON EFFECTIVE STATIC ELASTIC CONSTANTS

EVGENI M. CHESNOKOV, Yuri A. Kukharenko (both at Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya,10, Moscow 123810), John Queen (at Conoco Inc., Seismic Imaging Technology Center, 1000 S.Pine,P.O.Box 1267, 4487 RW, Ponca City, OK -74602-1267, USA), and Peter Yu. Kukharenko (at Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya,10, Moscow 123810)

Investigations of the influence of inhomogeneities on the tensor of effective elastic constants usually assume elliptically shaped inclusions. The usefulness of this assumption is quite broad because a wide range of shapes, from needles to spheres, can be represented. At the same time this approximation is rather nerrow, because elliptical inclusions imply a uniform or homogeneous strain field throughout the inclusion. This does not correspond to the real situation found in icroinhomogeneous rocks.
In this paper inclusions of an arbitrary shape are considered. A method for the description of the shape of inhomogeneities is developed. This allows us to calculate analytically the influence of shape on elastic constants of media containing spheres of various radii, hemispheres and spherical segments. Combining these segments allows us to model media with "flower" shaped inclusions. In this case "flowers" can have different petals. Mathematically this means that in integration over wave vector, we can take into account Fourier components which are determined by the shape of the inclusions.
A numerical procedure for the calculation of the effective elastic tensor elements including the influence of various shapes of inclusions is developed. This procedure also accounts for structural correlations in locations and size of inclusions.

MATHEMATICAL MODELING THE PHYSICAL PROPERTIES OF ARTIFICIAL AND NATURAL ROCK SAMPLES

Alexander A. Vikhorev, EVGENI M. CHESNOKOV, and Irina O. Bayuk (all at Institute of Physics of the Earth Russian Academy of Sciences, ul. Bol'shaya Gruzinskaya 10, Moscow, 123810 Russia, email: echesn@uipe-ras.scgis.ru)

Effective physical characteristics of porous-cracked anisotropic media were calculated. In order to find the effective elastic tensor, the generalized singular approximation was applied. The effective tensor was used to compute the angular dependencies of longitudinal and shear wave velocities. The dependencies were compared with experimental data obtained for artificial samples of porous-cracked media. A good agreement between theoretical and experimental values of the body waves were established. For the effective medium in question, the theoretical seismograms of longitudinal and shear waves were calculated, which were compared with the oscillograms observed in experimental study (Rathore et al., 1995).

EARTHQUAKES AND THEIR SPECTRAL ESTIMATIONS USING EINSTEIN DECONVOLUTION

Dan LOEWENTHAL, Raymond & Beverly Sackler (Faculty of Exact Sciences Department of Geophysics and Planetary Sciences and Tel Aviv University (Ramat Aviv 69978, Israel. email: danlo@jupiterl.tau.ac.il)

In a recently patented idea, I have conjectured the validity of dual fields theory, which teaches us how seismic or electromagnetic phenomena can be analysed to a much higher precision in comparison to a single field analysis.
In its acoustic embodiment these dual fields are the pressure and the particle velocities fields, as registered by hydrophones and geophones, respectively. This can be effectively done in ocean bottom environment. According to this theory both these fields are initiated by the same source. They both solve the same classical wave equation in regions of homogeneous layers but they differ and are nonlinearly coupled through the boundary conditions, where they possess opposite sign reflection coefficients. Since the source is common, it convolves both fields. Thus, its Green's function is estimated by the ratio of these fields defined through its Z transform polynomials. Using transform ratio of these two fields, a rational polynomial presentation of the system is attained, where the source wavelet cancels out. This allows deterministic spectral estimation similar to the maximum entropy or bayesian estimators. But while the bayesian and maximum entroy estimators are of trial and error statistical approach, our source de-convolution, which is the essence of Einstein-Lorentz velocities additions-subtractions formula, is deterministic in nature.

AFTERSHOCKS SEQUENCE OF THE 1997 ZIRKUH (GHAEN-BIRJAND) EARTHQUAKE IN EAST-CENTRAL IRAN

M.R. GHEITANCHI (Geophysics Institute, University of Tehran, Tehran, Iran. email: mrghchee@chamran.ut.ac.ir) M. Raeesi (Geophysics Institute, University of Tehran, Tehran, Iran. Email: mraeesi@iman.ut.ac.ir)

On 10th May 1997, a shallow destructive earthquake occurred in east-central Iran (07:57:29.7 GMT, 33.825N, 59.809E, depth 10km, mb 6.4, Ms 7.3, Mw 7.1; USGS). The mainshock happened along the southern extension of an earlier quake in 1979 and caused extensive damage and 1563 human lost. The field study reported 113km NW-SE trending new discontinuous surface faulting produced by the mainshock. The predominant faulting was right-lateral strike-slip. The recorded waveforms are complicated. Furthermore, the reported long duration of shaking also indicated that the faulting during the mainshock was complex. In order to study the aftershock activity, a temporary seismic network was deployed within the meizoseismal area shortly after the occurrence of the mainshock. The seismic activity was monitored for two months. The network included seven portable digital PDAS and three analog Sprengnethers MEQ-800 systems. The aftershocks were determined by using the HYPO71PC software and good locations were selected on the basis of RMS smaller than 0.3s. The distribution of epicenters suggests that aftershock activity appeared to be close to the macroseismic epicenter having focal depths in the range of 1-20 km. This indicates that the faulting is mainly taking place in the upper crust. Aftershocks extend over an approximately 120km long zone with a general NW-ES elongation. The seismicity appears to be more scattered than along a fault zone. Three barriers were determined by aftershock distribution which two of them coincide with gaps between surface rupture segments. As the number of the seismic stations is very limited, focal mechanism solutions for a single event cannot be drawn. An attempt has been made to determine composite focal mechanisms for various aftershock clusters.

SOURCE CHARACTERISTICS OF THE 1998 GOLBAF, SOUTH-EAST IRAN, EARTHQUAKE

M.R. GHEITANCHI (Geophysics Institute, University of Tehran, Tehran, Iran. email: mrghchee@chamran.ut.ac.ir)

Golbaf in Kerman province, south-east Iran, is one of the seismically active regions in the country. On 14 March 1998 at 19h 40m 27.1 GMT, a strong earthquake occurred in Golbaf. The earthquake killed 5 people, injured 50, destroyed 2000 homes and left 10,000 homeless in the Golbaf area. The USGS located the mainshock as 30.15N-57.57E with magnitude mb=5.9, Ms=6.9, and Mw 6.6. Harvard University reported a Centroid Moment Tensor analysis for the mainshock. It shows two nodal planes striking 153 (dipping 65 SW) and 61 (dipping 86 SE). A similar solution was given by USGS. The mainshock was associated with a fresh surface faulting and preliminary focal depth determination indicated a shallow focal depth.
Shortly after the occurrence of the mainshock, the University of Tehran deployed a temporary seismic network in the affected area to observe the aftershock sequence and carried on field investigation. In this study, using the results of field observation and aftershocks study the teleseismic body waveforms of this earthquake are inverted to their sources to investigate the source characteristics. The result of this study suggests that the mainshock was a single event having a strike-slip mechanism. Rupture during the Golbaf earthquake initiated in the epicentral area and propagated bilaterally to southeast and northwest. Assuming a NW-SE direction for the fault strike, as revealed from the field investigation, the mainshock has a right-lateral strike-slip mechanism, which is predominant in this region. The seismic moment is calculated to be M0=7.12 *10 **25 dyne-cm. Approximating the rupture area by L*(L/3) and the fault length L=30 km, the average stress drop will be about 35 bar and the estimated static displacement is about 80 cm.

ON THE STUDY OF STRESS STATE OF EARTH CRUST AT TATARSTAN OIL REGION

Kamil MIRZOEV ("TATaria-Oil", Tatarian prospecting, Chernyushevcky 6/2, 420503, Kazan, Russia Email: seismo@kazan.su), Albert Lukk , Sergei Yunga (both at Institute of physics of the Earth, Moscow, 123810, B.Gruzinskaya, 10, Email: syunga@uipe-ras.scgis.ru)

One of the first attempt of estimate some features of stress state of Russian plate is presented. This new evidences of stress-strain state are obtained for a territory of Tatarstan. Stress state study presented here is available through small earthquakes data acquisition and processing. They are based on our instrumental seismological observations of numerous weak local earthquakes and their fault plane solutions. Local seismic network consist from more then 10 stations. Determination of composite earthquake focal mechanism is performed on the base of P-wave first arrivals in the framework of standard approach. Preliminary results of the SE-NW compression stresses are obtained. Proceeding from these representations, it is possible to believe, that the recent tectogenesis process should be displayed in more preferable development strike-slip faults on systems of submeridional and sublatitudinal orientations, as well as thrust and overthrust faults on planes of south-east and north-west incidence. These results are correspond to really observable dominant orientation of tectonical joints and microfractures.
Corresponding indication on prevailing development on a territory of Tatarstan and Bashkortostan regional bend of microfractures of north-east direction is reported by Stepanov et al, 1994, 1995. There are the basis to believe, that between fracture tectonics and recent evidences of tectonical and seismic activity there is reasonably close interrelation. It can assists in the establishment of geological correlation models with regard to migration of hydrocarbons.

RUPTURE CHARACTERISTICS OF THE 25 MARCH 1998 ANTARCTIC EARTHQUAKE

Masayuki KIKUCHI and Yoshiko Yamanaka (both at Earthquake Research Institute, University of Tokyo, Tokyo 113-0032 Japan, email: kikuchi@eri.u-tokyo.ac.jp) Keiko Kuge (Department of Geophysics, Kyoto University, Kyoto 606-8502 Japan) Tatsuhiko Hara (International Institute of Seismology and Earthquake Engineering, Building Research Institute, Tsukuba 305-0802 Japan)

A very curious earthquake occurred in an ocean area of the Antarctic plate. We investigate the rupture characteristics of this earthquake using the teleseismic body waves and long-period surface waves recorded by IRIS network. The results of body-wave inversion show two clusters of subevents.
The first cluster consists of a few subevents propagating 60 km to the west during the initial 60 s. The other subevent cluster, which is located at about 120 km west of the epicenter, ruptures during 70-90 s after the initial break. The focal mechanism has a nearly pure strike-slip with NW-SE tension, and almost unchanged during the main process. The westward rupture is also observed in the radiation of long-period surface waves, for which we obtain a total rupture length of about 150 km by assuming two-subevent rupture. The moment tensor solution determined from the surface waves is characterized by strike-slip faulting with NW-SE tension with a large non-double-couple component (NDCC). The NDCC is so significant that it cannot be attributed to long-wavelength lateral heterogeneity of the Earth interior. A temporal and spatial separation of the subevent clusters alone cannot also explain this NDCC, which seems to require other origin than the earthquake source.

STATISTICS OF SEISMICITY AND SOURCE PROCESSES OF EARTHQUAKE SWARM AROUND KAMIKOUCHI, JAPAN, IN 1998

Hiroshi Aoyama, Satoshi IDE, Minoru Takeo and Naoshi Hirata (all at Earthquake Research Institute, Univ. of Tokyo, 1-1-1 Yayoi Bunkyo, Tokyo, 113-0032 Japan, E-mail: aoyama@eri.u-tokyo.ac.jp, ide@eri.u-tokyo.ac.jp)

On August 7, 1998, an earthquake swarm activity began from Kamikochi, Nagano pref., Japan. To make detailed analysis Earthquake Observation Center (EOC), Earthquake Research Institute (ERI), University of Tokyo, installed two broadband seismometers in the

swarm region. These data are used for hypocenter determination and various analyses together with routine seismic networks. During first 4 months of the activity, about 7500 hypocenters are manually determined.We first made statistical studies of the seismicity. Because it has been reported that b-value of Gutenberg-Richter law exceeds 1 in some volcanic active regions, we investigated frequency-size relation of the seismicity and determined b-value. The b-value of overall activity is almost 1 and that for each cluster decreases to 0.5-0.8. This study alone cannot probe the relation to the volcano. We also studied the source rupture process for 17 earthquakes of ERI magnitude 4 or larger, using empirical Green's function method. The rupture of the largest event (Mw 5.2), which mainly propagated to the west and was the largest moment release, occurred 2 s after rupture initiation. More than a half of 17 events show such pre-process before the main moment release. This must be a regional feature of earthquake source process and might be related to some inhomogeneity of crustal structure.

SPATIAL AND TEMPORAL ANALYSIS, BY USING BAYESIAN AND CLUSTERING TECHNIQUES, OF A SEISMIC SERIES IN GRANADA BASIN (SPAIN)

E. CARMONA (1), G. Saccorotti (2), A.M. Posadas (1, 3), J.M. Ibáñez (1, 4), E. Del Pezzo (5), G. Alguacil (1,3) and J. Morales (1, 3). Instituto Andaluz de Geofísica. Universidad de Granada. Campus de Cartuja s/n. 18071 Granada. Spain.; Dipartimento di Fisica. Universita di Salerno. Via Salvador Allende. 84081 Baronissi, Salerno, Italy. Departamento de Física Aplicada. Universidad de Almería. 04071 Almería, Spain. Departamento de Física Teórica y del Cosmos. Facultad de Ciencias. Universidad de Granada. 18071 Granada, Spain. Osservatorio Vesuviano. Via A. Manzoni, 249. 80123 Napoli, Italy.

A seismic swarm located in the centre of Granada Basin (Spain) occurred between December 1988 and February 1989 is analysed in the present work. From more than 400 events we selected 132 earthquakes and micro-earthquakes recorded in at least four digital stations and with magnitudes ranging between 1.5 and 4.1. The first analysis procedure was to relocate the whole subset picking the first P-wave onset and its uncertainty interval. This analysis was done by standard location procedure as HIPO77. Second, the Bayesian analysis (a probabilistical approach) was applied, from the preliminary location, to the above data in order to obtain regions with maximum likelihood of hipocentral location at every event. The overlapping of these volumes provides the most probable distribution of the source volume. Third, the principle component analysis was applied to the hipocentral distribution obtained in the step one. This analysis has provided the main fault plane that was active during the swarm and other secondary planes.
We compared the focal mechanisms obtained by the inversion of the polarity of the first motion of the P-wave with the planes observed in the above analysis and with the source volume focused with the Bayesian analysis.
Finally we are comparing, by using cross correlation techniques, the different events located inside the source volume in order to distinguish families of events. This analysis is the previous step in case of a Master event location procedure.

HIGHER DEGREE MOMENT TENSOR INVERSION OF 1997 TIBETAN EARTHQUAKE (MS=7.4) USING FAR-FIELD BROAD-BAND RECORDING

Liu Ruifeng(Institute of Geophsics, China Seismological Bureau, Beijing 100081, CHINA, email: liurf@cdsndmc.css.gov)

We used a method presented by T. Dahm and F. Krueger to estimate parameters of the extended earthquake source using higher degree moment tensors at 27 centroid locations. A Taylor series expansion of Green's function around a single centroid is not accurate enough when working with seismic wave periods and wavelengths in the range of rupture duration and spatial extent of the fault, respectively. Introducing a grid of 27 centroid locations on the fault and using higher degree moment tensors we are able to adequately model body and surface waves with periods and wavelengths smaller than rupture duration and fault dimensions, under simplifying assumption an iterative inversion scheme is coded to estimate parameters of planar, Haskell-type faults. We have inverted the higher degree moment tensor of November 8, 1997 Tibetan earthquake using far-field broad-band recording of GSN, the best fit uni-directional rupture model indicated that rupture duration T=19.0 sec,fault length L=47km,fault width W=28km, scalar moment M0=2.1E20Nm, strike=77 dip= 88 rake=0. The result show that uni-directional models, rupture direction, fault and auxiliary plane and kinematic source dimension and time can be constrained with teleseismic body or surface wave.

INFLUENCE OF WEAK SEISMIC IMPACTS ON THE SEISMIC REGIME.

Nikolay T. TARASOV (OGGGGN Russian Academy of Siences, Leninskiy ave. 32a, Moscow, 117993, Russia, email: geodep@ipsun.ras.ru) Nadezhda V. Tarasova (United Institute of the Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya, 10, 123810 Moscow, Russia, email: tarasov@uipe-ras.scgis.ru)

The influence of the Semipalatinsk underground nuclear explosions on the seismic regime of the Garm region located at 1400 km from the test site has been studied. It was found that the occurrence of large events (K>10) and microearthguakes (K<5) after tests became higher than before them. The occurrence of earthquakes of 5<K<10 remains the same. High level activity of small earthquakes was observed from 1 to 30 days. Large earthquakes occurred in 5-7 days cycles. It was found that cycling of seismicity after explosions was connected with periodic discrete changes of activity maximum time delays in different geological structures. Explosions cause release of tectonic deformation process. The energy releases in the series of relatively weak earthquakes instead of one catastrophic event. These results were confirmed in the worldwide seismicity investigation from 1900 to 1997 years.

OBSERVATIONS OF LOCAL CODA USING A THREE-DIMENSIONAL SEISMIC ARRAY NEAR THE ATOTSUGAWA FAULT, CENTRAL JAPAN

Masahiro KOSUGA and Tomomi Saito (both at Faculty of Science and Technology, Hirosaki University, Hirosaki 036-8561, Japan, email: mkos@cc.hirosaki- u.ac.jp) Noriko Tsumura (Faculty of Science, Chiba University, Chiba 263-0022, Japan) Kazushige Obara (National Research Institute for Earth Science and Disaster Prevention, Tsukuba, 305-0006, Japan)

We have examined the characteristics of local coda using data from a small-aperture three-dimensional seismic array deployed near the Atotsugawa fault, the one of the most active strike-slip faults in Japan. The array consists of two subarrays; an L-shaped subarray with 36 seismometers and a spiral subarray with 40 sensors. The use of three-dimensional array with a vertical extent of 230 m gives an unique opportunity to directly estimate the vertical slowness.
We applied a semblance analysis to measure the time variation of coherence, back-azimuth, incident angle, and slowness of waves that pass the array. From close inspection of back-azimuth, we found that the incident azimuth of S-wave is systematically rotated clockwise from the theoretical one for both the earthquakes located to the NE and to the SW of the array. This observation is qualitatively explained by either local velocity heterogeneity or crustal anisotropy. We also found that some coherent phases arrive about 8 s after the P wave, making a flattening or even transient increasing of RMS amplitude. These phases have nearly the same slowness as the P-wave and show an steep incident to the array. Considering the lapse time from the P-wave, these phases are probably the scattered and/or reflected P-waves from the lower crust. The long duration (3-4 s) of coherent arrival suggests that the scattering and/or reflection is occurring in a thick zone rather than a thin sheet.

ON THE NATURE OF UNUSUAL SEISMIC PHASE, BEING OBSERVED IN SHORT-PERIOD S-CODA IN THE NORTH TIEN SHAN REGION

Yuri KOPNICHEV (Complex Seismological Expedition, Joint Institute of Physics of the Earth, Kamo str. 8a, Talgar, Almaty region, 483310, Kazakhstan, email: adm@cse.academ.alma-ata.su)

At the border between the mountainous areas of the North Tien Shan and the Chu and Ili basins an unusual seismic phase sharply stands out against a background of short-period coda on seismograms of local earthquakes and quarry blasts. This phase, which we denoted as SL, is observed most clearly at small epicentral distances (up to 30 km). It presents a compact tandem of almost monochromatic oscillations with periods of 1,5-1,8 sec and duration of ~6-10 sec. The lapse time, corresponding to a maximum amplitude in SL phase (tm) , varied from 102 to 131 sec. In a relatively 'quiet' tectonic situation, at the border between the Kendyktas range and the Chu basin, the particle motion in SL wave is in a horizontal plane. Apparent velocities of this phase are very low (they reach of ~70-80 m/sec). Very strong variations of tm values are observed in the Zaili deep fault zone: to the south from the fault, in the Zaili Alatau range area they are considerably higher, than to the north from it, in the Almaty depression area. This correlates with data on a big difference of shear wave attenuation in the lithosphere on both sides of the fault. On the basis of an analysis of experimental data it can be concluded, that SL group is formed by shear waves, being reflected from a thin layer with a large impedance contrast, which is located in the upper mantle at a depth of about 220-240 km. Possible reasons of an existence of this layer are discussed.

THE MORPHOLOGY OF THE SUBDUCTING SLAB BENEATH NORTHERN TAIWAN

KUO-FONG MA and Pei-Ru Jian (both at Institute of Geophysics, National Central University, Chuag-Li, 320-54, Taiwan, ROC, email: fong@sal.gep.ncu.edu.tw) Ban-Yan Kuo (Institute of Earth Sciences, Academia Sinica, Taiwan, ROC)

The converted phases from upper plate boundary of the subducting slab denoted as SP phases recorded by the CWBSN (Central Weather Bureau Seismographic Network) for events in northern Taiwan (24.0°N £ latitude £ 26.0°N, 121˚E £ longitude £ 122°E, 60km £ depth £ 300km, and ML ≥ 4.0) provide us an advantageous opportunity to construct the morphology of descending slab. We apply the polarization filter and theoretical travel time analysis to the 3-compoent records to identify the conceivable SP converted waves. The initial velocity model with subducting slab used as theoretical travel time calculation was based on the recent tomographic results. The model is constructed by considering that the velocity contrasts among the discontinuities are fixed, while the upper boundary of the slab is allowed to change. We separate the events into several groups according to their paths to stations. Considering the travel time residual of ts-tsp between the observed and the constructed models for different groups, we make out the upper boundary of the subducting Philippine plate beneath northern Taiwan for various profiles. The results show that the subducting slab has a dip angle of about 45 to 50 degree and reaches to the depth of about 100 km beneath northern Taiwan. The subduction also tends deeper to the east, while shallower to the west.

SHEAR WAVE SPLITTING AND ANISOTROPY OF THE EARTH'S CRUST: OBSERVATIONS AND MATHEMATICAL MODELLING

Maria A. KRASNOVA, Alexander A. Vikhorev, Irina O. Bayuk and Evgeni M. Chesnokov (all at Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya 10, Moscow, 123810, Russia, email: mkrasnova@uipe-ras.scgis.ru)

An experimental study of the structure of the Earth's crust based on the records of shear waves from low energy earthquakes was carried out for two regions: the south-western seismic zone of Iceland and the Germab seismoactive zone in the Ashkhabad test site. The goal of the study was to distinguish anisotropy of elastic properties and to estimate the depth to the anisotropic layer, its thickness, seismic velocities and composition. The results of the study of 241 three-component seismic records from 50 crustal earthquakes permit to assign a 20% anisotropy of elastic parameters in the central part of the south-western seismic zone of Iceland to 1.75 km layer at the depth of 3 km. The study of 418 seismograms from 81 earthquakes, recorded by seven three-component seismic stations, revealed a 5 km thick upper crustal layer in the Germab seismoactive zone with 14% of elastic anisotropy. Mineralogical models of the crustal composition in the regions of study were used to calculate effective elastic moduli and crustal density by the method of generalized singular approximation. Spatial distribution of seismic velocities and synthetic seismograms were calculated for the estimated elastic moduli and densities and for the set of hypocenters, corresponding to the observed one. The comparison of the calculated and observed seismic velocity distribution, as well as of real and synthetic seismograms permitted to specify the structure and the composition of anisotropic layers.

WESTERN US MANTLE STRAIN PROVINCES INFERRED FROM SHEAR WAVE SPLITTING

D. SCHUTT, University of Oregon, US (email: schuttd@newberry.uoregon.edu)

Three tectonic provinces lie near the Yellowstone Hotspot: the Yellowstone Swell , deformed by the passage of the hotspot; the extensional Basin and Range; and the Precambrian craton.

Of these three provinces, only the Yellowstone Swell produces shear wave splitting measurements that are easily explained. In this region, the fast polarization direction of the SKS phase is nearly constant, and is most reasonably explained by the simple shear of the Yellowstone Hotspot asthenophere as the North America plate moves southwesterly with respect to the more stable interior of the Earth. In contrast, newly analyzed data from three arrays outside the Yellowstone Swell (in conjunction with previous studies) show complex anisotropy, and imply that the Swell is a distinct anisotropic province within the western United States. We find measured fast axis orientation changes with back azimuth at individual stations, and also changes from station to station for a given event. That no obvious strong anisotropic fabric has develped beneath North America, particularly in the Basin and Range where the asthenosphere should be well-developed, suggests that the upper mantle is not deforming in a simple, homogeneous manner.

OPTIMIZING MODEL PARAMETERIZATION IN 2D SEISMIC TRAVELTIME TOMOGRAPHY

Zoltán WÉBER (Seismological Observatory of the Hungarian Academy of Sciences, H-1112 Budapest, Meredek u. 18., Hungary, email: weber@seismology.hu)

In seismic traveltime tomography a set of linear equations is to be solved for the unknown slowness perturbations. The matrix of this set of equations (the raypath matrix) is usually ill-conditioned because the model space contains more details than can be resolved using the available data. The condition of the raypath matrix can be characterized by its singular value spectrum: the larger the area under the normalized singular value curve and the greater the rank of the matrix, the better the condition of the inversion problem and the more independent pieces of information may be gained from the data. The structure of the raypath matrix depends on the source-receiver configuration and the model parameterization. Since the source-receiver geometry is often fixed (e.g. in earthquake tomography), conditioning can only be influenced through the model parameterization, i.e. the structure of the model space.
In this paper we illustrate a method for finding an optimal, irregular triangular cell parameterization that best suits the raypath geometry. We present a practical measure of conditioning that is to be minimized. Since this measure depends on the model parameterization in a highly nonlinear manner, a simulated annealing algorithm is used to find the optimal parameterization. We show that the condition of the raypath matrix corresponding to the parameterization determined by optimization is much better than that corresponding to a regular rectangular parameterization with the same dimension. The method is demonstrated through some cross-borehole tomographic examples with given acquisition geometries.

EMISSION TOMOGRAPHY - FRUITFUL APPROACH FOR SEISMIC STUDY IN THE 21ST CENTURY

Irina J.TCHEBOTAREVA(Inst. Earth Physics RAS,B.Gruzinskaya 10,Moscow 117234, Russia, email: chari@synapse.ru)

Seismic observation by means of a dense seismic array composed from 3-component stations allows us to develop new advanced methods of study of the fine structure of the Earth and seismic emission. One of such methods is emission tomography which permits to locate sources of weak continuous seismic signals, to estimate amplitude and spectrum of underground radiation from the active sources and scatterers. Different parts of seismic records supply different kind of geophysical information. Using records of the direct P and S waves of a seismic event, we receive images of the source of the event. Analysis of the coda part of seismic records gives the 3-D image of a scattering structure and a distribution of active volumes of seismic radiation induced by direct waves. Analysis of a seismic noise detects the active volumes of seismic emission being a kind of trigger effect in the energy-saturated Earth. Emission tomography is a device for seismic monitoring in the volcanic and tectonic active areas, mines and oil and gas deposits: a set of images in the consequent time windows shows the evolution of seismic sources distribution. The possibilities of emission tomography are illustrated by the results of computer modeling and study of the data of seismic observation over volcanic front in the northern Kanto, Japan. Detected scattering and emission anomalies relate to the real geological objects. Active volumes revealed from noise analysis are the same that the volumes of induced emission in the 'late' coda. Now the emission tomography studies are unique because of a small number of suitable observations but in the nearest future, with a developing of seismic designs, this powerful method can become a routine one. By means of choice of a suitable frequency band and array aperture we can carry out study in different scales, from the crustal to the global one.

RELOCATION OF LARGE HISTORICAL EARTHQUAKES GLOBALLY USING MODERN TECHNIQUES

A VILLASENOR, T M Boyd (Colorado School of Mines, Golden, CO 80401 USA, ph. 1-303-273-8590; e-mail: antonio@gldage.cr.usgs.gov) E R Engdahl, K M Shedlock (U.S. Geological Survey, Denver, CO 80225 USA)

Although earthquakes have been instrumentally recorded for nearly 100 years, source parameters (epicenter location, depth and magnitude) for events that occurred before the full implementation of the World-Wide Standardized Seismograph Network (WWSSN) during the early 1960's are poorly constrained. In most cases,
this is simply because modern data analysis techniques have yet to be applied to the available observations, which, for the most part, are preserved as written records, not in a computer-ready, digital data format.
We have undertaken the uniform relocation of all earthquakes reported prior to 1964 in the International Seismological Summary (ISS), the Bureau Central International de Seismologie (BCIS) Bulletin and other available bulletins. Arrival times tabulated in these bulletins are converted to computer-readable form using optical character recognition (OCR) software. After examining the observations for obvious translation errors and establishing the locations and codes of the recording stations, the arrival times are converted to a standard format (ISC 96-byte). Each earthquake is then relocated using the ak135 earth model, and P, S PKP, and re-identified depth phases (pP, sP and pwP).
In this presentation, we show and discuss results from relocations of earthquakes of magnitude equal to or greater than 6.5 during this period. This systematic re-determination of historical earthquake locations permits the better definition of seismic zones globally, which can be readily applied to a range of seismicity, seismotectonic and seismic hazard investigations.

RELOCATION OF FRENCH NUCLEAR EXPLOSIONS IN THE TUAMOTU ARCHIPELAGO

Eric BERGMAN (Global Seismological Services, 601 16th St., #C390, Golden, Colorado 80401, USA, ph/fax: 1-303-278-4089, email: bergman@seismo.com) E. R. Engdahl (Department of Physics, University of Colorado, Campus Box 390, Boulder, Colorado 80309-0390 USA, ph: 1-303-735-4853, fax: 1-303-492-7935, email: engdahl@lemond.colorado.edu)

Between 1968 and 1996 the French government conducted nuclear tests at Muraroa and Fangataufa, atolls of the Tuamotu Archipelago in the south central Pacific. Although the true locations and origin times of these tests have never been released, the limited extent of the atolls allows strong constraints to be placed on the true locations. The ISC Bulletin and USGS datasets contain arrival time data for 91 explosions, which comprise a particularly attractive dataset for methods of multiple event relocation. We applied the Hypocentroidal Decomposition (HCD) method to examine the effects of network coverage and the use of different phase sets on the estimation of epicenters and origin times. Relocations are performed using several phase sets: P only, and P plus PKP phases, with distance-dependent phase weighting based on observed variances. One useful criterion of success is the ability to separate Muraroa events from the nearby Fangataufa events. The statistical rigor of the HCD method allows such a distinction to be made in most cases. Confidence ellipses are calculated separately for the relative locations of the events with respect to the cluster's centroid and for the centroid itself. The relative locations form a pattern which may be shifted to provide an optimal match with the shape of the atolls. Comparing this shift with the location of the centroid provides insight into the applicability of the travel time model (ak135). The improved locations and origin times should have application as a known source for studies of deep earth structure.

EARTHQUAKE LOCATION ON IRREGULAR GRIDS

Todd Nicholson, MALCOLM SAMBRIDGE, OLI GUDMUNDSSON (Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia; email: malcolm@rses.anu.edu.au.)

Over the past five years the advent of high performance computing has led to increased interest in grid search methods for earthquake location. This approach has several advantages over matrix methods in that it overcomes numerical stability problems associated with matrix inversion, avoids the calculation of derivatives and allows flexibility in choice of data fit measure. Previously grid search methods have been restricted to simple, or nested, regular grids (i.e. based on rectangular cells) in three or four dimensions, which are searched for a best fit solution. Even with modern computers this often involves a search over an enormous number of possible solutions and may not be practical for routine use. Here we propose a simple procedure for locating hypocentres on a completely unstructured mesh. The advantage is that the mesh may be generated automatically from a set of nodes with any chosen distribution, allowing finer discretization in regions where events are more likely, e.g. defined by previous seismicity, local geology or other factors. We illustrate the approach by building an irregular mesh from global seismicity using Delaunay tetrahedra, and locating earthquakes by a process of pattern matching with previous events. The novelty is that no seismic earth model is required.

ACCURATE HYPOCENTER DETERMINATION USING STATION CORRECTIONS: IN THE CASE OF SOUTH-WEST OFF HOKKAIDO IN JAPAN

Masaki Nakamura (Seismology & Volcanology Research Department, Meteorological Research Institute, 1-1 Nagamine, Tsukuba, Ibaraki, 305-0052, Japan, email: mnakamur@mri-jma.go.jp)

One of the approaches of accurate hypocenter determination is the station correction method. This method is usually applied to earthquake activity in relatively small area, such as swarm. Hurukawa and Ohmi (1993) proposed a new method where station corrections vary as a function of hypocenter coordinates. They applied it to the earthquake observation network covering about 200 km * 200 km, and showed its effectiveness. But their method encounters difficulties when earthquakes are poorly surrounded by stations, as is often the case of earthquakes in the sea. We still expect good results if we can combine their method with some accurate hypocenters for reference. This is shown in this study. After 1993 Hokkaido Nansei-Oki Earthquake which occurred south-west off Hokkaido in 1993, Hino et al. (1994) installed 18 pop-up type oceanbottom seismometers covering the focal region at intervals of 5 - 30 km, and determined focal parameters of aftershocks. Then station corrections as a function of hypocenter coordinates are obtained based on them, and focal parameters of earthquakes occurred in the region are re-determined. Main results are the following: 1. Hypocenters determined by Japan Meteorological Agency (JMA) and those re-determined by the conventional method of station corrections based on them, are mostly distributed shallower than 40 km, while hypocenters re-determined in this study are mostly distributed shallower than 20 km. 2. Aftershock segments, especially the segment north-west of Okushiri island, are smaller than those of JMA hypocenters etc. 3. If data of Okushiri station near the analyzed region are excluded, hypocenter distribution becomes remarkably thicker. It will be possible to determine accurate hypocenters all over Japan by this above method, if accurate reference hypocenters are available which are determined by pop-up type oceanbottom seismometers, depth phase, and so on. I thank to the members of Hino et al. (1994) for providing hypocenters.

THE CALIBRATING CURVES FOR MACROSEISMIC MAGNITUDE DETERMINATION IN THE ARIA OF CAUCASUS,TURKMENISTAN,TURKEY

Ye.A.Khrometskaya (United Institute of the Earth Russian Academy of Sciences,Moscow,123810 Russia;0952541564; e-mail: kondor@uipe-ras.scgis.ru)

The macroseismic magnitude (MMC) is determined as an average macroseismic intensity MCK-68 reduced to the hypocentral distance 30 km by calibrating curve.The MMC values are correlated with MLH,MPVA and logE (Rautian,1982). The curves were obtained for Caucasus, Turkmenistan, Turkey. The scale can be used for determination of magnitudes of historical earthquakes from macroseismic data. The calibrating curves were used for redetermination of macroseismic magnitudes of several strong earthquakes in this area.

LOCAL MAGNITUDE SCALE CALIBRATION FOR VRANCEA (ROMANIA) INTERMEDIATE-DEPTH EARTHQUAKES

Olivia Bazacliu (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: olivia@infp.ifa.ro) Mircea RADULIAN (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: mircea@infp.ifa.ro)

The present paper is focused on two main problems: (1) the determination of a reference curve for magnitude computation in case of Vrancea intermediate-depth earthquakes, and (2) the correlation between the new proposed local scale magnitudes and other source- or propagation-related parameters (seismic moment, stress drop, peak ground motion values etc.). To this purpose an extended waveform data set provided by the Romanian local seismic

networks of S13 instruments (short-period velocities, vertical components) and K2 instruments (accelerations, three components) is investigated. More than 100 events with magnitude between 2.5 and 7.1, located in the depth range from 60 to 180 km. are considered. Peak displacements and velocities and spectral values (P- and S- body waves) are used to obtain the reference curve (amplitude versus hypocentral distance). Influences of site amplification factor, focal mechanism and focal depth are estimated. The calibration of the computed magnitude with the seismic moment and a rapid earthquake quantification procedure are analyzed.

SEISMOLOGICAL NETWORK IN REPUBLIC OF MACEDONIA: HOMOGENEOUS MAGNITUDE SYSTEM

Dragana Cernih (Seismological Observatory, P.O.Box 422, 91000, Skopje, Republic of Macedonia, email: dcernih@seismobsko.pmf.ukim.edu.mk) Lazo PEKEVSKI (Seismological Observatory, Faculty of Natural Sciences and Mathematics, Sts Cyril and Methodius University, Skopje, Republic of Macedonia, email: lpekevski@seismobsko.pmf.ukim.edu.mk)

A Homogeneous Magnitude System (HMS) has been determined for the territory of the Republic of Macedonia, for the four telemetred seismological stations: Skopje (SKO), Valandovo (VAY), Ohrid (OHR) and Bitola (BIT). Earthquake network magnitudes (NM) can be estimated for weak regional earthquakes using amplitude observations from these stations. Method of basic station for determining station corrections and a combined method, based mainly on the graphical method and on the method of moving averages, for determining improved magnitude calibrating function were used. The station corrections for VAY, BIT and OHR, relative to SKO, and the improved calibrating function for Sg waves observed for the range of epicentral distances 55-205 km, were obtained through four successive iterations using 450 HMS station amplitude observations. The calibrating function for Lgh and Sg waves determined by Karnik (1968) was used as the initial calibrating function.

WHY DOES THE EARTH OSCILLATE CONTINUOUSLY?

Genevieve Roult and Nicolas Denis (both at Institut de Physique du Globe de Paris, 75252 Paris-Cedex 05, France; email: groult@ipgp.jussieu)

It is well established that the fundamental modes of the Earth are excited even on seismically quiet days and the Earth is oscillating continuously, because of still unexplained dynamic processes. The GEOSCOPE network, which started in 1982, provides us with long time high quality seismic data to better observe this phenomenon. We can now detect the resonance frequencies of the Earth even in absence of earthquakes. Analysis of the WUS station (the GEOSCOPE station with the lowest noise level), and the TAM station (with simultaneous recording of a microbarograph) helps us to make a preliminary interpretation of these background oscillations. While the exact causes are not clear, they may be of internal origin (for example tectonic motions) or external origin (for example atmospheric turbulence). These oscillations may be an interesting example of atmosphere-solid earth interaction, but we must first eliminate possible sources including small earthquakes usually ignored in the data processing, undetected earthquakes, slow and silent earthquakes.

THE THERMAL CHARACTERISTICS OF LAB DEDUCED FROM MAGSAT MODEL

Xiaoqing GAO(Lanzhou Institute of Plateau Atmospheric Physics,CAS, 730000 Lanzhou, P.R.China, email: xqgao@lzu.edu.cn) Giovanni P Gregori(Istituto di Fisica dell'Atmosfera, CNR, 00133 Rome, Italy, email: gregori@atmos.ifa.rm.cnr.it)

It is well known that electric currents exist in the Earth. The Earth's magnetic field is produced the the currents. These currents can produce heat because of the resistance of the material of the Earth(called Joule heat).This electric current can be derived from geomagnetic field data or model. Till now, the best geomagnetic field model(MAGSAT) had been gotten by satellite global observation in 1979-1980. By this model, the global distribution of Joule Heat on ALB(Asthenosphere-Lithosphere Boundary) (direct proprotion to electric current square) had been calculated.It is found that the distribution of Joule Heat on ALB matches the global geothermal zones very well.And the strongest Joule's Heating is located below Tibet Plateau, the youngest and the highest plateau on the Earth. It seems that the geothermal heat mostly comes from ALB, it is contralled by Joule's Heating process.

THE RELATIONSHIP BETWEEN GEOTHERMAL VORTEX AND EARTHQUAKE

Maocang Tang and Xiaoqing GAO(both in Lanzhou Institute of Plateau Atmospheric Physics,CAS, Lanzhou 730000, P.R.China, email: xqgao@lzu.edu.cn)

Earthquake always companies by thermal process. The change of soil temperature at different depths shows the underground thermal process. The data of soil temperature observed in more than 180 meteorological observatories in China for the period of 1980-1993 have been analyzed. And the concept of Geothermal Vortex was proposed and defined. The result shows that there are close relationship between geothermal vortex and earthquake.Earthquake always happened at the edge, with high gradient, of geothermal vortex. The stronger the geothermal vortex, the stronger.
The earthquake. It is possible to predict dangerous areas of earthquake by following the movement of geothermal vortexes. Based on the statistical facts, a thermal-dynamic process linking geothermal vortex and earthquake has been proposed.

PROBABILISTIC ASSESSMENT OF EARTHQUAKE HAZARD IN THE INDIAN SUBCONTINENT

IMTIYAZ A. PARVEZ (Department of Geology, Kumaun University, Nainital,INDIA. Presently at the Department of Earth Sciences, University of Trieste, ITALY, email: parvez@geosun0.univ.trieste.it

Avadh Ram (Department of Geophysics, Banaras Hindu University, Varanasi - 221005, INDIA)

The Indian subcontinent is one of the most seismic prone areas of the world. Himalayan mountains in the north, mid-oceanic ridges in the south and earthquake belts surrounding the Indian plate all show that the subcontinent has undergone through extensive geological and tectonic processes in the past. The probability of the occurrence of earthquakes with magnitude 6<Mb<7 during a specified interval of time have been estimated on the basis of four probabilistic models namely Lognormal, Weibull, Gamma and Exponential distribution for the Indian subcontinent. The seismicity map has been prepared using the earthquake catalogue from the period 1963-1994 and six different zones have been identified on the basis of clustering of events. The model parameters have been estimated by the method of Maximum Likelihood Estimates (MLE) and Method of Moments (MOM). A computer program package has been developed for all the four models which represents the distributions of time intervals fairly well. The logarithmic of likelihood (lnL) are estimated for testing the models and different models have benn found to be plausible. The probability of different magnitude threshold has been evaluated using Gutenberg-Richter formula LogN=a-bM for magnitude distribution. The constants a and b have been computed for each region and found to be varying between 5.46-8.53 and 0.87-1.34 respectively.

MODELLING EARTHQUAKE SWARMS NEAR VALSAD (GUJRAT), INDIA USING CHAOTIC DYNAMICS

H.N. SRIVASTAVA and S.N. Bhattacharya (both at India Meteorological Department, New Delhi-110003, India, e-mail: snb@imd.ernet.in) D.T. Rao and Sanjay Srivastava (both at Gujrat Engineering Research Institute, Vadodara-50007, India)

Valsad district in South Gujarat near the western coast of the Peninsular India experienced earthquake swarms since early February, 1986. A total number of 21,830 earthquakes were recorded during March 1986 to June 1988. The daily frequency of earthquakes for this period was utillsed to examine deterministic chaos through evaluation of dimension of strange attractor and Lyapunov exponent The low dimension of 2.1 for the strange attractor and positive value of the largest Lyapunov exponent suggested chaotic dynamics in Valsad earthquake swarms. In the neighbouring Koyna region, strange attractor dimension of 3.41 suggested it to be a new measure of seismotectonics. These results have been compared with the modelling parameters needed near the continent-continent collision type of Indian-Eurasian plate boundary. It is found that based on dynamical concepts, more reliable techniques for earthquake hazard assessment can be developed as compared to that using Gutenberg frequency magnitude relationship attempted so far.

"PARAMETRIC-HISTORIC" PROCEDURE FOR SEISMIC HAZARD ASSESSMENT AND ITS APPLICATION FOR EARTHQUAKE HAZARD MAPPING IN SUB-SAHARAN AFRICA

Andrzej KIJKO (Council for Geoscience, Geological Survey of South Africa, Private Bag X112, Pretoria 0001, South Africa, Email: kijko@geoscience.org.za); Gerhard Graham, (Council for Geoscience, Geological Survey of South Africa, Private Bag X112, Pretoria 0001, South Africa, Email: gerhardg@geoscience.org.za)

A new methodology for probabilistic seismic hazard analysis (PSHA), is described. The approach combines the best features of the "deductive" (Cornell, 1968) and "historical" (Veneziano et al., 1984) procedures. The maximum regional magnitude mmax is of paramount importance in this approach and the authors present some of the statistical techniques that can be used for evaluation of this important parameter. The approach permits the utilisation of incomplete earthquake catalogues. It is assumed that typical catalogues contain two types of information: historical macroseismic events that occurred over a period of a few hundred years, and recent instrumental data. The historical part of the catalogue contains only the strongest events, whereas the complete part can be divided into several subcatalogues, each assumed complete above a specified threshold of magnitude. The approach also takes into account uncertainty in the determination of earthquake magnitude. The technique has been developed specifically for the estimation of seismic hazard at individual sites, without the subjective judgement involved in the definition of seismic-source zones, when specific active faults have not been mapped and identified, and where the causes of seismicity are not well understood. As an example of the application of the new technique, the results of a typical hazard analysis for a hypothetical engineering structure, frequency dependent hazard maps for South Africa and Sub-Saharan Africa are presented.

SOME STATISTICAL CHARACTERISTICS OBTAINED FROM A LARGE NUMBER OF EARTHQUAKES IN CHINA BY SINGLE-LINK CLUSTER METHOD

Yanlu MaHuilan Zhou (Graduate School at Beijing, University of Science and Technology of China, 100039 Beijing, China)

We have used SLC method, introduced by C. Frohlich etc, to analyze the spatial and temporal properties of 43,260 earthquakes (Ms>=3.0) occurred in China and its neighbors between 1970 and March 1998.
After computing the space-time SLC frame of these earthquakes, we have got three results: (1) The earthquake clusters obtained from cutting all the links exceeding a special cut-off length D show an obvious fractal characteristic. The number of clusters and the number of earthquakes within the cluster exhibit explicitly a scaling invariance. This characteristic is maintained when D is varied between 30 and 100 km. (2) We considered two distribution functions about the link length in the frame: w1(r)=N(<r)/N0, w2(r)=L(<r)/L0. The function w1(r) is the statistical empiric distribution function of link length that is treated as a random variable. N0 is the total number of links, N(<r) is the number of links which lengths are shorter than r.

The function w2(r) is closely related to the fragmentation distribution. L0 is the total length of links. L(<r) is the sum of link lengths which are shorter than r. We find that Weibull function w(r)=1-exp[-(kr)d] fits w2(r) very well. We can also match w1(r) with a Weibull function, but the fitting result can not pass the Kolmogrolov non-parameter test. So we can not say that the links obey Weibull distribution. And we can not conclude that they do not obey Weibull distribution, because the non-random sample of links can also explain the result. When we delete the pre- and after shocks, we can got a new catalog and a new frame which distribution of link length can pass the statistic test. (3) We considered that slips of a frame in a time interval. We can use the variation of parameters- d and k in w(r) to describe the variation of distribution of earthquakes in space and time. We found the d value declined so much in 1976,which may be concerned with the high level of seismicity in that period. However, the variation of year by year can only show some gross information in such a large region.

SW1/W/02-B5 1000

THE PECULIARITIES OF THE SEISMICITY LATITUDE DISTRIBUTION AND THE EARTH ROTATION

Boris W. LEVIN (*Shirshov Oceanology Institute of RAS and Russian Foundation for Basic Research, 32a Leninsky prosp., Moscow, 117334 Russia; levin@rfbr.ru) Yeugeny Chirkov (**Union Institute of the Earth Physics of RAS, 10 Bolshaja Gruzinskaja, Moscow, 123810 Russia; email: chirkov@uipe-ras.scgis.ru)

The analysis of the latitude distribution of the earthquakes number and its energy on the base of NEIC catalogues (1900-1993) is presented. The peculiarities of the latitude distribution of the seismicity connected with the Earth`s rotation has been found. We had made the hystograms of the earthquake numbers and its energy as a function of a latitude F from 90 deg. N to 90 deg. S at period of 1900-1993. We had found that the latitude distribution of the event numbers N(F) is similar to the curve describing a dependence R^2(F) or I(F) where R is a distance from the axis of rotation and I is an inertia momentum of mass unit of the Earth crust. It was also discovered the local maximum of the earthquake number in the region of so-called "critical parallelÔ 35 deg. N which was introduced by A. Veronne (1912) and theoretically grounded by F.Krasovsky and V. Magnitsky 1941). The comparison of the seismicity latitude distribution in West hemisphere and in the East one showed that most of local maximums of the seismicity for first hemisphere is coincident with the corresponding local minimums of seismicity in other hemisphere as rule, and on the contrary. Revealed peculiarities confirm the axis symmetry of the seismicity distribution that may be considered as sign of connection between seismicity and the Earth rotation.

SW1/E/03-B5 1015

A NEW SYNTHETIC EXPERT SYSTEM FOR QUICK SEISMIC HAZARD ASSESSMENT AND LOSS ESTIMATION

Yueqing Zhu, Ping Hao (Center for Analysis and Prediction, China Seismological Bureau, P.O.Box 166 Beijing, 100036, email: zhuyq@sun.ihep.ac.cn)

Earthquakes usually make very serious catastrophes to humanity. It is necessary very much to have a quick assessment and estimation on the hazard and risk caused or will be made by the strong earthquake for all the countermeasures for preparedness prior to earthquakes and also search, rescue and relief operations post quakes, not only for the decision-makers, commanders, but also for the public, which had been shown by many historical lessons obviously. But what to do and how to do it is a important problem.
The Author and his research group have completed a new approach of the methodology and also software system development on a synthetic expert system for quick seismic hazard assessment and loss estimation. This system is consisted of several modules on data management, evidence acquisition, knowledge processing, reasoning, decision-making and output, contents different functions on geological, engineering hydrological, site soil dynamics, seismological, construction, population and economical conditions recognition and seismic wave attenuation and people activity laws application and some additional functions. It is an intelligent system combined several different disciplines, an advanced software system integrated functions of different software environments (such as VP, GIS et al.), also a practical earthquake hazard assessment and loss estimation system.

STUDY ON SOME SEISMOLOGICAL PREDICTION INDEXES AND SYNTHETIC PREDICTION METHODS FOR 5 SEISMIC ZONES OF SICHUAN PROVINCE, CHINA

Weibin Han and Guixi Yi et al.(Seismological Bureau of Sichuan Province, Chengdu, 610041,P. R. China, email: Hanwb@mail.sc.cninfo.net)

In this paper,6 seismological prediction indexes: variation rates of capacity dimension and informationdimension, algorithmic complexity, seismicity quiescence index, b value, mean square deviation from lg N=a-bM and total area of faults ,and 4 synthetic prediction methods: combined probability,pattern recognition, fuzzy clustering and neural net method have been carefully studied for 5 major seismic zones of Sichuan and its neighbour region, China. Using more than 20 years' data since the beginning of 1970' for the 5 seismic zones, the change curves of the 6 seismological prediction indexes with time have been calculated, taking 1 a as the time window and 0.5 a as step length. After selected and determined the criterions of recognizing precursor and prediction regulations, the prediction ability of the 6 seismological indexes have been tested by using prediction mark R. Then 4 synthetic prediction methods based on the 6 seismological indexes have been researched,and their prediction ability have been tested and compared by using prediction mark R,too.
The results show: (1) For most of the seismic zones, indexes and synthetic prediction methods, the prediction marks R are higher than the critical mark value Ro for assessing random prediction at the confidence level of 97.5% . (2) Generally, the prediction ability can be raised by using any one of 4 synthetic prediction methods.(3) When the prediction ability of the 4 synthetic prediction methods are compared, it seems that the R value of the combined probability method and pattern recognition method are higher.

VARIATION OF ATMOSPHERIC INGREDIENT CONCENTRATION BEFORE EARTHQUAKES

Tokiyoshi MATSUDA, Hiroshi Matsumoto and Motoji Ikeya (Department of Earth and Space Science, Graduate school of Science, Osaka University, 1-1 Machikaneyama, Toyonaka, Osaka 560-0043, Japan, Email: toki@ess.sci.osaka-u.ac.jp)

We proposed an electromagnetic model of fault to explain seismic electromagnetic signals (SEMS) in which electric charges are induced around the epicenter before earthquakes by the piezo-electricity of quartz [1]. Nitrogen oxide (NO) is produced by natural electric discharge phenomena of atmospheric lightning [2]. Earthquake lightning before the Kobe Earthquake (Hyogo Pref. Jan. 17, 1995, M=7.2) due to dark atmospheric discharge is reported, which might produce NO [3]. We analyzed the variation and distribution of NO concentration at atmosphere monitoring stations affiliated to local Environmental Protection Agencies (EPA), near epicenters of large earthquakes. In case of the Kobe Earthquake, the concentration of NO was 199 ppb, about 7 times as large as average level for a few hours, 8 days before the earthquake. There was an increase in radon concentration in deep well water on the same day [4]; Count of SEMS at LF (163 kHz) also increased [5]. Thunderstorm was more than 150 - km away from the epicenter. Since it is hard to consider that the NO is generated by thunder (atmospheric lightning). The EPA data related with other major earthquakes (M > 6.0) also indicate the increase concentration of NO. About earthquake in Kagoshima (Kagoshima Pref. 1997 Mar. 26, M =6.2), the NO concentration increased to 30 ppb, about 3.5 times more than average level for one hour, 8 days before the earthquake. The results of the analysis suggest the relation between NO concentration and large earthquakes.

SW1/W/07-B5 1130

FROM INTERMEDIATE-TERM CN PREDICTIONS TO MICROZONING: HOW TO USE AVAILABLE INFORMATION TO INCREASE EARTHQUAKE PREPAREDNESS

ANTONELLA PERESAN (Department of Earth Sciences, University of Trieste, via Weiss 4, 34127 Trieste, Italy, Email: anto@geosun0.univ.trieste.it) Giuliano F. Panza (Department of Earth Sciences, University of Trieste, via Weiss 4, 34127 Trieste, Italy and The Abdus Salam International Centre for Theoretical Physics, SAND Group, Trieste, Italy)

The possibility to combine CN intermediate-term earthquake predictions, pattern recognition of earthquake-prone areas and deterministic hazard maps, in order to associate CN Times of Increased Probability (TIPs) to a set of appropriate scenarios of damage, is examined. The algorithm CN indicates the probable occurrence, inside a given space-time window, of events with magnitude greater than a fixed threshold Mo, on the basis of a quantitative analysis of the seismic flow. Hence, when a TIP is given, it is feasible to select from the available databases, produced for seismic hazard estimations and based on historical and instrumental data, the subset of expected sources included within the monitored region. This source data-set can be used as seismic input for the realistic modelling of ground motion, thus identifying, inside the confined region alerted by CN, the zones where is possible an optimisation of the mitigation measures. The advantage of this procedure mainly consists in the time information provided by predictions, indicating the urgency of intermediate-term actions oriented to damage reduction within relatively limited areas.
In a further step, pattern recognition methods can be applied to identify, independently from seismicity information, sites where events with magnitude larger than 6.5 may occur, based on the assumption that such earthquake-prone areas are associated to unstable tectonic structures formed by faults or lineament intersections. This procedure and CN algorithm can be viewed as independent experts, therefore when CN indicates a TIP, it is also possible to identify a set of scenarios of damage for the strongest events, associated to the earthquake-prone areas included in the region. This procedure will provide useful information to increase preparedness of safety measures and to indicate a priority for detailed seismic risk studies to be performed on a smaller scale, such as the microzoning of the built environment.

SOFTWARE PACKAGE FOR DETECTION OF LOCAL EARHTQUAKE PREPARATION SIGNS (LOW-FREQUENCY FOREGOING SEISMIC SIGNALS).

Elena V. Sassorova (State Oceanographic Institute, 6 Kropotkinsky per., Moscow, 119838 Russia; email: sasor@geoph.ioras.msk.ru)

It is discussed the properties of low-frequency seismical signals foregoing main shock and the methods developed for its detection. The foregoing low-frequency seismical (FLFS) signals were already discribed as a sign of the earthquake preparation (B.W. Levin, E.V.Sasorova, 1994, 1996; P.F.Ihmle, T.H.Jordan, 1994; L.Brevdo, 1998). These signals have: a period from 3 to 200 s, forecast time before P-wave arrival in area from 20s to 1.5 hours , small amplitude. Richter magnitude for such events were above 5.5. It should be noted that the real data have the signal to noise ratios well below than unit (sometimes less than 0.001), that the FLFS signals may appear as a packet of pulses several times in pre-history period. In this case it is more efficient to use simultaneously wellknown canonical methods as well as unorthodox data processing methods for extraction, description and quantitative estimations of the measured signals. It is discussed software package developed for picking up FLFS signals, for detection of the faint modification of the observed data, for analysis of the signal structure , for extraction of the repetitive groups of the alike signals.This package is based on the using unorthodox data processing methods such as extremal statistics, pattern recognition, linguistic description and linguistic recognition, the neural networks, fuzzy set methods. It may be used for data processing any one of multi-channal geophysical data and for simultaneously processing of different data type.

SPACE-TIME ANALYSIS OF MULTIDISCIPLINARY GEOPHYSICAL OBSERVATIONS ASSOCIATED WITH EARTHQUAKE ACTIVITIES IN NORTHEN PART OF NORTH CHINA (6< M < 6.5) IN 1989-1998

Jiadong QIAN, Cao Aiming, Meng Guojie (all at Center for Analysis and Prediction, China Seismological Bureau, P.O.Box 166, 63 Fuxing Ave., Beijing, 100036, China, email: jdqian@sdb.csdi.ac.cn) A.V. Ponomarev, G.A. Sobolev (both at United Institute of Physics of the Earth, Russian Academy of Sciences, Moscow, Russia, email: avp@uipe-ras.scgis.ru) V.G.Gitis (Institute for Information Transmission Problems, Russian Academy of Sciences, Moscow, Russia, email: gitis@ippi.ras.ru)

Northern part of North China is one of special regions in the researches of earthquake prediction in China, where a densest monitoring network of geophysical observations for searching precursors, in the whole China, has been working for over the past 30 years since 1966 till now, and the seismicities in the same period of time could be characterised by 3 stages: the strong one in 1966-1976, the quiet one in 1977-1988 and the medium-strong one since 1989.
A space-time analysis of multidisciplinary geophysical observations associated with the third stage in which three medium-strong earthquakes (6<M<6.5) has occurred, is described in this paper on the basis of Geotime computer environment through a joint project of Sino-Russia co-operation. In comparison with the analysis for the case study of 1976 Tangshan earthquake in the previous time of the co-operation, the analysis shown in this paper was done on the following approaches: (1) The stability of the analysis in Geotime environment had been checked as some stations involved in it was replaced by the others. (2) Some modifications for the program had been made in order to continue the analysis whenever some interruption of observations might take place so that the modified program could be applied not only for the retrospective predictions in the case studies, but also for the test of earthquake predictions in the real time. (3) The separations in the time series had been made into two parts with high and low frequency component respectively.
Final results from the space-time analysis are given in this paper to show that there seems to

be a pretty good relation between the dynamic pattern and the earthquake occurrence of Zhangbei-Shanyi earthquake (M=6.2, Jan. 10,1998, Hebei Province), 200 km northwest of the capital.

ANALYSIS OF SPACE-TIME PARAMETERS OF SEISMIC PROCESS FOR CORINTHOS GULF AND THIVA-OROPOS REGIONS IN GEOTIME INSTRUMENTAL ENVIRONMENT

V.GITIS, (Institute for Information Transmission Problems, RAS, Moscow, Russia email: gitis@iitp.ru) B.V.Osher (Institute Physics of the Earth, RAS, Moscow, Russia, email: osher@iitp.ru), G.Papadopoulos (Institute of Geodynamics, National Observatory of Athens, email: g.papad@egelados.gein.noa.gr)

The main idea of GeoTime technology is based on the alternative method of data representation and analysis. The time variations of geophysical parameters synchronously measured at different points of the region and the data of the earthquake catalogue are transformed into 3D rasters with two spatial and one temporal co-ordinate. It is assumed that after elimination of seasonal rhythms in the absence of earthquake preparation the 3D-raster fields are inhomogeneous in space, but quasistationary in time. The appearance of a precursor, which occupies a certain related subset of elements of the raster, violates the stationarity of the process. Statistical hypotheses testing techniques are used to determine the non-stationarity and to estimate its level of significance. Space-time analysis of seismic data for Corinthos Gulf and Thiva-Oropos regions was made in GeoTime environment. 3D-rasters of representativity of earthquake catalogues, seismic activity, b-value, fractal dimension and RTL criterion are discussed. This work is supported within INCO-COPERNICUS Project ASPELEA, contract number ERBIC-ISCT-97-0200

SPATIAL-ENERGY INDICES OF ACOUSTIC EMISSION AND SEISMIC PROCESSES

E. YURKOV (Institute for Information Transmission Problems, RAS, Moscow, Russia, email: jork@iitp.ru)

Acoustic emission arising with destruction of rock samples under pressure is analogue of seismic process. Such known indices as b-value, frequency of seismic events and others are widely used for analysis of seismic and acoustic processes. Here the new indices describing spatial-energy variability of acoustic and seismic sequences are offered. The inertial index is based on use of inertia tensor in application to an acoustic (seismic) sequence. The inertia tensor is calculated how it is accepted in the mechanics, provided that mass proportional to energy is attributed to each acoustic event. The index of spatial variability is a special case of the inertial index, provided that energies of all acoustic events are equal. This index has statistical meaning, as it is connected to hypothesis test about distinction between two random sets. These and other indices were calculated during processing the acoustic emission data received in experiments on destruction of rock samples. The results of the analysis have shown that the offered indices are especially sensitive to spatial-energy variability of acoustic process. The work is partially supported by Russian Foundation on Scientific Research, project # 97-07-90326.

VARIATIONS OF THE LOW FREQUENCY MICROTREMORS PARAMETERS AS EARTHQUAKES INDICATOR.

Yury Tarasenko and ELENA MUSIENKO (both at Institute of Seismology, Asanbai 52/1, 720060 Bishkek, Kyrgyzstan, email: kis@imfiko.bishkek.su)

The space-time the strong earthquake (M>5.0) distribution in the Tien-Shan region and variations of azimuth and amplitude of the low frequence wave filtered from microtremors records on periods 60 sec and 120 sec have been analysed to improve understanding of physical processes closely connected with earthquakes phenomenon. We used digital records of microtremors velocity (nm/sec) selected daily in the same quietest time for periods 1992 (100 days), whole 1995 and 1997 and 1998 (152 days).During this time 6 earthquakes with M>5.0 occurred in the radius 400 km. Software SAC was applied to estimate mathematicaly maximum amplitude of the low frequence wave on one of horizontal components at certain azimuth. Observation for the time periods mentioned above have shown that stability of the wave amplitude and azimuth are closely connected with strong earthquakes (M>5.0) occurence. Sharp variations of the wave azimuth (from 10 to 90 degrees) and either amplitude amplification or decrease tens times as much were beginning at all points of observation for 35-45 days before each strong event. Then the low frequence wave parameters were being stable during 5-15 days before events and later. These facts put on an idea that reconstruction of the crustle stress field is completed for 5-15 days before strong events. As for small earthquakes (M<5.0) similar wave parameters variations took place only at a few points situated in the radius 100 km from source.

PHYSICAL BASIS OF A FORECASTING METHOD FOR EARTHQUAKES AND VOLCANOS' ACTIVITY ACCORDING OBSERVATIONS OF VARIATIONS OF NEUTRON FLUX NEAR THE EARTH'S CRUST

Beliaeva E.A., Kuzhevskij B.M., Nechaev O.Yu., Skobeltsyn Institute of Nuclear Physics, Moscow State University, Vorobjovy Gory, 119899, Moscow, Russia, e-mail: bmk@srdlan.npi.msu.su

Made during many years (from 1990) observations of variations of thermal and slow neutrons' fluxes in seismo-active (Pamir) and seismo-quiet (Moscow) regiona of the Earth allow to prove following: 1. Earth's crust makes a substantial contribution into full flux of such neutrons near the crust. 2. There are observed variations of neutron flux with in amplitude and different duration, part of which correlate with tidal wave in the Earth's crust, which is induced by interaction of the Earth and the Moon. These two claims result in followin one: deforamtions of the Earth's crust cause variations of thermal and slow neutrons' flux near the Earth's crust, especially displayed in the seismo-active reagions. Methods for forecasting of earthquakes and volcanos' activity are developed on this basis.

SIMULATION OF PHYTOPLANKTON ANNUAL CYCLE IN LAKE BAIKAL, ECOLOGY CONTROLLING BY HYDRODYNAMIC AND OPTICS

Sergei V.SEMOVSKI (Limnological Institute SB RAS, P.O.Box 4199, Irkutsk, 664033 Russia, email: Semovsky@lin.irk.ru)

Lake Baikal is the deepest and the most voluminous freshwater basin in the World. Great depth and narrow shelf produce the peculiar horizontal and vertical exchange of water masses. Many processes in the lake can be considered as analogy of those typical for the deep ocean and marginal seas. From other hand, highly endemic lake Baikal ecosystem is under studies for long time, many features are known there much better then those in oceans and seas.
The model is presented for Baikal epipelagial ecosystem annual variability focusing on dynamics of main taxonomical phytoplankton groups. Bio-optical block of underwater optical field simulation includes impact of all optically active components of ecosystem.
Main features that should be described using the model are the follows: winter-spring under-ice diatoms bloom (the most abundant is Aulacoseira baicalensis) that is controlled by under-ice convection and optical properties of ice; spring deep mixing and blocking of phytoplankton development; summer picophytoplankton bloom (with prevaling green-blue Sinechocystis limnetica Popovsk.); autumn diatoms (Cyclotella minuta) bloom, autumn deep mixing and Aulocaseira spores transport from bottom zone into surface layer. The main objectives of the model development is to investigate factors influencing known interannual variability in spring diatoms bloom, full diatoms extinction during cold paleoclimates, autuminal diatoms prevailing during 16-19 century, etc.

ROCK LOBSTER JASUS EDWARDSII LAVAL RETENTION BY THE WAIRARAPA EDDY OFF NEW ZEALAND

STEPHEN M.CHISWELL (National Institute of Water and Atmospheric Research, NIWA,PO Box 14-901, Kilbirnie, Wellington, New Zealand, email: s,chiswell@niwa.cri.nz)

In February 1988, Jasus edwardsii larval catches off the east coast of New Zealand were binomial in size and stage of development. Mid-stage larvae (presumed to be from the 1997 cohort) appear to be contained within a large permanent eddy found offshore known as the Wairarapa Eddy. Late-stage larvae (1996 cohort) have a statistically distinguishable different distribution from the mid-stage larvae, being found closer inshore of the eddy. Pueruli (also 1996 cohort) were found well inshore of the eddy. Surface currents derived from TOPEX/Poseidon altimeter measurements of sea level are used to model passive tracer distributions designed to simulate larval concentrations. The numerical simulations show that the different distributions of the three groups cannot be explained on the basis of their different time histories to advection alone. Mid-stage concentrations appear to be well described by passive drift alone, but the simulations suggest some mechanism inducing shoreward transport is needed for both pueruli and late-stage phyllosomas. Observed pueruli concentrations are best matched by adding a shorewards-directed speed of 8-10 cm/s for between 1 to 3 weeks before the date of the cruise. Late-stage phyllosoma concentrations are best matched by adding speeds of 4-6 cm/s. Sustained shorewards swimming speeds of 8-10 cm/s are well within the estimates of swimming speed that have been reported elsewhere for pueruli. To our knowledge, directed horizontal swimming has not been reported for hyllosomas, yet in the final stage, the pleopods are as well developed, as they are in the pueruli. These final stage larvae could well use forward pleopod propulsion to allow them to swim.

P11/E/07-B3 0910

CIRCULATION AND DEEP WATER VENTILATION PROCESSES IN THE CASPIAN SEA SIMULATION USING 3-D PEM AND THERMODYNAMIC ICE MODEL

Rashit A. IBRAYEV and Artem S. Sarkisyan (Institute of Numerical Mathematics, Russian Academy of Sciences, Gubkin str.8, 117951, Moscow, Russia, email: ibrayev@inm.ras.ru) Emin Ozsoy and Halil I. Sur (Institute of Marine Sciences, Middle East Technical University, P.K.28 Erdemli-Icel, 33731, Turkey, email: ozsoy@inm.metu.edu.tr) Corinna Schrum (Institute of Oceanography, University of Hamburg, Troplowitz str.7, Hamburg, D- 22529, Germany, email: schrum@dkrz.de)

A 3-D PE GCM coupled with an ice sub-model is used for the study of seasonal and interannual variability of the Caspian sea circulation. ECMWF derived fluxes, and river inflows are used to force the model. Wind-driven shelf currents and basin-scale interconnected recirculation gyres define the horizontal pattern of circulation. Our results support the earlier hypothesis that the Volga river inflow plays a significant role in driving the southward longshore currents along the western coast. Predominant southward and westward winds create downwelling along the western shelf and upwelling along the eastern shelf, supported by consistent satellite observations. Gravitational sinking of dense water on the northern shelf slope occurs as a result of local freezing and vertical mixing of cold water originally formed on the northern and eastern shelves. Changes of sea level and production of dense water under ice sheet occur in response to interannual changes in the water balance based on river inflow and evaporation fluxes. As a result, ventilation of the deep water is decreased when the sea level rises. Our model results are in agreement with the analyses of historical and recent data, indicating decreasing oxygen in the deep waters of the Middle Caspian Basin during the epochs of rising sea level.

P11/E/04-B3 0930

OBSERVATIONS OF SEDIMENT RESUSPENSION AND TRANSPORT IN THE COASTAL AND BOTTOM BOUNDARY LAYERS OF LARGE LAKES WITH ACOUSTIC DOPPLER CURRENT PROFILERS

JAMES H. SAYLOR and Gerald S. Miller (Both at: National Oceanic and Atmospheric Administration, Great Lakes Environmental Research Laboratory, 2205 Commonwealth Blvd., Ann Arbor, MI 48105; e-mail: saylor@glerl.noaa.gov)

Data from Acoustic Doppler Current Profilers (ADCP) deployed in the nearshore region of southeastern Lake Michigan provide evidence of sediment resuspension and the cross-shelf transport of these materials during episodes of winter wind storms. Significant increases (+20 dB) in echo intensity and current velocity correlate well with satellite imagery of a sediment-laden plume transporting material in a cyclonic flow around the basins perimeter. A decrease in echo intensity to near background levels following the resuspension event suggests that the larger particles settle out, leaving the very fine material that remains visible in satellite imagery for many days. In Lake Champlain, a long, narrow and deep lake that forms the boundary between the states of New York and Vermont, bottom sediment resuspension caused by surges and gravity currents in the density-stratified lake water has also been documented in acoustic profiler records. Although no concurrent measurements of Total Suspended Material have been achieved in either lake, the ADCP results show that resuspension events can be detected using these instruments. With calibration of sediment concentration and echo intensity at each site, it appears that quantitative values of sediment fluxes can be determined.

ABSOLUTE FLUXES UTILISING DIRECT VELOCITIES, ACROSS 8.5N IN THE ARABIAN SEA IN JUNE 1995

L. M. BEAL, (Lamont-Doherty Earth Observatory, Palisades, NY 10964, USA
email: ibeal@ideo.columbia.edu); A. Ffield, R. L. Molinari and W. D.Wilson

Meridional volume fluxes into the Arabian Sea have been estimated using a combination of the geostrophic approximation and direct velocity measurements. The data were collected during the southwest monsoon of June 1995, as NOAA repeat line I1R, nominally along 8.5N. Direct velocity measurements show that winds drive strong southward fluxes of (about 19 Sv) over the upper 50 m, which appear to be partially compensated by a northward flow of subsurface waters between 50 and 290 m depth in the interior, and by the intense northward flow of the Somali Current at the western boundary. The cumulative transport in this surface layer was found to be 8 +/- 2 Sv from on-station shipboard and lowered ADCP velocity profiles. Below 290 m, velocities and shears are generally an order of magnitude smaller than in the surface intensified flows. Here, where we expect the flow to be dominated by rotation, geostrophic velocity has been referenced to the detided, cross stream component of LADCP velocity. The resultant structure of the section transport per-unit-depth from geostrophy and from LADCP is quite different. Geostrophic fluxes suggest a deep overturning, with northward transport below 2400 m of 22 Sv, while LADCP suggests 0.4 Sv. Since the Arabian Sea is closed to the north of the I1R section, the former transport would require an unrealistic scale of upwelling throughout the basin, and hence, evidently the LADCP-referencing scheme would appear to be flawed, certainly for this low baroclinic mode circulation. For comparison, taking geostrophy referenced to 2000 dbar across the section, the overturning is 13.3 Sv; still rather large. The horizontal transport structure, on the other hand, shows that geostrophic and LADCP fluxes are well matched; largely an artifact of the referencing method used. The depth-integrated transport structure is dominated by bands of alternating northward and southward fluxes, with particularly strong circulations to the east of the Carlsberg and Chagos- Laccadives Ridges. The accumulated transport along the section (below 290 m) is about 22 Sv. The next step for this analysis is to establish the representativeness of the one-time section and, subsequently, to enforce a mass balance on the circulation.

P11/E/06-B3 1010

THE RESPONSE OF SEMI-ENCLOSED SEAS TO SYNOPTIC ATMOSPHERIC FORCING

Christopher N.K. MOOERS, HeeSook Kang, and Lianmei Gao (OPEL/RSMAS,University of Miami,4600 Rickenbacker Cswy.,Miami,FL33149- 1098, USA, email: cmooers@rsmas.miami.edu, hkang@rsmas.miami.edu, lgao@rsmas.miami.edu)

Semi-enclosed seas are under the influence of atmosheric forcing (wind stress,surface pressure,heating/cooling,and evaporation/precipitation)on a variety of space and time scales from mesoscale to synoptic scale to intra-seasonal,seasonal/annual,inter-annual,and so forth. Here, the primary interest is in the oceanic response to synoptic scale forcing. Because of the joint effects of Earth's rotation, ocean density stratification, and continental margin topography, the response of semi-enclosed seas to synoptic forcing can be rich, ranging from transient coastal upwelling or downwelling, to coastally trapped waves, storm surges, transient jets and fronts, transient surface and bottom mixed layers, convection/ventilation, and so forth.
Numerical simulations (using POM) of the response of the Japan (East)Sea to wintertime extratropical cyclone/cold front outbreaks, and the Intra-Americas Sea to summertime tropical cyclones, are used as examples. The synoptic atmospheric forcing (with mesoscale resolution) utilized is provided by relatively new sources; e.g., a spaceborne scatterometer (NSCAT) and a mesoscale atmospheric model (MM5). By comparing with the response to more conventional,lower-resolution atmospheric forcing fields, the sensitivity of semi-enclosed seas is illustrated. Conversely, the space-time-amplitude resolution and accuracy requirements of atmospheric forcing for quality simulations of semi-enclosed seas circulation are beginning to be better defined by these response studies.
Looking ahead, the new sources of synoptic atmospheric forcing information (with mesoscale resolution)offer the potential for driving simulation and predictive models of circulation in semi-enclosed seas with higher accuracy on a routine(operational)basis.

THE SOUTH CHINA SEA RESPONSE TO TROPICAL CYCLONE ERNIE 1996

Peter C. CHU (Naval Postgraduate Research, Monetary, CA93943, USA Email: chu@nps.navy.mil); and Joseph Veneziano

We study the response of the South China Sea (SCS) to a tropical cyclone using the Princeton Ocean Model (POM) with 20 km horizontal resolution and 23 sigma levels conforming to a realistic bottom topography. A high-resolution surface wind field was established to represent Tropical over the SCS . Its translational velocity is determined using the best track storm course and speed from post-storm analysis by the United States Navy Joint Typhoon Warning Center at Guam (JTWC), and its relative velocity to e storm center is determined using a recently developed tropical cyclone wind profile model (TCWPM). To obtain the wind field both inside and outside a tropical storm, a background (climatological) wind field is blended. The calculated wind field is verified using the JTWC analyzed wind profile data. The integration of the POM model was divided into pre-experimental and experimental stages. During the pre-experimental stage the model was integrated for 34 months and three days from an initial at rest state with three-dimensional climatological January temperature and salinity fields, forced by the climatological monthly mean wind stress. The final state from the pre-experimental run

was taken as the SCS condition for 4 November 1996, the initial condition for the experimental stage. During the experimental stage, the POM model was forced by TCWPM modeled wind field, simulating Tropical Cyclone Ernie, for eighteen days. Our results show that the POM adequely simulated ocean responses to tropical cyclone forcing. Near-surface ocean respons es simulated by the POM included strong asymmetrical divergent currents with near-inertial oscillations, significant sea surface temperature cooling, biased to the right of the storm track, and sea surface depressions in the wake of the storm. Subsurface responses included intense upwelling and cooling at the base of the mixed layer to the right of the storm track. Several unique features used by coastal interactions with storm forcing, were also simulated by the model. Along the coast of Luzon a sub-surface alongshore jet was formed, a warm anomaly off the northern tip of Luzon was significantly enhanced by surface layer convergence and storm surges simulated along the coasts of nd Vietnam.

P11/E/14-B3 1110

A COASTAL AIR-OCEAN COUPLED SYSTEM (CAOCS) FOR THE SOUTH CHINA SEA MULTI-EDDY STRUCTURE

Peter C. CHU,(Naval Postgraduate Research, Monetary, CA93943, USA Email: chu@nps.navy.mil) Shihua Lu, and Yuchun Chen

A coastal atmosphere-ocean coupled system (CAOCS) is developed to study the South China Sea (SCS) mesoscale eddy formation in May 1995. The oceanic component consists of the Princeton Ocean Model (POM) with 20 km horizontal resolution and 23 sigma levels conforming to a realistic bottom topography. The atmospheric component consists of a recent version of the regional climate model (RegCM2) with 40 km horizontal resolution and 16 vertical levels. The model domain (98.84-121.16 degree E, 3.06 degree S-25.07 degree N) covers the whole SCS and surrounding land and islands. The lateral boundary conditions for the atmospheric component come from European Center for Medium-Range Weather Forecasts (ECMWF) analyses of observations, and for the oceanic component come from observational oceanic inflow/outflow at the open boundaries. The surface fluxes of water, heat (excluding solar radiation), and momentum are applied synchronously with opposite signs in the atmosphere and ocean. Flux adjustments are not used. The CAOCS model simulation agrees well with an extensive airborne expendable bathythermograph (AXBT) survey of the South China Sea (SCS) conducted in May 1995, and shows the capability of simulating the SCS multi-eddy structure in May 1995: a central SCS warm-core anticyclonic eddy surrounded by several cool-core and warm-core eddies.

P11/E/15-B3 1130

AN AIRBORNE EXPENDABLE BATHYTHERMOGRAPH SURVEY OF THE SOUTH CHINA SEA, MAY 1995

Peter C. CHU (Naval Postgraduate Research, Monetary, CA93943, USA Email: chu@nps.navy.mil), C.W. Fan, C.J. Lozano, J.L. Kirling

An extensive airborne expendable bathythermograph survey of the South China Sea (SCS) conducted in May 1995 and historical data are used to analyze and infer the upper layer (300 m) synoptic structure and general circulation. The primary thermal feature observed was a central SCS warm pool surrounded by several cool pools. The size of the warm pool decreased with depth from approximately 200,000 square kilometers at 50 m depth to about 70,000 square kilometers at 300 m depth. The maximum temperature of the warm pool was 30 degree C, appearing near the surface. At the depth of 50 m, the temperature of the central SCS warm pool was 29 degree C, and the temperature of the five surrounding cool pools ranged from 26 degree C to 22 degree C. A three-dimensional estimate of the absolute velocity field was obtained from the observed temperature field and a climatological salinity field using the P-vector inverse method. Striking circulation features were the existence of dual anticyclonic eddies in the central SCS warm pool and the existence of cyclonic eddies associated with the cool pools. In the upper layer the tangential velocity of the dual central SCS anticyclonic warm-core eddies is around 30-40 cm/s and that of the five cyclonic cool-core eddies varies from 10 cm/s to 40 cm/s. The tangential velocity of all the eddies decreased with depth. At 300 m depth, it became less than 5 cm/s for all the eddies.

WARMING AND LONG-TERM VARIATION IN THE EAST/JAPAN SEA; A GLOBAL IMPLICATION

Kuh KIM and Kyung-Ryul Kim (both at Research Institute of Oceanography, Seoul National University, Seoul 151-742, Korea, email: kuhkim@ocean.snu.ac.kr); Young Oh Kwon (School of Oceanography, University of Washington, Seattle WA 98195 USA, email: yokwon@ocean.washington.edu)

Potential temperature in the East Sea has risen about 0.03 deg C at 3000 m and 0.25 deg C at 500 m since 1940s. Salinity has undergone a differential change with depth at the same time; an increase above 1200 m, but a decrease below it since 1965. During the same period the concentration of the dissolved oxygen has changed in three layers; a decrease in the upper 500 m, an increase at 500-1400 m and another decrease below 1400 m. The warming and reduction in the dissolved oxygen in deep and bottom waters indicate that the rapid ventilation which kept the East Sea rich in oxygen as high as 6.0 ml/L in the past may have stopped or have been reduced significantly. Meanwhile increase of both salinity and dissolved oxygen at intermediate depths is possible only through introduction of a new water mass at this depth. A simple one-dimensional model suggests that continuation of this process would deplete the bottom water in 30 years. The East Sea seems to act as a miniature ocean for monitoring and prediction of the change in the thermohaline circulation in oceans associated with the global warming.

A NOTE ON THE TAIWAN WARM CURRENT

Le KENTANG (Institute of Oceanology, CAS, Qingdao 266071, PRC, email: ktle@ms.qdio.ac.cn)

The Taiwan Warm Current is one of the major currents in the East China Sea. It is traditionally believed that the Taiwan Warm Current (TWC) is to the east of the East China Sea Coastal Current and flows roughly along the coast of the Zhejiang and Fujian Provinces from the southwest to the north. However, with the increase of the field data it is found that the origin of the TWC Water varies seasonally. In other words, it can originate from the Taiwan Strait or from the intrusion of Kuroshio northeast of Taiwan or from the both. On the other hand, some contour maps of the isopycnal surface given by Su and Pan in 1987 suggested that the TWC actually had two branches, one inshore and one offshore. However, the plane distributions of the monthly-mean temperature and salinity in <<Marine Atlas of Bohai Sea, Yellow Sea and East China Sea>> (1992) have shown that the hydrological structure in the region north of Taiwan has remarkable annual variations due to monsoon, coastal currents off the continent, intrusion of Kuroshio. Also, the seasonal surface current maps in it have displayed that the surface currents in the same region have different seasonal patterns and the so-called inshore and offshore of the TWC may have different origins. It would be better to suggest that the inshore one still remain its traditional nomenclature, the TWC, and the offshore one can be named as the East China Sea Warm Current.

CURRENTS AND EDDIES IN THE ABYSSAL WATER OF THE JAPAN SEA

Masaki Takematsu, Alexander G. Ostrovskii (both at Research Institute for Applied Mechanics, Kyushu University, Kasuga 816-8580, Japan, email: takematu@hikari.riam.kyushu-u.ac.jp)

Moored current measurements were made for the first time at seven sites in the Japan Basin, the northern half of the Japan Sea, in an attempt to directly explore the velocity field in the highly homogeneous abyssal water of the semi-enclosed marginal sea. Duration of the current measurements was 1 to 3 years depending on specific site.
The current meter data thus collected revealed that the abyssal water of the Japan Basin is very energetic with vertically coherent currents and eddies of the order of 10cm/s. Surprisingly, the currents and eddies exhibit marked seasonal variability even in the deepest layers. The observed new current features are discussed in comparison with remotely sensed data (sea surface temperature and drifter tracks) and results of numerical simulation with Princeton Ocean Model. New findings about the Liman Current along the Primorye coast are also described.

VALIDATING MULTIYEAR OCEAN-MODEL RUNS FOR MARGINAL SEAS

Frank Janssen and Corinna Schrum (both at Institut of Oceanography, University of Hamburg, Troplowitzstr.7, D-22529 Hamburg, Germany, email: janssen@ifm.uni-hamburg.de)

Many ocean scientist believe that the time has come to leave the global scale in climate modelling. Much hope lies in the enhancement of our knowledge of interannual and decadal variability of the ocean from regional coupled model experiments. Semi-enclosed and marginal seas are highly preferable areas for these kind of studies, not only because of the sensitivity of their physical and biological systems to small climate changes, but also their great importance for men. But a detailed analysis of model results only makes sense if it can be guaranteed that the model system is able to give the wanted answers with the needed accuracy: Systematic model validation is therefore of outmost importance! First steps of a systematic validation procedure for a shelf sea model, integrated up to the decadal time scale, will be presented. Model results are taken from a 15 year model run with the HAMSOM (Hamburg Shelf Ocean Model) forced by ECMWF re-analysis data. The model area is the North Sea/Baltic Sea system, which is one of the areas with the highest coverage of observed data worldwide. This area can be seen as a kind of test case. If we fail to come to a consistent validation with the amount of available observations here, there is little hope that this will be possible elsewere.

P11/W/09-B3 1500

TRANSPORT AND STRUCTURE OF THE ATLANTIC INFLOW TO THE NORTHERN SEAS BASED ON LONG TERM CURRENT MEASUREMENTS

Kjell Arild ORVIK, Øystein Skagseth and Martin Mork (Geophysical Institute, University of Bergen, Allegaten 70, N-5007 Bergen, Norway)

This study deals with the inflow of warm and saline North Atlantic water to the Northern Seas, this important factor for climate, ecology and biological production in Northern Europe. The investigations are carried out in the Svinøy Section just to the north of the Faroe-Shetland Channel cutting through the core of the Atlantic inflow to the Norwegian Sea. This is because recent investigations show that different branches of the Atlantic inflow through the Scotland-Greenland gaps merge through confluence in a two-branch flow crossing the Svinøy Section, making this site very suitable for monitoring the Atlantic inflow. Based on long term current measurements from 3-5 mooring lines from April 1995 to October 1998 in combination with shipboard ADCP, SeaSoar-CTD and CTD transects, transport estimates and spatial current structures will be presented. For the first time the two-branched Norwegian Atlantic Current has been revealed with a striking inner and outer branch. The inner branch shows properties as a 30-50 km wide, nearly barotropic flow trapped over the steepest slope between depths of 200 m and 900 m, while the outer branch makes its appearance about 200 km further offshore just above the 2000 m isobath as a 30-50 km wide jet with baroclinic properties extending down to 400 m depth. In between the observations show strong spatial variabilities in an eddy and recirculation pattern. The Atlantic inflow shows variabilities over a broad frequency band with periods from days to weeks. Seasonal and interannual variabilities are also prominent. Presumably, high inflow events are forced by wind impact which is also revealed in the high correlation with the North Atlantic Oscillation (NAO) index, mirroring the strength of the westerly wind-field in the North Atlantic. Thus, the most dominant seasonal signal is found in the seasonality of the winds.

P11/W/29-B3 1520

USE OF AN OPTICAL SATELLITE SENSOR SUCH AS SEAWIFS...

Dr Bernard WALTER (NorthWest Research Associates, USA)

Use of an optical satellite sensor such as SeaWiFS is limited in its ability to adequately monitor spatial and temporal changes in biological productivity in an area frequently covered by clouds such as over the Southeast Bering Sea shelf. In order to extend this monitoring capability we study the relationship between patterns seen in Synthetic Aperture Radar (SAR) imagery, which is not affected by cloud cover, and those seen in ocean color measurements from SeaWiFS imagery over this area during a period in June, 1998. We attempt to identify characteristic patterns or features in SAR imagery associated with areas of high (low) biological activity. The link between biological activity and SAR is through the fact that planktonic material produce fatty acids and alkanes that produce films on the ocean surface. These natural films cause damping of capillary and short gravity waves sensed by SAR thus producing dark slick signatures in SAR imagery. We focus on the period: June 19-22, 1998

where we have coincident SAR and SeaWiFS imagery. Winds were generally light (3-5 m/s) during the period. The SeaWiFS images show a large region over the SE Bering Sea shelf with low chlorophyll concentration (1 mg/m3) associated with a coccolithophore bloom. There was a large increase in chlorophyll concentration near 57.5-58.5 deg N, 168 deg W with values 10 mg/m3 southward toward St. Paul Island. The SAR images during this period consistently show striking differences in radar backscatter patterns between the areas indicated as having high chlorophyll concentration and low chlorophyll concentration in the SeaWiFS images. In general in the areas of high chlorophyll, the SAR images show considerable eddy activity delineated by dark bands presumably caused by the natural surfactants from the biological activity. There is a definite transition in backscatter pattern in the region of high horizontal chlorophyll gradient, from the eddy activity to a rather featureless backscatter pattern. We will explore the use of texture analysis as a way of quantifying the differences in backscatter patterns between the high and low chlorophyll regions and investigate the effects of wind forcing on these results. These preliminary results point to the possibility that SAR imagery may be able to delineate regions of high and low biological activity.

P11/E/26-B3 1600

ON WATER AND SALT EXCHANGE IN A FRICTIONALLY DOMINATED STRAIT - CONNECTING THE BALTIC WITH THE NORTH SEA

BERTIL HAKANSSON (Swedish Meteorological and Hydrological Institute, S-60176 Norrkoping, Sweden, email: bertil.hakansson@smhi.se)

A hydraulic model is applied to one of the straits in the transition area between the Baltic and the North Sea. It is calibrated and validated with independent datasets of ship-borne ADCP transect measurements and an array of moored current meters. The model is able to explain 0.91 and 0.79 of the variance, respectively. It is forced with sea level data, which representativity is studied in some detail. The 1993 volume and salt exchange are investigated. It is found that the annual salt import is of the same magnitude as during a Major Baltic Inflow event. A twenty-year time series of calculated water exchange is used to estimate the average export of water. This estimate is used in a Baltic Sea water budget to evaluate the mean water exchange in Oresund and the Great Belt strait. It is found that the mean water outflow is distributed as 1.9:1 between the two straits, indicating that Oresund has a more efficient barotropic water exchange than the Great Belt. It is also demonstrated that the water exchange anomalies, on a decadal time-scale, closely follow the Baltic drainage area runoff anomalies.

P11/E/09-B3 1620

SOME ASPECTS OF THE STUDY OF THE BALTIC SEA

Natalia STASHCHUK, Vasiliy Vlasenko (both Marine Hydrophysical Institute, Kapitanskaya Str. 2, Sevastopol, 335000, Ukraine, , email: vlasta@ukrcom.sebastopol.ua); Vadim Paka and Nikolay Golenko (both Atlantic Branch of P.P. Shirshov Oceanology Institute, Mira Street 1, Kaliningrad, 236000, Russia, email: paka@ioran.kern.ru

Two interesting phenomena revealed in the Baltic Sea during 29 Cruise of R/V "Professor Shtokman" are investigated. The first one is the local widening of a pycnocline with vertical scope of about 30 m and horizontal scale of 12-20 km near a shelf break of the Gotland Deep. Two possible mechanisms of the formation were investigated by means of mathematical modeling. At first the in-situ data were explained as an "internal surf", generated by seiches in the region of a steep slope. A comparison of the in-situ data with the results of mathematical modeling rejected the hypothesis. The more realistic one is that baroclinic seiches oscillations can form local zones of a shear instability. This leads to a widening of a pycnocline in these zones due to a mixing.
Analysis of the in-situ measurements conducted in Stolpe Channel after the salty water inflow has shown the narrowing and uprising of isohalines to a sea surface on the northern periphery of the channel and their widening and deepening in the southern part of it. It was supposed that the system of near bottom currents generated during inflow was the reason of marked structure. By use of mathematical modeling it was obtained that the North Sea waters moving eastward along the channel form a bottom boundary layer.
The Ekman drift excited due to the Coriolis force generates the water transport across the channel in the bottom boundary layer. It can lead to the formation of an asymmetrical structure of hydrophysical fields across the channel.

P11/W/13-B3 1640

BOTTOM BOUNDARY LAYER DYNAMICS IN THE BALTIC SEA TYPICAL SUBREGIONS

Jüri ELKEN and Urmas Raudsepp (Estonian Marine Institute, Paldiski St. 1, 10137 Tallinn, Estonia, email: elken@phys.sea.ee, raudsepp@phys.sea.ee)Tarmo Kõuts (Estonian National Maritime Board, Hydrographic Service, Lasnamäe St. 48, 11413 Tallinn, email: kouts@gwb.ee)

Observational data are presented for slopes and interior of deep basins (Gotland Deep), shallow straits (Irbe Strait) and medium-deep semi-enclosed basins (Gulf of Riga). The strongest signal in near-bottom currents comes from wind-forced barotropic motions of the basins. In the flat-bottom areas, the current speed may exceed 15-20 cm/s (Ruhnu Deep in the Gulf of Riga, full depth 53 m). Barotropic motions are more amplified on the slopes and connecting straits. In the Irbe Strait, resonance with the Baltic Sea seiches drives 24-h period current oscillations which amplitude may exceed 60 cm/s at stronger winds. Apart from the fluctuating part, steady density-driven current components are evident in the channels and on the slopes. The 3D-circulation model (a free surface version of the Bryan-Cox model) is used to further investigate the bottom boundary layer dynamics. The modelled current response to the major forcing factors is in agreement with the observed current dynamics. A sediment dynamics model and a Lagrangian particle transport model are superimposed on the circulation model. The calculations are used to estimate the sediment resuspension/deposition and redistribution. The results are compared with the observed fluff layer dynamics and sediment distributions.

P11/W/02-B3 1700

GAS BUBBLE CONCENTRATIONS IN THE BALTIC SEA AND THEIR ROLE IN GAS EXCHANGE

Jaromir Jakacki (1), Zygmunt Klusek (1) and (2) (1: Institute of Oceanology, PAS, ul. Powstañców Warszawy 55, 81-712 Sopot, Poland; 2: Pedagogical University, ul. Arciszewskiego 22, S_upsk, Poland)

Gas bubble concentrations in the surficial water layer in the Baltic sea were measured using the multi-frequency acoustical system. The concentration estimations were performed using non-linear response of bubble in an acoustical field of high intensity. Dependence of bubble concentrations on wind speed and on the depth have been established. Gas fluxes car-ried into sea water by the bubble population were estimated.

MEDITERRANEAN SEA

P11/W/06-B4 0930

RADIATIVE EQUATIONS AND CLIMATIC BEHAVIOUR OF THE MEDITERRANEAN BASIN.

Maria Elisabetta SCHIANO and Mireno Borghini (both at Istituto per lo studio dell'Oceanografia Fisica-CNR, Forte S. Teresa, 19036, La Spezia, Italy, email: schiano@estosf.santateresa.enea.it); Costante Luttazzi (Istituto di Fisica dell'Atmosfera-CNR, Rome, Italy)

An analysis is performed on the systematic discrepancies observed over the Mediterranean Sea between direct measured radiative fluxes and predictions obtained by the most widely used bulk formulae. The investigation has been carried out using direct measurements of solar radiation, atmospheric radiation, sea surface temperature and meteorological parameters collected over the Mediterranean Sea in the last ten years. The climatic features of the basin are charged for the failure of the equations. Particularly, it is shown that formulae developed for the mid-latitude oceans cannot be applied over the Mediterranean Sea owing to the interactions between the warm sea surface and the lower atmosphere. These strongly affect the surface parameters producing some conditions very different from typical mid- latitude situation. Moreover, the analysis reveals that, due to the strong variability, a single equation is unable to reproduce the fluxes at the surface of the Mediterranean Sea all year round. The twofold climatic behaviour of the Mediterranean region, where are present both tropical and mid-latitude aspects, requires distinct equations, probably involving different surface variables.

P11/W/23-B4 0950

MODELLING THE MEDITERRANEAN UNDER DERIVED FLUX FORCING

Paul Myers and Keith HAINES (both at Department of Meteorology, University of Edinburgh, JCMB, Kings Buildings, Edinburgh, EH9 3JZ, U.K., email: paulm@met.ed.ac.uk; kh@met.ed.ac.uk)

A long term integration of a Mediterranean model is performed with surface forcing of derived heat and freshwater fluxes. The model remains stable under these fluxes over a 100 year integration, reproducing the major water masses of the Mediterranean quite accurately. With the flux surface boundary condition, internal variability at interannual and interdecadal periods is enhanced. Levantine Intermediate Water (LIW) production of 1.3 Sv occurs and a detailed examination of LIW budgets in the model is given. Interannual variability in the production of LIW is shown to be related to changes of the main path of the Mid-Mediterranean Jet and the advection of Modified Atlantic Water to the west or east of Cyprus. Furthermore, the flux boundary conditions permit the discovery of multiple equilibria in the basin's thermohaline circulation, with a second state involving a circulation collapse, with only intermediate water formation. This state is similar to that hypothesized for sapropel formation in the Holocene. Both states are characterized by similar hydraulic conditions at the Strait of Gibraltar, with significantly submaximal volume transport and large freshwater transport. A further intermediate stats exists with near maximal transport and small freshwater transport.

P11/E/25-B4 1010

NUTRIENT TRANSPORT MECHANISMS AND THE DYNAMICS OF THE PLANKTON PRODUCTION IN THE NORTHEASTERN MEDITERRANEAN

Aysen YILMAZ, Ilkay SALIHOGLU, Suleyman TUGRUL, Dilek EDIGER, Yesim COBAN YILDIZ and Mehmet YAYLA (Middle East Technical University Institute of Marine Sciences, P.O.Box 28, 33731, Erdemli-Icel / TURKEY)

The eastern Mediterranean is one of the well known region of low productivity in the world due to limited nutrient supply to its surface layer from external and internal sources. The seasonality and the magnitude of primary productivity are principally determined by the extent and duration of winter mixing which provides nutrient input from intermediate layers to the euphotic zone. Chlorophyll-a concentrations measured in the last 10 years ranged from 0.01-0.5 µg/L in summer to 0.1-1 µg/L during the late winter-early spring bloom period. A well-developed deep chlorophyll maximum (DCM) near the base of the euphotic zone is a characteristic feature of the Northeastern Mediterranean throughout almost the whole year while this peak was broadened and observed at shallower depths during bloom periods. Nevertheless this prominent feature disappeared under severe winter conditions, as experienced in the winters of 1992, 1993 and 1995. The chlorophyll-a concentrations up to 3 µg/L were observed and the thickness of the euphotic zone decreased from 60-80m to 50-55m in the Rhodes cyclonic eddy and its peripheries. Such exceptional events in terms of phytoplankton activity attributed to the instant changes in the nutrient transport mechanisms since chimney type of structures were observed and the euphotic zone was fully enriched by the nutrients due to extreme hydrodynamical events experienced in these years.
The deep water of the Northeastern Mediterranean is relatively rich in dissolved inorganic nutrients (NO_3=4-6 µM and PO_4=0.15-0.22 µM) but it posses a relatively high N:P ratio (=26-28) compared to the deep oceanic values (=14-17). Therefore, nutrient inputs from the deep layer to the surface waters by advective and convective mixing in winter occur with the indicated high ratios. This process most probably leads to phosphorus-limited algal growth in the euphotic zone of the eastern Mediterranean. The bioassay experiments proceeded in the last two years supported this phenomenon and when the excess amount nutrients were provided to the phytoplankton populations, phosphorus seems to stimulate the growth. Moreover, the limited nutrient supply from the deep waters with relatively high N/P molar ratios of dissolved nutrients is expected to affect the chemical composition of biogenic particles synthesized in the euphotic zone and it has been shown that N/P molar ratio in POM is generally higher than the Redfield ratio.

P11/E/11-B4 1050

THE POEM-BC PROGRAMME (PHYSICAL OCEANOGRAPHY OF THE EASTERN MEDITERRANEAN BIOLOGY AND CHEMISTRY): A REVIEW OF ITS DISCOVERIES

Paola MALANOTTE-RIZZOLI (Bldg. 54-1416, Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, 77 Massachusetts Ave., Cambridge, MA 02139, USA, Email: rizzoli@ocean.mit.edu)

Physical Oceanography of the Eastern Mediterranean (POEM), an international collaborative program sponsored by the United Nations Educational Scientific and Cultural Organization and the Intergovernmental Oceanographic Commission, has studied the Eastern Mediterranean since 1985. After a preparation phase, POEM studied circulation and physical processes from 1985 to 1990, resulting in three unexpected findings.
Researchers discovered a closed thermohaline cell in the deep-bottom layers of water that originates in the Southern Adriatic and spreads into the Eastern Levantine, the Eastern Mediterranean "conveyor belt" [Roether and Schlitzer, 1991]. Also found were multiple scales of interacting motions that define the general circulation at the basin, sub- basin, and

mesoscale [Malanotte-Rizzoli and Robinson, 1988; POEM Group, 1992]. And two convective regions with related water mass formation were found. The first is a deep convection cell in the Southern Adriatic, where the Eastern Mediterranean Deep Water (EMDW) was formed between 1985 and 1987.
Second, a convective region exists, rather more extensive than previously recognized, surrounding the Levantine Rhodes gyre where intermediate convection leads to the formation of Levantine Intermediate Water (LIW). Deep convection has also been observed in the Rhodes gyre leading to the formation of Levantine Deep Water (LDW) [Ozsoy et al., 1993]. The results of POEM Phase I are summarized in a group paper [POEM Group, 1992] and in a special issue of Deep Sea Research devoted to POEM results [Robinson and Malanotte-Rizzoli, 1993]. In 1990, POEM evolved into POEM-BC, an interdisciplinary project with a biology and chemistry component. Field work began with a basin-wide interdisciplinary survey carried out in October 1991 by five research vessels from Greece, Israel, Turkey, and Italy, which contributed two research vessels. A second interdisciplinary survey was carried out in March 1992 in the Ionian and Cretan Seas by two of the research vessels. The data set collected is helping to quantify the distributions of major inorganic nutrients and biological properties in the context of the physical processes of the basin. A major observational effort was finally carried out in winter 1995 with the execution of the LIW formation experiment. The three objectives of the experiment were to define the process of LIW formation through the successive phases of preconditioning, convection and formation, and spreading and dispersion; to study the internal (deep) and external...

P11/W/24-B4 1130

CHANGES IN THE SALT INVENTORY OF THE EASTERN MEDITERRANEAN AND THEIR RELATION TO RECENT SHIFTS IN WATER MASS FORMATION AREAS

Birgit KLEIN (Uni of Bremen, Institue of Environ Physics P.O.Box 330440 D28334 Germany Email: Ulf.Klein@uni-breman.de); and Wolfgang Roether

Large scale hydrographic and tracer surveys performed in the framework of POEM and POEM-BC/MATER have provided snapshots of the dramatic change in the thermohaline circulation of the Eastern Mediterranean that has taken place between the late 1980ties and the mid 1990ties. During this period the Aegean was established as a source of deep waters, discharge of which had pronounced effects on water mass properties and on circulation within the deep water regime. The most prominent effect of the new deep water source is the strong increase in salinity over much of the deep waters. An open question to date has been to identify the source of this salinity increase. Three scenarios are possible: internal redistribution of salt in the basin, changes in the fresh water fluxes through the surface or changes in the salt transport through the Strait of Siciliy and the Bosporus.
In order to investigate this question salt inventories of the Eastern Mediterranean have been computed for the period before 1988 and for 1995. The comparison of these inventories indicates an apparent increase in salt content of 5.7 10**13 kg. It assumes a constant volume and changes in water volume through variations in the fresh water flux have therefore to be removed from the estimate. Internal redistribution of salt is also noted and links salinity changes between intermediate and deep water masses on sub-basin scale. An increase of the net E-P flux of 20 cm/y averaging over 8 consecutive years would be required to explain the apparent salt content increase. Available estimates of evaporation and precipitation confirm increases in the net evaporation rate for the period concerned but of a much lower magnitude, accounting only for about 40% of the apparent salt content increase. We find that the required import of salt into the Easterrn Mediterranean to close the budget is related to changes in water mass characteristics in the Strait of Sicily. Hydrographic data from the Strait of Sicily indicate a strong increase in salinity of the inflowing water from the Western Mediterranean. The effect of the flow through the Bosporus is assumed to be small.

P11/E/19-B4 1150

UPDATING EASTERN MEDITERRANEAN TRANSIENT

BENIAMINO BRUNO MANCA, Osservatorio Geofisico Sperimentale, Trieste, 34016 Italy, email: bmanca@ogs.trieste.it Giuseppe Civitarese, Istituto Talassografico di Trieste - CNR, Trieste, Italy, email: civitarese@TS.CNR.IT Maurizio Ribera d'Alcala', Stazione Zoologica "A. Dohrn", Napoli, 80121 Italy, email: maurizio@alpha.szn.it

The recent change in the thermohaline circulation of the Eastern Mediterranean hase been characterized by a large outflow of Cretan water at Deep and Intermediate layers. Especially the second one has, apparently, replaced the LIW as the main Intermediate Water Mass in the Eastern Ionian Sea. In addition, a significant modification in the nutrient distributions with an uplift of the main nutricline by several hundred meters has been observed. A basin-wide cruise, carried on December 1998-January 1999, in the Ionian Sea allows to determine the present characteristic and distribution of water masses as well as the chemical and biological fields. The aim of the cruise is to reveal regions where the local dynamics could enhance the vertical flux of nutrients and eventually affect the pool of the photic zone. Cruises conducted in previous years after the first observations on the "new state" of the Eastern Mediterranean reveal that the new properties in water masses have rapidly affected the marginal seas and the Western Mediterranean, which in turn suggests that a new steady state will be probably reached relatively soon. We discuss data collected during the cruise in connection with a possible reconstruction of the damping process occurring in the Adriatic and Ionian Seas.

A WINTER INTERMEDIATE WATER EDDY EAST OF THE ALBORAN SEA

D. A. SMEED and J. T. Allen (Southampton Oceanography Centre, Empress Dock, Southampton. SO14 3ZH, email: das@soc.soton.ac.uk) J. Tintoré (Universitat de les Illes Balears, Palma de Mallorca)

During the second cruise of the OMEGA project the towed CTD SeaSoar was deployed to survey the upper 350m of the water column in the eastern Alboran Sea and extreme western Algerian basin. Fluorescence, optical back scatter and light were measured along with conductivity and temperature with an effective along track resolution of 4km. The combined data sets have enabled a detailed description of the different upper ocean water types and the fronts that separate them. The Almeria Oran front forms at the eastern boundary of the Alboran Sea gyre system, in the upper 150- 200 m of the water column, and separates waters of predominantly Atlantic origin from those formed in the Western Mediterranean Sea. Below these surface waters, but above the Levantine Intermediate Water, Winter Intermediate Water, believed to be formed to the north of the Balearic Sea, is often observed. However, to our knowledge, this is the first time a discreet eddy of Winter Intermediate Water, a "WEDDY", has been found in the extreme western Algerian basin. Repeated surveys of the region allowed us to observe the evolution of the eddy over a period of 40 days.

P11/E/16-B4 1420

MESOSCALE VARIABILITY IN THE EASTERN ALBORAN SEA IN DECEMBER 1997 JANUARY 1998

Yves GRATTON (INRS-Océanologie, Rimouski, Qc, Canada, G5L 3A1. Email: yves_gratton@uqar.uquebec.ca); Louis Prieur (LPCM, 06230 Villefranche-sur-mer, France. Email: prieur@ccrv.obs-vlfr.fr); Caroline Lafleur (INRS-Océanologie, Rimouski, Qc, Canada, G5L 3A1. Email: caroline_lafleur@uqar.uquebec.ca)

This paper describes the slow evolution of the mesoscale coherent structures observed in the Eastern Alboran Sea aboard the MV Atalante between November 30, 1997, and January 16, 1998. This scientific cruise was the second segment of the french Almofront (ALMería-Oran front) program. The observed initial configuration is characterized by the Atlantic Jet meandering around an anticyclonic eddy. In this configuration the density front lies exactly on the imaginary line between Almería (Spain) and Oran (Algeria). Three weeks later, the meander structure is more pronounced and the front has moved eastward. A mushroom-shaped structure can be observed in the satellite IR image of December 23. Another three weeks later, the eddy has moved eastward and the coherent structures observed on the thermal images are much more difficult to interptet, but the jet and the density front can still be observed in the density-velocity field. We also show that, contrary to what was observed in April-May 1991 (Almofront I), the structures observed in the satellite thermal images correspond to the deeper, geostrophic structures.

P11/E/05-B4 1440

ANALYSIS OF FLOW AND TRANSPORT MEASUREMENTS IN THE STRAIT OF GIBRALTAR

Burkard BASCHEK and Uwe Send (both at Institut fuer Meereskunde, Meeresphysik, Duesternbrooker Weg 20, D-24105 Kiel, Germany, Email: bbaschek@ifm.uni-kiel.de)

To resolve the net inflow into the Mediterranean Sea, as well as the temporal changes of the exchange flow, transport estimates at the Strait of Gibraltar have to have an accuracy of at least 0.1 Sv. This is still a challenge in physical oceanography and requires measurements with a high temporal and spatial resolution. These were carried out during the EU-Projet CANIGO (Canary Island Azores Gibraltar Experiment) between October 1995 und June 1998. Extensive measurements with vessel-mounted ADCP, CTD, lADCP and XBT during the reasearch cruises `Poseidon 217' and `Poseidon 234' were focused on the eastern entrance of the Strait of Gibraltar and were complemented by moorings in this region.
This data set was used to develop an inverse model to describe the currents and the vertical movement of the interface at the eastern entrance of the Strait of Gibraltar as a function of 2-D space and time. With this model the mean current speed and the volume transports in both layers were integrated across the section, where the correlation between tidal currents and the movement of the interface was included in the transport estimates.
In addition, acoustic transmission across the strait, which was tested during the CANIGO-Project, were compared with the model transports and the longperiodic components of the currents were determined after removing the tidal currents from the observations. Seasonably varying hydraulic effects are visible in the data and were accounted for in the analysis.

P11/W/19-B4 1500

OBSERVATIONS OF BIOPHYSICAL INTERACTION AT THE ALMERIA-ORAN FRONT

S. FIELDING, J. T. Allen, N. Crisp, D. A. Smeed and H. S. Roe (Southampton Oceanography Centre, Empress Dock, Southampton, email: sof@soc.soton.ac.uk); P. Velez (Universitat de les Illes Balears, Palma de Mallorca, Spain)

The Almeria-Oran front forms at the eastern boundary of the Alboran Sea gyre system. During RRS Discovery cruise 224 (part of the observational phase of EU MAST 3 project OMEGA) five repeat, high resolution, multidisciplinary surveys were made of the Almeria-Oran front. Hydrographic data were obtained with the towed undulating vehicle, SeaSoar. Concurrent with this, in-situ and remotely sensed biological data were collected using sensors fitted to SeaSoar, an optical plankton counter (OPC) and a fluorometer, as well as a hull mounted RDI ADCP and towed Simrad EK500 multifrequency sonar. Phytoplankton and zooplankton samples were collected to compliment and calibrate the in situ and remotely sensed data. Analysis of temperature and salinity on density surfaces, derived from the detailed hydrographic data, traced the high salinity, high temperature signature of Mediterranean surface waters entrained into the frontal jet and drawn down and across the front with a subduction velocity estimated to be 30-40 m/day. From the rapid repetition of the surveys we infer the advection of vorticity and predict regions of vertical motion. Solving the quasi-geostrophic omega equation, we have calculated vertical velocities (~15-20 m/day) and have compared the diagnostic picture of mesoscale vertical motion with that inferred from isopycnal maps of salinity and potential vorticity. Fluorescence data show that phytoplankton is also subducted at the front. Similar advection of zooplankton is also seen using acoustic backscatter data from both the ADCP and EK500 data. A high level of acoustic backscatter mirrors the downward subduction of the phytoplankton, persisting at times when diel migratory behaviour takes other zooplankton upwards towards the surface. Biological distributions in the vicinity of the front therefore result from interactions between physical processes and animal behaviour. OPC data and acoustic backscatter data (used in combination with net data and appropriate scattering models) can distinguish different biological communities in different water masses.

P11/W/07-B4 1520

ATMOSPHERE-OCEAN FLUXES, CLIMATIC VARIABILITY AND EXCHANGES BETWEEN THE EASTERN MEDITERRANEAN AND THE BLACK SEA

Emin OZSOY (Institute of Marine Sciences, Middle East Technical University, P.K. 28 Erdemli - Icel 33731 Turkey, Email: ozsoy@ims.metu.edu.tr), Leonid I. Ivanov and Vladimir Belokopytov (Marine Hydrophysical Institute, Kapitanskaya St., 2a, Sevastopol, 335000, Ukraine, Email: leonid@alpha.mhi.iuf.net)

The Eastern Mediterranean Basin and the Black Sea constitute two largely isolated water bodies of the world ocean, surrounded by land and constrained by exchanges through straits. Both regions appear highly sensitive to anthropogenic or climatic change, as a result of their isolation, enclosed geometry, being subject to large gradients in properties, transport from land, and their relatively small inertia in comparison to the ocean. Comparable effects of anthropogenic and natural variability in the ocean-atmosphere-land system makes diagnosis of environmental issues difficult. The marine environmental changes are most readily felt near the coast, adjacent to the continental shelf and abyssal regions.
Typical circulations, coherent features, convective mixing and upwelling events in the two interconnected Seas, their short and long-term variability, as well as synchronisms, differences and similarities in terms of intrinsic scales and forcing functions, are displayed, based on intensive oceanographic and satellite observations in the last decades. Local forcing and remote atmospheric connections to systems such as the North Atlantic Oscillation are exemplified. Decadal and longer term climatic atmospheric variability, with intensified effects

on air-sea fluxes in the region, their coincidence with convective events are studied, based on the analyses of atmospheric, oceanographic and satellite data. Coincidence of recent changes with the massive formation of Eastern Mediterranean deep waters during the Great Aegean Anomaly, and with pycnocline mixing in the Black Sea are investigated.
Atmospheric fluxes of momentum and heat obtained from ECMWF re-analysis data sets of 1979-1993, simultaneous satellite based and in-situ air and sea-surface temperatures, as well as marine heat storage and mixing characteristics based on time series of oceanographic measurements in the two seas are used to analyse their variability and interrelations. The results indicate a great degree of synchronism on interannual and decadal scales, and suggests strong atmospheric events and climatic variables linked to water mass formation.
The Turkish Straits, connecting the two Seas through the Bosphorus and Dardanelles Straits and the Sea of Marmara serves as a transition between them and reflects the changes taking place in the adjacent seas. However, the variability of both the forcing and the response affecting this relatively small, dynamic system is much greater. Various types of forcing and mass budgets, including river discharges into the Black Sea, atmospheric pressure and wind stress in the adjacent seas, and internal dynamics of the Straits determine the response. In addition, the mixing taking place along the Straits and the exit regions have strong consequences for the circulation and mixing in the adjacent Seas. These aspects are studied, based on available measurements and information.

P11/E/17-B4 1600

PHYSICAL-BIOLOGICAL INTERACTION DURING DEEP WINTER MIXING IN AN EASTERN MEDITERRANEAN WARM CORE EDDY

Stephen BRENNER, Nurit Kress (both at National Institute of Oceanography, Israel Oceanographic and Limnological Research, Haifa 31080 Israel, Email: sbrenner@mail.biu.ac.il), Tamar Zohary (Kinneret Limnological Laboratory, Israel Oceanographic and Limnological Research, Tiberias 14102, Israel) and Michael D. Krom (Department of Earth Sciences, Leeds University, Leeds LS2 9JT, UK)

The Shikmona gyre, a recurrent warm core eddy located to the south of Cyprus, has been observed during nearly every cruise conducted in this region since 1982. Detailed CTD data collected during the period 1987-1992 showed that the water in the core of the eddy is renewed every 2-3 years. Winter sampling of the eddy on two different occasions (Feb 1989 and Mar 1992) showed that a phytoplankton bloom occurs in late winter during the deep mixing phase. The bloom was not delayed until the establishment of springtime stratification as has been observed in other warm core eddies. In Mar 1992 viable phytoplankton and bacteria were found uniformly distributed throughout most of the deep mixed layer, from the surface to 500 m which is well below the euphotic zone. As a first step in studying the physical and biological processes involved, an NPZD model coupled to a Mellor-Yamada turbulence model was used to simulate the bloom dynamics.

P11/W/22-B4 1620

BOTTOM WATER OUTFLOW IN THE STRAIT OF OTRANTO – SEASONAL AND YEAR-TO-YEAR VARIABILITY

Miroslav GACIC, Dino Viezzoli and Vanessa Cardin (Osservatorio Geofisico Sperimentale, P.O.Box 2011, 34016 Opicina (Ts) Italy, email: mgacic@ogs.trieste.it, dviezzoli@ogs.trieste.it and vcardin@ogs.trieste.it)

A bottom water outflow from the Adriatic Sea has been monitored with three bottom mounted ADCP's since March 1997. The most energetic low-frequency sub-inertial variability of the Adriatic outflowing current component occurs at time scales of the order of a week. Superimposed on these variations are seasonal and year-to-year fluctuations. Spatial distribution of the bottom flow suggests that the vein of the outflowing bottom water has horizontal dimensions of about 15 km while in the vertical the vein is about 100 m thick. Sub-inertial variations at weekly time scales manifest in occasional current reversals. Seasonal variations are of the order of 1 cm/sec while the interannual variability is slightly stronger. Seasonal variations show a maximum in the outflow in May and a minimum in November which can be explained in terms of the filling up/emptying the South Adriatic Pit dense water reservoir. Year-to-year variations in the bottom water outflow have been shown to be correlated with the surface buoyancy losses and consequently with the intensity of the vertical convection and the deep water formation. Calculations of the average bottom water fluxes separately for the pre-conditioning and for the post-convection periods have confirmed importance of both the year-to-year and seasonal signal. The estimates of the Adriatic Bottom Water fluxes are in the range from 0.13 Sv. in a post-convection of the winter 1997/98, to 0.08 Sv. occurring in a pre-conditioning period of the same winter. The obtained values are about 50% smaller than those obtained previously (winter 1994/95). It is not clear whether these differences are due to the uncertainties in estimating the water fluxes or make part of the long-term variability (the winter 1994/95 surface buoyancy losses were stronger than in both 1996/97 and 1997/98).

P11/W/12-B4 1640

INTERANNUAL VARIABILITY OF THE PYSICAL AND BIOCHEMICAL PROPERTIES OF THE WATER MASSES IN THE STRAIT OF SICILY

Mario ASTRALDI, Gian Pietro Gasparini, Anna Vetrano, Stefano Vignudelli (all at CNR-IOF, La Spezia, IT, email: astraldi@estosf.santateresa.enea.it) Fabio Conversano, Maurizio Ribera d'Alcala' (both at Stazione Zoologica, Napoli, IT)

The Strait of Sicily is a key-region for the control of the waters flowing between the Eastern and Western Mediterranean. While the surface layer is entirely occupied by Modified Atlantic Water, repeated hydrographic measurements have allowed to identify two different water types coming from the Eastern Mediterranean: the classical Levantine Intermediate Water and a colder water type flowing next to the bottom and identified as uplifted Eastern Mediterranean Deep Water (EMDW). Both of them enter the Tyrrhenian Basin, where the EMDW progressively sinks at about 1600-1800m of depth and mixes with the resident Tyrrhenian Deep Water. The long term monitoring of the hydrographic properties of these water masses permitted to evidence significant trends in temperature, salinity and in other biochemical properties, which seem to be in agreement with the recent modifications observed in the Eastern Basin. These changes, influencing the characteristics of the outflow from the Eastern Basin, induce significant variations of the physical and biochemical properties in the sub-surface layers of the western Mediterranean Basin.

P11/E/21-B4 1700

THE MEDITERRANEAN OLIGOTROPHY AND THE GIBRALTAR CONSTRAINT

MAURIZIO RIBERA D'ALCALA' (Stazione Zoologica "A. Dohrn", Napoli, 80121 Italy, email: maurizio@alpha.szn.it); Giuseppe Civitarese (Istituto Talassografico di Trieste - CNR, Trieste, Italy, email: civitarese@TS.CNR.IT); Fabio Conversano (Stazione Zoologica "A. Dohrn", Napoli, 80121 Italy, email: fabio@alpha.szn.it); Alessandro Crise (Osservatorio Geofisico Sperimentale, Trieste, Italy, email: Crise@oce715b.ogs.trieste.it)

Present Mediterranean Sea is widely considered an oligotrophic basin, both in terms of production and upper layer nutrient stock. This statement has been questioned a few times stressing the role of short duration intense episodes in proximity of fronts, sub-basin gyres etc. observed in situ and from satellites on the overall budget. Nevertheless a reliable estimate of average annual production for the basin does not exceed 80-100 g C m-2 for the Western Med and 30-50 g C m-2 for the Eastern Basin. This is not very far from the average values of the neighboring Atlantic Ocean at same latitudes but, probably because of the extremely low values in the Eastern Mediterranean, this feature called for an explanation linked to some specificity of the Sea. The main characteristic of the extant Mediterranean is the inverse estuarine circulation that also causes a net loss of nutrients at Gibraltar. The evidence of this negative balance generated the paradigm of the Mediterranean being oligotrophic because it exports nutrients to the Atlantic.
We question this recurrent explanation of Mediterranean oligotrophy showing that the internal dynamics of the basin and the fluxes at the boundaries basically determine the functioning of the system and that the "Gibraltar constraint" is only of minor relevance in determining its low level of production.

P11/E/20-B4 1720

HINDCAST AND FORECAST OF THE IMPACT OF MEDITERRANEAN TRANSIENT ON THE ECOSYSTEM

Alessandro CRISE (Osservatorio Geofisico Sperimentale, CP 2011 Opicina, Borgo Grotta Gigante 42/C, Sgonico, Trieste, 34016 Italy, email: scrise@ogs.trieste.it); Giuseppe Civitarese (Istituto Talassografico di Trieste - CNR, Trieste, Italy, email: civitarese@TS.CNR.IT); Beniamino Bruno Manca (Osservatorio Geofisico Sperimentale, Trieste, 34016 Italy, email: bmanca@ogs.trieste.it); Maurizio Ribera d'Alcala' (Stazione Zoologica "A. Dohrn", Napoli, 80121 Italy, email: maurizio@alpha.szn.it)

After the observation of the transition in the thermohaline circulation in the Eastern Mediterranean the hypothesis of a quantitative and qualitative change in basin biological production, because of the nutrient redistribution, has puzzled the Mediterranean scientific community. Several cruises have been conducted since then, mostly on sub-regions of the Ionian and Levantine seas, whereas the hypothesized redistribution, would have impact on the whole basin, albeit with different effects. To verify the consistency of the above hypothesis an implementation of MOM-NPZD, a coupled eco-hydrodynamical three-dimensional model will be used to study ongoing processes as diagnostic tool for hindcasting and forecasting changes on short time scales. Data deriving from a January 1999 Cruise will be blended with model estimates for the same period in order to obtain new inital conditions for further integration, so to improve present knowledge on the ongoing change. A comparison with available low resolution SeaWiFS data will also be carried out. For the first time in this area, the results of this study would track changes in ecosystem structure due to climatic transients while they are occurring.

P11/W/15-B4 1740

MODELLING OF THE MEDITERRANEAN SYSTEM CHANGES UNDER CLIMATE VARIATIONS AND HUMAN IMPACT

Vladimir MADERICH (Institute of Mathematical Machine and System Problems NASU, Pr. Glushkova, 42, Kiev, 252187, Ukraine, Email: vlad@maderich.pp.kiev.ua)

The one-and-a-half dimension multilayer Lagrangian model LATOX was supplemented by models of straits to simulate changes in the system of the Mediterranean seas, forced by the climate variations and anthropogenic factors. A comparison is given of the Black Sea, Eastern and Western Mediterranean response on (a) the fallout of radionuclide dating back 60th, (b) the increase of the freshwater consumption and (c) post-glacial climate changes. The results of simulation show that the interaction through straits plays key role in variability of thermohaline fields and matter transport in the Mediterranean sub-basins on the scale of decades. Among other things, an exchange through straits and freshwater balance result in the difference in the temporal evolution of total amount of 137Cs in the Black Sea, Western and Eastern Mediterranean. It was shown a sensitivity of the Mediterranean to the changes in the freshwater balance. It should be pointed out that recent river diversions are as yet distinctly smaller than the natural variability of the freshwater balance in the Mediterranean and Black seas. The calculations showed that the process of transition of the Black Sea from closed water body with low salinity 7000 years ago to the recent state was not accompanied by the deep convection events. These latter with appearance of hydrogen sulphide in the surface layer can take place under the conditions of steep growth of the water consumption in the sea drainage basin superimposed on the climate change effects.

INTERMEDIATE AND DEEP WATER MASS DISTRIBUTION IN THE EASTERN CHANNEL OF SICILY AND WESTERN IONIAN SEA AS OBSERVED DURING SYMPLEX EXPERIMENT

Salvatore Marullo and Bruno Buongiorno Nardelli (Centro Ricerche Casaccia – ENEA, Via Anguillarese 301, 00060 S. Maria di Galeria (Roma), Italy, email: salva@gorgona.casaccia.enea.it); Rosalia Santoleri (Istituto di Fisica dell'Atmosfera, CNR, Via del Fosso del Cavaliere, 100 Roma, Italy, email lia@oceano.ifa.rm.cnr.it); Paola Malanotte Rizzoli (Department of Earth, Atmospheric, and Planetary Sciences – MIT – 77 Massachusetts Avenue, Cambridge, MA 02139, USA, email: rizzoli@ocean.mit.edu)

In the framework of the SYMPLEX (SYnoptic Mesoscale PLankton EXperiment) experiment, the eastern area of the Sicily Channel and neighbouring western Ionian Sea were surveyed from 1996 to 1998. About 600 CTD casts have been collected during three surveys and the data have been analysed in order to study the intermediate water exchanges between the eastern Mediterranean Sea and the Sicily Channel. It has been found that Levantine Intermediate Water (LIW) enters the Sicily Channel from a southern passage between Medina bank and the Tunisian shelf, at depth of 200-300 m, being characterised by a salinity of 38.76*0.1 and a temperature of 13.9*0.2 °C. A second possible pathway for the LIW is the eastern sill, between Malta island and Medina bank. In that sill, LIW was flowing eastward during 1996 and 1997 surveys, while a westward inflow has been observed in 1998. In correspondence to the inversion of the flow at the eastern sill, a clear increase of the salinity (from 38.70 to 38.74) and temperature (from 13.35 to 13.45 °C) at 2500-3000 m has been observed in the CTD stations of the neighbouring western Ionian Sea, associated to the spreading of the Cretan Deep Water (CDW) in the Ionian Sea.

P11/L/02-B5 0850

POTENTIAL VORTICITY AND VERTICAL MOTION AT A MEANDERING UPPER OCEAN FRONT

Bruno Buongiorno Nardelli (Centro Ricerche Casaccia – ENEA, Via Anguillarese 301, 00060 S. Maria di Galeria (Roma) – Italy – email: bruno@gorgona.casaccia.enea.it); Sefania Sarnocchia (Istituto Sperimentale Talassografico di Trieste, Viale Romolo Gessi 2, 34100 Trieste – Italy, email: sparnocchia@ts.cnr.it); Rosalia Santoleri and Fabrizio D'Ortenzio (Istituto di Fisica dell'Atmosfera – CNR, Via del Fosso del Cavaliere 100, Roma. Italy, email: lia@oceano.ifa.rm.cnr.it)

The 8-km horizontal resolution data collected by R/V Urania during SYMPLEX 1998 survey (SYnoptic Mesoscale PLancton EXperiment) have been analysed to describe the structure and dynamics of the upper 250 m in a small region along a frontal structure east of Capo Passero (western Ionian Sea).
The geostrophic field is inferred by adjusting the velocities derived from an Acoustic Doppler Current Profiler (ADCP) to the density field measured by a CTD (Conductivity Temperature Depth), with the constraint of no horizontal divergence and of thermal wind balance. Data were optimally interpolated over a regular 3-dimensional grid and used to compute the vertical component of the ageostrophic circulation by solution of the omega equation. The relative importance of stratification, relative vorticity and twisting terms in the Rossby-Ertel potential vorticity is then examined along selected isopycnals, together with the associated vertical motions and vortex stretching.

P11/L/03-B5 0910

THE THERMOHALINE CIRCULATION OF THE MEDITERRANEAN SEA FROM LAGRANGIAN NUMERICAL STUDIES

Volfango Rupolo , Vincenzo Artale (C.R. Casaccia ENEA, 00060 S. Maria di Galeria, Roma, Italy, email: volfango@canaletto.casaccia.enea.it); Bruno Blanke, Sabrina Speich (Laboratoire de Physique des Oceans, Cnrs-Ifremer-Ubo, Brest, France, Sabrina.Speich@univ-brest.fr); Daniele Iudicone, Rosalia Santoleri (Istituto di Fisica dell'Atmosfera – CNR, Via del Fosso del Cavaliere 100, Roma. Italy, email: daniele@oceano.ifa.rm.cnr.it)

Integration of Lagrangian particles in velocity output from a numerical circulation model were used to study the thermohaline circulation of the Mediterranean Sea. This study is developed in the context of TRACMASS, a EEC-MAST III project. Particle trajectories were computed off line using an appropriate scheme that fully respects the non divergence of the 3D flow. Lagrangian analysis allows to evaluate accurately mass transfer between various sections of the basin and make easier visualisation of water mass pathways. Velocity output from different model experiments were used in order to study sensitivity to the surface forcing time variability. The dependence of the results from the time sampling of the eulerian velocity field is studied.

P11/L/04-B5 0930

A SENSITIVITTY STUDY OF THE CIRCULATION OF THE ALBORAN SEA AND THE GULF OF CADIZ: THE RESPONSE TO A REALISTIC TOPOGRAPHY

Gianmaria SANNINO (CASPUR – Universita "La Sapienza" – Via Aldo Moro, 15, Roma, Italy, email: sannino@caspur.it); Vicenzo Artale (Centro Ricerche Casaccia – ENEA, Via Anguillarese 301, 00060 S. Maria di Galeria, Roma, Italy, email: vincenzo@casaccia.enea.it); Roberto Conversano (instituto di Fisica, Universita "La Sapienza" Via Aldo Moro, 15, Roma, Italy,
email: sannino@gorgona.casaccia.enea.it)

The three-dimensional sigma-coordinate Princetown Ocean Model is used to investigatee the influence of the topography on the surface and deep circulation of the Alboran Sea and the Gulf of Cadiz. The topography constraint is analysed by comparing an experiment with a flat bottom with an experiment with an experiment with a real bathymetry. In the present study horizontal model domain covers the area form 13W to 0 longitude and from 33N to 38N in latitude, the grid resolution is variable: the horizontal ranging from about 2km within the Strait to 10km in the western and 9 km in the eastern end. The realistic topography is obtained by merging the very high resolution LODYC data (about 1km) with the standard ETOPO5 data. In all the numerical experiments the ocean starts from rest; the Gibraltar Strait is "closed by dam" that separate two reservoirs filled with water of different densities and is opened at the initial time. In order to remove spurious oscillations found in the frontal zone during the spinup phase the Smolarkiewicz upstream-corrected advective scheme was implemented and used in the model instead of the standard centred advection scheme.

P11/E/28-B5 0950

THE STUDY ON THE ANNUAL OSCILLATION IN ALTIMETRY DATA

DEL ROSARIO Alsono, J.J Catalan Perez-Urquioloa (1)(Dept of Applied Physics, Poligiono del Rio San Pedro, Cadiz, Spain, Email: rosario@galeon.uca.es); M. Catalan-Morollon (Real Oservatorio de Armada, C/Cecilio Pujaazon s/n 11100, San Fernando, Cadiz); M. Bruno Mejias (1) M Ruiz Canavate(1) A. Villares-Duran(1)

One of the common characteristics of the inspection of altimetric data records is the presence of a annual oscillation. When a classical spectral analysis is carried out the frequency of the annual oscillation is close to 1 cycle /year (Sa tidal wave). However a more advanced frequency analysis gives that such an oscillation is not always centred at such a frequency. Sometimes is shifted right or left.
With this a very important questions is opened. When the annual oscillation is eliminated some energy persists around such a frequency, so the source of such extra energy must be identified. In order to carry out this study we have selected a large area, from the Cape Juby (North Africa) to England on a meridan. Data record have been four years at the crossover points of the Topex Poseidon mission in the selected area.
The scientific contribution of this work can be summarised as follows. We present a method for isolating the annual the annual oscillation from altimetric data records taken as a basis the tide generation potential RATGP95 as an application of the Empirical Orthogonal Function Decoposition. We have also made an analysis of the evolution of the amplitude and phasa lag of the annual wave is latitude. The same procedure is applied on the residual data where energy is still at the annual frequency giving the evolutin of the amplitude with h elatitude.

P11/L/05-B5 1010

INTERANNUAL CHANGES OF THE NUTRIENT EXCHANGE BETWEEN THE CRETAN SEA AND THE EASTERN MEDITERRANEAN

Ekaterini SOUVERMEZOGLOU, Evangelia Krasakopoulou (both at National Centre for Marine Research, Institute of Oceanography, Hellinikon 16604, Athens, Greece, email: katerina@fl.ncmr.gr, ekras@fl.ncmr.gr)

The systematic study of the nutrient regime in the Eastern Mediterranean since 1985 permitted to identify the chemical signature of the recent drastic changes in the deep thermohaline circulation.
Within the period of 1986-1987 Adriatic Sea is still the main contributor to the Eastern Mediterranean Deep Water (EMDW). The sporadic contribution of the Aegean Sea in this period is manifested by the intermittent outflow of the Cretan Deep Water (CDW) in form of "high oxygen -low nutrient" patches detected in the vicinity of Cretan Arc regions.
In the years following 1987 both density and transport rates of CDW are increased resulting to the addition of very dense and well oxygenated waters in the deep and bottom sections of the Eastern Mediterranean displacing upwards the waters of Adriatic origin. The oxygen increase and the nitrate decrease in the deep and bottom layers of the Eastern Mediterranean is in the order 0.3 ml/l and 1mM respectively.
Important modifications on the nutrient and oxygen distribution in the intermediate layers of the Eastern Mediterranean derived by the changes in the deep circulation through the straits. The lifting of the deep waters enriched in nutrients the intermediate layers of the basin. The concentration of nutrients in the intermediate layer of the Cretan Sea are found sometimes double than those observed during the previous years, due to the intrusion of this "nutrient rich -oxygen poor" layer compensating the deep water outflow.

THE BLACK SEA

P11/E/29-B5 1050

MODELLING TOP-DOWN CONTROL IN THE BLACK SEA PELAGIC FOOD WEB BY GELATINOUS CARNIVORES

Temel OGUZ (Middle East Technical University, Institute of Marine Sciences, Erdemli, Icel, Turkey, e-mail: oguz@ims.metu.edu.tr); Hugh W. Ducklow (Virginia Institute of Marine Sciences, The College of William and Mary, Gloucester Point, VA, USA, e-mail: duck@vims.edu); Paola Malanotte-Rizzoli (Massachusettes Institute of Technology, Department of Earth, Atmospheric and Planetary Sciences, Cambridge, MA, USA, e-mail: rizzoli@mit.edu)

The changes taking place in the overall annual plankton structure of the Black Sea ecosystem in response to increasing grazing pressure by gelatinous carnivores are studied by a series of simulations using a one dimensional, vertically resolved, coupled physical-biochemical model. The pelagic food web is represented by two groups of phytoplankton (diatoms and dinoflagellates), bacterioplankton, microzooplankton, omnivorous mesozooplankton, carnivorous mesozooplankton (dominated by medusae), the ctenophore Mnemiopsis leidyi and the giant omnivorous dinoflagellate Noctiluca scintillans. Dissolved and particulate organic nitrogen as well as nitrate, nitrite and ammonium constitute its other components.
This study demonstrates the combined role of bottom-up forcing by anthropogenic nutrient enrichment and top-down control by gelatinous predators on the Black Sea plankton system. The model is first shown to reproduce reasonably well the observed planktonic food web structure at a particular location of the Black Sea for which a year-long data set with 2-to-4 week intervals is available from 1978. This simulation represents the typical eutrophic ecosystem conditions of the late 1970's and early 1980's. Additional simulations are performed for the eutrophication-free (unperturbed) ecosystem conditions of the late 1960's, and to explore the role of Mnemiopsis leidyi introduced into the already perturbed ecosystem of the late 1980's. These simulations are also validated by extended observations from specific years. The results indicate that much weaker and almost uniform plankton distributions characterize the unperturbed ecosystem of the 1960's for most of the year. The increased anthropogenic nutrient load together with population explosions in the opportunistic species during the 1970's lead to practically uninterrupted phytoplankton blooms. Mass development of the ctenophore Mnemiopsis leidyi causes even more pronounced and longer-lasting phytoplankton blooms due to stronger "top-down" control introduced into the ecosystem.

P11/E/27-B5 1130

THE RECENT CHANGES IN THE NUTRIENT COMPOSITION OF THE BLACK SEA AND OBSERVATIONS ON THE PHYTOPLANKTON PRODUCTION

Aysen YILMAZ, Mehmet YAYLA, Yesim COBAN YILDIZ, Suleyman TUGRUL and Ilkay SALIHOGLU (Middle East Technical University, Institute of Marine Sciences, P.O.Box 28, 33731, Erdemli-Icel/TURKEY, phone: 090-3245213434, Fax: 090-3245212327, e-mail: yilmaz@ims.metu.edu.tr)

Recent changes have been documented in the riverine discharge in the northwestern shelf of the Black Sea in both diminished flow and in nutrient concentrations (decrease in Si and increase in NO3) and these changes have caused increases in both amplitude and frequency of phytoplankton blooms with major shifts in taxonomic groups. Between the 1960-1980 the proportion of non-diatoms has increased eight-fold and during 1980s average phytoplankton biomass in the NW shelf increased eight-fold. These changes are evident in the deep region of the sea as rates of primary production and chlorophyll-a concentrations have both doubled between the mid 1970s and early 1990s. In 1970s and 1980s, primary production in the Black Sea displayed two phytoplankton maxima throughout the year; the major one occurred in early spring while a secondary peak appeared in autumn. Recently (1990s), additional summer blooms have frequently been observed in both the coastal and open waters. Water transparency has significantly changed in the Black Sea in the recent years. Secchi disk depth had decreased from 20-21m to 15-16m between 1920-1980. The values in excess of 15m were no longer observed after 1990 and the mean values were only 6-10 m in the 1990-1993 period and then it started to increase again after 1993. The main reason for the drastic decrease in the water transparency was the enhanced bloom of Peridinium and Coccolitophores during 1986-1992 period. The interannual variations observed in the chlorophyll-a concentrations after 1990s were more significant and pronounced than the ones observed in 1970s and 1980s. It was observed that the general trend was the increasing of different index of pelagic productivity during the last 40-50 years (1950s, 1960-1990s).
Coastal waters of the Black Sea are principally fed by the riverine input whereas the cyclonically dominated open ecosystem is mainly controlled by the influx of nutrients from the oxygenated lower layers by vertical diffusion and wind induced mixing processes that is much effective in winter. However, the input from the anoxic layer is limited due to the presence of a permanent halocline in the Black Sea. Halocline coincides with the suboxic zone where intense denitrification and redox-dependent processes also limit nitrogen and phosphorus input to the productive layer. In comparison, the role of atmospheric sources of nutrients appears to be marginal.

INTRODUCTION TO POSTERS 1150

P11/P/01-B5 Poster 1150-01

STUDY OF LAYERED STRUCTURES IN SEMI-ENCLOSED SEAS (PERSIAN GULF)

A.A.BIDOKHTI and M.Sagliafi (both at Institute of Geophysics, Tehran University, P.O.Box 14155-6466: Tehran, Iran. email: bidokhti@chamran.tu.ac.ir).

Excessive evaporation in semi–enclosed shallow seas as the Persian Gulf, specially in summer, can lead to a buoyancy driven exchange between these waters and the open sea. Such exchange leads to a strongly stratified sea (mainly two layer, warm fresher water, over cold salty water). In the middle of the Gulf, fine layered structure is observed in CTD records. Such layered structure with good regularity can be due to, two mechanisms; one regular internal waves which can break and produce fine structures. The other mechanism, which is the more probable one is the double diffusive convection, which can occur near the middle of the Gulf where colder fresher water from the north meets warm salty water from the south. Near such a frontal region, the double diffusive regime can lead to layered structures. Typical thickness of the layers is about 3–5 m. This is in agreement with calculations based on typical horizontal temperature gradient and vertical salinity gradient. Typical CTD of such layered water will be shown, including their spatial spectrum. These regular structures, will be discussed in terms of the two proposed mechanisms. Meanwhile, some results of laboratory simulation of the double diffusion, with horizontal temperature gradient of salt stratified fluid will also be presented.

OIL POLLUTION IN MUSCAT COAST, GULF OF OMAN

EL Samra M.I., TAREK OTHMAN and AL Kharousy, L. G. (National Institute of Oceanography and Fisheries, Suez-Egypt, P.O.182)

The oceanic region including the Arabian Gulf, Strait of Hormuz and Gulf of Oman is one of the most important waterways in the world. One of the most important ports in the region is Mina AL-Fahal. It is located at The coast of Muscat. All of petroleum activities such as loading/unloading and refining operations in Sultanate of Oman are concentrated there. In addition, there are four operating companies concerned with the production, storage, refining, marketing and transport of Oman export blend crude and refined products, and also importing refined petroleum products.
Water and sediment samples were collected from the marine area of Muscat City, during winter and summer,1995. Concentrations of total hydrocarbons were measured using spectrofluorometer, while the identification of different fractions was investigated in detail using GC/MS technique. The types of PAHs whither, substituted or unsubstituted were discussed relevant to the source of pollution. Long chain alkylated hydrocarbons and alkyl–substituted aromatic hydrocarbons were identified in Muscat coast. Levels up to 499.77 ppb of phthalate were measured in sediments of the port of Mina Al–Fahal.

DISSOLVED PETROLEUM COMPONENTS ALONG SUEZ SUEZ CANAL

TAREK OT and EL Samra M.I. (National Institute of Oceanography and Fisheries, Suez-Egypt P.O.182)

The Suez Canal area is subject to oil pollution from ship's oil and refuse, atmospheric fallout (result from oil refineries) and domestic usage (sewage and agricultural wastes). The total annual oil tanker traffic in the Suez Canal routes amounts to 2472 vessels or a quantity of oil estimate is ~98 million tons during 1997.
Water and sediments samples were collected from the Suez Canal during,1997. Examination of these samples using spectrofluorometric technique to assess the contents of petroleum hydrocarbons reveals that the area is moderately polluted. Levels of polycyclic aromatic hydrocarbons (PAHs) were measured in water of the Suez Canal. Advanced technique GC/MS was used for the analysis. The presence of fluorene is reported at low concentration ranges from 0.14 - 0.21 µg/L in the Suez Canal as a result from heavy traffic ships in addition to atmospheric fallout of automobile exhausts in cities and towns distributed along the Canal. Phthalate was found in the middle of the Canal reflecting the degradation of high parent molecular weight fractions. Concentrations and molecular structures were formulated and discussed in detail.

THE HYDROGRAPHY OF THE GULF OF AQ ABA

Ibrahem A, A. Maiyza, Ahmed Ramadan HASSAN (both at NIOF, Suez P.O. Box 182, EGYPT, Tel (062) 360015, Fax 002(062) 360016, Leila Saado Balloomel, and Lobna Mohammed Salah (both at Physics Department, Faculty of Science, Cairo University).

The Gulf of Aqaba (29–29.5°N and 34–35°E, 70–km long, 14–26 km wide and up to 1829 in deep) is the NE segment of the Red Sea. A narrow sill at the Straits of Tiran separates it from the Red Sea. The major factors influencing the hydrographic regime are the physiographic elements and its climatic setting within an arid area. The water masses in the Gulf are almost one in winter due to the vertical convection. In spring the surface layer tend to separate due to the surface heating and the exchange with waters of Red Sea origin. In summer and autumn distinct three water masses appeared. A surface one, which is a mixture of Aqaba and Red Sea waters. A subsurface one of Red Sea origin enter the Gulf at the Straits zone and as a new Gulf water mass created at the northern zone and turn back southerly, partially emerge to the Red Sea as a subsurface current and partially as result of many factors turn back to the bottom of the Gulf. A deep water mass, which in some cases can be divided, into deep and near bottom water masses. The water masses can be differing in magnitude and space depending to some extended on the interannual variability, which play an important role in the hydrography of the Gulf of Aqaba. The central zone participates the northern zone as a source of the Gulf deep water, at which the Red Sea water start to slope downward. The wind system, which may change suddenly in magnitude and/or direction, has great influence on the hydrographic regime of the Gulf of Aqaba.

COASTAL BENTHIC COMMUNITY OF THE PECHORA SEA

Nikita V. Kucheruk, Pavel V. RYBINKOV, Filipp V. Sapoznikov (all from Oceanology Institute RAS, Nakhymovsky 36, 117518 Moscow, Russia, email: fisher@ecosys.sio.rssi.ru)

Investigations of the Eastern shallow water part of the Pechora sea were carried out in 1998 August-October. About 200 samples of macrobenthos, 90 samples of meiobenthos and 130 samples of microphytobenthos were taken in 50 station at 5-25 m depths. The peculiarity of the region was the minimal macrobenthos diversity and biomass at shallowest (5-10 m) stations. Maximal macrobenthos biomass and species richness was found for >20 m depth at constantly negative temperature values. Maximal biomass of meiobenthos at the area studied barely exceeded 0.5 g /m2. At that, contribution of pseudomeiobenthos reached in average 40-50%. In all samples treated numerical dominants were nematods, but their mass share amounted only 20 % . Approximately the same contributions to total biomass made Harpacticoida and Ostracoda. In general meiobenthos fauna of the Pechora sea coastal part was quite poor both from qualitative and quantitative point of view. Microphytobenthos of bottom sediments upper layers was mainly represented by diatoms. Their biomass amounted 180-720 g/m2. There were totally 173 species identified. All the diatoms may be divided in two groups: species, settled down from water column (Melosira and Thalassiosira) and initially benthic forms (Raphoneis, Navicula and Nitzschia). The pattern observed, may derive from cooling of sea water in the and of October.

OCEAN CLIMATE OF THE BALTIC SEA AND KATTEGAT-ANALYSIS OF HISTORICAL DATA OF SALINITY AND SEA LEVEL.

Peter WINSOR (Earth Science Center, Box 460, Gvteborg, Sweden, Email: pewi@oce.gu.se)

As a part of the Swedish regional climate modelling programme SWECLIM the ocean climate of the Baltic Sea and the Kattegat is examined by means of analyzing historical data series. Defining today's climate state and its natural variability is necessary in order to be able to modell future climate change. The data consists of long time series (about 100 years) of salinity, temperature, sea level, and river runoff. These series are analyzed statistically regarding the variability on different time scales. The integrated estimates include the vertically integrated freshwater height F (F=1/Sref*sum[Sref-S(z)]dz, where Sref is a reference ocean salinity), the sea level, the barotropic water exchange between the Kattegat and the Baltic Sea, and the ice extent of the Baltic Sea. Prominent findings include:
Most of the variability of the freshwater height of the Baltic Sea is on time scales of months or longer, whereas nearly all variability in the Kattegat is on months or less. Furthermore, about half of the Baltic Sea freshwater variability can be explained in terms of the interannual variability of the runoff to the Baltic Sea. The rest of the variability is related to variations of the intermediate or deep water inflows from the Kattegat.
For periods longer than one month Samuelsson and Stigebrant 1996 have shown that the Baltic Sea acts as an open fjord with increasing amplitudes from the mouth and inwards. Most of the sea level variance on time scales longer than two months is due to external forcing, i.e., the sea level in the Kattegat and the freshwater supply to the Baltic Sea.

P11/W/14-B5 Poster 1150-08

SEASONAL VARIABILITY OF THE LA PEROUSE STRAIT WATER STRUCTURE AND WATER MASSES

Pishchalnik V.M., ARKHIPKIN V.S. (1)SakhNIRO Yuzhno-Sakhalinsk 693016 Russia email: pvm@tinro.sakhalin.ru; 2)Department of Oceanology Moscow State University Vorobijvy Gory Moscow 119899 Russia email: arkhip@ocean.geogr.msu.su)

In this report the quantitative estimate of a seasonal variability of volumes and heat content of the La Perouse Strait water masses is given. For this purpose the data on temperature and salinity on 48 standard oceanographic stations for period with 1948 on 1994 were used. In total about 10000 observations. The analysis of obtained outcomes allows to make the following conclusions. In without ice period in the La Perouse Strait three water masses are selected: Surface Water (SW), Okhotsk Water (OW) and Japan Surface Water (JW). The singularities of spatial distribution of water masses in research region cause presence of two types of a water structure: subarctic and subtropical. In the spring, summer and autumn a majority of strait volume (70-80 %) takes waters of the subarctic structure. The subarctic water structure consists of two water masses - SW and OW. The subtropical structure of waters is submitted by warm the Soya Current and places in a narrow coastal zone (10-15 miles) near the Hokkaido Island. On mean stations the parameters of water vertical stability in both structures are calculated. Values of common vertical stability of water in the subarctic structure much more, than in subtropical. In the spring and summer in both structures the contribution of temperature in common vertical stability much greater, than the contribution of salinity. In the autumn this ratio a converse. The significant seasonal variability of the SW and JW characteristics is detected. OW within all year has the stabile characteristics. In the summer the main reserve of heat is concentrated in Surface (48 %) and Japan Surface (42 %) Waters. Because of seasonal oscillations of volumes of water of a subtropical structure is appreciated seasonal variability of the consumption of the Soya Current, which can reach 0.4-0.5 Sv.

FORMATION AND CIRCULATION OF THE INTERMEDIATE WATER IN THE NORTHWESTERN JAPAN SEA AND THEIR DECADAL CHANGES ACCOMPANIED BY CLIMATE CHANGE

Tatsuro WATANABE (Japan Sea National Fisheries Research Institute, Niigata, Japan, email: tatsuro@jsnf.affrc.go.jp); Akifumi Nakata (Hokkaido Fisheries Experimental Station, Yoichi, Japan)

By using winter CTDO data, isopycnal analyses were done to clarify the formation and circulation of the intermediate water in the northwestern Japan Sea. On the surface of 26.8 sigma-theta, since the Tsushima Warm Current (TWC) outcrops around 42.5N, extremely high salinity water of TWC can be cooled directly there. On the surface of the density from 27.2 to 27.34 sigma-theta, high salinity and high dissolved-oxygen water can be seem in the northwestern Japan Sea, off the Hokkaido Island. Since there are not any origins of high salinity except TWC, it is suggested that TWC is the origins of the intermediate water of the Japan Sea. By using historical data of the temperature and the salinity distributions in the northwestern Japan Sea, it can be shown good agreements with the variability of the formation of the intermediate water and the intensity of surface cooling and the supply of high salinity water by TWC.

MUSSEL (MYTILUS EDULIS) FILTERING OF THE BALTIC-SEA OUTFLOW THROUGH THE ÖRESUND - AN EXAMPLE OF A LARGE-SCALE ECOSYSTEM RESTORATION

Johan RODHE (Göteborg University, Department of Oceanography, Box 460, S-405 30 Göteborg, Sweden, email: joro@oce.gu.se) Joel Haamer (National Board of Fisheries, Institute of Coastal Research, Nya varvet, byggnad 31, S-42 671 Västra Frölunda, Sweden)

Investigations were undertaken, aiming at a quantification of the filtering capacity by the mussels at the sill in Öresund, one of the straits connecting the Baltic Sea with the Kattegat. The investigations included observations of hydrography and currents together with the content of nutrients in the water, chlorophyll-a and phytoplankton. Following the water over the vast mussel banks at the sill, we found that about 75% of the phytoplankton biomass was removed from the water. The clearance rate, defined as the volume of water cleared from organic matter per unit time and unit ash-free dry-weight of soft tissues of the mussels (AFWD), was estimated at 7 l h-1 g-1. Judging from the total amount of mussels, we found that the mussels at the sill have the capacity to clear the outflow from the Baltic Sea, through Öresund, almost completely. We also found that the plankton biomass recovered after the passage of the sill.

CONSIDERATION IS GIVEN TO THE PROBLEM OF DEFINING AING ZONE NEAR AN OUTFALL

SHERWIN T (Uni of Wales, Bangor, Wales, UK Email: tjs@uces.bangor.ac.uk)

Consideration is given to the problem of defining a mixing zone near an outfall, particularly when the zone is to be used to examine eutrophication problems. It is demonstrated that long term, and often non-tidal, coastal residual currents play a important part in flushing nutrients away from a long sea outfall, and can render the definition of a mixing zone in terms of the tidal excursion irrelevant when a pollutant has a long decay time. Consequently far field effects, such as the interaction of neighbouring outfalls, may be more important than is implied by the mixing zone concept. These ideas run counter to the guidelines published by the Comprehensive Studies Task Team for the application of the European Union Urban Waste Water Treatment Directive in UK waters, which emphasises the use of a tidal mixing zone for eutrophication problems.

P11/W/17-B5 1400

HYDRO-OPTICAL INVESTIGATIONS IN THE EASTERN MEDITERRANEAN AND WESTERN BLACK SEA FROM RV HORIZONT, 1998

Viktor I. Man'kovsky, Alexey V.MISHONOV, Mark V. Solov'ev (Marine Hydrophysical Institute, National Academy of Science of Ukraine, 2 Kapitanskaya St., Sevastopol, 335000, Crimea, Ukraine, email: mishonov@alpha.mhi.iuf.net)

Scientists from MHI NASU performed a cruise on R.V. Horizont from 5 May to 4 June 1998. The beam attenuation coefficient (BAC), Secchi disk depth and watercolours, by the Forele-Ulle scale, were measured in the eastern Mediterranean and the western Black Sea. The main research areas were the Levantine Sea (Crete-Rhodes area), the Aegean Sea (Dardanelles Straits region), and the Black Sea (continental slope area westward of the Crimean peninsula). The BAC was measured at seven wavelengths in samples taken from Nansen bottles from different depths on stations and surface samples were taken from a bucket en passage. BAC fields at 0, 40, and 80 meters depth, Secchi disk depth field, and watercolour field were obtained from these areas. Results from the BAC spatial field, obtained from the Rhodes-gyre area, showed upwelling deep water. This was demonstrated at all depths (0, 40 and 80m). The spectral distribution of the BAC showed different shaped spectra for upwelling waters compared to down-welling waters. The optical assessment of the Levantine Sea waters shows it to be oligotrophic waters. This confirms previous research in 1981-1983. In the Dardanelles Straits area the frontal zone, where waters from the Marmara Sea mix with Aegean Sea waters, was recognised from the BAC field as well as from Secchi disk data. This frontal zone was 15 - 18 nautical miles wide. The SeaWiFS images for this period shows this feature in the chlorophyll-a concentration field. The spectral distribution of the BAC in this area shows increased light attenuation in the violet range of the spectra and a shift of minimal values to the yellow area. This is evidence of high concentration of "yellow matter" in this area. In the Black Sea the optical properties were measured twice on one transect along 34°E at the beginning and at the end of the cruise. A further polygon survey was carried out westward of the Crimea. A quasi-stationary anti-cyclone gyre was observed from the data, which is well known for this area and relates to the interaction between the main Black Sea current and the continental slope. The spatial distribution of the optical properties in this area correlates well with the hydrographic data, which were obtained simultaneously. The spectral distribution of the BAC in this region indicates a significant increase in the violet-green spectral range with minimal values in yellow area. The concentration of "yellow matter" in this area is high and these waters can be classified as meso/euphtrophic. Results obtained from this cruise allowed assessments to be made of the optical conditions and comparisons between the different, but connected, parts of the Mediterranean basin. These data are very important for the continuation of the long-time series data, which have been collected by the MHI NASU for the Mediterranean and Black Seas.

P11/E/23-B5 1420

WINTER MIXING EVENTS IN THE BLACK SEA

Leonid I. IVANOV, Vladimir Belokopytov (Marine Hydrophysical Institute, Kapitanskaya St., 2a, Sevastopol, 335000, UKRAINE; e-mail: leonid@alpha.mhi.iuf.net); Emin Ozsoy (Institute of Marine Sciences, Middle East Technical University, P.K. 28 Erdemli - Icel 33731 Turkey; e-mail: ozsoy@ims.metu.edu.tr)

A scientific assessment of the role of winter mixing and water mass formation in the Black Sea is essential for a better understanding of the impacts on the transports of pollutants and organic matter, and on the evolution of the suboxic layer and the chemocline, as well as on the entrainment of nutrients from the pycnocline into the euphotic zone. We present results on the history of winter mixing events over the period from 1923 to present to discuss the depth dependence of the magnitude and phase of long-term temperature fluctuations in the pycnocline, and to provide estimates of the heat flux through the pycnocline for characteristically mild, moderate and severe winter atmospheric conditions. Temporal and spatial variability is analysed as a function of depth, salinity and density.
The effects of winter mixing events are well preserved in the T,S structure, while the individual convection events have limited effect in modifying main pycnocline on a seasonal time scale. The magnitude of temperature fluctuations decreases exponentially with increasing depth. Major cooling periods, with a net decrease of temperature in the entire pycnocline above 16.5 sigma-t, occurred in the late 20's - early 30's, early 50's, middle 80's and early 90's. An analysis of surface fluxes and heat content of the pycnocline on a regional basis allows to infer that, typically, the pycnocline is exposed to cooling for a short periods in confined areas.

P11/E/01-B5 1440

NITROGEN IN THE BLACK SEA: FLUXES, CYCLING AND BUDGET

Sergey KONOVALOV, Leonid Ivanov and Anatoliy Samodurov (all at Marine Hydrophysical Institute, Kapitanskaya 2a, Sevastopol 335000, Crimea, Ukraine, email: sergey@alpha.mhi.iuf.net, leonid@alpha.mhi.iuf.net)

Drastic eutrophication has been primarily recognized as the reason of adverse changes in the Black Sea ecosystem over the last three decades. This is true for many other semi-enclosed and marginal seas all over the world. Nitrogen is considered as the leading nutrient among the others to be responsible for various aspects and results of eutrophication. While the source of nitrogen in the Black Sea is well known, the budget, cycling and loss of this nutrient are poorly investigated. To fill this gap 1.5-D model of vertical exchange in the Black Sea pycnocline has been applied to assess nitrogen fluxes and losses, as well as to reconstruct its budget, in the oxic/anoxic transition zone of the Black Sea. Field data on distribution of nitrogen and other basic properties (oxygen, sulfide, temperature and salinity) have been analyzed in order to verify the results of modeling and to estimate changes in the overall budget of nitrogen in the Black Sea. The results demonstrate notable increase in the overall inventory of nitrogen (mainly in form of ammonia). They also reveal that the main part of the load of inorganic nitrogen is stored in water column. Vertical exchange in the pycnocline plays important role in governing cycling and losses of nitrogen in the Black Sea. The flux of ammonia from the anoxic zone is enough to compensate the down ward flux of nitrate supporting hypothesis of effective denitrification in the layer of pycnocline. The amount of nitrogen that is annually replenished in the oxic/anoxic layer from external sources is close to 30% of the river-born load into the basin. Unlike ammonia, residence time of nitrate in the layer of the main pycnocline is fairly short and it lies on scale of a year.

P11/E/08-B5 1500

SULPHIDE BUDGET IN THE BLACK SEA

Leonid I. IVANOV, Sergey Konovalov and Anatoly Samodurov (Marine Hydrophysical Institute, Kapitanskaya St., 2a, Sevastopol, 335000, UKRAINE; e-mail: leonid@alpha.mhi.iuf.net)

The Black Sea, an example of an estuary basin, being globally the largest body of anoxic waters, presently, is facing rapid environmental degradation. An assessment of its present state and prediction of its future, among other issues, implies better understanding of the processes maintaining vertical structure of the anoxic layer. The specific objective of this sudy was to estimate the sulphide production rates and fluxes. The 1.5-dimensional model of vertical exchange in the Black Sea has been applied to calculate vertical fluxes of sulphide and a distributive lateral flux of dissolved oxygen into the suboxic and anoxic layers. The latter is maintained by the Bosporus effluent. Calculations were based on stratification and sulphide vertical distribution averaged over the period from 1985 to 1995. The results, however, are not sensitive to the period of averaging. This is especially true for the upper layer of the anoxic zone where vertical gradients of sulphide are proved to be practically unchanged in recent decades.
The magnitude of the suphide total flux (advective and diffusive) for the entire basin reaches its maximum, 13E10 M/yr, at about 300 meters. From that point it decreases upward to about 6E10 M/yr at the top boundary of the anoxic layer and downward to less than 4E10 M/yr at 1000 meters. A remarkable feature of the flux vertical distribution is absence of a general resemblance with the profile for the flux of ammonia, which should be expected, unless their losses are controlled by different mechanisms. Oxidation of sulphide takes place within the sulphidic layer, but not only at the top boundary as for ammonia. The sulphide production rate, calculated with the consideration of oxidising capacity of Bosporus inflow, shows general decrease with increasing depth.

P11/E/18-B5 1520

THE STUDY OF MESOSCALE MOTIONS IN THE SHELF ZONE OF THE BLACK SEA

Vasiliy VLASENKO, Natalia Stashchuk, Vitaliy Ivanov (Marine Hydrophysical Institute, Kapitanskaya Str. 2, Sevastopol, 335000, Ukraine, e-mail: vlasta@ukrcom.sebastopol.ua)

The response of the Black Sea shelf zone to a short period (up to one day) wind action is investigated. The analysis is carried out on the basis of in-situ and remote sensing data and with the help of mathematical modeling. It was found that the vertical stationary circulation cell was formed in the shelf interior due to the wind action. It characterized by virtue of water ascent near the coast and descent in the region of the shelf break. Near inertial horizontal oscillations in the open part of the sea and vertical oscillations over the slope are generated. The inertial oscillations may lead to meandering of the Black Sea rim current and its interaction with the shelf edge. That, in turn, gives rise the considerable vertical displacements of a pycnocline above the shelf edge, which, in the long run, generate progressive internal waves. The shoreward-oriented long internal wave, due to the nonlinearity of the wave process, disintegrates into a packet of intensive shortperiod internal waves, many times measured in the shelf zone of the Crimea.
The nearcoastal upwelling and mesoscale motions have also an essential influence on the dynamics of the upper boundary of the Black Sea hydrogen sulphide zone. The upward fluxes of cold bottom water are accompanied by the displacement of the upper boundary of the hydrogen sulphide zone and its penetration into the layer enriched by oxygen. As a result, an extensive co- existence zone is formed over the shelf-break area in place of upwelled water. As was obtained theoretically an confirmed experimentally, the area with small oxygen concentration remains over the shelf break after the end of the chemical reaction between two dissolved gases. This extended area with low oxygen concentration may be considered as a "trace" of the upwelling event.

P11/W/08-B5 1600

THE RESPONSE OF THE BLACK SEA ECOSYSTEM TO SOME PHYSICAL PROCESSES

J. Staneva, E. Stanev (both at the University of Sofia, 5, J. Bourchier Street, Sofia 1126, Bulgaria, e-mail: joana@phys.uni-sofia.bg); Ch. Lancelot (Universite Libre de Bruxelles, CP221, B-1050, Belgium, e-mail: lancelot@ulb.ac.be

This study presents the state of the art of the 3D coupled physical-biological model of the Black Sea ecosystem resulting from the online coupling of the Modular Ocean Model modified for its application in the Black Sea with the mechanistic ecological model BIOGEN. Both models were developed, tested and analyzed separately before their online coupling. The Modular Ocean Model was implemented in the Black Sea with two horizontal resolutions: 5, or 15 min. New parametrizations were added in order to take into account the specific physical processes prevailing in this almost enclosed ocean basin. The diapycnal mixing was calibrated against independent measurements of chemical tracers. Data on Chernobyl tracer penetration were used for Model validation. This comparison shows that the model simulates correctly the pathways and the rates of penetration of signals originating at sea surface and presents a reliable tool for water mass and ecological modeling. BIOGEN is a mechanistic ecological model of high trophic complexity (34 biogeochemical state variables) that was established in order to assess the response of the north-western Black Sea ecosystem to human-induced changes and predict its future evolution. The model was first implemented by coupling it with physical models of increasing spatio-temporal complexity and running it with different human-induced forcings in order to analyse its ability to reproduce correctly historical ecological events recorded since the 1960. Preliminary results of the performance of coupled 3-D physical -biological models are analysed. The impact of some physical processes on the Black Sea ecosystem as well as the role of the physical processes in driving interannual variability in ocean primary production is studied. The simulated phytoplankton patterns are compared with the CZCS and SeaWiFS satellite data.

P11/W/01-B5 1620

DEEP-SEA ZERNOV'S PHYLLOPHORA MEADOW IN THE BLACK SEA:THE COMBINED RESULT OF HYDRODINAMICS AND ECO-MORPHOLOGICAL PLASTICITY OF PHYLLOPHORA NERVOSA (D.C.) GREV. (RHODOPHYTA, GIGARTINALES)

Olga V. MAXIMOVA, Nikita V. Kucheruk, (both from Oceanology Institute RAS, Nakhymovsky 36, 117851 Moscow, Russia, email: kucheruk@ecosys.sio.rssi.ru)

Zernov's Phyllophora Meadow is a unique deep-sea (up to 60 m) ecosystem of unattached form of red alga Phyllophora nervosa. It had been discovered in 1908 and since that time was intensively explored and used for agar-containing biomass prey. Its area up to the 60-th was about 10 km2 but now it is decreasing each year due to anthropogenic euthrophycation of Black Sea. Our investigation is based on the last information about the current system of the North-western Black Sea and original experimental data on Phyllophora's morphological transformations. The Meadow has a near-shore origin in the thickets of attached Phyllophora nervosa form. From our point of view, the currents and circulations ensure the stability of Meadow's spatial location, and Phyllophora's eco-physiological peculiarities give the opportunity for its existence in the form of self-dependent semi-closed population.

"CLOSED, SEMIENCLOSED AND MARGINAL SEAS: PHYSICAL, CHEMICAL AND BIOLOGICAL PROPERTIES". LIGHT ABSORPTION BY PHYTOPLANKTON, DETRITUS AND DISSOLVED ORGANIC SUBSTANCES DURING DIATOM AND COCCOLITHOPHORE BLOOMS IN THE BLACK SEA: IMPACT ON ALGORITHMS FOR REMOTE SENSING

Churilova T.I., Berseneva G.P., Georgieva L.V. (Institute of Biology of the Southern Seas of National Academy of Science of Ukraine Crimea, Ukraine, Sevastopol, 335011, P.O.Box 13, e-mail: churil@ukrcom.sebastopol.ua); Stanichny S.V. (Marine Hydrophysical Institute of National Academy of Science of Ukraine, 2 Kapitanskaya st., 335000, Sevastopol, Crimea, Ukraine, e-mail: odmi@alpha.mhi.iuf.net)

The satellite-based remote sensing of the water leaving radiance allow to assessing the surface chlorophyll concentration. Standard algorithms for estimating chlorophyll a concentrations perform quite well for regions of the ocean where scattering and absorbing components of seawater covary with these pigments. The development of realistic models, require algorithms with reflect variability in biological and optical characteristics. The work presented here is an analysis of data collected during the monitoring of bio-optical properties (chlorophyll a and pheophytin a concentrations, light absorption spectra by particles, phytoplankton,detritus and dissolved organic substances, species composition of phytoplankton, cells and biomass concentration) of surface water which was conducted in the central western part of Black sea in February-December 1998. The blooming of big diatom (Rhyzosolenia alata) was observed in March and blooming of coccolithophore (Emiliania huxleyi) – in June. The high concentration of pigment (1.9 mg.m-3) were corresponding to big diatom bloom. During the diatom bloom the chla- specific absorption coefficient (aph*) was decreased due to high degree of packaging of pigment in cells. The values of aph* in blue maximum (678nm) were 0.015-0.016 m2 .mg-1, the ratio between red and blue maximum of absorption spectra (R) - 1.8. The contribution of detritus to total light absorption by particles (ad(440)/ap(440)) is decreased to 19 %. During coccolithphore bloom chlorophyll a concentrations were 0.15-0.21 mg.m-3, the values of aph*(678)- 0.019-0.023 m2 .mg-1, the ratio R 2.5-2.6. The contribution of detritus to total light absorption reached to 58 %. It is apparent that light absorption by dissolved organic matter (as) for both blooming was practically not variable.

VERTICAL MIXING ON THE BLACK SEA SHELF

Iossif Lozovatsky (P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences Moscow, 117851, Russia; also at Department of Mechanical and Aerospace Engineering, Arizona State University, Tempe, AZ, 85287-9809, USA, Email: i.lozovatsky@asu.edu); Sergei Shapovalov (P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences Moscow, 117851, Russia, email: smshap@glas.apc.org)

Study of turbulence in the regions essentially free of tidal forcing may have some resemblance to laboratory experiments that have been carried out under idealized conditions (with only a few energy input mechanisms), making comparison of laboratory and field data possible. The measurements of the kinetic energy and scalar dissipation in the shallow shelf waters of Black Sea were accompanied by meteorological and hydrological background observations. The power spectra of turbulent fluctuations and corresponding correlations between buoyancy lengthscales are discussed. The dependence between normalized Thorpe scale and patch Reynolds and Richardson numbers found in our measurements give more insight on a scaling problem for stratified microstructure patches. The regions with active and fossil turbulence were identified at different depths using the relationship between the mixing activity parameter and the buoyancy Reynolds number. Statistics of the mixing coefficients for certain turbulent regions, calculated from the probability distribution functions of eddy and scalar diffusivities and by using the bootstrap method are presented. The domain-averaged turbulent diffusivities vary from 4 cm2/s in the boundary layers to 0.2 cm2/s in quasi-homogeneous patches inside the thermohalocline. An appropriate averaging of microstructure variables taken separately for each specific turbulent regions leads to substantial improvement of the correlation between eddy and scalar vertical diffusivities. Influence of inertial oscillations on small-scale shelf dynamics is discussed.

PECULIARITY OF VERTICAL CHLOROPHYLL DISTRIBUTION IN THE BLACK AND MEDITERRANEAN SEA

Oleg A. YUNEVl, Zosim Z. Finenkol, Vladimir I. Vedernikov2, Aysen Yilmaz3 (lInstitute of Biology of Southern Seas, National Academy of Sciences of Ukraine, Sevastopol/UKRAINE; 2 P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences, Moscow/RUSSIA; 3Middle East Technical University, Institute of Marine Sciences, Erdemli-Icel/TURKEY)

From oceanographic studies carried out in the last two decades it is clear that the mechanisms controlling the biochemical cycle are not uniform throughout the World Ocean. Phytoplankton, the major component responsible for the primary production in the sea, has a principal influence on biochemical cycling from local to global scales. A major objective in oceanography today is estimating the mean and the variance of all parameters describing process of photosynthesis in the sea on a global basis. The greatest variability of the primary production characteristics is observed in basins (to which the Black and Mediterranean Seas can be concerned) with vastly expressed seasonal changeability.
The aim of this investigation is the research of common features in vertical chlorophyll (CHL) distribution in various seasons and in different parts of two interconnected basins with use of mathematical representation of vertical CHL profiles.
In the present study the data obtained in Ukrainian, Russian and Turkish cruises during the last twenty years on the vertical CHL and CHL fluorescence in situ (FLU) distribution in both seas were analysed and parameterised. The CHL profiles with as few as six data points were admitted for parameter estimation. These were found to be adequate to characterize the profile, provided that the data points were well distributed around the peak. For the calculation of CHL and FLU profiles parameters and statistical estimation we used a package of the applied computer programs SigmaPlot for Windows and ANOVA.
The analysis of the Black Sea data has shown, that the forms of vertical CHL and FLU distribution have some types: 1) quasi-homogeneaus; 2) with one well advanced and symmetric maximum; 3) with an asymmetrical maximum in the upper half of photosynthetic zone 4) with two maxima (or more than two), which are comparable or differ on amplitude; 5) distribution, when CHL and FLU gradually decreases with depth beginning from a surface.
The first of the listed types is characteristic of a winter period in the Black Sea, when there is the vertical mixing or active upward transporting nutrients from the bottom layers into euphotic layer. The profiles of the second and fourth types are more often observed in summer-autumn period, when the temperature stratification of water mass is a barrier to penetration of additional nutrients from the bottom layers into the well-lit surface layer. The vertical distribution of the third type is characteristic of spring,...

INFLUENCE OF WATER MASS DYNAMIC ACTIVITY ON NUTRITIONAL CONDITION OF CALANUS EUXINUS IN THE SOUTHERN BLACK SEA

Tatyana V. YUNEVAl, Oleg A. Yunevl, Ferit Bingel2, Ahmet E. Kideys2, Georgy E. Shulman1 (lInstitute of Biology of Southern Seas, National Academy of Sciences of Ukraine, Sevastopol/ UKRAINE; 2Middle East Technical University, Institute of Marine Sciences, Erdemli-Icel/TURKEY)

Calanus euxinus is the main trophic link between phytoplankton and many fish species in open part of the Black Sea. Calanus food supply, and consequently their fecundity and abundance are characterized by significant spatial variability (Vinogradov et al., 1992). It is possible to assume, that the reason of such variability are the non-uniform hydrophysical conditions of plankton environment.
For confirmation of this hypothesis we investigated dependence between lipid content in the body of Calanus as result of food supply (nutritional condition) (Sargent and Henderson, 1986) and dynamic activity of water mass in the places of copepods stay. The samples were collected in the southern part of the Black Sea at two cruises RV "Bilim" (Institute of Marine Sciences, Erdemli, Turkey) during period of steady density stratification (September-October 1996 and July 1997). The bottom border of aerobic layer was used as pattern of dynamic activity; this value is determined as the depth location of density dt = 16.2. In the Black Sea location of dt = 16.2 at the depth of 100-120 m was indicative of cyclonic gyre and descend to 160-200 in depth - of anticyclonic eddy (Murray et al., 1993). Physical patterns (T, S0/00, dt,) were measured at the stations using Sea Bird Electronics Model 9 CTD System. Calanus euxinus were captured by Nansen plankton net (112 mm mesh size, 0.7 m diameter). Females of the size range 3.3-3.5 mm were used for analyses.
It was shown significant spatial variability of the lipids content in the body of Calanus (30 -120 mg per individual). There is close negative correlation (r = 0.79-0.90; n = 26; P < 0.01) between the level of reserve lipids (wax esters and triacylglycerols) and total lipids too (composed in average on 72 % of first ones and on 10 % of second ones) and the depth location of dt = 16.2 in the places of copepods stay. The structure lipid (phospholipid) contents had not significant correlation (r = 0.3). It is important to note, that quantitative expressions for the relationships in 1996 and 1997 were similar to each other, despite of temporal and spatial differences in sampling stations.

LATERAL OCEAN TRANSPORT PROCESSES IN THE ARCTIC BASIN

Robin D. MUENCH (Earth & Space Research, 1910 Fairview East., Suite 102, Seattle, WA 98102-3620, USA, email: rmuench@esr.org)

The relative importance of mechanisms that laterally transport water, heat and dissolved materials differs in the Arctic from that at lower latitudes because of the low energy levels and small baroclinicities that typify high latitude oceans. The primary mechanism for advective transport in the Arctic Ocean, below the upper mixed layer which is frictionally coupled to a wind-driven ice cover, is by way of strongly barotropic boundary currents that overlie the steep continental slopes around the peripheries of the basins. These currents provide the Arctic Ocean with a cyclonic overall circulation and bifurcate into branches that overlie the steep flanks of the several mid-ocean ridge systems to comprise an interlocking family of closed or partially closed gyres. There are regions, such as surrounding the Chukchi Rise and along the Alpha-Mendeleyev and Arctic Mid-Ocean ridges, where significant gaps exist in our understanding of the circulation. The central basins remote from steep bottom slopes and the associated currents are low in energy. Small-scale structures observed across the Makarov, Amundsen and Nansen basins suggest that molecular processes such as double diffusion play a significant if uncertain role in lateral transport there. Our understanding of these structures remains at the level of hypothesis development. Isolated observations of both warm and cold-core eddies in the central basins suggests that these, too, are important to central basin property transports. The role of fronts remains uncertain, as does the importance of dynamic interaction between the peripheral currents and complex bathymetric features. The balance of transport mechanisms results in relative isolation of the central basin waters when compared to the peripheral or ridge-oriented systems. More quantitative understanding of this balance awaits improved field and theoretically-based analyses of the dominant mechanisms.

P13/E/12-B1 0910

A TWO-DIMENSIONAL TIME-DEPENDENT MODEL OF A WIND-DRIVEN COASTAL POLYNYA: APPLICATION TO THE ST. LAWRENCE ISLAND POLYNYA

M. A. MORALES MAQUEDA, A. J. Willmott (both at Department of Mathematics, Keele University, Keele, Staffordshire ST5 5BG, UK, email: m.a.morales.maqueda@maths.keele.ac.uk)

We present a two-dimensional model of the temporal evolution of a wind-driven coastal polynya. Given the time-varying surface winds and heat fluxes, the model calculates the growth rate, distribution and motion of frazil ice within the polynya, and the mass fluxes of frazil ice and consolidated new ice at the polynya edge. The difference between these two mass fluxes determines the velocity of advance/retreat of the polynya edge. Analytical solutions of the model are found for the case when the coastline is a straight line segment of length D (an idealised representation of an island). Two time-scales and two spatial scales are shown to be important in characterising the polynya: the consolidated new ice and frazil ice time-scales, tc and tf, respectively, and the offshore and alongshore adjustment length-scales, Ro and Ra, respectively. The time-scale tc is the time required for the polynya to grow ice of thickness equal to the collection thickness of frazil at the polynya edge. The time-scale tf is the time it takes frazil to cross the equilibrium width of the polynya, which is, in turn, determined by the length-scale Ro. In combination, tc and tf control the time-scale for the polynya to respond to variations in the atmospheric forcing. The length-scale Ra measures the sensitivity of the polynya edge to alongshore variations in the coastline geometry. It is shown that if Ra is comparable to D then the offshore dimension of the polynya and the time-scale for the polynya to reach equilibrium can be very different from those obtained from a one-dimensional formulation. The model is applied to the study of seasonal and short-term variability of the St. Lawrence Island Polynya.

P13/E/04-B1 0930

THE PAST ANALOGIES OF RECENT CHANGES OF THE ARCTIC BASIN T,S CHARACTERISTICS.

PISAREV S.V. (P.P. Shirshov Institute of Oceanology, RAS, 36 Nachimovsky ave.,117218, Moscow, Russia, email: sergey@pisarev.msk.ru)

Large and widespread warming of the Atlantic layer, salting of the upper layer of the Eurasian Basin, substantially retreating of the cold halocline from the Eurasian Basin were selected among others recent remarkable changes of the Arctic Ocean to try to reveal the similar phenomena in the past.
All available unclassified observed T,S data of the Arctic Basin, including WODB98, MOODS, and data from old Russian collections, were used to describe the incomplete picture of the past variability. To characterise the recent changes, the results of well known measurements of "Rossiya"-90, "Oden"-91, "Henry Larsen and Polar Star"-93, "Polarstern"-93,96, "SCICEXs"-93,95,96, "TAPEX-94", "Louis S. St.-Laurent"- 94 were collected. The published results of these expeditions and, partly, observed data were used. The data of "Lance"-93,94,95, "Logachev"-94, "Yasnogorsk"- 95, and "Ak.Fedorov"-98, that not widely discussed before, were also added to represent modern changes. The winter and summer T,S fields of EWG (1997,98) were applied as climatology to compare scarce observed stations with each other. The analogies in the past were found, in one or another degree, for all recent changes.

P13/E/17-B1 0950

TRANSFORMATION OF ATLANTIC WATERS IN THE BARENTS SEA AND THEIR FLOW TO THE EURASIAN BASIN THROUGH ST. ANNA TROUGH

Ursula SCHAUER (Alfred-Wegener-Institut fuer Polar- und Meeresforschung, D-27515 Bremerhaven, Germany, email: uschauer@awi-bremerhaven.de), Bert Rudels (Finnish Institute of Marine Research, FIN-00931 Helsinki Finland) Harald Loeng (Institute of Marine Research, N-5024 Bergen-Nordnes, Norway), Robin Muench (Earth & Space Research, Seattle, WA 98102-3699 USA) Jim Swift (UCSD Scripps Institution of Oceanography, La Jolla, CA92093-0214, USA)

The ventilation of the Arctic Ocean basins is largely associated with the input of water from the Barents and Kara Seas. Using hydrographic observations, made in the Barents Sea and along the shelf edge of the Kara Sea between 1991 and 1996, and time series of current, temperature and salinity from moorings in the eastern Barents Sea, we discuss the flow and the modification of the water masses between the western Barents Sea and the St. Anna Trough. The inflow of warm, saline Atlantic-derived water from the Norwegian Sea and the low salinity Norwegian Coastal Current feed a permanent eastward flow. An additional input of fresh water is melted ice which is advected from the central Arctic Ocean and the Kara Sea. These three water masses are modified through cooling and the freezing/melting cycle. Two distinct modes are formed, which leave the Barents Sea eastward and descend down the St. Anna Trough. The lighter mode is winter water of low salinity, thus confined to the upper layers, which leaves the Barents Sea seasonally at temperatures close to freezing point. The largest and most dense contribution consists in more saline but only moderately cold bottom water which is formed in the polynya west of Novaya Zemlya through highly brine-enriched water. Subsequent lateral mixing with warmer Atlantic water feeds a bottom-intensified flow throughout the year. At present conditions, both modes form a low salinity input of about 2 Sv to intermediate depths of the Arctic Ocean.

P13/W/26-B1 1010

INTERANNUAL VARIABILITY OF SUMMER SEA-ICE THICKNESS IN THE LAPTEV SEA AND THE TRANSPOLAR DRIFT

Hajo EICKEN (Geophysical Institute, University of Alaska, Fairbanks, AK 99775-7320, USA, Email: hajo.eicken@gi.alaska.edu); Christian Haas (Alfred Wegener Institute, D-27515 Bremerhaven, Germany)

The dominant sea-ice circulation pattern in the Eurasian sector of the Arctic Ocean is the Transpolar Drift (TPD), exporting ice from the Siberian shelves across the central Arctic Ocean into the Greenland and Barents Seas. Large-scale sea-ice models indicate that the highest net ice production rates in the interior Arctic (on the order of 2-3 m/yr) are found in the Laptev Sea in the upper reaches of the TPD. The present study focusses on the interannual variability of sea-ice thickness in the source area of the TPD and how contrasting atmospheric circulation regimes impact ice thickening in the Laptev Sea and adjacent sectors of the Arctic.Ice-thickness data sets were collected during icebreaker expeditions in the summers of 1991, 1993, 1995 and 1996 through electromagnetic induction measurements and drilling. Level-ice thickness varied considerably in the Laptev Sea, with modal thicknesses at the end of the melt season ranging between 1.2 and 1.9 m. Higher mean and modal thicknesses in 1993 and 1996 are associated with recirculation of second-year ice over the Laptev Shelf and severely reduced summer melt, both strongly influenced by the dominant spring and summer atmospheric circulation patterns with low pressure dominating over the central Arctic. Low ice thicknesses in August of 1995, a year of a record minimum summer ice extent, are mostly the result of excessive surface melt, associated with advection of warm air from the Siberian continent. A Lagrangian thickness-evolution study and an analysis of the thickness and composition of level ice downstream in the TPD indicates that (level-)ice thickness anomalies tend to decay as they are advected across the Arctic Basin due to both dynamic and thermodynamic processes.

P13/W/22-B1 1050

ADVANCED MODELING OF RECENT VARIABILITIES IN THE ARCTIC OCEAN

Wieslaw MASLOWSKI, Albert Semtner (both at Department of Oceanography, Naval Postgraduate School, Monterey, CA 93943, USA, email: maslowsk@ucar.edu), Bob Newton, Peter Schlosser, Douglas Martinson (all at Lamont-Doherty Earth Observatory, Palisades, NY 10964, USA, email: bnewton@ldeo.columbia.edu)

Recent observations of the Arctic Ice Pack and the upper ocean circulation and water mass structure indicate dramatic changes taking place in this region, as compared to known climatologies. Submarine observations, sea ice buoy data, and various hydrographic sections made in the 1990s show large scale and large magnitude anomalies in distribution and in characteristics of sea ice, fresh water, and Atlantic Water in the Arctic Ocean. Those changes seem to be strongly associated with variability of the atmospheric circulation in the northern high latitudes. Changes in the atmospheric circulation manifested by prolonged summer cyclonic activity in the central Arctic and weakening of the high pressure system over Greenland have been known to occur in that region since the late 1980s.
In order to understand the Arctic Ocean system response to such variable atmospheric forcing, a high resolution, basin-scale, coupled ice-ocean model of the Arctic is used. This model is forced with ECMWF re-analyzed atmospheric forcing for 1979-93 to simulate sea ice and ocean conditions before and during the 1990s. Results from the 15-year simulation show changes in large scale ice and ocean circulation, including the distribution of arctic river runoff and Pacific Water. Comparison of model results for the 1980s and 1990s shows basin-scale changes in the distribution of sea ice and water masses in the upper ocean. Circulation of fresh water on the arctic shelves (as modeled by multiple river tracers), communication with deep basins and its export through Fram Strait and through the Canadian Archipelago vary significantly throughout the time of simulation. Relationships of sea ice and oceanic fluxes to the large scale atmospheric systems as represented by Arctic Oscillation (AO) and North Atlantic Oscillation (NAO) are investigated.

P13/W/25-B1 1110

SIMULATION OF THE INTERANNUAL VARIABILITY OF THE WIND DRIVEN ARCTIC SEA ICE COVER DURING 1958-98

Gilles ARFEUILLE, (National Institute for Earth Physics, PO Box M.G 2 Bucharest, Romania Email: ardel@infp.ifa.ro) Lawrence A. Mysak, Louis-Bruno Tremblay

A thermodynamic-dynamic sea ice model based on a granular material rheology developed by Tremblay and Mysak is used to study the interannual variability of the Arctic sea ice cover during the 41-year period 1958-98.
Monthly wind stress forcing derived from the National Centers for Environmental Prediction (NCEP) Reanalysis data is used to produce the year-to-year variations in the sea ice circulation and thickness. We focus on analyzing the variability of the sea ice volume in the Arctic Basin and the subsequent changes in sea ice export into the Greenland Sea via Fram Strait. The relative contributions of the Fram Strait sea ice thickness and velocity anomalies to the sea ice export anomalies are first investigated, and the former is shown to be particularly important during several large export events.
The sea ice export anomalies for these events are next related to prior sea ice volume anomalies in the Arctic Basin. The origin and evolution of the sea ice volume anomalies are then related to the sea ice circulation and atmospheric forcing patterns in the Arctic. Large sea ice export anomalies are generally preceded by large volume anomalies formed along the East Siberian coast due to anomalous winds which occur when the Arctic High is centered closer than usual to this coastal area. When the center of this High relocates over the Beaufort Sea and the Icelandic Low extends far into the Arctic Basin, the above ice volume anomalies are transported to the Fram Strait region via the Transpolar Drift Stream. Finally, the link between the sea ice export and the North Atlantic Oscillation (NAO) index is briefly discussed. The overall results from this study show that the Arctic Basin and its ice volume anomalies must be considered in order to fully understand the export through Fram Strait.

P13/W/24-B1 1130

PARAMETRIZATION OF ICE CATEGORIES IN A COUPLED ICE-OCEAN MODEL

Hitoshi Shinkai, Motoyoshi IKEDA (Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, Japan, email: shinkai@ees.hokudai.ac.jp); Tatsuro Watanabe (Japan Sea National Fisheries Research Institute, Fisheries Agnecy, Niigata, Japan)

Parametrization of ice categories in a sea ice model for the simulation of a seasonal ice cover is investigated. In various sea ice models, only two idealized thickness levels (two category model) are used : i.e., thick and thin, which is taken to have zero thickness and treated as open water. Hence, new ice freezing over open water is forced to merge immediately with the thick ice. However, in the situation of low ice concentration at lower latitudes, such as the Okhotsk Sea, the two category ice model may overestimate air-sea heat flux through thin ice (open water). We propose three ice categories : thick ice, open water and thin ice which is produced over open water and stays to be thin until it is deformed mechanically. The thin ice among the thick ice has much weaker effects on ice pressure, and a higher ice concentration is preserved than the two category model. The thin ice in the three category model prevents air-sea heat flux resulting in less ice formation. The consequences during a decay period is faster melting, because smaller ice volume overcomes the albedo effects of the thin ice (vs. open water). The parametrization of thin ice is found to be important for simulation of the seasonal ice cover in the Sea of Okhotsk, and a step-by-step toward a multicategory ice model.

P13/W/01-B1 1150

CONVECTION IN THE STRATIFIED OCEAN WITH BACKGROUND GEOSTROPHIC CURRENT

Yutaka YOSHIKAWA, Kazunori Akitomo, and Toshiyuki Awaji (Department of Geophysics, Graduate School of Science, Kyoto University, Kyoto, 606-8502, Japan. email: yosikawa@kugi.kyoto-u.ac.jp)

Numerical experiments are performed using a 3D nonhydrostatic model to understand convective and water formation processes in the stratified ocean with background geostrophic current. The model ocean is a rectangular one (50km x 50km x 1km) on an f-plane. Background current is initially given, geostrophically balancing with upward- domed density structure.
With the beginning of uniform surface cooling, convective plumes of about 1-km scale develop and vertically homogenize the water column in the upper layer. At the same time, they accelerate the growth of baroclinic instability; unstable waves of 5-km wavelength develop at the periphery of the dome more rapidly than unstable waves due to pure baroclinic instability. Another effect of convection is to induce significant vertical motion in the preferred place provided by baroclinic unstable waves, upward motion on the ridge and downward on the trough. These up- and downward motions extend to greater depths along isopycnal surfaces, compared with those due solely to either convective or baroclinic instability. As a result, the upper layer water is effectively subducted to form patches with anticyclonic eddy at around the base of pycnocline. This is a possible formation process of eddies containing newly ventilated water as observed south of the Labrador Sea

P13/W/27-B1 1210

POLYNYA SIMULATIONS: A COMPARISON OF A FLUX MODEL AND A HIGH RESOLUTION DYNAMIC-THERMODYNAMIC SEA ICE MODEL

H. BJORNSSON, L.A. Mysak (Department of Atmospheric and Oceanic Sciences, McGill University, Montreal, Canada), Andrew J. Willmott and Miquel M. Morales (Department of Mathematics, Keele University, Keele, Staffordshire, UK)

The current theoretical understanding of wind-driven polynyas is based on flux models, which are generalizations of the steady state models of Lebedev and Pease. In these flux models, a polynya will evolve according to the balance of the nearshore ice formation and the offshore wind-driven ice transport. In these models, two types of ice are considered: the newly formed frazil ice, and the consolidated frazil ice pack. The boundary between the two ice types is the polynya edge. The influence of internal ice stresses is not considered, and thus the flux models are limited in that they employ no ice rheology.
Ice rheology is employed in traditional dynamic-thermodynamic sea ice models. However they do not consider different ice types (i.e. frazil and consolidated ice), which means that even though they correctly model the same thermodynamic processes as the flux models do, a clear polynya edge is not guaranteed. We apply a recently developed sea ice model to simulate a polynya edge in a semi-enclosed channel for several different wind directions, and compared the results with those obtained with a flux model.
We show that in the cases where the ice flow is not affected by internal ice stresses (eg, along-channel winds), the results from the two types of model compare extremely well, although the definition of the polynya edge in the ice rheology model becomes arbitrary. For the cases where there is an onshore wind component, the ice rheology model gives a clear polynya region and an ice pack region with a polynya edge separating the two. In this case, however, there were greater differences in the results for the two types of models, unless special care was taken to ensure that the effects of rheology were implicitly accounted for in the flux model. We performed sensitivity experiments to see if the flux model results depended on the spatial non-uniformity of ice production within the polynya and the along-channel motion of the ice pack. We found only a slight sensitivity to these variables. The flux model proved to be more sensitive to the spatial variability in the cross-channel velocity component of the ice pack. This is the variable in the ice model that is most affected by rheology. Using the same cross-channel velocity component in both models gave results that compared quite favorably.

DYNAMICS OF OCEAN IN POLAR SEAS

P13/E/10-B1 1400

ON THE SENSITIVITY OF SOUTHERN OCEAN SEA-ICE TO THE SURFACE FRESH WATER FLUX: A MODEL STUDY

S. J. MARSLAND (Max-Planck-Institut fuer Meteorologie, Hamburg, Germany,
Email: simon.marsland@utas.edu.au) J.-O. Wolff (ICBM, University of Oldenburg, Oldenburg, Germany, Email: wolff@icbm.de)

An investigation of the ocean/sea-ice interaction in the Southern Ocean has been carried out using the Hamburg Ocean Primitive Equation Model (HOPE). Coupled to this is a thermodynamic model of sea-ice growth and melt, and a dynamic model of the sea-ice momentum balance employing a viscous-plastic rheology. Two versions of the model have been formulated: a high resolution re-entrant channel model along the East Antarctic coastline; and a medium resolution model of the entire southern hemisphere. Both models are found to be very sensitive to the magnitude of the surface fresh water flux (SFWF). The high resolution model has been tested for a range of values of a space and time constant precipitation minus evaporation (P-E). The time mean sea-ice extent is found to be linearly correlated to the magnitude of the P-E, and for the case of zero P-E there is a complete breakdown of the seasonal cycle of sea-ice advance and retreat, characterised by large scale oceanic convection and above freezing sea surface temperature. In the medium resolution version the occurrence of a large scale convective polynya in the Weddell Sea is found to depend critically on the magnitude of SFWF. There the polynya forms for two of the three P-E climatologies considered when no glacial meltwater is added to the SFWF, but does not form for any of the P-E climatologies when a contribution (10 cm/annum) due to glacial melt water is added to the region south of 60 degrees South. It is concluded that the Weddell Sea is the most marginally stable region of the Southern Ocean, and given this, that a negative anomaly in the P-E to that region in the early 1970's would be sufficient cause to explain the observed Weddell Polynya.

P13/E/07-B1 1420

STRUCTURE AND CHARACTERISTICS OF DICOTHERMAL LAYER IN THE ANTARCTIC OCEAN

BENNY N. PETER (Department of Physical Oceanography, Cochin University of Science & Technology, Fine Arts Ave, Cochin, India 682016, email: benny@md2.vsnl.net.in)

Dicothermal layer, a peculier temperature structure of cold water, sandwiched between the warm waters above and below is observed in the surface layers of high latitude oceans, and is conspicuous only during summer. From the vertical section of temperature along various longitudes in the Antarctic Ocean the dicothermal layer has been identified. This layer occupies between 50 and 150m depth and extends upto about 52 degree south from the Antarctic Coast. Characteristics such as salinity, temperature, thermosteric anomaly, oxyty and sound velocity in the dicothermal layer have been analysed. The dicothermal layer is associated with relatively high gradient of temperature, salinity, density and oxyty. The sound velocity decreases with depth in the dicothermal layer and attains a minimum at the core of the layer and then increases downwards. Thus, the sound wave is less attenuated along this channel. The dicothermal layer shows much spatial variation in the Antarctic Ocean. The occurrence and extent of this layer mainly depends on mixing processes.

P13/E/11-B1 1440

A SIMPLE ICE-OCEAN COUPLED MODEL IN THE ANTARCTIC MELTING SEASON

Kay I. OHSHIMA (Institute of Low Temperature Science, Hokkaido University, Kita-19, Nishi-8, Kita-ku, Sapporo 060-0819, Japan, email: ohshima@soya.lowtem.hokudai.ac.jp)

In the Antarctic Ocean, sea ice melts mostly on the bottom and lateral faces by the heat input (mainly solar radiation) through the open water area. We propose a simple ice-upper ocean coupled model in which sea ice melts only by the ocean heat supplied from the air. The model shows that the relation between ice concentration and upper ocean temperature (CT-relation) converges to a certain asymptotic curve with time, which explains the relation observed in the Antarctic summer by Ohshima et al. (1998). The model also shows that the ratio of the heat used for the melting to the heat input into the open water from the air is determined by the ice concentration at that time. When the model is applied to the summer condition in the Antarctic Ocean, it roughly reproduces meridional retreat of sea ice, suggesting that the melting of sea ice be determined by the local balance to the first approximation. When the model is extended to two-dimensional in the meridional direction with the inclusion of the wind-drift effects, reproduction of the sea ice retreat has further progressed. This two-dimensional model can describe the following ice albedo feedback effect; once the ice concentration is decreased by the divergent wind field, the heat input to the upper ocean is enhanced, leading to further decrease of ice concentration. This mechanism can partly explain the year to year variation of the sea ice retreat in the Antarctic Ocean. Best-fit value of heat transfer coefficient, the key parameter in this model, becomes almost the same value both from CT-relation and meridional retreat of sea ice, and the value is also consistent with the result of McPhee (1992).

P13/E/14-B1 1500

THE DYNAMICS OF THE ANTARCTIC CIRCUMPOLAR CURRENT

A. GREZIO (School of Ocean and Earth Sciences, University of Southampton, Southampton Oceanography Centre, Southampton S0 14 3ZH, U.K., E-mail: a.grezio@soc.soton.ac.uk); N. C. Wells (Department of Oceanography, University of Southampton, Southampton Oceanography Centre, Southampton S0 14 3ZH, U.K., E-mail: n.c.wells@soc.soton.ac.uk)

The Antarctic Circumpolar Current (ACC) is the only current which flows around the globe without interruptions and connects all oceans to the South Polar regions. The ACC current is driven eastward by a strong wind field, and eddies together with topographic obstacles are crucial in the ACC dynamics. Eddies transfer heat from the lower latitudes to the higher latitudes. They also transfer momentum downward from the surface to the lower layers in the ACC. It is already known that the ACC undergoes interannual changes of the volume transport. Studies on the ACC transport are important for understanding of how rapidly these transfers take place. The dynamics of the ACC is investigated by two partial eddy-resolving models (Fine Resolution Antarctic Model -FRAM- and Ocean Circulation and Climate Advanced Model -OCCAM-). Those models are used in order to understand the role that eddies play in the main balance of the mean circulation in the dynamics of the ACC. Results from the vorticity budget in the OCCAM will be presented and compared with previous studies in the FRAM. Significant differences arise in the two models because of the wind forcing, the rigid-lid condition (in FRAM) and the free-surface condition (in OCCAM). Seasonal and interannual transport variability are going to be evaluated in OCCAM at the Drake Passage in order to analyse the mechanisms that control temporal variability in the Antarctic Circumpolar Current.

P13/E/05-B1 1520

OPEN OCEAN CONVECTION AND POLYNYA FORMATION IN A LARGE-SCALE ICEPOCEAN MODEL

H. Goosse, T. FICHEFET (both at Institut d'Astronomie et de Geophysique G. Lemaitre, Universite catholique de Louvain, Chemin du Cyclotron, 2, 1348 Louvain-la-Neuve, Belgium, email: hgs@astr.ucl.ac.be)

The formation of an offshore polynya located in the Southern Ocean near the Greenwich meridian is analysed in a large-scale ice-ocean model. This area, which receives at depth an inflow of relatively warm water from the Antarctic Circumpolar Current (ACC), is preconditioned for convection in the model by a wind-driven upwelling and by the convection that has occurred the preceding year. In autumn and early winter, the brine release during ice formation, which is enhanced due to ice divergence, is sufficient to remove the fresh layer caused by summer ice melting and to induce a deepening of the mixed layer. This incorporates warm water in the surface layer which, in a first step, slows down ice formation followed by ice melting in a second step. Then, the freshwater forcing associated with ice melting tends to stabilise the

water column, but the destabilising effect of the oceanic cooling has a large magnitude, even though ice transport convergence prevails now. As a result, convection continues until the total disappearance of the ice at the end of September. Convection stops only when the atmosphere warms up in November. This mechanism of polynya formation seems fairly realistic and the polynya is located in a region where such features have been frequently observed. Nevertheless, the polynya is too wide and persistent in the model, probably because of a too low density at depth and because of the coarse resolution of the model. A passive tracer released in the polynya area shows that the polynya area contributes significantly to the renewal of deep water in the Weddell gyre and that it is major component of the Antarctic Bottom Water (AABW) inflow to the Atlantic.

P13/W/16-B1 1600

NUMERICAL MODELING OF THE CIRCULATION AND SEA ICE IN THE REGION OF PRYDZ BAY, ANTARCTICA

Le KENTANG, Shi Jiuxin (Institute of Oceanology, Chinese Academy of Sciences, Qingdao 266071, PRC, email: ktle@ms.qdio.ac.cn)

A coupled sea ice-mixed layer-isopycnal general circulation model formulated on isopycnal coordinates is used to simulate annual variations of the circulation and sea ice in the region of Prydz Bay, Antarctica. Both dynamic and thermodynamic processes are included in this model. The initial condition and forcing fields were calculated from the monthly-mean observed data. To obtain a resolution sufficient enough for the study region, the grid space was to be designed as a varying one.
The simulated circulation pattern and sea ice cover agree reasonably well with the observations. Some new phenomena were found. The computed circulation show that there is a clockwise gyre with annual and inter-annual variation in Prydz Bay. The water exchange between both inside and outside the day is weak, which mainly occurs in the mouth of the bay, where vertical mixing probably exists. The eastward Antarctic Circumpolar Current in the northern deep region is not really zonal due to topography. The ACC is changeable with seasons. The amplitude of the current is widest in spring. The divergence zone exists between the westward and eastward currents. Many eddies appear in this region. The sea ice cover in this region has a obvious asymmetry annual cycle (the freezing period is longer than the thawing period, which is well consistent with the observation one.

P13/W/08-B1 1620

ON THE COMMUNICATION BETWEEN THE WEDDELL AND SCOTIA SEAS

M.P. SCHODLOK, H.H. Hellmer (Alfred-Wegener Institute for Polar and Marine Research, D-27568 Bremerhaven, F.R. Germany, e-mail: mschodlok@awi-bremerhaven.de)

The Scotia Sea is filled with newly ventilated Weddell Sea Deep Water (WSDW) which in turn is a vital part for the ventilation of the World Ocean abyss. Depending on the formation process and/or its location along the Weddell Sea periphery, deep and bottom water masses follow different routes to fill the Scotia Sea. Observations along the South Scotia Ridge, i.e. including the Weddell-Scotia confluence region, are limited in space and time possibly leaving escape-routes undiscovered. As a part of the BRIOS (Bremerhaven Regional Ice-Ocean Simulations) project a stand alone ocean model (SPEM) is focused on the Weddell-Scotia confluence region with a resolution of ~20 km. The model is initialized with hydrographic data from Southern Ocean Atlas. The surface forcing data are averaged monthly means from a stand alone sea ice-mixed layer model, based on 6-hourly ECMWF (1985-1993) re-analysis data. Lagrangian floats deployed at different locations served as a tool to examine various pathways for deep and bottom water renewal within the Scotia Sea. Modelled characteristics of the WSDW throughflow into the Scotia Sea through Orkney Passage (~40W) are shown and compared to observations.

P13/W/05-B1 1640

EAST ANTARCTIC SEA-ICE DRIFT: OBSERVATIONS AND MODELLING

Petra HEIL (Antarctic CRC, Hobart, Tasmania, Australia, email: petra.heil@utas.edu.au); Xingren Wu, Ian Allison (Antarctic CRC and Australian Antarctic Division, Hobart, Tasmania, Australia, email: x.wu@utas.edu.au, ian.allison@utas.edu.au)

Many of the characteristics of polar sea ice that are important to global climate processes are influenced by the ice drift and deformation. This work presents an overview of the buoy-derived sea-ice drift off East Antarctica (20 - 160E) and compares these data with modelled ice drift fields. Possible improvements in the simulation of sea-ice dynamics over this region are suggested.
The buoy-derived velocity field confirms the broad-scale feature of East Antarctic sea-ice drift. This consists of a westward drift in the coastal current, an eastward current north of the Antarctic Divergence, and a broad region of northward ice transport in Prydz Bay. Sea-ice velocities in the coastal current (0.22 m/s) are generally higher than elsewhere (0.17 m/s), and the flow in the coastal current appears to be steered by the shelf break. In the region between 20 and 152.5E the average meridional component of the coastal current is southward, but small. This average is strongly influenced by a southward component in the flow west of Cape Anne (45E). In contrast, persistent northward ice outlets from the coastal current are found in the region east of Prydz Bay. Although these northward transport rates are smaller than in Prydz Bay itself, they contribute considerably to the divergent character of the region. The drift pattern appears to be largely robust with time, with some variance in the meridional flow. There is some evidence of a seasonal cycle in the sea ice drift speed. The length of the buoy-data record (1985 - 1998) is not sufficient to derive long-term changes, however interannual variability has been identified in the region east of Prydz Bay.
A coupled atmosphere-sea ice model is used to simulate the sea ice over this region. A simple scheme for sea-ice dynamics is currently applied in the model with only the compressive stresses effective in the sea ice. Ice of low concentration moves in free drift from atmospheric wind forcing. At high ice concentration the resistance of sea ice is considered. Preliminary results suggest that the model can simulate the broad structure for the sea-ice drift over this region. However, comparison with the buoy-derived sea-ice field suggests that there is a general tendency for northward transport in the model; also the magnitude of the sea-ice speed appears to be underestimated. Improvement of the ice rheology should remedy the simulations. Some experiments with modified sea-ice dynamics are underway. We will present results from these simulations.

P13/W/10-B1 1700

OBSERVED WATER MASS PROPERTIES AND OUTFLOW ACROSS THE WEDDELL-SCOTIA CONFLUENCE: A SPANISH CONTRIBUTION TO THE DOVETAIL PROJECT

Ileana BLADE, Marc A. Garcia (both at Laboratori d'Enginyeria Marítima. Universitat Politècnica de Catalunya. c/ Jordi Girona 1-3, Edifici D-1. 08034 Barcelona, Spain. email: garcial@etseccpb.upc.es)

As part of the international DOVETAIL project, a series of CTD stations were obtained in the Weddell-Scotia Confluence (WSC) region in January-February 1998, in an attempt to characterize the source waters for the WSC and quantify the Weddell Sea outflow into the Scotia Sea through the Confluence. Due to adverse ice conditions, the two projected meridional transects across the Confluence, to the west and east of the South Orkney Islands, could not extend poleward of 61S. Nevertheless, it is clear that the waters in the WSC are characterized by weakened CDW temperature and salinity maxima compared to those found in the adjacent Scotia Sea waters to the north and at a station farther southwest in the NW Weddell Sea -- though nowhere was the water colder than 0ºC, in contrast to previous summer observations in that area. On the basis of this one Weddell Sea station available, it appears that the WSC waters, at densities of 27.8 kg/m**3, cannot result from an isopycnal mixture between waters to the north and south, which supports earlier results calling for a shelf water contribution to the mixture. As for the Weddell Sea outflow into the Scotia Sea, geostrophic transports computed across a zonal section along the WSC and the ridge separating Powell Basin from the Scotia Sea reveal inflow into the Scotia Sea of both Warm Deep Water (1.7 Sv) and Weddell Sea Deep Water (1 Sv). Neutral density surfaces show sinking of Weddell Warm Deep Water from depths of 1000-1500 m on the southern side of the ridge to depths below 2500 m in the northern Scotia Sea (58S). On the other hand, the meridional flow across the gap to the east of the South Orkneys between Bruce Bank and Laurie Island is directed poleward. These results confirm that waters from the NW Weddell Sea, presumably mixed with (colder, fresher) waters from the eastern shelf off the Antarctic Peninsula, contribute to the deep ventilation of the Scotia basin.

P13/W/03-B1 1720

THE INFLUENCE OF MAUD RISE ON OCEAN CIRCULATION AND SEA ICE DISTRIBUTION IN THE WEDDELL SEA

Ralph TIMMERMANN and Aike Beckmann (both at Alfred-Wegener-Institute for Polar and Marine Research, D-27568 Bremerhaven, Germany, email: rtimmerm@awi-bremerhaven.de)

Water mass circulation and sea ice distribution in the Southern Ocean are generally assumed to be strongly affected by the bottom topography in the eastern Weddell Sea. Maud Rise is the most prominent bathymetric feature in this area. As a part of the BRIOS (Bremerhaven Regional Ice-Ocean Simulations) project a coupled ice-ocean model for the the Weddell Sea has been developed. A sigma-coordinate primitive equation ocean model (SPEM) is coupled to a dynamic-thermodynamic sea ice-model with viscous-plastic rheology (based on Hibler/Lemke). Model runs are initialized with data from the Hydrographic Atlas of the Southern Ocean and forced with wind, cloudiness and temperature fields of the 6h-reanalyses of the European Centre for Medium Range Weather Forecasts (ECMWF). In the reference integration, the simulated circulation in the Weddell Sector of the Southern Ocean features a double cell structure of the Weddell Gyre. Its vertical structure is revealed by trajectories of (numerical) floats which are deployed at different depth levels along the Greenwich meridian. Sensitivity studies using a modified bottom topography in the eastern Weddell Sea indicate that the double cell structure of the Weddell Gyre is strongly controled by the presence of Maud Rise while the effect on the sea ice distribution seems to be less pronounced.

P13/L/02-B1 1740

VARIOUS NATURE OF INTERNAL WAVES GENERATION BY AN ICEBERG IN SHELF ZONE

Lyudmila Pisarevskaya (Arctic and Antarctic Research Institute, 38 Bering st., 199397, St.-Petersburg, Russia)Olga SHISHKINA (Institute of Applied Physics, Russian Academy of Sciences,46 Ul'janov st., Nizhny Novgorod, 603600, Russia, email: ols@hydro.appl.sci-nnov.ru)Valeriya Vasilieva (State Marine Technical University,3 Lotsmanskaya st., 190008, St.-Petersburg, Russia)

One of the typical features of the Arctic zone of the ocean is a sharp pycnocline presence in summer time. Such a natural condition provides internal waves induction in the near-surface water layers. Previous theoretical and experimental investigations proved that under some conditions drifting icebergs may act as sources of short-period internal waves.
In the present work both theoretical and experimental study of both stationary and nonstationary internal waves generation by an iceberg drifting under water flow and wind influence was fulfilled. Some experimental data on plane regular internal waves interaction with the wave system induced by the drifting iceberg will be presented. Conditions of nonlinearity influence on internal waves formation were analysed. Experimental results on lee internal waves propagation in a fluid with the pycnocline - type stratification in the presence of regular plane internal waves are presented. Internal waves generation by the agrounded iceberg in the shelf zone taking into account its melting followed by intensive air bubbles injection (up to 10% of melting water volume) was considered as well. It occurs due to the pycnocline upvelling following bubbles emerge. Natural observations of the 6-meters pycnocline shift near the agrounded iceberg are presented.

DYNAMICS OF SEA AND OCEAN IN POLAR SEAS

P13/W/19-B2 0930

SIMULATIONS OF ANTARCTIC SEA ICE IN GLOBAL CLIMATE MODELS

Siobhan P. O'FARRELL (CSIRO Atmospheric Research Aspendale, 3195, Australia. email: Siobhan.O'Farrell@dar.csiro.au)

The CSIRO coupled ocean-ice-atmosphere climate model includes a full dynamic thermodynamic ice model with cavitating fluid rheology. A number of simulations have been undertaken with the model for different greenhouse forcings and for different formulations of ocean eddy mixing (the latter alters the density structure in the Southern Ocean). This talk will examine the response of the ice in the Southern Ocean to the greenhouse signal. A number of simulations will be presented: a) where the seasonal cycle has been improved over the original simulation and b) simulations where different values for the ocean-ice heat flux have been employed.
One of the shortcomings of the CSIRO coupled model is the coarse resolution (3.2 degrees in latitude by 5.6 degrees in longitude). While this enables i more climate simulations to be undertaken, the ice is poorly resolved around the Antarctic continent which leads to problems with the seasonal cycle of ice retreat in some locations and poor representation of the thicker ice of the Weddell sea. These shortcomings do have significant implications for the freshwater coupling between the ice and ocean components of the coupled model. Currently the Antarctic bottom water generated in the coupled model is driven more by salinity flux adjustment terms than by levels of brine release onto the continental shelf in areas of high ice production.
The experience gained in running the atmosphere- ice component of the coupled model at higher resolution has been used in the upgraded CSIRO climate model which is at finer resolution (1.875 degrees in latitude and longitude). Results from this new atmosphere-ice model will be shown. The improved rates of ice freezing around Antarctica will reduce the dependence on flux adjustment terms in the coupling process. It is noted that two of the recent generation coupled models which have been run without flux adjustment terms (NCAR CSM,

HADCM3) still encounter some of their greatest problems in the Antarctic region where the models have difficulty getting the ice to drive realistic amounts of bottom water. There has been some discussion recently over the likelihood of the rates of formation of Antarctic bottom water decreasing under a warmer climate. To be able to predict such changes with any confidence, it is crucial that the model has realistic ice production rates which may balance any increases in freshwater from precipitation and glacial melt.

SEA-ICE WITH FREE-DRIFT DYNAMICS IN THE HADLEY CENTRE GCM

Doug CRESSWELL and Jonathan Gregory (Hadley Centre for Climate Prediction and Research, The UK Met. Office, London Road, Bracknell, Berkshire, RG12 2SY, UK, email: dcresswell@meto.gov.uk, jmgregory@meto.gov.uk)

Results are presented from the current Hadley Centre coupled model, HadCM3, which has completed a 1000 year simulation of pre-industrial climate. The model comprises a 2.5 x 3.75 degree latitude longitude atmospheric GCM coupled to a 1.25x1.25 degree ocean model and a sea-ice model based on Semtner zero layer thermodynamics in which the ice drifts with the ocean current. The coupled model runs stably without flux adjustment. The drift in global-average surface air temperature is only 0.1K in the first 1000 years. The sea-ice climatology of the model will be described, and compared with observations. The model ice has a realistic seasonal cycle, slightly over-estimating the extent of the ice in winter. There is good agreement with satelite data on the geographical distribution of the ice.
A revised version of the model has been run with free-drift sea-ice dynamics, in which the ice has an independent velocity calculated to give a balance of forces, including the effect of windstress. The rheology of the ice is represented in both schemes by a restriction on the convergence of thick ice. The free-drift scheme generally increases ice velocity and causes an increase of ice volume in winter. An improvement was seen in the simulation of the areas of ice production off the Siberian and Antarctic coasts. Results of these experiments will be presented.

P13/E/06-B2 1010

ICE CLASSES BASED MODELLING OF ICE THICKNESS REDISTRIBUTION

Jari HAAPALA (Department of Geophysics, P.O. Box 4, FIN-00014 University of Helsinki, Finland, Email: Jari.J.Haapala@helsinki.fi)

Pack ice is a mixture of several ice types and open water. Each ice type has its own characteristic thickness, temperature, roughness etc., and has an specific effect on the ice dynamics, and heat and momentum exchange between the atmosphere and the ocean. Present ice models resolve an amount of the open water, the mean ice thickness and distinguish ridged ice from level ice. That approach has been extended and a new ice thickness redistribution model has been formulated where the pack ice is decomposed to open water, two different type of undeformed ice, and rafted, rubble and ridged ice. The ice thickness distribution model has been included to a coupled ice-ocean model and numerical experiments has been made for the simulation of the Baltic Sea ice season. The benefits of the extended ice classification are a separation of the thermally and mechanically produced ice and a better description of the minimum ice strength. Also different thermodynamic growth/melting rates of the ice types can be introduced to the model, hence giving more detailed seasonal evolution of the pack ice. In addition, the six level ice thickness distribution model gives more information about the surface properties (surface temperature, albedo, roughness) of pack ice.

P13/W/02-B2 1050

OPEN-OCEAN DEEP CONVECTION DUE TO THERMOBARICITY

Kazunori AKITOMO (Department of Geophysics, Kyoto University, Kyoto 606-8502, JAPAN, Email: akitomo@kugi.kyoto-u.ac.jp)

Properties of open-ocean deep convection due to thermobaricity at high latitudes have been investigated. Scaling argument shows that two types of open-ocean deep convection are possible. The first type appears in a homogeneous ocean, or in a deepening mixed layer. The increased apparent buoyancy flux due to thermobaricity makes the scales of convective properties larger than those without thermobaricity. The ratio of thermobaric to nonthermobaric scales is determined only by the ratio of the nonthermobaric convective size to the characteristic depth for thermobaricity to be effective. In a nonrotating frame, then, thermobaricity becomes effective when the ocean depth is comparable with the characteristic depth, as previous studies showed. In a rotating frame, thermobaricity is most effective with slow rotation and low temperatures. In the actual situation, thus, thermobaricity is not so effective even in polar oceans because the earth rotation confines the convective size to a smaller level. The second type of deep convection is driven by pure thermobaric instability in a two-layer ocean where a cold, fresh mixed layer overlies a warm, saline deep layer, as often observed in polar oceans. It causes an abrupt overturning of the water column. Scales of convective properties are dependent on the difference of water temperature between the two layers, the initial size of plume and the Coriolis parameter (or time), but not on the surface cooling rate directly. With actual parameters, convective properties and the associated buoyancy flux are much larger than those of the first type. Observed vertical profiles of water temperature and salinity suggest that the first type of deep convection could occur in the Greenland Basin while the second type in the Weddell Sea. Numerical experiments with a three-dimensional nonhydrostatic model confirms the above results based on the scaling argument except that the convective size is determined by the product of characteristic scales of velocity and time whether the ocean is shallow or deep, rotating or nonrotating.

P13/W/12-B2 1110

REGIONAL FOCUS OF A GLOBAL TIDAL MODEL: THE POLAR REGIONS

F. LEFEVRE (email: Fabien.Lefevre@cnes.fr), F. Lyard (email: Florent.Lyard@cnes.fr), C. Le Provost (email: Christian.Le-Provost@cnes.fr) (all at LEGOS/GRGS, UMR5566 CNES-CNRS-UPS, 14 Avenue E. Belin, 31400 Toulouse, France)

The CEFMO hydrodynamic model and the associated data assimilation code is the only one global model to include the ice-shelf covered seas like the Weddell Sea, the Ross Sea, or the Amery ice shelf basin. A new version of our hydrodynamic finite element tide model combined with a revised data assimilation procedure is now available, referred as the FES98 solutions. These global solutions, including the polar regions which are not included in the altimetric empirical models, show now an overall accuracy comparable with the one of the latter. The modelling of the tides in the polar regions is made more difficult due to the lack of accurate data, especially on the ocean bottom topography. The situation is even more complicated below the permanent ice shelves. Nevertheless, a significant effort was made to prescribe the correct water column height and grounding line in these regions. Its finite element discretization allows a realistic modelling in the coastal areas (with horizontal resolution ranging from 10 to 1 kilometer). The model output are the tidal elevation and currents. The tides can interact with many processes, such as, among others, the ice melting below the ice shelves (through a background turbulence) or transport, grounding line variations, the water mixing etc... Actually, the regions with intense tidal dissipation are known to show strong water mixing. In addition, the tides can be responsible of a mean transport, which is somehow connected to the tidal energy flux. A collection of model zooms on regions of interest are presented, with a particular focus on ice covered seas, shelf edges and energetically active regions.

P13/P/01-B2 1130

ICE AND SALT TRANSPORTS IN THE WEDDELL SEA

Sabine HARMS, Eberhard Fahrbach, Volker H. Strass (all at Alfred Wegener Institute for Polar and Marine Research, Postfach 12 01 61, 27515 Bremerhaven, Germany, email: sharms@awi-bremerhaven.de).

Time series of ice thickness in the Weddell Sea are evaluated together with hydrographic observations and ice drift for estimation of the freshwater fluxes into and out of the Weddell Sea. Ice draft is measured with moored Upward Looking Sonars (ULS) since 1989 along two transacts across the Weddell Sea. One transect, extending from the tip of the Antarctic Peninsula to Kapp Norvegia, covers the flow into and out of the southern Weddell Sea. The other transect, extending from the Antarctic continent northward along the Greenwich Meridian, covers the exchange of water masses between the eastern and the western Weddell Sea. On average wind and current force a westward ice transport in the east into the Weddell Sea and a northward ice transport in the west out of the Weddell Sea. Near the coast, in the southern Weddell Sea and along the tip of the Antarctic Peninsula, offshore winds push ice away from the coast and new ice is continuously formed in these regions, indicated by low ice draft modes (< 0.3 m) and high surface salinities (> 34.25). When offshore winds weaken or reverse to onshore ice is deformed. In the presence of opposing currents and the coast the ice thickness increases. On its way along the southern part of the Weddell Gyre the ice grows continuously. The mean ice draft increases from 1.6m in the eastern inflow at the Greenwich Meridian to 2.2m in near Kapp Norvegia and 2.7m in the western outflow. The mean ice export out of the Weddell Sea is (57±21) x I03m3 s- 1, corresponding to a net freshwater export due to drifting sea ice of (0.06±0.02) Sv. This freshwater export exceeds the average amount of freshwater gained by precipitation (Bromwich and Cullather,1997) bv a factor of three. The net amount of salt gained by sea ice formation is (15±7) x 105 kg s-1.

P13/L/01-B2 1150

A LINK BETWEEN SEA ICE EXPORT FROM THE ARCTIC AND THE NAO

Bruno TREMBLAY (Lamont-Doherty Earth Observatory of Columbia University, USA)

In the past decade, an increasing trend in the North Atlantic Oscillation (NAO) index has been observed. A high NAO index will influence the strength of the westerlies in the mid-latitude of the North Atlantic and could also result in different atmospheric circulation pattern in the Arctic. Since regional and large scale anomalous wind patterns in this region can produce fluctuations in ice export from the Arctic through Fram Strait, a link between the state of the NAO and the export of ice out of the Arctic is possible. A dynamic-thermodynamic sea-ice model is used to study the interannual variability of the sea ice export from the Arctic through Fram Strait during the 1958-98 period. The model is forced with monthly varying wind stresses and air temperatures from the NCEP reanalysis data. The simulation results show a significant correlation between the ice export and the NAO index time series. When the NAO index is positive, the Icelandic Low is extending further north into the eastern Arctic and the Arctic High is located closer to the Beaufort Sea. During those periods, the Transpolar Drift Stream (TDS) is well developed, leading to a large ice export from the Arctic. During a negative phase of the NAO, the Arctic High moves closer to the Siberian coast and the TDS tends to feed into the Beaufort Gyre leading to a smaller ice export. During these periods, the atmospheric circulation is such that more ice is found in the East Siberian Sea (at the source of the TDS); these ice thickness anomalies are advected out of the Arctic during subsequent periods of high exports, tending to reinforced the ice export anomalies.

SATELLITE OBSERVED SEASONAL AND INTERANNUAL VARIABILITY OF THE ODDEN FROM 1973 THROUGH 1997 AND ENVIRONMENTAL EFFECTS

Josefino C. COMISO (Laboratory for Hydrospheric Processes, Code 971, NASA/GSFC, Greenbelt, MD, USA, 20771, email: comiso@joey.gsfc.nasa.gov), Peter Wadhams (Scotts Polar Research Institute, University of Cambridge, Cambridge, England, email: pw11@cam.ac.uk), and Lef Toudal Pedersen, Technical University of Denmark, Dept. of Electromagnetic Systems, Bygning 348, DK-2800 Lyngby, Danmark, email: ltp@emi.dtu.dk)

The Odden is a regular ice feature phenomenon in the Greenland Sea that is believed to have a profound influence on the convection and circulation characteristics of the ocean in the region. Although it had been observed and reported by early explorers, it was not until the satellite era that it's size, shape, and characteristics became apparent. It usually occurs early in the winter and forms as an ice tongue, a bulge, or an island depending on atmospheric and oceanographic forcing. The most frequently observed development of the Odden is as an area of locally-grown frazil and pancake ice along the cold polar Jan Mayen Current which diverts eastward from the East Greenland Current. Such composition has been confirmed during field programs carried out in this region. However, on some occasions, the ice cover in the Odden has been observed late in the season to be made up of multiyear or old ice advected from the Arctic Ocean through the Fram Strait and the Greenland Sea. Our study makes use of satellite passive microwave historical data to investigate the seasonal and interannual variability of the size, extent, and type of the Odden since 1973. High resolution satellite SAR and AVHRR data was used to improve our interpretation of the passive microwave data, the resolution of which is relatively poor. Our analysis reveals large interannual variability in time of occurrence, persistence, and type. Also, the Odden appeared every year except in 1984, 1994, and 1995. We observed that the size and extent varies with wind and surface temperature but the correlation of the distribution of the ice cover with the bathymetry is weak although the feature is usually along the Jan Mayen fracture zone. Analysis of the influence of environmental effects that sometimes cause transistions from a bulge feature to an ice tongue, and from an ice tongue to an island will be presented. Also, the potential impact of rapid ice growth to convection and of the presence of multiyear and old ice in late spring to the carbon cycle in the region will be discussed.

P13/E/16-B2 1440

SATELLITE-DERIVED DYNAMICS OF SOUTHERN OCEAN SEA ICE

Mark R. DRINKWATER and Xiang Liu (Jet Propulsion Laboratory MS: 300-323, 4800 Oak Grove Drive, Pasadena, CA 91109, USA, email: mrd@pacific.jpl.nasa.gov)

Antarctic ERS-2, RADARSAT Synthetic Aperture Radar and ERS-1/2 Scatterometer images were analyzed with SMMI radiometer image time-series data to investigate seasonal variability in satellite-tracked sea-ice dynamics in the Southern Ocean during 1992. Supporting field data were acquired during 'in-situ' experiments including the winter 1992 Ice Station Weddell and Winter Weddell Gyre studies. A variety of surface measurements were made during these experiments including Argos-buoy deployment and GPS drift measurements. These are used in conjunction with International Program for Antarctic Buoys drift trajectories for ice-motion tracking validation. Comparisons between gridded SSMI ice-motion vectors and ECMWF/NCEP analyses indicate that large-scale drift is forced predominantly by the long-term mean, large-scale synoptic pressure field. Only sub-daily SAR sea-ice tracking can capture high-frequency fluctuations, driven by polar lows or tidal forcing. In these cases, sea-ice drift can respond rapidly to changes in forcing on semi-diurnal time scales depending on the location with respect to the coastline. Seasonality of ice drift, particularly in the Weddell and Ross Seas, is linked to ice extent and compactness, and internal ice stresses transmitted through the pack ice from the coast. Three-monthly seasonal climatologies are presented of austral winter of ice drift in the Southern Ocean. The large Weddell and Ross Sea gyres are clearly resolved along with key seasonal and spatial attributes of their cyclonic circulation. Regional time series of ice dynamics parameters are used to illustrate correlations with meteorological forcing. Persistent divergence such as that occurring in the Ronne-Filchner polynya system results in large fractions of new ice. Similarly, convergence zones produce large fractions of deformed ice and characterize the dynamics of regions where perennial ice is observed. High shear strains also help delineate the axis of the Antarctic divergence in many places in the ice cover. In these regions, the separation between the coastal 'east wind drift' and ACC-dominated drift regimes is characterised by zonally extended regions of intense shear.

SEA ICE THICKNESS DERIVED FROM ERS-1 AND 2 ALTIMETER OBSERVATIONS

Neil PEACOCK, Seymour Laxon (University College London 17-19 Gordon Street, London, WC1H 0AH, UK)

A new technique to directly measure sea ice freeboard from ERS-1 and 2 spaceborne altimetry has recently been developed. This offers the potential to provide up to 250,000 estimates of ice thickness per month over a large fraction of the Arctic Ocean. There is a critical need to calibrate and validate these thickness estimates prior to their widespread application to climate-related problems.
In this paper, we present the results of comparisons of these measurements, obtained between 1993 and 1998, with in situ Upward-Looking Sonar (ULS) measurements from moored buoys in Fram Strait, and ULS measurements made from US Navy submarines. The statistical properties of the thickness data sets acquired using these methods will also be investigated, and estimates of the corresponding errors in our thickness measurements will be derived.
Potential applications of this unique data set will then be discussed, which include the monitoring of ice thickness in the Arctic Ocean and Fram Strait, and the ability to estimate ice flux from the Arctic Ocean into the Greenland Sea. Future spaceborne altimeter missions, such as ENVISAT, will allow observations of this important climatological parameter well into the next century.

POLAR SEA ICE MOTIONS CHARACTERIZED FROM 20 YEARS OF PASSIVE MICROWAVE SATELLITE IMAGERY

W.J. EMERY, C. Fowler, J.A. Maslanik (CCAR Box 431, University of Colorado, Boulder, CO 80309, USA)

An approximately 20 year time series of daily passive microwave maps of polar sea ice have been constructed using the Special Sensor Microwave/ Imager (SSM/I) for the years 1987-1997, and the Scanning Multichannel Microwave Radiometer (SMMR) for the years 1979-1987. While the sensor channels and the specific ice concentration algorithms are different for these two sensors the basic imaging of the ice surface as used for the computation of sea ice motion, is quite similar between the two instruments. Arctic sea ice motions are analyzed in conjunction with ice trajectories from the Arctic ice buoy program while the Antarctic ice motions are based on the passive microwave imagery alone. Means are calculated for the entire time period, for both decades and then for individual years to characterize the interannual variability of the ice motion fields. Standard deviations for these same periods reveal where the ice movements are most variable. Empirical orthogonal functions (EOFS) are computed from the ice motion maps to indicate the basic patterns of ice motion. These patter are found to correlate well with structures of the atmospheric pressure and hence geostrophic wind patterns. The EOFS for the Arctic and the Antarctic are quite different reflecting the very different forcing functions operating in the Antarctic.

THE ESTIMATIONS OF SEA ICE EXCHANGE BETWEEN THE ARCTIC SHELF SEAS AND THE ARCTIC BASIN

Alexander MAKSHTAS and Sergey Shoutilin (both at Arctic and Antarctic Research Institute, 38 Bering Street, St.Petersburg, 199397, Russia, email: maksh@aari.nw.ru)

Sea ice exchange between the Barents, Kara and Laptev seas and the Arctic Basin was investigated using a large-scale dynamic-thermodynamic model (for period 1958 - 1997 years) and semi-empirical method, based on empirical relation between atmospheric surface pressure gradient and drift velocity (for period 1936 - 1996 years). Estimates of sea ice exchange of the Laptev sea, calculated using empirical relation between ice flux and air pressure difference at polar stations Kotelnyy and Cape Cheluskin, showed strong seasonal and interannual variability with an absolute minimum of sea ice export to the Arctic Basin in 1957 year and did not reveal significant trends for the entire period.In opposite estimates for the Kara sea, obtained with the same method and atmospheric surface pressure data from meteorological stations Cape Arcticheskiy and Ostrov Rudolf, showed strong positive trend of ice export to the Arctic Basin, especially during last three decades, when sea ice export from the Kara sea almost reached values from the Laptev sea. The dynamic-thermodynamic model, validated with empirical method for sea ice area exchange allowed to estimate sea ice mass exchange and to made some numerical experiments on sensitivity of the Arctic Basin sea ice cover to the hypothetical Arctic climate changes. This experiments showed strong dependence of sea ice mass exchange to increasing of atmospheric surface layer temperature and incoming longwave radiation.

INTERANNUAL AND DECADAL VARIABILITY OF THE GIN/BARENTS SEAS SYSTEM

S. PIACSEK, A.Warn-Varnas, R.Allard (Ocean Science Division, Naval Research Laboratory, Stennis Space Center, MS, 39529, USA; email: piacsek@nrlssc.navy.mil); A.Mehra, D.Dietrich (CAST, Mississippi State University, Stennis Space Center, MS, 39529)

The variability of the Greenland-Iceland-Norwegian (GIN)/ Barents Seas system has been investigated via analysis of hydrographic data and numerical models. Data has been extracted mainly from the NODC's WOA94 database and from 9 successive cruises by the SACLANT Research Center in the 1986-1993 period. A watermass census was performed for regions where the data density warranted it.
Model results were generated with two models, one spherical including the North Atlantic and one polar stereographic including the whole Arctic Basin. Forcing was derived from the NCEP reanalysis files (2.5 deg) and the US Navy's NOGAPS GCM output (1 deg).
The model results revealed an increased inflow of Atlantic water (AW) into the Arctic Basin during the 90's, with the dominant circulation patterns and transport magnitudes shifting from the West Spitsbergen Current to the Barents Sea branch flowing north along the Novaya Zemlya coast. A recirculation of AW southward along the east coast of Svalbard, very prominent in the '80s, almost disappeared except for 1994. The outflow of deep water (DW) from the Arctic through the Fram Strait consisted of two branches, one fed by waters coming from the Eurasian Basin and one from the Canadian Basin. The hydrographic data analysis revealed a gradual decrease of AW until 1989, and then a gradual increase in the 90's.
The DW exhibited an opposite behavior, peaking in 1989 and then decreasing. Furthermore, the DW constitution changed from Norwegian Sea Deep Water (NSDW) to a class warmer than -.5 deg C.

P13/E/03-B2 Poster 1600-03

SPATIAL AND TEMPORAL VARIABILITY OF WATER MASSES IN FRANZ-VICTORIA TROUGH

Ivanov V.V., Korablev A.A. (Arctic and Antarctic Research Institute, 38 Bering st., 199397, St.Peterburg, Russia, email: vivan@ aari.nw.ru); PISAREV S.V. (P.P.Shirshov Institute of Oceanology, RAS, 36 Nachimovsky ave.,117218, Moscow, Russia, email: sergey@pisarev.msk.ru)

The WODB-98, MOODS, local Russian and Norwegian databases, recent measurements of RV "Polarstern" in 1993 and RV "Lance" in 1993,94,95 were used to describe the spatial and temporal variability of water masses in Franz-Victoria Trough (between the Victoria Isl. and Franz Joseph Land). The data obtained during the multidisciplinary research cruise carried out in October 1998 from the board of Russian RV "Ak. Fedorov" were used also. About 750 stations were collected for 1923-1998. The water masses of the Franz-Victoria Trough were classified based mainly on the T,S characteristics. It was noted, that the main features of spatial distribution of the water masses of the region were determined by bottom relief. The conclusion concerning general circulation within the Trough was made. The interannual variability of atlantic water temperature, heat content, and spreading was also determined.

DEVELOPMENT OF AN IMPROVED DYNAMIC-THERMODYNAMIC SEA ICE THICKNESS DISTRIBUTION MODEL FOR CLIMATE APPLICATIONS

Todd ARBETTER (McGill University, Montreal, Quebec, CANADA); Judy Curry, Julie Schramm (University of Colorado,Boulder, Colorado, USA)

One of the major challenges in climate modeling is development and implementation into general circulation models of a sea ice model that accurately predicts sea ice mass balance, ice extent, interfacial fluxes, and the associated feedbacks with the atmosphere and ocean. Initially, general circulation models contained simple parameterizations of sea ice thermodynamic and dynamic processes. The development of sophisticated stand-alone ice dynamic models facilitated improvement in the treatment of ice dynamics in GCMs. However, while there has been substantial progress in the development of single-column thermodynamic sea ice ice models, little work has been done to unify sophisticated thermodynamics and dynamics into a single model.
Towards this end, a new sea ice model is described which incorporates the sophisticated thermodynamics of a single-column sea ice model developed at the University of Colorado into an existing basin-scale dynamic-thermodynamic model. Using a viscous-plastic dynamic model and an ice strength parameterization which accounts for a distribution of sea ice thicknesses, the model resolves a domain covering the Arctic Ocean and much of its surround seas. Beneath the ice at each grid cell is an interactive ocean mixed layer. A preliminary comparison of baseline characheristics of the model with observations indicates that the new model performs reasonably well in terms of its reproduction of ice surface albedo, ice surface temperature, and ice thickness distribution.

P13/W/09-B2 Poster 1600-05

CHANGES IN THE NORTH SLOPE CLIMATE AND THE SEA ICE CONCENTRATION IN THE ADJACENT BEAUFORT SEA

Gerd WENDLER and Blake Moore (both at Geophysical Institute, University of Alaska, Fairbanks. 903 Koyukuk Dr., Fairbanks, AK, 99775-7320 USA, email: gerd@gi.alaska.edu)

Significant climate change has been observed in recent decades in the Western Arctic. Two climate variables in particular show this quite clearly; temperature and sea ice concentration. Western Arctic temperatures have increased; the observed temperature rise, however, varies significantly from one season to another (it is most pronounced in the winter and spring) and over multi-year time scales. This makes it difficult to explain the trend as a direct consequence of increasing greenhouse gases in the atmosphere. At the same time, the sea ice concentration has decreased in the southern Beaufort Sea. Temperature variations were found to correlate with changes incloudiness associated with specific synoptic patterns. Increased cloudiness was correlated with a warming of the temperature in winter, but with a cooling in summer, indicating that the temperature regime in winter is strongly influenced by the long wave radiation.We were able to analyze systematically the area in the southern Beaufort Sea using a portion of the international Sea Ice Grid (SIGRID) produced by National Ice Center. Weekly sea ice concentration consisting of 0.25 degree latitude by 0.50 degree longitude grids derived from satellites for the period 1972-1994. We limited our preliminary study to the coastal Beaufort Sea south of 72° North, and between 142° and 152° West. There are two main processes which influence the sea ice conditions, namely thermodynamics and dynamics. The thermodynamics determines the formation and decay of the sea ice and is directly related to the surface energy budget, while the dynamics determines the transport of sea ice, which is strongly related to atmospheric dynamics. Other factors such as ocean currents also play a major role.
The annual average ice concentrations shows a decreasing ice concentration. Forcing the best linear fit through the data points, a decrease in the yearly average sea ice concentration from over 88% to 81% can be observed for the 24 year time period. A temperature increase of about

1°C was also observed during this time. If the annual temperature values are plotted against the annual values of the sea ice concentration, a good statistical variance (r2 = 0.48) was found. For shorter time periods, especially during times when the ice concentration can vary considerably (e.g. fall), the relationships become even better. This presentation will concentrate on the underlying causes of these changes which are not well understood. The primary forcing mechanisms that underlie these changes will be discussed. The observed trend of decreasing sea ice concentration is continuing. This fall (1998) the lowest ice concentration since the start of the record has been observed.

THE ROLE OF TRANSIENT EDDIES IN ACC DYNAMICS IN CROZET PLATEAU REGION OF THE SOUTHERN OCEAN

Vladimir IVCHENKO (Jet Propulsion Laboratory/NASA, M/S 300-323, 4800 Oak Grove Drive, Pasadena, CA 91109, USA, Email: voi@sundog.jpl.nasa.gov)

A vigorous eddy field is observed in TOPEX altimeter data around the Crozet Plateau, especially around the northern branch and downstream of the Plateau. The important question that is addressed in this study is how transient eddies affect the mean flow? This problem has been studied using the output of two fine resolution numerical models: the Fine Resolution Antarctic Model (FRAM) and the Parallel Ocean Programm (POP). The level of eddy kinetic energy (EKE) throughout the region is much greater in POP than FRAM, due to better horizontal resolution.
Although maximum values in FRAM are just as high as in POP, these values are restricted around the northern flank and downstream of the Plateau. The most important source of the EKE is the eddy buoyancy term. In both models instability analysis showed that baroclinic instability is likely to be the main mechanism responsible for generating EKE. Transient eddies are found to be responsible in shaping the flow structure and transferring momentum in both the Horizontal and vertical directions. The eddy flux of the potential vorticity has been split into rotating and divergent parts by solving a Poisson-type equation, using iteration schemes with appropriate boundary conditions. The rotational part is found to be quite large in the western and north-western part of the Crozet storm track.

BEAUFORT AND CHUKCHI SEA SEASONAL VARIABILITY

Tatiana Proshutinsky and Andrey PROSHUTINSKY (Institute of Marine Science, University of Alaska Fairbanks, Fairbanks, AK 99775-7220, USA email: prosh@ims.alaska.edu) James Maslanik (Colorado Center for Astrodynamics Research, University of Colorado, Boulder, CO 80309 USA, e-mail: jimm@northwind.colorado.edu)

Arctic navigation, oil and gas exploration, and arctic pollutant transport depend on arctic environmental conditions. Existing atlases, manuals, and reference books contain multi-year mean environmental variables and their multi-year mean seasonal variability; however, uncertainties sometimes result from the existing atlases because they do not take into account climate change and climate variability. Our work is motivated by the recent finding of two regimes (or two climate states) of arctic atmosphere--ice--ocean circulation described by Proshutinsky and Johnson [1997]. Seasonal variations in the ice concentration, ice thickness, and ice drift, ocean currents, ocean temperature, and salinity, atmospheric pressure, wind speed, cloudiness, and precipitation, river discharge, and permafrost temperature are different for cyclonic and anticyclonic arctic climate states. In this poster we present the atmospheric, ice, oceanic, and terrestrial signals showing seasonal variability of environmental parameters during cyclonic and anticyclonic climate states in the Beaufort and Chukchi seas using observational data and results of numerical modeling.

THE COUPLED ATMOSPHERIC BOUNDARY LAYER- SEA ICE - UPPER LAYER - DEEP OCEAN MODEL FOR INVESTIGATION OF SEASONAL, INTERANNUAL AND INTERDECADE VARIABILITY OF WATER CIRCULATION AND TERMOHALINE STRUCTURE IN THE ARCTIC AND ATLANTIC OCEANS

G.A. SEMYONOV (Arctic and Antarctic Research Institute, 38 Bering St., St-Petersburg, 199397, Russia)

For simulation and investigation of climate large-scale circulation evaluation in the Atlantic Ocean (AO) and the Arctic basin (AB) the three-dimensional efficient hydro-thermodynamical model, based on the primitive equations with used of a hydrostatics and Boussinesque approximation with free surface, was built. The calculating area includes the regions from the equator to the Bering strait. To improve the finite-difference approximation in the Denmark, Frame and Faeroe-Shetland straits the spherical coordinate system with pole placed in point 75 N & 40 W (in Greenland) was designed. The ocean model has a variable resolution from 28 km (Greenland Sea) to 312 km (near equator). The model uses a total of 47 levels in the vertical. The method of solving equations this model is based on the split method. The atmospheric boundary layer is parametrized with the help of integrated model. The model of n ice cover is based on the primitive equations of dynamics both thermodynamics of ice and snow. The upper mixed - layer of ocean is parametrized by using the K - theory, that allows to calculate coefficients of vertical turbulent exchange of momentum, heat and salt by solving the equation of balance of kinetic turbulent energy. Application of the effective non-explicit numerical schemes allows to execute calculation using time steps equal 24 hour for period of 100 years and more. The model reproduces three-dimensional circulation of waters, evolution of a sea surface elevation, termohalin of structure, annual course of variability of an ice cover, distribution of a firm suspension and various pollutions both on a surface of the sea and in thickly waters at the task of temperature of air and height of geopotential of 850 mb of a surface above the AB and AO.

NEW OBSERVATIONS FROM BOTTOM PRESSURE RECORDERS IN THE WEDDELL SEA

M.J. SMITHSON (CCMS-Proudman Oceanographic Laboratory, Birkenhead, Merseyside, L43 7RA, U.K., e-mail: msm@ccms.ac.uk)

Recent studies of the southern Weddell Sea using a hydrodynamic numerical tide model have shown that it is not possible to model simultaneously the tides of the open ocean and the tidal motion of the ice shelves (Ronne and Filchner). Specifically, in order to reproduce the ice shelf movement near the grounding line unrealistic model parameters in the region of permanent ice cover, in particular the bottom friction coefficient, must be used. The effect of this is to destroy any agreement between model and observations in the open ocean, especially near to the permanent ice front. Existing observational data indicate the presence of an amphidrome in the principal semidiurnal tides close to the Ronne Ice Shelf but its position is uncertain. Its existence is also borne out by the model results and its position is very sensitive to model parameters.
A number of bottom pressure recorders were deployed in the region at the beginning of 1998, from H.M.S. Endurance. These are due to be recovered in January/February 1999. The data from them should provide valuable information to help fix the location of the amphidrome and hence reduce significantly the uncertainties in the model parameters.

A STRONG FRONT OVER THE NORTHERN ARCTIC MID-OCEAN RIDGE

Robin D. MUENCH, John T. Gunn (Earth & Space Research, 1910 Fairview East, Suite 102, Seattle, WA 98102-3620, USA, email: rmuench@esr.org); Tim Boyd (College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR, 97330, USA, email: tboyd@oce.orst.edu)

Oceanographic temperature (T), salinity (S) and dissolved oxygen concentration (O2) were measured continuously along a closely spaced array of transects that were made across and roughly normal to the northern portion of the Arctic Mid-Ocean Ridge system from the U.S. Navy submarine Hawkbill. Additional T and S data were collected as vertical profiles at selected sites using expendable probes. The transects were run at a sensor depth of 212m, and the vertical profiles extended from about 20m down to 1000m depths, providing detailed documentation of the Atlantic Water layer. A strong T and S front was seen to coincide approximately with the axis of the Ridge. Maximum Atlantic Water T increased from about 1.1°C to nearly 2.3°C across the front from north to south, and S increased by about 0.06 psu. The frontal distributions of T and S showed complex wavelike undulations and discrete features. Some were consistent with the presence of mesoscale eddies, while others appeared to be associated with the bottom topography. An eastward flowing current filament about 20 km wide coincided over part of the system with the southern slope of the central rift valley. Current speeds in this filament were estimated based on offsets in the cruise track to exceed 25 cm/s. Neither the high T nor the eastward current is consistent with the concept of a cyclonic gyre occupying the Nansen Basin. The eastward current, whose presence is consistent with topographic control by the steep axial rift valley, may be an extension of a continuous northward flow through Fram Strait. The high T suggests, also, a more direct route from Fram Strait than would be consistent with flow within a large cyclonic gyre.

MODELLING OF THE SEASONAL DYNAMICS OF THE WATER MASSES, ICE AND RADIONUCLIDE TRANSPORT IN THE KARA SEA

Liudmila Koziy, Vladimir Maderich, Nugzar MARGVELASHVILI, Mark Zheleznyak (all at Institute of Mathematical Machine and System Problems NASU, Glushkova pr. 42, Kiev 252187, Ukraine.)

The numerical THREETOX code was used to simulate 3-D hydrodynamic fields, ice transport, suspended sediment transport and the dispersion of the radionuclide in the Kara Sea and adjacent areas of the Barents Sea and Arctic Ocean. The code includes the hydrodynamics sub-model, ice sub-model, suspended sediment transport and radionuclide transport sub-models. The hydrodynamics is simulated using the, time-dependent, free surface, primitive equation model. The modified Hibler type dynamic-thermodynamic model describes the momentum balance, nonlinear ice rheology, mass balance and the ice strength. The ice thickness distribution is a two-level representation (compactness and ice thickness). An important role of seasonally varying ice cover in the seasonal dynamics of the Kara Sea was shown. At summer, the western and northern flows of the Ob and Enisey plume are transformed in the slope current that flows to the Severnaya Zemlya. Another current flows along the north coast of the Novaya Zemlya. The residual tidal currents are important in narrows (e.g. Karskie Vorota Strait and Ob and Enisey estuary mouths). The water exchange through the Karskie vorota is bi-directional. At winter the ice sheet covers almost all area of the Kara Sea. The strong current flows from the Karskie Vorota and merges with Ob-Enisey flow in the northern part of the sea. The numerical results agree quite well with the observations. These peculiarities of the Kara Sea circulation strongly affected on the radionuclide transport. Weak and seasonally varied currents near Novaya Zemlya coast result in the long residence time for radionuclides dumped in the Novaya Zemlya fjords and the Novaya Zemlya trough.

ON PHYSICAL NATURE OF LARGE-SCALE ANTICYCLONIC GYRE IN THE NORWEGIAN SEA WATER DEPTH

Anatoly PERESKOKOV (Russian Research Institute of Hydrometeorological Information - World Data Center, 6 Korolyov St, Obninsk 249020, Russia, email: peres@meteo.ru)

Anticyclonic vorticity in the thick layer of deep water over Lofoten hollow in the Norwegian Sea is a paradox, especially in view of the cyclonic winds of the Icelandic lows, and the fact that neither the density field nor the available measurements suggest an anticyclonic circulation of the surface waters. No doubt, the topography largely determines the characteristic features of the stationary circulation of the Norwegian Sea waters. However, the circumstantial evidence suggests that an important role may be attributed to a redistribution of the Atlantic waters heat from upper layers to the lower ones through salt finger convection. Our calculations show close agreement between the area with the highest likelyhood for salt fingers, given through the density ratio, and the region of the relative temperature maximum at every horizontal surface of 800-1500 m water thickness. The centre of the temperature maximum is quasi-stationary in this deep layer near 69,5 N, 3,5 E. A quite natural response to the generation of this quasi-stationary horizontal inhomogeneity of physical and topographical origin (with less density) is the initiation of an anticyclonic circulation. Since variations in the gire intensity can not but influence the transfer of the Atlantic waters heat to the higher latitudes, the monitoring of the parameters of dynamic and thermal regime at some certain depths could possibly be the positive contribution to the ice prediction.

P13/W/23-B2 Poster **1600-13**

THERMAL INSTABILITY OF WATER SATURATED SEA ICE SHEET BOUNDED BY MELT POND

Pjotr BOGORODSKY (Arctic & Antarctic Research Institute, 38 Bering str., 199397 St.Petersburg, Russia, email: vivanv@aari.nw.ru)

Fresh melting water accumulates during summer period in the melt ponds at the ice surface and percolate it forming so-called "underice melt ponds". Heating from above by radiation flux can induce convection resulting intensifying processes of air-sea energy and mass exchange. However, the permeability of intermediate ice sheet provides interaction of fresh liquid layers by the way that all they form unit combine sysrem. At the present work the analysis of its convective stability is performed. The external boundaries of the system are considered as free or hard surfaces with constant heat fluxes. The critical values of Rayleigh numbers depending of determining parameters (coefficients of heat diffusivity of ice and fresh water, thickness and permeability of ice) are found out from the analysis of linearized spectrum problem. At dedaction of equations for eigenvalues the method of series expansion is used. The study is restricted by the longwave instability of monotonic perturbations. The simplicity of such an approach allows to easy transform to extreme cases cases of approximation of

dimensionless ice thickness to zero (unit). In these cases the expression obtained for critical Rayleigh number transforms to the known value for single liquid (porous) layer with heat insulated boundaries. When summerizing results it may be concluded that 1) the dynamical boundary conditions on the system outer surfaces do not principally affect the instability character; 2) the ice sheet permeability changes at its fixed thickness do not influence on the value of critical Rayleigh numbers; 3) the increasing ice sheet thickness lead to significant stabilization on the longwave mode of instability.

MODELING SEA-ICE AND WINTER PROCESSES IN THE LABRADOR SEA

C.L.TANG

Sea-ice and winter processes in the Labrador Sea are studied with an hierachy of numerical models: (a) 1-D mixed-layer model; (b) 3-D coupled ice-mixed layer-ocean model; (c) 3-D coupled ice-Princeton Ocean Model. The re-analysis data of ECMWF and NCEP are used for the calculations of heat and water fluxes. The archived oceanographic data at BIO are objectively analyzed to produce the initial ocean state. The models successfully simulate the seasonl change of sea-ice coverage. Ice grows in the inner shelf and melts in the outer shelf regions. Heat loss of the ocean reaches a maximum at the end of January. The highest heat loss, 250 to 400 W/m**2, occurs in the northern Labrador Sea between 56N and 63N in ice-free waters near the ice edge. Sea ice significantly reduces the heat loss with a typical values of 50 W/m**2. In the open sea, surface cooling causes the mixed layer to deepen continuously through winter. The mixed layer reaches a maximum depth of150m to 450m in late March. Across the southern shelf, observations indicate that the mixed-layer depth decreases from 80m in mid-shelf where the water is completely covered by ice to 25m at the ice edge. The temperature under the pack ice is near the freezing temperature and increases to 0 deg at the ice edge. The variation of the mixed-layer properties across the shelf is simulated by the D mixed-layer model. The relative contributions from wind mixing, buoyancy production and short-wave radiation to the mixed-layer properties vary with space and time, and are closely related to sea ice.

NEW BIO-OPTICAL MEASUREMENTS FROM AUTONOMOUS PLATFORMS

T. DICKEY (University of California at Santa Barbara, 6487 Calle Real, Suite A, Goleta, CA 93117, (805) 893-7354; email: tommy@icess.ucsb.edu)

During the past few years, our group and collaborators have made bio-optical and physical observations using autonomous platforms including moorings and autonomous underwater vehicles (AUVs). The variety of optical (and chemical) measurements is expanding rapidly. Our work has focused on the development of new systems capitalizing on emerging multi-spectral sensors, novel platforms, and specialized telemetry technologies. In this review, examples of these new interdisciplinary sampling systems, data acquired with the systems, and interpretation of these data will be discussed. Sites for the studies include the North Atlantic near Bermuda (Bermuda Testbed Mooring) and coastal waters off the east coast of the United States. Phenomena including eddies, fronts, internal waves, sediment resuspension, and ocean response to hurricanes have been captured during these studies. The relations among physical, biological, and optical properties and processes are being explored and modeled using these data sets.

P15/W/01-B3 1000

MEASUREMENTS AND MODELS OF THE BACKWARD SCATTERING COEFFICIENT

Robert A. MAFFIONE (Hydro-Optics, Biology, and Instrumentation Laboratories, 55 Penny Lane, Watsonville, CA 95076, email: maffione@hobilabs.com)

The backward-scattering coefficient, bb, has historically been one of the most undersampled ocean-optical properties. Yet it is a key optical parameter for ocean-color remote sensing and underwater visibility. Due to the difficulty in measuring bb, most investigators have resorted to modeling it based on other optical parameters which can be measured and on chlorophyll concentration. Now, with the availability of new instrumentation, namely the HydroScat backscattering sensors, bb can be easily and accurately measured at selected wavelengths across the visibile spectrum. How bb is measured with the HydroScat will be presented, along with results from a number of cruises in coastal waters around the east and west coasts of the United States. Results include not only spectral measurements of bb, but also concomitant measurements of the spectral absorption and beam attenuation coefficients, remote-sensing reflectance, chlorophyll concentration, and particle size distributions. These results were used to both test published models involving bb, and to derive new models based on more complete data set than has historically been available.

P15/W/03-B3 1025

BIO-OPTICAL INVESTIGATION OF THE AMAZON OUTFLOW REGION IN DIFFERENT SEASONS

Eugeny Afonin, Alexey MISHONOV, (Marine Hydrophysical Institute, 2 Kapitanskaya St., 335000, Sevastopol, Ukraine, e-mail: mishonov@alpha.mhi.iuf.net); Oleg Yunev (Institute of Biology of the Southern Seas, 2 Nakhimov Ave., 335011, Sevastopol, Ukraine, e-mail: yunev@ibss.iuf.net); Bob Williams (Plymouth Marine Laboratory, Prospect Place, The Hoe, Plymouth, PL1 3DH, United Kingdom, e-mail: bw@ccms.ac.uk).

A large data set of bio-optical parameters: upwelling radiation spectra, Secchi disk depth, colour of the seawater and concentration of phytoplankton pigments was obtained in the western tropical Atlantic during three expeditions of the RV Akademik Vernadsky (36th, 37th & 41st cruises). Research was carried out during different seasons (spring, summer & autumn) and against a background of different hydrographic situations. The region where the Amazon water mixes with oceanic water produces a wide variety of conditions in optical, biological and hydrographic properties. Remotely sensed seawater colour data for this region, obtained from CZCS and SeaWIFS sensors, were analysed to build up pictures of seasonal patterns. These patterns were correlated against ship collected spectrophotometer data and parameters measured in-situ in the three seasons. Measurements were taken of water transparency, chlorophyll concentration, number & biomass of the phytoplankton cells. These data were obtained from surface samples simultaneously together with hydrographic data. Changes in water colour in frontal zones were investigated and described.

P15/L/26-B3 1110

PARTICULATE ABSORPTION VARIABILITY IN THE ARABIAN SEA DURING BRITISH AND US JGOFS CRUISES

C.C. TREES (Center for Hydro-Optics & Remote Sensing, San Diego State University, 6505 Alvarado Rd., Suite 206, San Diego, CA 92120, email: ctrees@chors.sdsu.edu); J. Aiken (Plymouth Marine Laboratory, Prospect Place, Plymouth, United Kingdom); R. Bidigare (Department of Oceanography, University of Hawaii, Honolulu, HI 96822); J. Marra (Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY 10964)

Bio-optical properties were measured in the Arabian Sea and the Gulf of Oman during two British and five US JGOFS cruises (August 1994 to December 1995). Remote sensing algorithms have been developed relating water-leaving radiance ratios to diffuse attenuation coefficients, HPLC measured pigments and particulate absorption coefficients. Pigment specific total particulate and phytoplankton absorptions, when normalized to HPLC measured chlorophyll a, showed no spatial or temporal trends, indicating that the 'pigment packaging effect' is minimal. The variability in the pigment specific absorption coefficient is so large that for primary productivity modelling efforts, the use of a constant coefficient is probably not appropriate
for this region.

P15/L/22-B3 1135

ACTIVE IMAGING THROUGH TURBID WATER USING POLARIZED LIGHT

J G WALKER, P C Y Chang, E Jakeman K I Hopcraft, B Ablitt, (University of Nottingham, University Park, Nottingham, NG7 2RD, UK) D L Jordan and G D Lewis (Defence Research Agency, Malvern, Worcestershire WR14 3PS, UK)

Results are presented of a Monte Carlo study of the influence of using polarising optics in underwater imaging. The study considers a number of single-ended illumination and imaging geometries. The study is concerned with active illumination systems and considers both linear and circular polarisation illuminations. The simulation tracks the propagation of the light through the multiply scattering medium and rigorously calculates the Stokes vectors describing the polarisation state of each ray as it propagates. Results are presented for three types of scattering particles; spherical Rayleigh particles, non-spherical Rayleigh particles and spherical Mie particles. The object is treated as a planar diffuse reflector with various polarisation properties; namely, a target which preserves the incident polarisation state and a target which randomises the polarisation state of the light it scatters. The results clearly indicate that the effectiveness of polarisation discrimination in active-illumination imaging systems in overcoming the effects of light scattering are critically dependent on the polarisation properties of the surface to be imaged as well as those of the scattering medium.

RADIATIVE TRANSFER AND BIO-OPTICAL MODELLING

P15/L/28-B3 Invited **1200**

APPARENT OPTICAL PROPERTIES AND LAMBERT-BEER'S LAW, A NEW THE ORETICAL APPROACH

Robert MAFFIONE (Hydro-Optics, Biology, and Instrumentation Laboratories, 55 Penny Lane, Watsonville, CA 95076, email: maffione@hobilabs.com)

In the development of simplified radiative transfer or bio-optical models, a common approach is to apply the so-called Lambert-Beer's law to diffuse attenuation coefficients, usually referred to as apparent optical properties (AOP's). The diffuse attenuation coefficients are therefore treated as a linear sum of the individual attenuation coefficients of the various constituents of sea water. It is straightforward to show that this is theoretically incorrect, although this approach is thought to be a fairly good approximation. However, there is also a problem with the interpretation of the constituent attenuation coefficients that seems to have been overlooked. By a proper redefinition of the constituent attenuation coefficients, given here, a more useful interpretation arises and, moreover, the Lambert-Beer's law is shown to apply in a completely consistent mathematical fashion. Other useful mathematical results from this redefinition are described.

RADIATIVE TRANSFER AND BIO-OPTICAL MODELLING

P15/W/02-B3 1400

USING ANALYTICAL OPTIC CHANGES PREDICTIONS OF PLANKTON DEMOGRAPHY

Liu Cheng-Cheng (Huxley School, Imperial College, London SW7 2BP email: c.c.liu@ic.ac.uk); John Woods (Huxley School, Imperial College, London SW7 2BP email: j.woods@ic.ac.uk)

We report the first successful use of the Radiative Transfer Equation (RTE) to compute the irradiance profile interactively in a plankton ecosystem model. We have done so by incorporating a modified version of the analytical Hydrolight code (Mobley 1994) into the WB plankton ecosystem model (Woods and Barkmann 1994), which previously followed normal practice in using an empirical code (Morel 1988) to compute the vertical distribution of solar irradiance. When integrated by the Lagrangian Ensemble method (Woods and Barkmann 1994) the model simulates the demographies of explicit populations of diatoms and copepods treated as individuals. We have compared the annual cycle of those demographies in simulations based on the two optical methods: analytical and empirical. The former simulates BOFS (Lowry and Cramer 1994) data much better than the latter. However, the empirical code

provides a good first order simulation of the annual cycle in plankton demography. Compared with the empirical method, the analytical method predicts that the peak of the spring bloom in phytoplankton occurs 10 days later, and that copepod reproduction is 15% lower. Analytical optics provides a better prediction of satellite observations of the spring bloom.

P15/W/06-B3 1420

MODELLING THE SPECTRAL ALBEDO OF THE SEA JUST ABOVE THE WATER SURFACE FOR DIFFERENT TROPHIC TYPES OF CASE I WATERS

Slawomir B. WOZNIAK (Institute of Oceanology, Polish Academy of Sciences (PAS), ul.Powstancow Warszawy 55, Sopot, PL 81-712, Poland, email: woznjr@iopan.gda.pl)

A theoretical spectral model for calculating albedo of the sea just above the surface is developed. Model takes into account a part of irradiance reflected from the sea surface, as well as a part of irradiance scattered backward in the water body. As a 'surface part' of the model the previously developed model of downwelling and upwelling irradiance reflectance from and transmittance through a wind-ruffled sea surface was used. As an 'underwater part' of the model the theoretical formulae for distribution of radiance just below the sea surface (quasi single scattering model) and semi-empirical spectral model of absorption and backscattering were used. Based on the mathematical apparatus of the model the numerical calculations for different meteorological and hydrodynamic conditions and different trophic types of water were performed. Selected parts of calculations containing complex spherical integration were approximated with the polynomial functions. That procedure enabled to develop the simplified polynomial method for estimating the values of the albedo of the sea.

P15/E/03-B3 1440

DETERMINATION OF INHERENT OPTICAL PROPERTIES FROM SEAWIFS IMAGES

Gerald MOORE (CCMS, Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: G.Moore@CCMS.AC.UK); Jim Aiken (Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: J.Aiken@CCMS.AC.UK)

Models that invert inherent optical properties (IOPs) from satellite observations of reflectance provide an important intermediate stage in deriving remote sensed products that can be tuned for regional optical properties. The spectral reflectance derived from satellite observations in dependant on the absorption (a) and backscatter (bb) of the water itself, the a and bb of the biogeochemical constituents of the water column, the solar illumination and viewing geometry. Results from the Atlantic Meridional Transect (AMT) cruises and other published studies indicate that a and bb are highly constrained by the biogeochemistry. These biogeochemical constraints on the IOPs have been used to develop a model that can be solved by an interative procedure to determine the IOPs of both Case I and Case II waters, from measurements of above and below surface radiance reflectance, and irradiance reflectance. The effects of the viewing geometry are resolved by using discrete optical models for each viewing geometry. The procedure thus accounts for the BDRF effects on reflectance and enables the determination of the true normalised water reflectance and the diffuse attenuation coefficient. Results are shown for SeaWiFS imagery concurrent with the AMT-6 and AMT-6B cruises. Results from the model are validated against in-situ absorption, bio-optical measures and HPLC pigment analysis.

P15/L/19-B3 1500

BIO-OPTICAL MODELLING IN THE GULF OF AQABA (EILAT)

L. SOKOLETSKY, Z. Dubinsky, N. Stambler, D. Iluz and M. Shoshany (Bar-Ilan University, 52900 Ramat-Gan, Israel tel.: 972-3-5340856, 972-3-5358283; e-mail: sokolel@mail.biu.ac.i)

According to recently carried out Monte-Carlo simulations of H. R. Gordon and co-workers, four factors influence the upwelling radiance beneath the sea surface (Lu): the downwelling irradiance (Ed), the attenuation coefficient of Ed(Kd), the backscattering coefficient (bb) and the solar zenith angle beneath the sea surface (tetaw). We examine these factors on the basis of statistical processing of measured marine and atmospheric optical characteristics and of chlorophyll a (Chl a) and pheophytin concentrations, during the period 1990-1998 in the Gulf of Aqaba (Eilat) at different layers. We show that Lu is: (1) proportional to Ed; (2) decreases slowly with increase in Kd; (3) does not have a significant connection with bb and tetaw. Simple relationships between Kd, Ed and Luat the wavelength of 443 nm were obtained. Analogous, highly significant relationships between Chl a and these optical characteristics were also established. Our regional results, validated by us from ground-truth data for the northern Red Sea, will be compared with the global multichannel relationships used today by satellite sensors, such as SeaWiFS. Our aim will be to develop an optimal algorithm in term of precision and simplicity to suit the seasonally variable meso-oligotrophic waters under investigation.

DISCUSSION 1520

REMOTE SENSING, CALIBRATION, VALIDATION, INTERPRETATION AND METHODOLOGY

P15/L/29-B3 Invited 1550

CAN REMOTELY SENSED MEASUREMENTS PROVIDE ALL THE VARIABLES REQUIRED FOR OCEANIC CARBON CYCLE MODELS?

Jim AIKEN (Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: J.Aiken@CCMS.AC.UK)

Biological production drives all the processes in the ocean which relate to natural resources, fisheries and the sustainability of ecosystems and the air-sea exchange of biogenic gases, which are implicated in or responsive to the role of the oceans in the natural and anthropogenically forced green house effect and global climate change. A holistic approach, coupling large-area satellite remotely sensed observations of the marine environment, with oceanographic measurements of process rates and parameter values for models is a widely accepted approach for biological oceanography. Models can be used with remote sensing data, to extrapolate the in situ measurements horizontally to ocean basin scales and vertically to sub-surface layers, not measured by most remote sensors in space. Ultimately models will be used to predict the effects of pelagic primary production on the global biosphere and the responses of oceanic ecosystems to climate change.
Recent innovations of new measurements of phytoplankton photosynthetic parameter values (by Fast Repetition Rate Fluorometry, FRRF), new ocean colour sensors (SeaWiFS) and novel analytical bio-optical models have advanced the prospects for improved accuracy of basin scale productivity and carbon-cycle models. The models will be discussed, the availability of remotely sensed data assessed and the extrapolation to sub-surface layers considered.

P15/W/05-B3 1630

SATELLITE SENSING AND IN-SITU VALIDATION OF OCEANIC WATERS OF WESTERN AUSTRALIA

Peter RCS FEARNS, James E Davies, Mervyn J LYNCH (Remote Sensing and Satellite Research Group, School of Physical Sciences, Curtin University of Technology, GPO Box U1987, Perth WA 6845, Australia); Wilma J Vincent (School of Environmental Biology, Curtin University of Technology, GPO Box U1987, Perth WA 6845, Australia); Alan F Pearce (CSIRO Marine Laboratories, PO Box 20 North Beach WA 6020, Australia)

Curtin University researchers, in association with scientists from the CSIRO Marine Research and Fisheries Western Australia, have been conducting in situ validation of remotely sensed ocean colour products off Perth, Western Australia. On a monthly basis over a 27-month period, numerous biological and physical measurements have been made along a 40 km transect west of Hillarys Marina (20 km north of Perth). The 1997 launch of the ocean color sensor SeaWiFS (Sea-viewing Wide Field-of-view Sensor) provided remotely sensed ocean products coincident with in situ measurements along the Hillarys transect between November 1997 and December 1998.This paper presents a review of the in situ validation measurements of chlorophyll concentration, phytoplankton species counts, sea surface temperature (SST), temperature profiles, salinity profiles, and comparisons with satellite derived chlorophyll and SST measurements.

P15/W/07-B3 1650

HANDLING, PROCESSING AND FIRST INTERPRETATION OF SEAWIFS DATA IN THE GEOSONAR PROJECT

T. KNUDSEN, N. F. Carlsen, O. B. Andersen, and P. Knudsen (all at National Survey and Cadastre, Copenhagen NV, Denmark, email: thk@kms.dk); A. A. Nielsen, K. B. Hilger (both at IMM, Technical Uiversity of Denmark, Lyngby, Denmark)

The interdisciplinary project GEOSONAR (funded by the Danish Earth observation programme) analyses multi-disciplinary contributions to sea level and its variations on different time scales. This includes geodetic, oceanographic and meteorological effects on sea level, focussed in the North Atlantic and particularly the North Sea. In addition to traditional geodetic remote sensing techniques, such as altimetry, this project also involves the use of multi-channel scanning radiometers data, in the visible and infrared wavelengths. Data have been obtained from the Sea-viewing Wide Field-of-view Sensor (SeaWIFS), as well as from the NOAA advanced very high resolution radiometer (AVHRR), and the ERS along track scanning radiometer (ATSR). The results of a new handling and enhanced cloud removal scheme for SeaWIFS data is presented and the results are compared with data processed using the existing cloud removal scheme. This new cloud removal technique is based on maximum auto-correlation factors analysis (MAF). Extracting geodetic and oceanographic signal from these merged multi-channel data sources is non-trivial, however, the MAF analysis tool has also proven to valuable in the processing and initial interpretation of the data.

P15/W/08-B3 1710

SEASONAL BLENDED IN-SITU AND REMOTELY-SENSED OCEAN CHLOROPHYLL CLIMATOLOGIES

M.E. CONKRIGHT (NOAA/NODC, Ocean Climate Laboratory E/OC5, 1315 East-West Highway, Silver Spring, MD, 20910, USA, Email: mconkright@nodc.noaa.gov.W.W. Gregg (NASA/GSFC, Laboratory for Hydrospheric processes, Greenbelt, MD, USA, Email: gregg@cabin.gsfc.nasa.gov)

We have developed global seasonal climatologies of ocean chlorophyll, through the blending of in situ data (NOAA/NODC archives) and remotely-sensed data (NASA/GSFC archives) using the Conditional Relaxation Analysis Method. Blending of in situ chlorophyll and satellite remotely-sensed provides us with an enhanced data set by maximizing the strengths of each observational platform. Satellite chlorophyll data provide large horizontal coverage and improved temporal resolution but poor accuracy whereas in-situ data provide high quality (accuracy) but poor spatial and temporal coverage.
We focus on historical data from the Coastal Zone Color Scanner (CZCS) era (1978-1986), since sufficient in situ data are available for this time period. Differences between the blended and CZCS seasonal chlorophyll climatologies are observed primarily in coastal regions for all seasons. The blended climatologies are higher in these areas than the satellite data. These differences may have several sources, including time mismatches, sampling bias, and interannual variability. As data become available from satellites (e.g., from the Ocean Color and Temperature Scanner and Sea-Viewing Wide Field-of-View Sensor), and corresponding in-situ data are obtained, these methods will be expanded to produce a long-term blended data set encompassing the years 1978-1986 (years when CZCS was operational) and 1997-2002 (the period for which ocean color mission data are expected to be available.

P15/L/24-B3 1730

DERIVING BATHYMETRY FROM HYPERSPECTRAL DATA

W. D. PHILPOT (email: wdp2@cornell.edu, Cornell University, 220 Hollister Hall, Ithaca, NY 14853); and D.D. Kohler (email: ddk6@cornell.edu, Cornell University, 220 Hollister Hall, Ithaca, NY 14853)

Deriving bathymetric maps from passive remotely sensed imagery is an appealing prospect, but one that is prone to large errors and uncertainties. The advent of hyperspectral imagery raises the possibility of deriving more accurate bathymetric maps. Greater accuracy may be possible using standard analysis procedures but optimizing solutions using the greater number of spectral bands. It is more likely that new analysis procedures based on the spectral content of the data will yield greater accuracy in depth estimates as well as providing some information as to water quality and bottom reflectance. A new procedure that does take this extra information into account has been developed. The technique which is based on the use of spectral derivatives, significantly improves the accuracy of the depth estimates in test data. The technique is being adapted for use with hyperspectral image data.

REMOTE SENSING, CALIBRATION, VALIDATION, INTERPRETATION AND METHODOLOGY (Continued)

P15/E/01-B4 0900

ATMOSPHERIC CORRECTION OF SEAWIFS IMAGERY OVER HIGHLY TURBID CASE II WATERS

Samantha LAVENDER (CCMS, Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: S.Lavender@CCMS.AC.UK); Gerald Moore (CCMS, Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: G.Moore@CCMS.AC.UK)

The successful exploitation of remotely sensed observations of water colour requires the development of atmospheric correction methods in coastal waters, and the determination of the concentration of suspended particulate matter (SPM) concentrations in gravimetric units for use in mass flux studies and hydrodynamic models. The remote sensing of turbid waters (Case II) using SeaWiFS requires new approaches for the atmospheric correction of the data. Unlike open ocean waters (Case I) there is significant water leaving radiance at infrared wavelengths, so conventional 'dark pixel' atmospheric correction procedures are invalid. A coupled hydrological atmosphere model is described that solves the water leaving radiance and atmospheric path radiance in the near infra-red (NIR) over Case II turbid waters. The theoretical basis of this model is described, together with its implementation in the current CCMS/PML processing architecture called the SeaWiFS Automated data processing system (SeaAPS). SeaAPS and the resulting products are being validated using both in-situ measurements of water-leaving radiance and suspended particulate matter, in collaboration with European research projects. This research is an important step in deriving biogeochemical parameters for turbid Case II waters.

P15/L/21-B4 0925

ESTIMATION OF AEROSOL PROPERTIES FROM OCTS AND POLDER DATA FOR OCEAN COLOR REMOTE SENSING

Yasushi MITOMI (1), Riko HIGUTCH (1), Hajime FUKUSHIMA (2), and Tamio TAKAMURA (3).
(1) Remote Sensing Technology Center of Japan , Roppongi First Bldg. 8F, 1-9-9, Roppongi, Minato-ku, Tokyo 106-0032, Japan, Email: mitomi@restec.or.jp, hriko@restec.or.jp
(2) School of High-Technology for Human Welfare, Tokai University, 317 Nishino, Numazu 410-0395, Japan, Email: hajime@fksh.fc.u-tokai.ac.jp
(3) Center for Environmental Remote Sensing, Chiba University, 1-33 Yayoi-cho, Inage-ku, Chiba 263-8522, Japan

The atmospheric correction in ocean color remote sensing seeks to retrieve the water leaving radiances from the total radiances observed at satellite altitude. Its accuracy depends on the estimation error of the radiance scattered and absorbed by aerosol which is highly variable in both space and time. ADEOS/OCTS has three observation bands (670, 765, and 865nm) in the near-infrared region to measure aerosol properties (eg., aerosol type and optical thickness) and the radiances at 670 and 865nm are used to generate NASDA's OCTS ocean color productrs. POLDER onboard ADEOS together with OCTS has the aerosol observation bands similar to the OCTS and also has multi-angle polarization data, but its spacial resolution (7km * 6km) is inferior to the OCTS (700m at nadir). In this research, the aerosol informations derived by OCTS and POLDER were compared. Furthermore, an estimation method of the aerosol properties by the composite data from the two different sensors was discussed in order to improve an accuracy of the atmospheric correction. These results are reported in this presentation.

Presiding Chair: John Cullen (Center for Environmental Observation Technology and Research, Department of Oceanography, Nova Scotia Canada,)

PRIMARY PRODUCTION AND BIOGEOCHEMICAL FLUXES

P15/L/30-B4 Invited 0950

PRIMARY PRODUCTION FROM NEW SATELLITE OCEAN COLOUR SENSORS

André Morel and David Antoine

Based on a spectral light-photosynthesis model, previously operated in conjunction with the CZCS imagery, the primary production at global (and basin) scales has been derived from SeaWIFS data, namely from the monthly composites of the chlorophyll distribution, and over a period of one year. Climatological fields of temperature and mixed layer depth have been utilised for the derivation. The actual cloudiness fields, contemporaneous of the SeaWIFS data capture are not yet available, so that the climatological cloudiness fields (ISCCP data base, for the 1983-1990 period , previously used with the CZCS data) were again used to estimate the incident irradiation at the ocean surface, which is an input for the model.
Therefore the difference between the primary production estimates based on the data delivered by the two sensors (CZCS and SeaWIFS) can only originate from differences in the chlorophyll fields and in their temporal evolutions. The excellent consistency between the chlorophyll determinations made by the two sensors leads to an excellent agreement between the derived annual primary production at global and basin scales, despite slightly differing temporal evolution (in Pacific, in particular). Chlorophyll data from the OCTS instrument are also transformed in the same way into primary production maps, for a 8 months period, prior to the launch of the SeaWIFS instrument. A more realistic and accurate comparison between these results will be possible as soon as the actual cloudiness distribution for the involved periods are available. Sensitivity analyses effected with the model allow to predict that replacing an « academic » cloud field by an actual one will not entail large differences in terms of production.

P15/W/04-B4 1055

STATISTICAL RELATIONSHIPS BETWEEN LIGHT CONDITIONS IN THE SEA AND PHOTO-PHYSIOLOGICAL CHARACTERISTICS OF MARINE ALGAE.

Bogdan WOZNIAK (1,2), Jerzy Dera (1), Dariusz Ficek (2), Roman Majchrowski (2), Slawomir Kaczmarek (1), Miroslawa Ostrowska (1), Olga J. Koblentz-Mishke (3).1) Institute of Oceanology, Polish Academy of Sciences (PAS),ul. Powstancow Warszawy 55, Sopot, Poland, PL 81 -712, e-mail: wozniak@iopan.gda.pl 2) Institute of Physics, Pedagogical University in Slupsk,ul Arciszewskiego 22, Slupsk, Poland, PL 76 – 200 3) Shirshov Institute of Oceanology, Russian Academy of Sciences (RAS),ul. Krasikova 23, Moscow, Russia 117218.

Due to photo- and chromatic - acclimation processes of phytoplankton cells the light conditions in the sea affect the particular photosyntetic and photoprotecting pigments contents in marine phytoplankton cells. It is manifested in diversity of spectral absorption properties of phytoplankton and has also indirect influence on quantum yield of photosynthesis. The aim of this work is to find relationships between spectral composition and absolute level of the PAR irradiance in the sea and photophysiological characteristic of algae. This aim was achieved with statistical analysis of appropriate data sets from a few hundred stations from the world oceans. As a result the model which allows to estimate as follow: the phytoplankton pigments composition, the light absorption coefficient for all pigments and its components from photosynthetic and photoprotecting pigments for the given light conditions in the sea, was worked out. This model also allows to determine variability of quantum yield of photosynthesis due to changes in proportions between photosynthetic and photoprotecting phytoplankton pigments.

P15/W/09-B4 1115

MODELLED AND MEASURED PRIMARY PRODUCTION DISTRIBUTION IN THE BALTIC

Slawomir Kaczmarek (1), Miroslawa Ostrowska (1), Olga J. Koblentz-Mishke (2), Bogdan Wozniak (1). 1) Institute of Oceanology, Polish Academy of Sciences (PAS), ul. Powstancow Warszawy 55, Sopot, Poland, PL 81 -712, e-mail: kaczmar@iopan.gda.pl. 2) Shirshov Institute of Oceanology, Russian Academy of Sciences (RAS), ul. Krasikova 23, Moscow, Russia 117218.

The results of primary production modelling for the Baltic Sea, which is typical case 2 waters basin, are presented. Earlier established, the bio-optical relationships for oceanic case 1 water were a base of a primary production model. Using the empirical data gathered from the Baltic Sea the model's parameters were adopted to obtain a model appropriate for the Baltic. This model was used to estimate primary production in the Southern Baltic region, divided into 20 sub-regions. The mean monthly primary production have been calculated for each month of the year. As the model input data, the long-term (over 20 years) monthly means of hydro-meteorological parameters and surface chlorophyll a concentration have been used. The model results were compared with the map of yearly primary production obtained after analyses of long-term "in situ" measured data. Both data sets relate to the same period. Such comparison allows discuss the advantages and limitations of the primary production bio-optical modelling especially in the context of remote sensing data assimilation.

P15/E/04-B4 1135

DETERMINATION OF PHYTOPLANKTON PHOTOSYNTHETIC CHARACTERISTICS AND PRODUCTION FROM REMOTE SENSED REFLECTANCE.

Gerald MOORE (CCMS, Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: G.Moore@CCMS.AC.UK); Jim Aiken (Plymouth Marine Laboratory, Prospect Place, Plymouth PL1 3DH, UK, email: J.Aiken@CCMS.AC.UK)

Currently available remote sensed algorithms supply information in terms of biomass normalised to chlorophyll concentration. In addition, these algorithms implicitly fix the spectral shape of the absorption characteristics of phytoplankton, by using simple band ratios, and assume that optically active dissolved organic material (ODOM) is a fixed proportion of phytoplankton absorption. The use of an algorithm that inverts remote sensed reflectance to the IOPs of spectral absorption (a) and backscatter (bb) enables the determination of the major pigment classes chlorophyll, photosynthetic carotenoids, photoprotectant carotenoids, and co-varying ODOM concentration.
The results from the optical model have been used to differentiate the rate of phytoplankton photosynthetic pigment absorption from non-photosynthetic absorption, and thus derive production estimates based on fixed quantum yield.
The absorption model measurements are compared with data from the Atlantic Meridional Transect (AMT) cruise using in-situ absorption and simulated absorption derived HPLC pigment concentrations. The production estimates are compared with 14C measurements taken on the AMT-6 cruise. Production maps of the AMT cruise region are computed from data from the SeaWiFS sensor.

DISCUSSION 1155

P15/L/01-B4 Invited 1205

PRIMARY PRODUCTIVITY OF THE WESTERN ANTARCTIC PENINSULA REGION AND THE SOUTHERN OCEAN

Raymond SMITH & Heidi Dierssen (Institute for Computational Earth System Science (ICESS); University of California, Santa Barbara, CA, 93106, USA, email: ray@icess.ucsb.edu, dierssen@icess.ucsb.edu); Karen Baker & Maria Vernet (Scripps Institution of Oceanography(SIO/MRD); University of California, San Diego, La Jolla, CA 92093-0218, USA, email: kbaker@ucsd.edu, mvernet@ucsd.edu)

Phytoplankton production in the Southern Ocean is poorly known compared to temperate ecosystems. The relative inaccessibility, paucity of data, large area, extreme environmental conditions, and the potential role of the Southern Ocean carbon cycle in response to rising atmospheric CO2 are compelling reasons for optimizing models for the estimation of phytoplankton production remotely. Further, there is now strong evidence that the bio-optical roperties of these Antarctic waters are significantly different than temperate waters. Consequently, both the retrieval of chlorophyll concentrations and the subsequent estimation of phytoplankton production from satellite sensed reflectance measurements require regional specific algorithms for optimum accuracy. Based upon data from the Palmer Long Term Ecological Research (PAL/LTER) program we have optimized retrieval algorithms and utilized a depth-integrated primary productivity model to estimate biomass and productivity in Antarctic waters. Poductivity results are compared with previous published estimates and sensitivity studies evaluated. The space-time distribution and the seasonal and interannual variability are discussed within the context of contribution to the overall Southern Ocean marine ecology.

UV RADIATION MEASUREMNENTS AND ECOLOGICAL CONSEQUENCES

P15/L/18-B4 1400

ESTIMATING UV ATTENUATION AND PHOTOCHEMICAL REACTION RATES FROM REMOTE SENSING OF OCEAN COLOR

John J. CULLEN, Richard F. Davis, Barbara Nieke (all at Center for Environmental Observation Technology and Research, Department of Oceanography, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada, Email: John.Cullen@Dal.ca, Richard.Davis@Dal.ca, bnieke@raptor.ocean.dal.ca),

Sophia Johannessen and William L. Miller (both at Department of Oceanography, Dalhousie University, Email: schjohan@is2.dal.ca, William.Miller@Dal.ca).

Previously, we outlined a method for using measurements of upwelling radiance in the visible to quantify UV-dependent processes in aquatic systems: 1) attenuation coefficients for UV and visible irradiance are estimated from spectra of upwelling radiance at the surface, based on empirical relationships between ratios of upwelling radiance and near-surface diffuse attenuation coefficients; 2) total absorption is related to attenuation by accounting for geometry of the radiance field; 3) total absorption is partitioned among colored dissolved organic matter (CDOM; essential to photochemistry), water, and particulate matter using published coefficients for water, estimates of chlorophyll from blue:green reflectance ratios, and assumed chlorophyll-specific particulate absorption spectra; 4) solar irradiance at the surface is calculated from a model, tuned with observations from a filter-based radiometer; and 5) laboratory-derived action spectra, modeled irradiance, and estimated CDOM vs total absorption are used to quantify rates of photochemical transformation. In principle, this approach can yield synoptic estimates of photochemistry from airborne sensors. Here, we parameterize the model with recently obtained data from several marine environments, along with an action spectrum for photochemical production of carbon monoxide from CDOM, to estimate the photochemical production of CO using aircraft remote sensing of ocean color. The precision of key empirical relationships (e.g., between diffuse attenuation coefficients in the UV and ratios of upwelling radiance in the visible) is assessed, and the uncertainty of estimates is partially described.

P15/E/05-B4 1445

PENETRATION OF UVB IRRADIANCE INTO THE NORDIC SEAS AND ADJACENT COASTAL WATERS

Eyvind AAS (Department of Geophysics, University of Oslo, N-0315 Oslo, Norway, Email: eyvind.aas@geofysikk.uio.no); Niels K. Hoejerslev (Niels Bohr Institute of Astronomy, Physics and Geophysics, University of Copenhagen, DK-2100 Copenhagen O, Denmark,
Email: nkh@gfy.ku.dk)

Data for downward UVB irradiance at about 200 stations in the Nordic Seas and the adjacent coastal waters have been analysed. The depth where the irradiance is reduced to 10% of its surface value, Z(10%), ranges from 0.1 to 16 m. For comparison very clear ocean water (Gulf of Mexico) has a Z(10%) value around 35 m. In the German Bight the mean value of Z(10%) is 0.8 m, in the Kattegat 0.9 m, and in the Skagerrak 2.5 m. In the Norwegian Coastal Current the observed mean value is 4.6 m, while the mean values of Z(10%) in Svalbard waters have been observed to be either 5 or 10 m, depending on season. The Norwegian Atlantic Current has the mean value 15 m during non-bloom conditions, but phytoplankton blooms seem to be able to reduce Z(10%) by a factor of up to 3. Yellow substance, suspended organic and inorganic matter all contribute to the variation of Z(10%) in highly different proportions depending on both location and season. Solar elevations have a minor effect on Z(10%) according to the measurements performed in the region considered. Finally, penetration of UVB irradiance in waters dominated by yellow substance is not straightforward to model based on spectral irradiance measurements in the visible part of the spectrum. This is due to the fact that the spectral absorbance of yellow substance is much more complex than previously and traditionally anticipated.

P15/L/16-B4 1505

SEASONAL VARIABILITY IN THE RELATIVE PENETRATION OF UVR AND PAR IN TEMPERATE COASTAL WATERS

KUWAHARA, V. S.1, H. Ogawa2, T. Toda1, T. Kikuchi3, S. Taguchi1; (Faculty of Engineering, Soka University1; Faculty of Ocean Research, Tokyo University2; Faculty of Education and Human Sciences, Yokohama National University3)

Seasonal UVR penetration variability was surveyed for three consecutive years in the temperate coastal waters of Sagami Bay, Japan. Integrated mixed layer samples of sea- water were concurrently collected for chlorophyll a analysis. Dissolved organic carbon (DOC), particulate organic carbon (POC), and the absorption coefficient of the dissolved (acDM) and particulate material (acPM) were also measured during one year. The 1% attenuation depth of 305, 320, 340 and 380nm calculated from the diffuse attenuation coefficient (Kd) averaged 11.4Å}6.34, 14.06Å}8.30, 18.68±10.90, and 29.81Å}15.79m, respectively for the three years with minimum penetration occurring near summer solstice. Breaks in the slopes of Kd (multiple Kd patterns) were also observed during particular summer months for 340nm, 380nm, and PAR. The relative penetration of UVR into the euphotic zone (1% penetration depth of PAR) averaged 19Å}9% for 305nm, 24Å}11% for 320nm, 32Å}14% for 340nm, and 49Å}20% for 380nm accordingly. Seasonal variability in UVR transparency was attributable to changes in concentrations of DOC, Chl a, and POC. This was further supported by results from the acDM and acPM analysis. The percent contribution of acDM and acPM varied with season.

DISCUSSION 1525

P15/L/17-B4 1550

FLUX OF CARBONYL SULFIDE FROM THE OCEANS USING SEAWIFS CHLOROPHYLL CONCENTRATION ESTIMATESA.

J. KETTLE, T. S. Rhee, M. V. Hobe, and M. O. Andreae (Biogeochemistry Department, Max Planck Institute for Chemistry, P. O. Box 3060, D-55020 Mainz, Germany, email: ajkettle@mpch-mainz.mpg.de)

Carbonyl sulfide (COS) is a long lived atmospheric molecule which is oxidized in the stratosphere to sulfate particles which may alter the radiation budget of the earth's surface. One of the more important sources of COS is the upper ocean where it is produced photochemically as the result of the interaction of solar ultraviolet light with colored dissolved organic matter. The principal sinks of the molecule from the oceanic mixed layer are hydrolysis and surface outgassing to the atmosphere. The interaction between the production and loss terms controls the flux of the molecule to the atmosphere. The recent meridional transect of the James Clark Ross from England to the Falkland Islands in September-October, 1998 provided an opportunity to investigate the flux of COS to the atmosphere. During the cruise, atmospheric and sea surface concentrations of COS were measured, in addition to the ultraviolet absorbance and fluorescence of seawater, chlorophyll concentration, insolation, wind speed, and other meteorological parameters. Earlier measurements have suggested a relationship between the ultraviolet absorbance of seawater and the chlorophyll concentration. Using this relationship, it is proposed that the SEAWIFS data can be used to estimate the global CDOM absorbance. The global photochemical production of COS can then be estimated using climatological information for insolation. Using climatological temperature fields to constrain the physical hydrolysis process and climatological mixed layer depths to constrain the amount of dilution of the tracer, it is possible to develop a simple model of global COS near surface concentration and outgassing to the atmosphere.
The results of the ship expedition are used to verify the predictions of this simple model.

RESPONSE OF BACTERIOPLANKTON TO DIFFERENT INTENSITIES OF ULTRAVIOLET-B RADIATION: A MESOCOSM STUDY

Khaled CHATILA, Serge Demers, Behzad Mostajir, Jean-Pierre Chanut (all at Groupe de Recherche en Environnement Côtier, Institut des Sciences de la Mer de Rimouski (ISMER), Université du Québec à Rimouski, 310 Allée des Ursulines, Rimouski (Québec), Canada, G5L 3A1, email: khaled_chatila@uqar.uquebec.ca) Patrick Monfort (Laboratoire d'Hydrobiologie Marine et Continentale, Unité Mixte de Recherche "Écosystèmes lagunaires", Université Montpellier II - CNRS (UMR 5556) Case 093, F-34095 Montpellier Cedex 05, France, email: pmonfort@crit.univ-montp2.fr)

The recent decreasing trends of stratospheric ozone concentration and the subsequent increases of ultraviolet-B radiation (UVBR) reaching the Earth's surface have raised concern about the possible impact of this radiation on aquatic ecosystems. In July 1996, the effects of excluded, natural and artificially enhanced UVBR on the summer planktonic community (<240mm) of the lower St. Lawrence Estuary (Québec, Canada) were studied during a week-long mesocosm experiment. Experimental water was continuously mixed by a pumping system. The present work was a part of this experiment and addressed the response of bacteria to the tested light regimes. Our data suggest that UVBR may have both inhibiting (by directly acting on cellular processes) and stimulating effects on bacterioplankton (by increasing the release of labile substrates from UVBR stressed phytoplankton or by decreasing cells removal by UVBR sensitive bacterivores). On an ecosystem level, overall bacterial response to UVBR will be the net result of these competing processes.

P15/L/27-B4 1630

GLOBAL MAPPING OF UNDERWATER UV FLUXES AND DNA-WEIGHTED EXPOSURES USING TOMS AND SEAWIFS DATA PRODUCTS

Alexander VASILKOV, Nickolay Krotkov (both at Raytheon ITSS Co., 4400 Forbes Blvd., Lanham, 20706 USA), Jay Herman (NASA/Goddard Space Flight Center, Greenbelt, 20771 USA)

The global stratospheric ozone layer depletion results in an increase in biologically harmful ultraviolet (UV) radiation reaching the surface and penetrating to ecologically significant depths in the natural waters. Such an increase could be estimated on a global scale by combining satellite estimates of the UV irradiance at the ocean surface from the Total Ozone Mapping Spectrometer (TOMS) satellite instrument with the satellite ocean color measurements in the visible spectral region from the SeaWiFS instrument. In this paper we propose a model of seawater optical properties in the UV spectral region based on the Case 1 water model in the visible range. The inputs of the model are standard products of ocean color sensors: chlorophyll concentration and the diffuse attenuation coefficient at 490 nm. Penetration of solar UV radiation at different depths into open ocean waters is calculated using the quasi-single scattering approximation of the radiative transfer (RT) in the water. The separation of the ocean and atmospheric RT problems in the UV spectral region is discussed. The accuracy of the RT approximation in the water is tested using accurate Monte Carlo modeling. The sensitivity study of the underwater UV irradiance to atmospheric and oceanic optical properties is performed based on the model proposed. The simulations have shown that the main environmental parameters controlling the levels of the most harmful UVB (280-320nm) radiation underwater for clear sky conditions are: solar zenith angle, water optical properties and total ozone.Weekly maps of underwater UV irradiance and DNA weighted exposure are calculated using monthly mean SeaWiFS chlorophyll a and diffuse attenuation coefficient products and the TOMS-derived surface UV irradiance weekly maps. The final products include global maps of depths, at which UVB flux and DNA weighted dose rate are equal to 10% of their surface values.

LONG-TERM MONITORING OF OCEANIC SEISMICITY USING UNDERWATER ACOUSTIC TECHNIQUES

Christopher G. FOX, Robert P. Dziak (both at NOAA, Pacific Marine Environmental Laboratory, 2115 S.E. OSU Drive, Newport, OR 97365 USA email: fox@pmel.noaa.gov)

Monitoring oceanic seismicity using underwater acoustic techniques offers several advantages over land-based seismic networks, including a lower detection threshold, improved location accuracy, and the ability to monitor large areas of the ocean with relatively few sensors. The availability of the U.S. Navy's SOund SUrveillance System (SOSUS) to the scientific community has allowed long-term monitoring of seismicity in the North Pacific Ocean to be accomplished at relatively low cost. Detailed maps of overall seismicity are now available for structural interpretation of plate tectonic activity. Episodes of volcanic seismicity associated with seafloor spreading, generally with magnitudes less than 3.0, have been successfully detected by SOSUS three times and verified in the field. Patterns of intraplate deformation have also been discovered, including both isolated intraplate earthquakes and patterns of intraplate activity relating to large-scale stresses on the plate. Based on the success of its SOSUS efforts, NOAA developed and deployed an array of autonomous hydrophones in the equatorial Pacific in May, 1996. Seismicity from the equatorial region of the Pacific shows a similar pattern to that in the northeast Pacific, with most activity confined to subduction zones and transform fault zones, with some indications of intraplate seismicity and volcanic seismicity along the ridge crest. The inferred volcanic episodes along the fast-spreading-rate

East Pacific Rise (EPR) are of short duration relative to confirmed activity along the medium-spreading-rate Juan deFuca/ Gorda Ridges (hours-days versus days-weeks). These shorter volcanic episodes may simply represent the nature of the activity or perhaps reflect lower seismic magnitudes due to a thin brittle layer. In February 1999, a second array of hydrophones was deployed in the North Atlantic between 10N and 40N in a two-year experiment to monitor the Mid-Atlantic Ridge (D. Smith, WHOI; M Tolstoy, LDEO; C. Fox, NOAA, PIs). Analogy to the Pacific examples would predict fewer, longer duration volcanic episodes and larger magnitude fault plane earthquakes. Additional monitoring efforts, based on either routine ship access or the establishment of permanent ocean stations, will depend on partnerships with the international research community and other U.S. agencies, but could eventually lead to a global acoustic monitoring system.

P16/L/01-B5 0910

FOUR-YEARS' CHANGE OF THE TAG HYDROTHERMAL MOUND OBSERVED BY SUBMERSIBLESHINKAI 6500

Kantaro FUJIOKA (Deep Sea Research Department, Japan Marine Science & Technology Center, Yokosuka, 237-0061 JAPAN, email: fujiokak@jamstec.go.jp), Hitoshi Chiba (Institute for study of the Earth's Interior, Okayama University, 827 Yamada, Misasa, Tottori, 682-0193 JAPAN, email: hchiba@misasa.okayama-u.ac.jp), Harue Masuda (Department of Geophysics, Osaka City University, 3-3-138 Sugimoto, Sumiyoshi-ku, Osaka, 558-8585 JAPAN,
email: harue@sci.osaka-cu.ac.jp), MEGATRAIN scientific party

The TAG hydrothermal mound is one of the largest hydrothermal mounds known in the world. Since the first finding of the mound its whole edifice, stratigraphy and structure, chemistry and long-term change were made clear by the previous studies. Here we present new data sets on the location of active vents, type of smokers, and chemistry of the hydrothermal fluids. The TAG hydrothermal mound is migrating with NNE-SSW trending fault movement since 1994 to form the two new black smoker mounds east of the Central Blacksmoker Complex previously existed. The chemical compositions of the vent fluids did not change al all even 17 ODP drill holes were dug up on and around the TAG mound. We detected big change of the Eh, pH, CTDT and gamma ray intensity along the vents and faults on the mound. We also found the existence of the plume structure by the measurements during the descent and ascent the submersible. The TAG hydrothermal mound is now migration together with fault system suggesting that the pass way of the hydrothermal fluid changes without any reaction with the mound forming materials since 1994.

P16/E/03-B5 0930

DEEP-SEA SUBMERSIBLE MAGNETICS ACROSS A MID-OCEAN RIDGE

J. DYMENT, M. Ravilly (both at CNRS, IUEM, Univ. Bretagne Occidentale, Plouzané, France; email: jerome@univ-brest.fr); C. Honsho (Ocean Research Institute, Univ. Tokyo, Japan); M. Perrin (CNRS, ISTEEM, Univ. Montpellier II, Montpellier, France); H. Horen (Ecole Normale Supérieure, Paris, France); P. Gente (CNRS, IUEM, Univ. Bretagne Occidentale, Plouzané, France)

A unique set of magnetic data has been acquired on the Mid-Atlantic Ridge spreading segment at about 21°40'N during the Tammar cruise of R/V Nadir and deep sea submersible Nautile. The data include surface scalar magnetic field collected by the ship, sea-bottom vector magnetic field continuously measured along the dive track by a three component magnetometer attached to Nautile, and measurements of rock magnetic properties and absolute paleointensities on samples collected by the submersible. Fifteen dives make three almost-continuous traverses of the spreading center, and four additional dives at the axis allow examination of magnetic variations along the axis. The surface magnetic anomaly and the long-wavelength part of the sea-bottom magnetic anomaly were inverted to equivalent magnetization. Because they were measured close to the seafloor, the observed sea bottom anomalies contains short-wavelength variations produced by the topography and the up-and-down motion of the submersible. We estimate the magnetisation of the seafloor along the dive tracks by comparing the amplitude of these short-wavelengths with synthetics calculated for different uniform magnetisation of the seafloor. About 130 direct measurements of the natural remanent magnetisation and magnetic susceptibility have been made on the samples. In addition, successful determinations of the geomagnetic field paleointensity by the Thellier method have been obtained for 34 samples of the two traverses located in the segment center. These data offer a unique opportunity to study the structure and magnetic properties of the oceanic crust and the source of marine magnetic anomalies.

P16/E/13-B5 0950

LONG TERM DEEP SEAFLOOR MONITORING AT COLD SEEPAGE SITE OFF HATSUSHIMA ISAND IN SAGAMI BAY

Ryoichi IWASE, Hiroyasu Momma, Kyohiko Mitsuzawa and Katsuyoshi Kawaguchi (Deep Sea Research Department, Japan Marine Science and Technology Center, 2-15 Natsushima-cho, Yokosuka, 237-0061, Japan, email: iwaser@jamstec.go.jp)

Real time deep seafloor monitoring has been carried out for more than 5 years by the cable-connected observatory which was deployed at the cold seep community site at a depth of 1174m off Hatsushima Island in Sagami Bay, central Japan in 1993. It is equipped with video cameras, subbottom temperature probes, a current meter, a CTD, a seismometer and a hydrophone. Through 5 year monitoring, seasonal variations of subbottom temperatures which increased in spring and had a peak in April or May were observed, although the seasonal variations of water temperature were not so obvious. The increase of the amount of suspended particles which are considered to be produced by the spring bloom in the shallow water were also observed in spring by the video camera. The sedimentationn of these particles seems to affect the subbottom temperatures. The daily variations of subbottom temperatures which correlated with the variation of hydraulic pressure i.e. ocean tide were also observed. These are considered to have some relation with the behaviour of cold seepage. When the earthquake swarms occurred at about 7 km southwest of the observatory in March, 1997 and in April and May, 1998, mudflows were observed by the observatory. Considering from video images, bottom current profiles and the results of deep-tow survey around the observatory after the earthquake in 1997, mudflows seem to be caused by the landslides of the unstable surface sediment on the slope in the west of the observatory. The subbottom temperatures increased more than 1 degree C in only several days just after the occurrence of mudflows. These seem to be caused mainly by rapid sedimentation associated with mudflows.

P16/E/10-B5 1010

COMPREHENSIVE DEEP SEAFLOOR MONITORING SYSTEM OFF CAPE MUROTO, WESTERN JAPAN

Hiroyasu MOMMA (Ocean Engineering Department, JAMSTEC, 2-15 Natsushimacho Yokosuka 237-0061, Japan, e-mail: mommah@jamstec.go.jp)

Great submarine earthquakes at a scale of magnitude 8 (M8) occurred successively in 1944 and 1946 in the Nankai Trough off Cape Muroto and Kii Peninsula , the western region of Japan. Since similar great earthquakes have repeated at intervals between 100 and 150 years, there has been no seafloor seismic network in this area. As a step to increase the seafloor network, a comprehen sive deep seafloor monitoring system was developed by the JAMSTEC to monitor the seismic activity and deep-sea environment in the Nankai Trough off Cape Muroto. The system consists of observatories with a cable and without cable. The cabled observatory comprises of two accelerometer type seismometers, two Tsunami pressure gauges, a multi-sensor cable-end station with video camera, CTD, current meter, etc., 125 km long optical submarine cable, and a land station at Muroto. All the data are sent and stored in real time to the land s tation, and they are also transmitted to JAMSTEC and Meteorological Agency of Japan. It was deployed at water depths between 1,290 meters and 3,572 meters in March 1997. The observatory without cable comprises of a multi-sensor mother station and four satellite stations. The mother station is equipped with a velocity type seismometer, a Tsunami pressure gauge, a digital camera with flash, a CTD, an electro-magnetic current meter, two heat flow temperature probes, a hydrophone and 16 pop-up buoys. The data in mother station could be monitored monthly through satellites by releasing pop-up buoys. After one year long observation, all the data in 8 GB hard disc is retrieved by recovering the station. Each satellite station comprises of a long-term velocity type digital ocean bottom seismometer (OBS) which could be recorded three -component seismic data continuously for two months. The data in 2 GB Exabyte tape could be retrieved by recovering the station. The observatory without cable finished preliminary observation in 1998 for four months at a depth around 1,400 meters. In total, five systems, similar to that off Cape Muroto, will be deployed around Japan.

P16/E/04-B5 1050

MONITORING THE MID-ATLANTIC RIDGE: THE MOMAR PROJECT

Pascal TARITS and the Momar Working Group (IUEM/UBO, UMR CNRS 'Domaines Océaniques', Place Nicolas Copernic, F-2980, Plouzané, France, email: tarits@univ-brest.fr)

Over the coming years, the European and international community of multidisciplinary ridge researchers is seeking to initiate a comprehensive long-term program to monitor the Mid Atlantic Ridge (MAR) near the Azores (MOMAR). This program is designed to conduct in-depth inquiries into the issues of:
How does this mid-oceanic ridge environment change with time (in terms of seismicity, volcanism, hydrothermal venting and the distribution and characteristics of biological populations)? How do these changes affect heat and chemical transfer to the overlying ocean, ecosystem development, faunal succession and biological productivity? What are the components and space/time extent of the subseafloor biosphere? What are the dominant controls on volcanism, hydrothermalism and faulting at this ridge axis, and how are these processes connected?
This program is being initiated by InterRidge, an international program for the coordination of ridge studies that has a strong European component (7 out of the 9 member countries are European). It is planned to be the most ambitious and comprehensive effort to date for the multidisciplinary monitoring of a mid-ocean ridge system. It will follow up on previous experiments carried out by American researchers in the Pacific (mainly on the Juan de Fuca ridge) and by Japanese researchers on the East Pacific Rise. The program will extend the scope of these experiments beyond the monitoring of individual volcanoes or vent sites, to integrated monitoring of all axial processes in the studied region.
The MOMAR project will include the deployment in the Azores region of a variety of monitoring tools, some of which have been successfully deployed in the past, while some will need to be specifically designed. Efforts will be made to involve engineering specialists from industry backgrounds in the development of these tools, and to publicise their potential for monitoring other active underwater environments. The use of submarine cables and moored buoys to transmit data and provide the energy necessary to work these tools are also envisioned as part of the project and will require co-ordinated technological efforts on the part of the participating countries.

P16/W/03-B5 1110

NEPTUNE: A FIBER OPTIC TELESCOPE TO INNER SPACE

A.D. CHAVE (Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA; e-mail: alan@whoi.edu), J.R. Delaney (University of Washington, Seattle, WA 98195, USA)

Investigation of the Earth as a dynamic system will require new intellectual approaches in the ocean sciences. We submit that it will also require a co-ordinated investment in a new mode of conducting oceanographic investigations through the establishment of long-term (i.e., "permanent") observatories on the seafloor. To effectively model the complex interactions involved in ocean systems, a submarine presence must be used which returns four-dimensional (three spatial dimensions plus time) data sets from multiple arrays of physical, chemical, and biological sensors deployed specifically to characterise the covariant nonlinear behaviour of the major planetary systems. North East Pacific Time-integrated Undersea Networked Experiments (NEPTUNE) is a concept for a series of interactive seafloor observatories to investigate highly active plate tectonic and oceanographic systems off the Washington-Oregon coast. This can be accomplished by establishing a series of strategically-located, state-of-the-art seafloor observatories capable of 1) real-time transmission of data and images from many hundreds of instruments, 2) routine robotic responses controlled from shore, and 3) distribution of power to the system. The single-most important technology required to achieve this capability is a fibre-optic cable system, designed to link a series of seafloor communication nodes to shore, enabling and controlling the data flow and power transmission required for comprehensive long-term observations and routine remote interventions. In fact, with such a facility, individual seafloor instruments or arrays can become virtual Internet sites from which data retrieval, instrument control, or robotic intervention may be accomplished remotely by designated shore-side users.

P16/W/04-B5 1130

GLOBAL MULTIDISCIPLINARY OBSERVATIONS FROM SEAFLOOR OCEAN OBSERVATORIES

Dr. John A. ORCUTT IGPP (0225) (Scripps Institution of Oceanography, La Jolla, CA 92093, USA, email: jorcutt@igpp.ucsd.edu), Dr. Adam Schultz (Institute of Theoretical Geophysics, Department of Earth Sciences, Downing Street, Cambridge, CB2 3EQ, UK)

Oceanography, in contrast to many other Earth Sciences, has advanced almost solely through expeditions which examine phenomena in a limited area over a very limited time. Technology can now support, and scientific problems demand, continuous observations on a broad range of scales in understanding the dynamics involved in global processes in addition to the traditional approach of exploration. For example, the observation of change can only be accomplished by such continuous observations, whether a change in a climate system or the eruption of sections of a mid-ocean ridge. It is essential that oceanographers pursue the development, deployment, and operation of an integrated, permanent ocean observing system for seismology, oceanography, geomagnetism, geodesy, climate and other critical

observations. Such observations will lead directly to fundamental discoveries about the physical, chemical, and biological processes that, on all time scales, determine the structure, evolution, and climate of our planet. We envision a coherent network of observatories in the oceans with data broadly available to scientists, students, commercial interests, and other individuals and organisations. While the emphasis is on long-term observations at fixed, globally-distributed locations, it is essential that shorter-term, smaller-scale studies be promoted to minimise aliasing of important phenomena. The network will include 20-30 observatories distributed globally to provide measurements of geophysical phenomena. Most of these sites are in isolated regions and near-real-time delivery of data and the supply of power require specially-designed, long-life buoys which will be serviced annually (SeaStation) or less frequently (SeaBase). The buoys designed for global observations must be used to support shorter term (2 - 4 years) regional observations with plug-in access for individual experiments. These will be complemented by autonomous stations to ensure that the variety of spatial scales which characterise all geophysical fields can be sampled. 5 - 10 additional observatories will be required for this more temporary component of the global network.

P16/L/02-B5 1150

A BENTHOPELAGIC CONTACT ZONE IN THE OCEAN PATTERNS OF THE PLANKTONDISTRIBUTION IN THE NEAR-BOTTOM LAYER

Alexander L. VERESHCHAKA (Institute of Oceanology, Moscow, Russian Academy of Sciences. E-mail: alv@ecosys.sio.rssi.ru)

During 12 biological dives in the North Atlantic (hydrothermal fields Rainbow, Broken Spur, Logachev, Norwegian Sea, off Newfoundland, depths range from 1700 m to 3800 m), methods of the planktonic visual observations have been developed. This has became possible due to the huge energetic store (1.5-2 times more than in any other submersible) which characterises "Mir" submersibles and allows illumination of the water column during many hours of observations. Emphasis has been made on the detailed observations of the plankton distribution and biology within few hundreds of meter above bottom. All planktonic animals were shown to be divided into 2 principal groups: pelagic (not related to the bottom) and benthopelagic (associated with the sea- floor, this group may be subdivided further). Each group is characterised by certain patterns of distribution, behaviour, and feeding. Near the bottom there is an area called benthopelagic contact zone, where benthopelagic animals dominate and biological processes related to the bottom define the structure and function of the near bottom communities. This zone seems to be ubiquitous in the deep ocean, and was found an all studied depths both above hydrothermal fields and background areas. The thickness of this zone depends upon various biotic and abiotic parameters (examples given), the structure of this zone may be very complex (exemplified by the Broken Spur contact zone). The concept of a benthopelagic contact zone allows more perfect understanding of the biological structure of the ocean.

P16/E/07-B5 1400

UNDERWATER CABLE OBSERVATIONS OF OCEAN VARIABILITY IN THE NORTH PACIFIC

Agusta FLOSADOTTIR (Joint Institute for Studies of the Atmosphere and Ocean, JISAO/PMEL, Box 357941, University of Washington, Seattle, WA98115, U.S.A., email: agusta@pmel.noaa.gov)

Ocean current variability is a major contributor to the large-scale voltage differences observed between points on the sea floor. An example of successful interpretation of a voltage time series in terms of ocean transport variability has been given by J.C. Larsen's ongoing time series of cross-stream voltages in the Straits of Florida on time scales from days and now approaching the inter-decadal. Until recently, the Florida Current work was the only long underwater cable voltage time series in existence. Over the last few years, however, a network of basin-scale voltage measurements has been established in the North Pacific by the groups of L.J. Lanzerotti at Lucent Technologies' Bell Laboratories and A.D. Chave at WHOI in collaboration with the group of H. Utada at Tokyo University. The two longest time series are Hawaii-California, since 1990, and Guam-Japan, since 1992. While these data have been used in applications ranging from the Earth's geophysical structure to space weather, a large part of the frequency range has been shown to be dominated by signals of oceanic origin. Oceanographic analysis, however, has so far been based on what is by now less than half of the time series. An overview will be given of the cable voltage observations in the North Pacific, and their place among other large-scale ocean observations. The full Hawaii-California time series will be presented and discussed in terms of ocean variability.

P16/E/11-B5 1440

CENTRAL EQUATORIAL PACIFIC TOMOGRAPHY EXPERIMENT: PLANS AND PRELIMINARY RESULT

Iwao NAKANO, Toshiaki Nakamura, Hidetoshi Fujimori (Japan Marine Science and Technology Center, 2-15 Natsushima-cho, Yokosuka, Japan Email: nakanoi@jamstec.go.jp) and Bruce Howe (Applied Physics Laboratory, University of Washington, Seattle, USA, email: howe@apl.washington.edu)

JAMSTEC and APL made and started a joint program to set the acoustic tomography system to measure a shallow overturning which is thought to be related to interdecadal climate variability (Gu and Philander, Science 1997) as well as to measure the heat storage variation due to El Nino for two years (1998-2000). The acoustic tomography system was successfully deployed by the JAMSTEC tomography team in the Central Equatorial Pacific Region (0.5N to 13.6N, 177.7E to 172.1E) in early January, 1999. This system has a capability to transfer measured data for the experiment sites to the Land Station in real-time in addition to store it in the internal HDD. These transferred data is to be analyzed to reconstruct temperature and current fields in the region using the tomographic inversion. Topics at the early stage of the experiment will be presented and mentioned to the relation of El Nino.

P16/E/06-B5 1500

SIMULTANEOUS TRANSMISSION OF FIVE TRANSCEIVERS BY THE USE OF MULTIPLE M-SEQUENCES IN THE CENTRAL EQUATORIAL PACIFIC TOMOGRAPHY EXPERIMENTS

Toshiaki NAKAMURA, Tomoyuki Kanaizumi, Hidetoshi Fujimori, Iwao Nakano, (Japan Marine Science and Technology Center, Japan); Kurt Metzger (Michigan University, USA); and Bruce Howe (Applied Physics Laboratories, University of Washington, USA)

A tomography array which consists of five 200 Hz transceivers were deployed in the Central Equatorial Pacific in December 1998 and are under measurements for two years. The objective of this experiment which is an international collaborative work between JAMSTEC and APL-UW is to Monitor the variability of water temperature and current in relation to the El Nino. In our previous experiments, each transceiver transmitted in order every 30 minutes, and the total turn-around time was 2.5 hours. In this experiment, we intend to shorten a measurement time by a simultaneous transmission of five transceivers, which improves an accuracy of measurement for water current velocity due to reduce the effects of internal waves. In this case, however, each transceiver receives an overlapped signal of other transceivers. Multiple M-sequence signals are needed to discriminate mutual signals among transceivers. Five sets of M-sequences were chosen carefully and a simulation for discrimination of the overlapped signals were conducted under the condition of the practical geometry of the five transcievers. As the result, it is expected that the signal of each transciever can be received with the S/N ratio of over 20 dB.

P16/E/01-B5 1520

THE APPLICATION OF HIGH DATA RATE TRANSMISSION ON OCEANOGRAPHIC RESEARCH

XU Tianzeng (Department of Oceanography, Xiamen University, Xiamen, 361005, China, email: xmxu@jingxian.xmu.edu.cn)

Over the last decade, more attentions have been paid to underwater acoustic data transmission techniques. The partial reason is the increasing requirements of developing underwater vehicle, such as manned research submersibles, ROV and AUV. But the mission of high data rate transmission through underwater acoustical channel have to face a variety of serious and difficult problems arising from the channel: multipath spread, noise, fluctuation and so forth. With experiments, we have studied on some statistical characteristics of signal, multipath and noise as the theoretical foundation of signal processing in underwater acoustic channels for many years. Theoretical analyses and experimental results show that the techniques based on MFSK, together with corresponding anti-multipath, anti-fluctuation and anti-noise is an effective signal processing method suitable for high data rate transmission in the channels. Combined with the respective characters of acoustic data telemetry, digital speech communication and video image transmission, the corresponding experimental prototypes have been developed. These prototypes were tested in Xiamen harbor and got good results, for example, the video image can be transmitted omni-directionally to about 10km at the data rate of 8kbits/s by occupying 5 kHz frequency bandwidth, the speech communication can be transmitted to the same distance at 6kbits/s by occupying 4kHz bandwith. We also developed the deep-sea transduce. For the acoustical conditions in the deep-sea are much better than in the shallow-sea, the prototypes would be used to transmit the relative signals in the deep-sea research.

P16/E/02-B5 1600

ARCTIC CLIMATE OBSERVATIONS USING UNDERWATER SOUND (ACOUS)

Peter N. MIKHALEVSKY (Science Applications International Corporation, Ocean Sciences Division, 1710 Goodridge Dr., McLean, VA 22101, USA)

Since the early 1990's it appears that inflow of warmer Atlantic Water into the Arctic Ocean increased resulting in temperature increases in the Atlantic Layer that are continuing until today. Point measurements from icebreakers in 1991 and 1993 showed temperature increases of several tenths of a degree C over historical climatologies. In 1994 acoustic transmissions were made from a site north of the Svalbard Archipelago across the entire Arctic Ocean to receiver arrays located in the Lincoln Sea and the Beaufort Sea. The travel time measurements revealed an average .4 C increase in the Atlantic Layer. This was the first basin scale measurement of this large scale warming. Since 1994 there have been annual trans-Arctic submarine cruises and one trans-Arctic icebreaker cruise that have also observed these changes. The 1999 submarine SCICEX cruise in the Arctic is likely to be the last such cruise to be undertaken for some time. A network of sources and receive arrays arrays (the latter cabled to shore) would be able to provide year-round real-time masurements. Acoustic energy traverses the Arctic basin in approximately 30 mins. providing an integrated measurement of the Arctic Ocean temperature. Observations can be made on many acoustic paths over the Arctic on time scales unachievable by submarine, icebreaker or ice camps. Coupled atmosphere-ice-ocean modelling and analysis of recent data appear to support a decadal scale oscillation in the atmospheric and ocean circulation in the Arctic that may explain the recent warming and portend a return to cooler temperatures. The need for year-round real-time data from the Arctic is evident. A program called Arctic Climate Observations using Underwater Sound (ACOUS, from the Greek word "akous" meaning "listen!") is underway to establish an acoustic monitoring network in the Arctic. The first source and receive array were installed in Oct. 1998. Funding constraints limited the array to be autonomous, but a cabled array is being planned for installation in the spring of 2000. In addition to using the travel time measurements to obtain ocean temperature, research is underway to use the acoustic attenuation changes to measure changes in average sea ice roughness and thickness, and the use of multiple frequencies to measure the depth of the thermocline and thus the thickness of the upper mixed layer in the Arctic Ocean.

COHERENCE OF BOTTOM AND SUB-SURFACE PRESSURES AND SEA LEVELS AROUND ANTARCTICA

P.L.WOODWORTH, C.W.Hughes, M.Smithson and J.M.Vassie (Proudman Oceanographic Laboratory, Bidston Observatory, Birkenhead, Merseyside L43 7RA, UK, email: plw@pol.ac.uk) T.Whitworth (Department of Oceanography, Texas A&M University, College Station, TX 77843, USA, email: twhitworth@tamu.edu) and other US Collaborators R.M.V.Summerson (National Resource Information Centre, Canberra ACT 2600, Australia, email: rupert.summerson@brs.gov.au)

Since the late 1980s, the Proudman Oceanographic Laboratory (POL) and Texas A&M University have deployed bottom pressure recorders (BPRs) either side of, and in the middle of, the Antarctic Circumpolar Current (ACC) 'choke points' at the Drake Passage and south of South Africa and Australia. The object has been to provide information for the World Ocean Circulation Experiment (WOCE) on ACC transports for comparison to those obtained from coastal tide gauges, satellite altimetry and numerical models. This presentation shows some of the findings from the BP deployments, tide gauges and models. One significant feature observed is that large-scale coherence at the several mbar (cm) level does appear to exist between BPR sites and gauges many 1000s of kilometres apart from low frequencies (e.g. annual) to timescales of order 10 days. The data analysis is continuing, but so far the signals appear to be larger than those suggested by numerical models such as FRAM and OCCAM. Ongoing BP deployments will continue to be required beyond the WOCE observational phase, in order to acquire an extended time series of ACC transport, aided by the constant improvement in technology (e.g. via the use of air-launched 'expendable' BPRs). In addition, the availability and suitability of data from the Antarctic coastal sites (e.g. Faraday, Syowa, Mawson, Dumont d'Urville and several other sites) suggest that they might be appropriate data sources of ACC variability, although perhaps containing a greater degree of near-coastal local 'noise'. The continued development of the GLOSS tide gauge network in this part of the world is essential.

DEPARTURES FROM THE INVERSE BAROMETER MODEL OBSERVED IN TIDE GAUGE AND ALTIMETER DATA AND IN A GLOBAL BAROTROPIC NUMERICAL MODEL

Lucy MATHERS, Philip Woodworth (both at Proudman Oceanographic Laboratory, Bidston Observatory, Birkenhead L43 7RA, UK, email: lucy@pol.ac.uk)

The 'local inverse barometer' (LIB) model provides a simple description of the response of sea level to forcing from air pressure changes. It is widely used in oceanography as a correction to sea level data prior to ocean circulation studies. At high frequencies (periods typically less than 2 days), at very low frequencies (periods typically seasonal and longer), and in certain areas at particular timescales (e.g. in tropical areas at periods of around 5 days), the LIB model is known not to work well. In most other parts of the temporal spectrum, it is assumed to work reasonably well. In this presentation, results will be given of a worldwide search for departures from the simple LIB model using tide gauge data from about 100 sites in the global network and from the TOPEX/POSEIDON altimeter satellite. In addition, results will presented from a coarse-grid global barotropic model (a development of the coastal tide-surge model of Flather) forced by ECMWF air pressure and wind fields. Apparent dynamical features evident in all three data sets will be discussed.

CLIMATE CHANGE REVEALED BY SUBSURFACE TEMPERATURES: A GLOBAL PERSPECTIVE

Henry N. POLLACK, Shaopeng Huang (Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109-1063; email: hpollack@umich.edu; shaopeng@umich.edu); Po Yu Shen (Dept. of Earth Sciences, University of Western Ontario, London, Ontario N6A 5B7, Canada, email: pys@julian.uwo.ca)

Temperature changes at the Earth's surface propagate slowly downward into the rocks beneath the surface and modify the ambient thermal regime. Thus present-day subsurface temperatures provide evidence of temperature changes that have occurred at the surface in the past, a valuable complement to instrumentally-acquired temperature data and various temperature proxies in understanding the Earth's recent surface temperature history. With support from the international heat flow community, a global database of borehole temperatures has been assembled for the special purpose of climate reconstruction. In this paper we present a global perspective of climate change over the last five centuries based on analyses of temperature measurements in more than 600 boreholes from North America, Europe, Africa, Australia, Asia, and South America. The ensemble of individual reconstructions shows that in the 20th century the average surface temperature of the Earth has increased by about 0.5 K, and that the 20th century has been the warmest century of the past five. Almost 80% of the sites experienced a net warming over the past five centuries. The mean of the cumulative temperature change over the past five centuries is a warming of about 1.0 K. Many multi-proxy reconstructions also show the 20th century to be the warmest century in their respective reconstruction time intervals. The geothermal analysis, based on direct temperature data and a methodology totally different from the multi-proxy investigations, thus provides independent confirmation of the unusual character of 20th century climate.

MC02/W/14-B1 0930

INTEGRATIVE RECONSTRUCTION OF A GLOBAL GROUND SURFACE TEMPERATURE HISTORY FROM BOREHOLE TEMPERATURES AND OTHER PROXIES

Shaopeng HUANG, Henry N. Pollack (Dept. of Geological Sciences, University of Michigan, Ann Arbor, MI 48109-1063, email: shaopeng@umich.edu; hpollack@umich.edu)

Paleoclimatic proxies such as tree-ring density, pollen characteristics, and ice core isotope ratios all yield projections of past climate changes. Each proxy has its own strengths and limitations in reconstructing climate history. Borehole temperatures offer yet another perspective that can be integrated with traditional proxies to yield a composite reconstruction. Because of the selective filtering of thermal diffusion, borehole temperatures record only longer term trends of climate variation at increasing depths. A ground surface temperature history derived from a conventional inversion approach is typically characterized by robust determination of a long term mean temperature, but with increasingly poorer resolution of variations towards the remote past. In this study we integrate higher resolution proxy information into the inversion of borehole temperatures for the reconstruction of a global average ground surface temperature (GST) history. This approach comprises two steps. Subsurface temperatures from more than 600 boreholes from North America, Europe, Africa, Australia, Asia, and South America were respectively preprocessed with a standardized Bayesian inversion scheme with an a priori null hypothesis. The derived transient subsurface temperature components of the individual boreholes were assembled into a single average transient temperature profile. This global average borehole temperature profile was then inverted for a GST history reconstruction. To incorporate information made available by other disciplines, we employed proxy reconstructions as the a priori hypotheses in the second phase inversion. The second step inversion embeds the high resolution proxy reconstructions into the longer term trends determined from subsurface temperatures. The proxy reconstructions complement the borehole data with high frequency information and bridge the gaps due to sparse or missing data. Results show a general increase of about 1K in the GST over the last five centuries, with an increasingly strong warming trend in the 20th century.

MC02/E/10-B1 0950

BOREHOLE TEMPERATURES, CLIMATE CHANGE AND LAND DEVELOPMENT: EVIDENCE FROM CUBA

V. CERMAK, J. Safanda (Geoph. Inst., Czech Acad.Sci., 141-31 Praha, Czech Rep., email: cermak@ig.cas.cz); L Bodri (Geoph. Dept., Hung. Acad. Sci., 1083 Budapest, Hungary, email: bodri@gis.elte.hu)

Inversion of borehole temperatures to reconstruct ground surface temperature (GST) history is a good method to obtain both the long-term average GST and variations in the past GST at a site. To interpret the results in terms of climate change, the knowledge of the relation between the GST and the surface air temperature (SAT) is essential. Several researchers demonstrated that inverted GST history might comprise an apparent component reflecting temporal variations in land (vegetation) cover. Anomalous curvature observed in the uppermost 200-250 m of the measured T(z)-profiles in more than 30 boreholes in Cuba indicated a pronounced change in the past GST conditions. The calculated magnitude of the apparent recent warming revealed values as high as 5-8 K, which cannot be attributed to the natural climate variability. It was demonstrated that land cultivation may had contributed to the effective increase of the GST due to deforestation and consequent land exposure to solar radiation. The resulting GST change may thus by far surpassed the proper climate effect. To estimate the "vegetation correction" which is closely related to GST-SAT coupling, the measured T(z) data were first "corrected" by forward application of the long-term meteorological record of the mean annual air-temperatures in the Caribbean area.

MC02/E/07-B1 1010

ANALYSIS OF BOREHOLE TEMPERATURE RECORDS FOR GROUND TEMPERATURE HISTORY: FIRST RESULTS FROM INDIA

Roy SUKANTA, R. U. M. Rao (National Geophysical Research Institute, PO Bag 724, Uppal Road, Hyderabad 500 007, India, email: postmast@csngri.ren.nic.in)

Surface air temperature (SAT) changes can cause concomitant changes in ground temperature which diffuse downward by conduction causing a systematic perturbation to the subsurface temperature field generally in the top 100-150 m. Therefore the present day borehole temperature recods hold a Ground Temperature History (GTH). A set of sixteen carefully selected borehole temperature records, covering different parts of India and a depth range of 150 to 700 m, have been analysed for GTH. A simple linear increase in surface temperature, D, that started t years ago, was found to provide excellent fits to the ground warming related anomalies in all the temperature profiles. The D values range 1 to 2.5 Celcius degrees and t values, generally 50 to 150 years, and in a few cases 200 to 250 years. The trends are consistent with the long term trends of SAT increases from the Indian meteorological records. No spatial variation pattern could, however, be gleaned because of the limited data set. A more detailed coverage, with good number of properly sited boreholes would yield an improved picture. These results, the first from low latitudes (12-28 deg N) are in consonance with the trends in GTH delineated in higher latitudes, North America and Europe. Signals of cooling immediately preceding the recent warming found in Eastern Canada are however not observable in the present records.

QUANTIFICATION OF NATURAL CLIMATE VARIABILITY IN CENTRAL GREENLAND AND EAST ANTARCTICA USING BOREHOLE PALEOTHERMOMETRY

Gary D. CLOW (U.S. Geological Survey, Climate History Program, Denver Federal Center, Box 25046, MS980, Denver, CO 80225, USA; email: clow@usgs.gov); Edwin D. Waddington (Univ. of Washington, Geophysics Program, Box 351650, Seattle, WA 98195, USA; email: edw@geophys.washington.edu)

The most accurate way to determine the magnitude of past temperature changes in polar regions is through "borehole paleothermometry" in the ice sheets. We have used this technique to quantify the magnitude of natural climate variability during the Holocene at two locations: 1) GISP2 - central Greenland, 2) Taylor Dome - East Antarctica. At GISP2, there was a general decline in temperatures during the Holocene that parallels the drop in summer insolation at this latitude. The decline was weak from 10 ka to the mid-Holocene Optimum (MHO) at 4 ka. Temperatures then dropped 2 K from the MHO into the Little Ice Age (LIA). This cooling was briefly interrupted by a 0.5 K warming during the Medieval Warm Period (MWP) at 1 ka. Temperatures in central Greenland are currently 1.3 K colder than during the MHO and 0.4 K colder than during the MWP. At Taylor Dome, there too was a general decline in temperatures following the MHO. However, rather than experiencing the MWP at 1 ka, temperatures reached their coldest value of the last 4 kyr. During the "LIA", the Taylor Dome region experienced a dramatic 2 K warming. Thus, temperature changes on the multi-hundred year timescale during the MWP and LIA were anti-correlated in Greenland and the Taylor Dome sector of Antarctica.
This may be related to changes in the oceanic "conveyor" system. Within the context of Holocene natural climate variability, current temperatures in Greenland are not unusual while those at Taylor Dome are unusually warm.

MC02/E/19-B1 1130

BOREHOLE TEMPERATURES, METEOROLOGICAL DATA AND CLIMATE CHANGE

David S. CHAPMAN, Scott N. Putnam (Dept. of Geology and Geophysics, Univ. of Utah, Salt Lake City, UT 84112, USA, email: dchapman@mines.utah.edu); Robert N. Harris (RSMAS, Univ. of Miami, Miami FL 33143, USA)

The seminal analysis of borehole temperatures on the north coast of Alaska (Lachenbruch and Marshall, Science, 234, 1986) had two significant impacts. The study alerted us to 2-5 oC of surface warming in this century at high latitudes. An the detailed description of using temperature-depth profiles in boreholes to study global warming prompted mane geothermal laboratories into serious study of the geothermics of climate change. At Utah we concentrated our efforts on understanding the geothermal signal of climate change in low latitudes where the global warming signal is predicted to be small, on combining ground and air temperature records at the regional scale, and, at the local scale on establishing a geothermal climate-change observatory. Our work allows the following conclusions and observations: 1. Six boreholes sites in northwest Utah in homogeneous granite yield warming trends about 0.3 oC at the century time scale. Variability in the borehole results is comparable to variability in local surface air temperatures (SAT) warming trends. 2. Eight borehole sites in southeast Utah, in the layered sedimentary rocks of the Colorado Plateau, yield warming of 0.6 oC over the past 200 years, less than warming computed from 100-year SAT records. 3. Synthetic temperature-depth profiles computed in remarkable detail the temperature profiles at nearby borehole sites. 4. Weather station temperature records can be combined with borehole temperature logs to estimate mean surface air temperatures prior to the instrumental SATs. This 19th century baseline temperature in Utah is 0.6+-0.1 oC below the 1951-1970 mean temperature for the region. 5. Our Emigrant Pass Observatory has been operated for 4 years and has produced a wealth of meteorological data acquired simultaneously with subsurface temperature data. Ground and air temperature track each other but with important time-varying offests.

MC02/E/11-B1 1150

INVERSION OF BOREHOLE THERMAL DATA: NINETEENTH CENTURY WARMING IN CENTRAL CANADA CAUSED BY LAND DEVELOPMENT

Trevor LEWIS (Sidney Geophysical Consultants Ltd. and Geological Survey of Canada, Sidney, B.C. V8L 4B2, Canada)

Borehole temperatures within the conductive regime of the solid earth to depths of hundreds of metres often reflect a constant heat flow from below on which are superimposed temperature anomalies propagating downward from the surface of the earth. Such data can be inverted to obtain past temperatures at the top of the conductive zone, called here the ground surface temperature (GST). This boundary may be cms or metres below the actual ground-air interface. Analyses of such data show that 1-3 K increases of the past GST occur at the times of local deforestation at many, differing sites. The amount of heat formerly required for transpiration is approximately the amount required for this warming, and reduction in the evaporated water mainly increases summer temperatures. The water no longer transpired increases the runoff. In colder climates where there is seasonally frozen ground but no permafrost, the latent heat of ground moisture in the top several cms of the overburden buffers the underlying bedrock from freezing temperatures, causing average GSTs to be warmer than the average air temperatures. The GST is limited to following only changes in the air temperature above freezing and never goes below freezing. However, the effects of deforestation are undiminished in these climates. The widely observed regional warming of the GST in southern and central Ontario correlates with the period of deforestation and is attributed to the creation of farmlands in the nineteenth century. Warming is to be expected wherever the ground cover is decreased, or has been decreased in the past.

COMPARISON OF SOIL TEMPERATURE DATA DERIVED FROM BOREHOLE OBSERVATIONS WITH METEOROLOGICAL RECORDS

Serban VELICIU (Geological Institute of Romania, Caransebes 1; 78344 Bucharest, Romania, email: veliciu@igr.sfos.ro)

Comparison of surface temperature change estimated from borehole temperature profiles and observed surface air temperature and precipitation time series for periods in which the three signals overlap can strength the confidence in geothermal method for climatic reconstruction. To illustrate this will draw an example from the north Danube Plain, Romania, geographically located near the north 45 lat., where the meteorological records of temperature change against temperature-depth measurements have previously been interpreted in terms of temporal variations of ground surface temperature for the last two centuries. In order to quantify correlations of meteorological and geothermal data, the earth's response to surface air temperature as recorded in the nearby weather stations, has been modelled using the finite element method. For the weather stations from the Danube Plain the meteorological records indicate an average rise of temperature over the time interval 1850-1995, showing the century-long trend of +0.22 to +0.84 deg. C, determined by the least-square regression. This is also exhibited by the reconstructed ground surface temperature history deduced from temperature measurements in the wells. The inverse method used for the geothermal data set for Romania was based on the simple theory of 1-D heat conduction using the least square computing technique. The employed parametrisation scheme constrains the ground surface temperature history to a few changes. The ground surface temperature fluctuations for the considered time period do not generally exceed +2 or +3 deg. C and the quality of the measured temperature logs permitted to resolve not more that 2-3 climatic events.
The results from the measurements in the studied boreholes could be suspicious not because they indicate warming, but because the amplitude of warming that they indicate, as compared with the meteorological records. The suspicion concerns the question whether the perturbations observed in the boreholes are only climatic. However, direct comparison of the borehole temperature profiles and surface air temperature records is not possible for two main reasons: first, ground temperature is generally warmer than air temperature by 1-5 deg. C, second, changes in the earth's surface temperature are filtered and attenuated in the earth's surface by the process of heat conduction.

UPDATE ON THE USE OF TEMPERATURE RESPONSE TO SEQUENCES OF VOLCANIC ERUPTIONS TO DETERMINE CLIMATE SENSITIVITY

Richard S. LINDZEN (54-1720, MIT, Cambridge, MA 02139, USA); Constantine Giannitsis

A detailed consideration of the greenhouse effect permits a convenient determination of the ratio of surface flux changes relative to top-of-atmosphere changes associated with changes in atmospheric carbon dioxide. This has, in turn, permitted us to properly calibrate the recent attempt by Lindzen and Giannitsis to determine climate sensitivity on the basis of the observed temperature response to a sequence of volcanic eruptions. We have, furthermore developed a simple statistical analysis to ascertain the significance of the distinction between various sensitivities determined by this method.

MC02/W/05-B1 1430

IS THERE A SOLAR SIGNAL IN RECENT VARIATIONS IN GLOBAL CLOUDINESS AND CLOUD RADIATIVE FORCING?

Jon Egill KRISTJÁNSSON, Jorn Kristiansen (University of Oslo, Norway)

We have explored the possibility of a link between solar activity (via cosmic rays), cloudiness and climate, recently proposed as a factor in explaining global warming. Multi-year datasets of cloud cover from ISCCP- and DMSP-based satellite estimates have been investigated, as well as ERBE estimates of cloud radiative "forcing".
Comparing cosmic ray flux and global cloud cover from ISCCP we find a good correlation between 1986 and 1990, but between 1990 and 1993 the correlation is lower. A similar result is found when data over land as well as over the tropical regions are excluded. Those areas would be expected to be the least sensitive to an extra-terrestrial source of CCN, if this were to exist. The correlation between cosmic ray flux and DMSP cloud cover for the period 1987-1998 is even lower than when ISCCP data are used, but it should be noted that those data only cover water clouds. Furthermore, there does not appear to be any simple relationship between the cloud coverage and the radiative impact of clouds. This is probably due to year-to-year variations in cloud height and in the spatial distribution of clouds.
Our findings seem to undermine the alleged relationship between solar activity and climate through the proposed effect on cloud cover. The implication seems to be that other factors, e.g., El Niño or natural variability, play a larger role in determining year-to-year variations in cloudiness and cloud radiative forcing than any potential cosmic ray forcing.

MC02/E/23-B1 1450

EMPIRICAL ESTIMATES OF CLOUD EFFECTS ON THE NEAR-SURFACE AIR TEMPERATURE: COMPARISON WITH GCMS

Pavel Ya. GROISMAN (ICAR Project Scientist, National Climatic Data Center, Ashville, North Carolina, USA); Bomin Sun, Raymond S. Bradley, Frank Keimig (Dept. of Geosciences, University of Massachussetts, Amherst, MA, USA)

Using synoptic data for the past several decades over the Northern Hemisphere and tropics we estimate a normalised overall cloud effect on temperature, NOCET, as a sensitivity of near0surface air temperature, T, to the presence of cloud cover, CL, (NOCET = dT/dCL) and parameterise this derivative as a function of atmospheric humidity and snow cover. In humid tropics the effects of humidity and snow cover on NOCET vanish and asymptotic values of NOCET become spatially and seasonally unvarying an equal approximately –0.75 K/(tenth of cloud cover) for daytime and –0.2 K/(tenth of cloud cover) at night. Clouds are an internal component of the climatic system and "forcing" is not a proper term in describing their effects on the system. But this terminology is commonly used, and, using the terminology, we produced empirical estimates of cloud cover "forcing" of the present climate system.
We believe that it is important for GCMs (used in climate sensitivity studies, e.g., for contemporary and future climate change analyses), to properly reproduce the interaction (internal relationships) in the contemporary climatic system among cloud, snow cover, and near-surface humidity and temperature. Geographical patterns and time series of NOCET will be discussed and compared to similar estimates derived from several GCM simulations. The results indicate that a proper estimation of the sensitivity of surface air temperature to cloud cover is still a challenge to most of the GCMs tested. This impedes the accuracy of climate change assessments based on these models

MC02/W/07-B1 1510

PROXY AND MODEL-BASED ANALYSIS OF PATTERNS OF TEMPERATURE ASSOCIATED WITH SOLAR IRRADIANCE OVER THE LAST SEVERAL CENTURIES

Anne M. WAPLE, Michael E. Mann, Raymond S. Bradley (Department of Geosciences, University of Massachusetts, Amherst, MA, 0100359; email: awaple@geo.umass.edu, mann@snow.geo.umass.edu, rbradley@geo.umass.edu)

The multi-proxy temperature reconstruction of Mann et al. (1998) and irradiance reconstruction of Lean et al. (1995) as well as climate model data have been used to assess the degree to which characteristic spatial temperature patterns exist as a result of changes in solar irradiance over the last several centuries. The last 300-400 years contains the Maunder minimum as well as the Dalton Minimum and a period of relatively higher irradiance for comparison with the surface temperature. A band of tropical warmth in runs of a solar-forced coupled model (Cubasch et al. 1997) is corroborated by a positive correlation between irradiance and tropical Atlantic SSTs in the proxy reconstruction. However, much higher significant positive correlation exists in SE Asia and the western Pacific. This is despite high interannual variability in the region which matches well with reconstructed El Nino events identified by Quinn and Neal (1987). The high correlation in this area with irradiance forcing is in accordance with arguments suggesting a positive feedback mechanism in the western Pacific (Clement et al.1996) and this feedback is a phenomenon not adequately represented in the GCMs. In contrast, higher latitude Pacific temperatures show no coherence at all.
A land-sea contrast is an important feature in the correlation of irradiance and the proxy reconstruction. While Cubasch et al. (1997) also determine that a land-sea contrast is one of the major 'fingerprints' of a solar as well as the greenhouse gas signal, they find a 10-year lag provides the optimum response over most regions, however a 25-30-year lag is more appropriate over the ocean. We find that a 30-year lag provides the best correlation in many areas of the globe; a notable exception being the northern North Atlantic which has higher correlation at a 15-year lag. These patterns are also examined in the coarser solar-forced GISS atmospheric GCM of Rind and Lean (1998) which does not display the land-sea contrasteveident in the coupled model. The correlation is more consistently poitive over the globa and there is also a band of high correlation between irradiance and temperature in the tropics.

A MULTICENTURY CORAL GROWTH RECORD FROM FRENCH POLYNESIA: INTERANNUAL AND DECADAL SEA SURFACE TEMPERATURE AND SOLAR ACTIVITY VARIABILITY IN THE SOUTH CENTRAL PACIFIC

Frederic BESSAT (University of Sorbonne, 191 Rue St-Jacques 75 000 Paris, France, email: Frederic.Bessat@paris4.sorbonne.fr)

Since 25 years, annual density banding patterns in massive coral skeletons have promised to be the key to a weath of proxy climate information for ocean areas in the tropics. Living corals promise information covering the past several centuries with annual or better resolution. This paper present coral research designed to develop a multi-proxy approach to coral-based paleoclimatology. A new understanding and measurments (by computerized tomography) of coral growth has led to a refined 190 years record of calcification in massive coral from Moorea Island (17°30' S, 149°50' W, French Polynesia).Time series analysis (MTM analysis) of the coral density banding records reveals a concentration of variance at El/Nino-Southern Oscillation (3-6 years) frequency bands. In addition, inderdecadal spectral peaks are notable; 9,5 - 11,5 and 21,9 years peaks are found. These and others (stable isotope record) results indicate that the French Polynesia coral record is a valuable source of information on south central Pacific climate history.

THE NATURAL CLIMATE CHANGE DUE TO THE ACTIVITY OF GEOSPHERE

Xiaoqing GAO, Maocang Tang(both in Lanzhou Institute of Plateau Atmospheric Physics, Chinese Academy of Sciences, Lanzhou 730000, P.R.China, email: xqgao@lzu.edu.cn)

Over the past few decades, the most important advance in the earth sciences has been the development of the concept of a system: of a climate system and of an earth system. These concepts mark milestones toward the achievement of an adequate methodology for our discipline. It has now come to be realized that climate chnage can be deeply inflenced by the lithosphere as well as hydrosphere, the biosphere, and human activity, by ways of interaction(mass and energy fluctuations) at the boundaries of these spheres. But, the causal connections of interactions among these spheres remain poorly understood.
In this paper, the focus is on the influence of geothermal heat flux anomaly on climate change. The soil temperature at different depths (0.00m, 0.05m, 0.10m, 0.20m, 0.40m, 0.80m, 1.6m, and 3.2m) has been observed in more than 180 observatories in China, now. It is found that the heat flux anomaly is of a stable persistence, and has a good relationship with short term precipitation anomaly. It is meaningful for climate prediction.

TRENDS IN 500 HPA WINDS OVER ESTONIA

Sirje KEEVALLIK (Tartu Observatory, 61602 Toravere, Estonia)

It is widely recognised that changes have taken place in frequencies of different circulation patterns in Europe during recent decades. The aim of the present paper is to find out if respective changes can be noticed also in the 500 hpa wind components above Estonia. For this purpose, data on wind direction and velocity have been drawn from vertical soundings at Tallinn aerological station. Situations in January and July have been analysed during a 30-year period of 1961- 1990. It can be said that in

MC02/W/08-B1 Poster 1600-04

AIR-GROUND TEMPERATURE TRACKING IN NORTH DAKOTA

William SCHMIDT (Univ. of North Dakota, Dept. of Geology and Geological Engineering, PO Box 8358, Grand Forks, ND 58202-8358, USA, email: wischmid@badlands.nodak.edu)

Understanding the long-term tracking of air and ground surface temperatures is necessary for any borehole paleoclimate study, particularly in regions of snow cover and ground freezing. The duration of the surface air temperature record is insufficient to determine if observed global warming is due to anthropogenic effects or natural climatic fluctuations. The geothermal record enables better spatial and longer temporal resolution of climate change. Several borehole

climate change studies have demonstrated warming in North America in the past five centuries. However, most published results have been based on the assumption of consistent and uniform tracking of air and ground temperatures. This assumption may be valid in some cases, but it is likely that parameters in the soil that affect energy transfer undergo seasonal or decade scale variations. Secular variations in these parameters produce regional discrepancies in climate change magnitudes as determined by borehole records and recorded surface air temperatures. We examined a data set recorded between October 1980 and April 1990 at Fargo, North Dakota. Standard climatic variables, as well as 21 subsurface values ranging in depth from 1cm to 1170cms, were recorded. The heat flow at the site is completely conductive, with no non-climatic effects present. A 2-D numerical conduction model produced temperatures within +/- 0.2K of observed temperatures below 1m depth. The two main factors causing winter divergence of air and subsurface temperatures are insulation due to snow cover and latent energy due to soil moisture freezing. Latent energy holds the ground temperatures at freezing until all the water present has frozen. The extent of this warming effect is dependent on volumetric moisture content at the onset of ground freezing. Volumetric heat production in the model simulates latent energy due to ground freezing and thawing. Modelled annual heat production values during ground freezing show a correlation (r squared = .61) with total precipitation 3 months prior to ground freezing. Decade-scale warming in the upper few centimeters of the ground surface is due to an increase in the number of days with snow cover. January the frequency of the westerlies has increased and the frequency of the easterlies decreased. A general increase in the wind velocity can be noticed. In July main changes are associated with meridional winds: the frequency of the northerlies has increased and that of the southerlies decreased. Wind velocity has increased for the easterlies and southerlies and decreased for the westerlies. These tendencies have been analysed from the point of view of the European circulation patterns (Grosswetterlagen) - a synoptic-climatological classification of surface and upper-air pressure patterns elaborated in 1944 by F. Baur, P. Hess, and H. Nagel.

MC02/E/06-B1 Poster 1600-05

PECULIARITIES OF CLIMATIC IMPACT OF THE ORBITAL FORCING IN VARIOUS GEOLOGICAL PERIODS

V. A. BOL'SHAKOV (Geographical Dept., Moscow State University, 119899, Moscow, Russia)

It is known that periodicities of orbital elements variations (OEV) were nearly constant during the Mesozoic and Cenozoic. However, climatic influence of the orbital forcing varied from one geological period to another. OEV determined the rhythm of glaciations and deglaciations in the Quaternary. Periodicity in lake-level cycles connected with OEV was discovered in Late Triassic sediments. It should be noted that relative importance of the various orbital parameters in controlling climate has varied through geologic time. Precessional cycle (nearly 23 Kyr.) was detected primarily in warm periods of the Earth's geological history such as Miocene and Late Triassic. Climatic influence of the eccentricity cycle (about 100 Kyr.) was predominant in the Upper Pleistocene according to oxygen isotope data. The obliquity cycle (nearly 41 Kyr.) was the most important in the Lower Pleistocene. These data allow us to conclude that climatic impact of the orbital forcing depends not only upon orbital elements variations peculiarities but also upon terrestrial factors and possibly some other cosmic factors.

DIABATIC AND ADIABATIC CONTRIBUTIONS TO THE DYNAMICALLY INDUCED CLIMATE OSCILLATIONS

Roman BELKRYAEV (Arctic and Antarctic Research Institute, 38 Bering str., 199397, St.-Petersburg, Russia, email: bekryaev@aari.nw.ru)

Global air surface temperature is one of the most important indices of climate variations. The typical point of view connects variations of the global mean air surface temperature with the fluctuations of the heat fluxes only. Diabatic heating or cooling (connected, for example, with changes in planetary albedo, cloudiness or heat fluxes from the ocean) are the most important causes of such variability. However, more than half of the extra-tropical mean air surface temperature variability is dynamically contributed and can be associated with the COWL (Cold Ocean Warm Land) structures (Wallace et al., 1995), NAO indices (Hurrell, 1996) or Arctic Oscillations (Wallace, 1998). Particularly, warm winters in the Northern Hemisphere are associated with the warm air anomaly over the continents and cold air anomaly over the ocean (and vice versa). Typical explanation is the following: the heat capacity of the underlying surface has a major influence in amplifying surface temperature changes over land while moderating them over the ocean. Strong variability of the large-scale atmospheric circulation and some other circumstances allow the hypothesis that an additional mechanism of global air surface temperature fluctuation exists. We suggest that short-term variations of the global surface air temperature may be partly a result of adiabatic vertical mixing.
For the purpose of research a run of a global atmospheric model, T10-L14 (Main Geophysical Observatory, St.-Petersburg, Russia) in the regime of perpetual January for 200 years' was carried out. An additional set of numerical 14-year runs with the T30-L14 MGO model, using annual cycle of incoming solar radiation and the sea surface temperature, has also been performed. Using Wallace et al's (1995) method of analysis and the results of the long-term MGO model integration, we have revealed the structures of the temperature field at the AT-1000 level, and outgoing long-wave radiation fields at the top boundary of the atmosphere.
Using monthly data, we have demonstrated the so-called COWL structures (Wallace 1995, 1996) in the temperature field; these are well correlated with the global mean air surface temperature (r=0.8 for daily and r=0.7 for monthly averaged data). We have found very strong negative correlation (r=-0.9) between the indices of the COWL pattern and eddy available potential energy in the low troposphere. These results allow us to suggest that at least part of the short-term air surface temperature variations can be...

EXTREME TEMPERATURES OVER ARGENTINA. ENSO AS A CLIMATIC VARIABILITY FACTOR

Matilde RUSTICUCCI, Walter Vargas (Detp. De Cs. De la Atmosphera, Universidad de Buenos Aires, 1428 Buenos Aires, Argentina, email: mati@at1.fcen.uba.ar)

The relevance of ENSO phases on temperature extreme situations in Argentina is presented here. Warm and cold spells of Maximum and Minimum daily temperatures are analysed from 40-year station data series in 24 stations covering all climatic zones, using the third quartile of each distribution of persistence and intensity to compare extreme situations. Each month was classified as extremely warm, cold or normal or El Nino, La Nina or Neutral. Cold spells are more persistent in northern Argentina with an autumn maximum. The maximum values persist from autumn to summer, only in the northeast. In general, maximum intensity values occurred in winter in the northern regions, and during the summer in central-southern Argentina, the exception being cases of extreme cold winters having extremely cold waves, in the south. Over the Andes Mountains, intensity values present a minimum. The third Quartile persistence values are between 3-5 days in a normal year, reaching 11 days in a cold year and between 2 and 4 in a warm one. This appears to be the key parameter to classify a month as warm or cold. Data from Northern Argentina present a more significant ENSO signal. In the south there is no significant difference between phases. In central Argentina, cold winter spells are more significant during La Nina. In spring, these waves are more persistent and intense than a normal year, and in some regions even than a cold one. In Winter both parameters are similar to those of a cold year, except in the south, where a cold summer is not explained by any of the ENSO phases. The relationship Nino-warm/Nina-cold is clearest in Northern Argentina, with the strongest Nina signal present in the spring. In general, the effects of El Nino or closer to give a normal month than a Neutral does. The third quartile values are lower when the data are classified according to ENSO phases than in warm / cold / normal cases, so the effect of ENSO phase differences on temperature regime is lower than the extreme climatic differences. Warm waves are more persistent but equally intense than cold ones. The ENSO effect is also highest over the northern regions, presenting largest values in winter, in opposite phase with the south, a characteristic also exhibited by cold waves. El Nino events bring more intense and persistent warm waves in the north, and more regionally homogeneous than La Nina ones. An extremely warm summer has more intense and persistent warm waves than any ENSO phase, while El Nino could better explain a warm winter in the north.

MILANKOVITCH THEORY: NEW CONCEPT

V.A. BOL'SHAKOV (Geographical Dept., Moscow State University, 119899, Moscow, Russia); P.V.Bol'shakov (NBZ Community, Olimpiisky pr., 30, 129272, Moscow, Russia)

The resent version of the astronomical theory of paleoclimate (ATP) - Milankovitch theory (MT) - meet some problems which retard further development of this theory and its practical applications. The main of them are the followings. 1. Discrepancy between the quantity and dates of glaciations according to Milankovitch diagram and OI data. 2. Period about 100 kyr. is of prevailing significance in OI records during the past million years. However, precisely this period correlated with variations of eccentricity is absent in the Milankovitch theory. 3.Glacial (even) OI stages coincides with the intervals of low eccentricity values. MT can not explain this fact too.
The analysis of MT, deep-sea oxygen isotope records, solar activity variations and its correlation with climate change allows us to propose the new concept of MT. "Insolation-climatic" (IC) diagram was constructed according this new concept. IC diagram has a good visual correlation with OI data for the last million years. So this new view on MT provides more full and direct confirmation of climate orbital forcing because our concept implies the climatic influence of all three orbital elements (including eccentricity) and it gives the opportunity of direct correlation of IC and OI graphs. Our new concept contains simple and real solving of the 100-kyr cycle problem.

SEASON'S PENDULATION AND CLIMATIC JUMPS

Ionel HAIDU (University "Babes-Bolyai", 1 Koglaniceanu Str., 3400 Cluj-Napoca, Romania, email: haidu@bioge.ubbcluj.ro)

This paper examines the hypothesis of season's pendulation at an interannual time scale and its statistical links with the climatic jumps. The work is done on observed time series of precipitation totals and mean surface air temperature, and on some derived time series. Several stations in Europe, representative positionally, were taken into account having more than 100 years of observations. The maximum and minimum season has been defined upon quantitative criteria. As consequence, both, the extreme seasons has no constant position within the year. Thus, the series of moments of occurring of maximum / minimum season within every year has been defined. Also, the time series of amplitudes between the extreme seasons has been considered. Abrupt changes and jumps in the annual and seasonal variations of precipitation total and mean surface air temperature were investigated using the Iwashima method. The jumps and the changes of the mean show a relative synchronism and have a regional character. Significang jumps or changes of the mean are to be noticed in the periods: 1800-1830, 1840-1860, 1870-1900, 1910-1930, around 1950 and 1980. From a statistical point of view, there are links between the season's pendulation, local trend and the climatic jumps. Some of the maximum season's pendulation seem to time correlated with some major volcanic eruptions.

GEOTHERMAL EVIDENCE OF RECENT WARMING IN THE URALS

Dmitry DEMEZHKO (Institute of Geophysics, Ural Branch of Russian Academy of Science, 100 Amundsen Str., 620016 Ekaterinburg, Russia, email: ddem@igeoph.mplik.ru)

Ground temperature changes, associated with climate changes, disturb the stationary underground temperature field. Thus borehole temperature measurements performed at present contain information about ground surface temperature (GST) changes in the past.
66 temperature-depth profiles recorded in the Urals (50-61 E Long) were investigated with the aim to reconstruct GST history. The mean GST history curve shows a cold period with temperature minimum in the 17-18 centuries followed by a fast warming in the 19th century (at the rate of 0.8-1.5K/100 years) and a moderate warming in the first 70 years of the 20th century (at the rate of 0.4K/100 years). The latest GST rising rate is lower than that for surface air temperature in the same period (0.8K/100 years) derived from meteorological data. Also some non-uniform spatial distribution of recent GST rising rate was noticed. It varies from about 0.5-0.9K/100 years in the southern one, and it appears no rising in the northern part. It is assumed that GST changes in the Urals are determined by a combined influence of surface air temperature changes and snow cover height oscillation. Statistical relationship between mean annual soil-air temperature difference and snow cover height has been established. Decrease in snow height about 10 cm may cause GST decrease about 0.6-0.7 K at stable air temperature.

LONGWAVE RADIATION IN THE SWISS ALPS

CH. MARTY(1), R. Philipona(1), C. Frohlich(1), A. Ohmura(2) ((1)Physikalisch-Meteorologisches Observatorium Davos, World Radiation Center, PMOD/WRC, CH-7260 Davos, Switzerland; (2)Institute of Geography, ETH, CH-8057 Zurich, Switzerland)

Monitoring of longwave downward radiation is one possibility to determine the effect of increasing greenhouse gases. A total of eleven stations between 400 and 3600m a.s.l. in the Swiss Alps are measuring short- and longwave radiation. The 4 years of data show the dependence on elevation, which is mainly due to water vapor content. Together with the shortwave measurement, information about the cloud forcing and its change with altitude is extracted.

ANOMALY METHOD FOR SELECTION OF THE GLOBAL, REGIONAL AND LOCAL CLIMATE

Tarzadin ULAANBAATAR (Department of Earth Sciences, National University of Mongolia, email: numelect@magicnet.mn)

The detailed and realistic maps of climate zones of the Earth must be prepared by mathematical selection of the global, regional and local climate. Present geographical, climate maps are shown the integrated impact of the geospheres, geographical objects and Sun on the weather. But climate is a whole hierarchy of complexity of global, regoinal and local climate regime. A best way of the theoretical description of successful prediction, realization, mitigation, rehabilitation strategies of climate change is to select it in global, regional and local scale. In aspect of this goal, I endeavoured to creat a mathematically adopted unswerving climate model, which is neccesary to play key role for theoretical standard climate regime and to be fundamental background for selection of the climate change in regional and local scale. In this paper, based on a new climate model, so-called anomaly method of their selection is presented.

PALEOCLIMATIC SIGNALS FROM TRANSYLVANIAN TEMPERATURE LOGS

Delia Zemira SERBAN (Institute of Geodynamics, 19-21 J.L.Calderon Str., R-70201, Bucharest, Romania, email: delias@geodin.ro); Soren Bom Nielsen (DEpartment of Earth Sciences, Geophysical Laboratory, The University of Aarhus, Finlandsgade 8, DK-8200 Aarhus N, Denmark, email: geofsbn@aau.dk); Crisan Demetrescu (Institute of Geodynamics, 19-21 J.L.Calderon Str., R-70201, Bucharest, Romania, email: crisan@geodin.ro)

Continuous temperature logs to depths of 1400 m in the Transylvanian Basin, Romania, in many cases show temperature gradient variations with depth which cannot be explained by depth variations in thermal conductivity, topography and groundwater flow. The only possible responsible agent seems to be the past surface temperature variations. The temperature logs have been interpreted by least squares inverse modelling with the surface temperature history and background heat flow as unknown parameters. The temperature data are too shallow to contain information about the temperature rise at the end of the last glaciation. However, several temperature profiles are consistent with a postglacial warming. Measurement technique, inversion methods and modelling results are discussed.

ASYMMETRIC CLIMATIC CHANGE OVER COASTAL CALIFORNIA: CAUSES AND CONSEQUENCES

Michael A. White, Ramakrishna R. Nemani, Daniel R. Cayan, Gregory V.Jones, Steven W. Running and Joseph C. Coughlan

Climatic change in coastal California has beendominated by asymmetric air temperature changes associated with dewpointtemperature increases. Regional mean California air temperatureincreases were tightly coupled to near-coastal Pacific sea surfacetemperatures, which in turn were highly correlated with Pacific specifichumidity and California dewpoint temperature. Higher dewpoint led to acompression of the diurnal temperature range and significant increasesin mean air temperature almost entirely caused by increases in nightminimum temperature. Warming was also highly seasonal, with most changeoccurring in spring. An increased frequency of low Pacific sea levelpressure systems resulting in dominantly southwesterly circulationpatterns since the 1976 shift in the Pacific decadal oscillation is alikely cause of increased advection of high humidity air masses overcoastal California. Biological consequences of such symmetric climatechange can be significant. In Napa/Sonoma valleys, the center of premiumCalifornia wine production, climatic change has dramatically improvedthe viticultural environment. Changes include: 65-day increase infrost-free growing season; 71% reduction in frost occurrence; 3.14°Cdecrease in growing season diurnal temperature range; 14% increase ingrowing season growing degree days; an estimated 23-day advance inflowering date; and a 7% decline in growing season vapor pressuredeficit. Over 1951-1997, there has also been significant improvements inboth wine quality and grape yield. Finally, since annual temperaturepatterns are generally forecast by winter sea circulation patterns,there appears to be some potential in forecasting wine quality fromwinter conditions.

A QUANTITATIVE ASSESSMENT OF THE ASSOCIATION BETWEEN WINTERTIME NORTHERN HEMISPHERE CIRCULATION INDICES AND TEMPERATURE

Anthony J. BROCCOLI, Thomas L. Delworth (both at NOAA/Geophysical Fluid Dynamics Laboratory, Princeton, NJ 08542, USA, email: ajb@gfdl.gov)

The North Atlantic Oscillation (NAO) and Arctic Oscillation (AO) are related measures of the regional and hemispheric strength of the Northern Hemisphere midlatitude westerlies. A number of studies, focusing on the winter season, have reported an association between Northern Hemisphere temperatures (both local and spatially averaged) and the NAO and AO indices. Accurately assessing the amount of recent warming associated with such changes in circulation is an important aspect of the detection and attribution of climate change. Using both observations and model output, we investigate the hypothesis that the coexistence of long-term trends in the NAO/AO indices and temperature during recent decades has led to an overestimation of the strength of the association between circulation and hemispheric mean temperature.

MODEL SIMULATION OF THE ARCTIC OSCILLATION TREND: IMPLICATIONS FOR ATTRIBUTION OF OBSERVED GLOBAL WARMING

Drew SHINDELL, Ron L. Miller, Gavin Schmidt (NASA Goddard Institute for Space Studies and Center for Climate Systems Research/Dept. of Applied Physics, Columbia University, New York, NY USA); Lionel Pandolfo (Dept. of Earth and Ocean Science, University of British Columbia, Vancouver, BC Canada)

The Arctic Oscillation (AO), a hemispheric-scale version of the North Atlantic Oscillation (NAO), is a prominent feature of climate variability. Changes in sea-level pressure (SLP) are highly correlated with wintertime variations in Northern Hemisphere surface air temperature, and the more than 10 K warming over Eurasia during recent decades is associated with a decrease in Arctic SLP and an increase in mid-latitude SLP. We present climate model results demonstrating that the observed trend, including its magnitude, can be induced by increasing greenhouse gases. This suggests that although the warming appears through a naturally occurring mode of variability, it is likely attributable to anthropogenic activities. The AO mode extends from the surface to the stratosphere. Our results indicate that stratospheric changes may have a significant effect on surface climate, and that dynamical forcing of climate change by greenhouse gases may be quite important, in addition to the direct radiative forcing. Because the AO is associated with a distinctive, large regional signature of warming, proper simulation of anthropogenic impacts on this mode is important for the detection of climate change.

AN ENSEMBLE OF CLIMATE CHANGE SIMULATIONS WITH GFDL'S COUPLED CLIMATE MODEL

Tapio SCHNEIDER (Atmospheric and Oceanic Sciences Program, Princeton University, Princeton, NJ 08544-0710 Email: tapio@splash.Princeton.edu)

Climate change detection has come to be viewed as the problem of detecting a climate change "signal" that is contaminated by the "noise" of natural variability. The signal is usually taken as the simulated difference between a reference climate and a changed climate, and the natural variability noise is assumed to be linearly superimposed on the signal and unaffected by climate change. Detection of climate change in the observed record is taken to mean that the projection of the observations onto the simulated signal is, in a statistically significant manner, greater than the projection of the simulated natural variability onto the signal.
In this paper, a view of climate change detection is proposed that does not rest upon a linear decomposition of the data into a signal and noise and does not require the assumption of an unchanging natural variability. Instead of framing climate change detection as a signal transmission problem and defining a signal as the difference between two climatic states, we seek those climatic features that, on the average, best separate several groups of climatic states, groups defined, for example, as probable decadal climates in a climate change scenario. Detecting a climate change in the observed record at a certain time then amounts to verifying the following: first, in the simulations the separating climatic features discriminate reliably between the climate at that time and a reference climate; second, the simulation of the separating climatic features is consistent with observations.

CLIMATE CHANGE ASSESSMENT OVER INDIA USING METEOROLOGICAL, TIDE GAUGE OBSERVATIONS AND REGIONAL MODELS

H. N. SRIVASTAVA (India Meteorological Department New Delhi-110003, India, email: snb@imd.ernet.in)

Surface and upper air meteorological observations have been used for 475 surface and 31 upper air observatories data for 1901 to 1986 and 1951 to 1980 respectively to understand the decadal and 30 years trend over India for maximum and minimum temperatures, rainfall, frequencies of cyclonic storms and western disturbances and sea level changes using tide gauge observations.
It is found that the regional variation in surface air temperature is well marked over the country showing a rising trend south of 23°N and a fall north of this latitude. For the country as a whole, the temperatures have shown slight rise similar to global observations. Rainfall variations are within the statistical limits except over hilly regions where they show a decrease. The frequency of cyclonic storms and western disturbances does not show a marked change on the decadal scale. The tide gauge observations do not indicate a significant trend over the coastal region of the country. Although regional climate models need considerable modification, some agreement with the surface air temperature variations over India has been found and discussed. The agreement with rainfall predictions is poor suggesting finer scale grid models.

A MULTI-VARIABLE APPROACH TO CLIMATE-CHANGE DETECTION

B. D. Santer, K. E. TAYLOR (Program for Climate Model Diagnosis and Intercomparison, Lawrence Livermore National Laboratory, Livermore, CA 94550, U.S.A., email: ktaylor@pcmdi.llnl.gov), E. Roeckner, T. M.L. Wigley, T. P. Barnett, C. Doutriaux, K. Hasselmann, G. C. Hegerl, J. J. Hnilo, P. D. Jones, and U. Mikolajewicz

To date, virtually all studies attempting to identify human effects on global climate have compared modeled and observed temperature fields. Here, we consider whether these effects can be more readily identified by considering the joint behavior of several different climate variables rather than the behavior of a single variable. Our multi-variable representation of the climate system (in both models and data) comprises roughly 25-30 indices. The indices are very large-scale spatial averages, incorporating information on the atmospheric general circulation, temperature and moisture. Index time series are computed in comparable ways from models and observations, using both high-pass and low-pass filtered data. The model-based multi-variable signal and noise estimates are taken from perturbation experiments and a control integration performed recently with the ECHAM4/OPYC coupled model developed in Hamburg. The experiments involve time-varying changes in well-mixed greenhouse gases, tropospheric ozone and sulfate aerosol direct and indirect effects. We first attempt to identify the model-predicted multi-variable fingerprints in the observations. We then compute EOFs of the normalized modeled and observed index time series and apply an ``optimal detection" strategy to enhance signal-to-noise ratios. Preliminary results indicate that this approach is useful in climate-change detection and attribution studies and also offers a useful internal consistency check on the ``between-variable" covariance relationships in models and data.

MC02/W/02-B2 **1130**

CLIMATE CHANGE DETECTION AND ATTRIBUTION USING SIMPLE GLOBAL INDICES

David KAROLY, Karl Braganza, Tony Hirst, Scott Power (Meteorology CRC, Monash University, Clayton, VIC 3168, Australia, E-mail: djk@vortex.shm.monash.edu.au)

Initial studies of global climate change have sought to identify significant changes in global mean surface temperature and to attribute such changes to human influences. However, cause-and-effect are difficult to identify unequivocally in such a simple globally-averaged measure. More recent studies have focussed on fingerprint methods, which make use of the spatial patterns of temperature change to try to attribute the observed changes to one or more climate forcing factors. However, fingerprint methods also make use of more complex multi-variate statistics and the results may be harder to interpret or to communicate than those using global mean temperature.

In this study, we seek to follow the detection and attribution methodologies used in fingerprint detection studies but apply them using a small number of indices of global climate change. These indices have been selected based on earlier studies of climate change detection and on some of the key features identified in the climate change fingerprints that have been used commonly. They include the global mean temperature, the global mean temperature contrast between land and ocean, the mean meridional temperature gradient between high and low latitudes, and the mean magnitude of the seasonal temperature cycle and of the diurnal temperature cycle on land.
First, the observed trends in these global indices are compared with estimates of natural variability from control coupled climate model simulations to detect significant changes. Next, they are compared with forced climate model simulations to try to attribute the observed changes to one or more causes. The combination of these simple global indices has more power to attribute climate change than does the use of global mean temperature alone. While this approach may not be as statistically powerful as the fingerprint method, it is easier to explain.

MC02/E/18-B2 1150

DETECTION AND ATTRIBUTION OF ANTHROPOGENIC GLOBAL WARMING USING OBSERVED TRENDS IN NORTHERN HEMISPHERE SNOW COVER AND SEA ICE AREAS

Alan ROBOCK (Dept. of Environmental Sciences, Rutgers - The State University of New Jersey, 14 College Farm Rd., New Brunswick, NJ 08901-8551, USA, email: robock@envsci.rutgers.edu); Konstantin Y. Vinnikov (Univ. of Maryland, USA); Ronald J. Stouffer (NOAA Geophysical Fluid Dynamics Lab., Princeton Univ., USA); David Robinson (Rutgers Univ., USA); John Walsh (Univ. of Illionois, USA)

We compare existing observed data on variations in Northern Hemisphere sea ice and snow cover areas with those from equilibrium and transient climate model runs. We plan to present results from the GFDL and Hadley Centre GCMs. Northern Hemisphere sea ice area has been decreasing during the last five decades. The observed trend and inter-annual variability of sea ice area are in a good agreement with the GFDL transient (aerosol +1%/yr CO2) scenario of global warming, and the observed trend exceeds the limits of its natural variability, as determined by a long GCM control run. Northern Hemisphere snow cover area has also been decreasing during the past three decades. The observed trend and inter-annual variability of snow cover area are larger than those in the GFDL transient scenario of global warming, but can be explained as an effect of model resolution, in which the model cannot reproduce small scale summer snow variations. The observed snow cover trend is also very significant. Thus, we claim that the observed decreases in Northern Hemisphere snow and sea ice are fingerprints of the anthropogenic effect on climate. Seasonal distributions of the observed trends in Northern Hemisphere sea ice and snow cover areas are different from the model predicted scenario of global warming, and we will examine possible reasons for this. We will examine the predications of snow and ice by other GFDL simulations and by the Hadley Centre GCMs to determine how dependent these results are on the particular climate model we used.

MC02/W/11-B2 1210

INFLUENCE OF CIRCULATION AND SHORT WAVE RADIATION ON REGIONAL AIR TEMPERATURE VARIABILITY IN CENTRAL EUROPE

Ingeborg Auer, Reinhard BÖHM (Central Institute for Meteorology and Geodynamics, Hohe Warte 38, A-1190 Vienna, Austria, email: reinhard.boehm@zamg.ac.at)

A new instrumental climatic data set is used to investigate two natural factors to explain central European temperature variability and its regional deviations from global mean variability. The data set has been elaborated during the past two years (project ALOCLIM: Austrian long-term climate). It covers Austria and parts of the surrounding countries. It has been homogenised carefully using both meta data information for documented breaks in the series and three different relative homogeneity tests for quantitatively non documented breaks. It covers more than 200 years thus reaching far into the pre-industrial period. With four high level sites in altitudes up to 3100m asl. (700hPa) and 10 to 50 low level sites it introduces also the third (vertical) component into climate time series analyses. As it consists of time series of 15 to 20 single climate elements, it is a multiple data set usable for real climatic analyses considering not only single elements but also their possible interactions, dependencies and forcings. In this contribution the data set is used to analyse two factors that explain to a high degree the regional temperature variability in the east alpine region. Circulation is the real background forcing factor – directly by heat advection and indirectly by its influence on cloudiness and radiation in the mountainous region of investigation. Circulation is studied by NAO (explaining up to 60% of temperature variance) and by local air pressure series which show a stupendously high correlation with temperature. The indirect circulation forcing via radiation is studied by the co-analysis of temperature and sunshine series. Also for those two climate elements there is a high correlation both for high frequent and low frequent variability. The conclusion is that regional temperature variability in central Europe is strongly governed by

ANTHROPOGENIC AND NATURAL CAUSES OF TWENTIETH CENTURY TEMPERATURE CHANGE

Peter A. STOTT, Gareth S. Jones, Simon F. B. Tett Hadley Centre for Climate Prediction and Research, U.K. Met. Office, London Road, Bracknell, Berkshire RG12 2SY, UK.

A new coupled ocean atmosphere general circulation model that does not include flux correction has been used for the first time to attribute twentieth century climate change to anthropogenic and natural causes. We have made two ensembles of climate runs, initialised from different starting conditions, one of which includes natural forcings due to volcanic dust and changes in total solar irradiance and the other of which includes changes due to well mixed greenhouse gases, sulpate aerosols (both direct and indirect effects) and tropospheric ozone. Our modelling represents a significant advance on previous work by including the atmospheric sulphur cycle and representing well mixed greenhouse gases explicitly. We compare spatial and temporal patterns of near-surface temperature change from the model and observations using an "optimal fingerprinting" methodology. First we determine whether any linear combination of the response to natural forcings and internal variability can account for the warming observed this century. Next we include anthropogenic effects and attribute the observed change to natural and anthropogenic factors.

MC02/W/13-B2 1430

DISTINGUISHING BETWEEN NATURAL AND ANTHROPOGENIC INFLUENCE ON ATMOSPHERIC VERTICAL TEMPERATURE STRUCTURE

D.C. HILL (Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire, OX11 OQX); M.R. Allen (Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire OX11 OQX); S.F.B. Tett (Hadley Centre, UK Met. Office, London Rd., Bracknell, RG12 2SY)

Current approaches to the detection and attribution of an anthropogenic influence on climate involve quantifying the level of agreement between one or more model-predicted forced-response patterns and observed changes in the recent climate record. Studies (e.g. Allen and Tett 1999) have shown that, for a decadal mean diagnostic of zonally averaged vertical temperature, a zero response to greenhouse gases can be excluded, while a zero response to the combined influence of anthropogenic sulphate aerosols and stratospheric ozone depletion cannot. It is thought that more information may be found in a seasonally resolved approach since the impacts of sulphate and ozone are seasonally modulated. Hence, a study on vertical temperature patterns for 3 monthly averaged data is carried out, including patterns consisting of concatenated winter and summer data. The results which exclude a zero response to greenhouse gases have not explicitly taken into account solar and volcanic activity. Output from runs of the Hadley Centre's HadCM2 model for various forcings (including greenhouse gases, greenhouse gases and sulphate aerosols, changing solar activity and volcanic aerosols) is used in an optimal fingerprinting study to evaluate the evidence for these natural and anthropogenic forcings in radiosonde observations of atmospheric temperature structure.

MC02/E/14-B2 1450

DETECTION AND ATTRIBUTION OF 20TH CENTURY CLIMATE CHANGE USING A SEASONALLY OPTIMISED DETECTION METHOD

Gareth S. JONES, Peter Stott, Simon Tett (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, RG12 2SY, UK, email: gsjones@meto.gov.uk)

We present the results of an `optimal detection' analysis on the near surface temperature record and simulations of a climate model (HadCM2). The analysis is over latitude, longitude, time and additionally seasons. Optimising over seasons increases the signal to noise ratio of detection of climate signals above that of an annual analysis. The influence of greenhouse gases and anthropogenic sulphate aerosols is detectable in the latter part of the twentieth century and the influence of greenhouse gases and solar irradiance changes is detectable in the early part of this century.

MC02/E/04-B2 1510

LOCAL VERSUS GLOBAL CLIMATE CHANGE DETECTION PROBLEMS IN ISRAEL

Alpert PINHAS (Dept. of Geophysics and Planetary Science, Tel Aviv University 69978 Ramat Aviv, Israel, e-mail: pinhas@cyclone.tau.ac.il); Tehilla Ben-Gai, Arie Bitan, Alexander Manes (Dept. of Geography, Tel Aviv University, 69978 Ramat Aviv, Israel.)

Significant changes in land usage have taken place since the National Water Carrier operation in the early 1960's. Such changes are reflected in the spatial distribution of the surface albedo pattern, obviously resulting in changes in the surface radiation balance and, subsequently, modifying the surface heat fluxes and the stability conditions of the Planetary Boundary Layer (PBL). This process of changes in momentum, moisture, and heat fluxes, known as the ANTI-DESERTIFICATION process, should also affect climatic parameters of the boundary layer: rainfall patterns, temperature patterns, moisture, air pressure and wind, followed by changes in instability that could affect synoptic systems and rainfall amounts. Estimations of the temporal changes in the albedo values for the last sixty years show large differences (of up to 0.2) in the surface reflection. A gamma distribution function that was fitted to the annual and monthly rainfall at 60 station for two normal periods, reveal appreciable changes, especially in the Southern part of the country, with more than 60 percent increase in the shape parameter. The monthly distribution revealed considerable changes in October, November and March. Daily maximum and minimum temperatures in Israel revealed a significant decreasing trend of both the daily maximum and minimum temperature, during the cool season (November to March), and an increasing trend during the warm season (April to October), resulting in increasing seasonal temperature range. Teleconnections with changing patterns of temperature and pressure anomalies observed in Israel showed Relatively high correlation of -0.8 and +0.9 between the North Atlantic Oscillation(NAO) Index anomalies and the cool season temperature and surface pressure anomalies in Israel, respectively. Radiosonde records from the Bet-Dagan aerological station of the Israel Meteorological Service reveals a clearly defined increasing trend in the moisture content, mainly during summer. The stability of the surface layer, characterized by the Bulk Richardson Number, shows a decreasing trend since early 1960s. Though it seems that the changes in climatic parameters, point to a possible link to land use changes, connections with global trends should also be considered. The relatively high correlation between temperature anomalies and the North Atlantic Oscillation supports this connection. No link was found to the Southern Oscillation. We will discuss the more general detection and attribution problems as discovered by the Israel complex case.

BAYESIAN PARAMETER ESTIMATION AND HYPOTHESIS TESTING OF CLIMATE CHANGE

Haroon S. KHESHGI, Benjamin S. White (both at Exxon Research and Engineering Company, Route 22 East, Annandale, NJ 08801, USA, email: hskhesh@erenj.com)

Comparisons between climate data and climate model results are generally used to i) improve estimates of future climate, i.e. estimate parameters, and to ii) attribute the causes of changes in observed climate, i.e. test hypotheses. We use related Bayesian statistical frameworks to treat these two tasks on a common basis. For hypothesis testing we apply the Neyman-Pearson Lemma to construct the most powerful test for a variety of climate models and attribution questions, and compute the relationship between false-negative and false-positive errors for this optimal test. Both statistical frameworks depend on the characterization -- including uncertainty -- of climate records, climate variability, and the expected climate signal. We apply these frameworks to aggregated model/data comparison -- global and hemispheric temperatures.

MC02/W/06-B2 1630

THE ASSOCIATION BETWEEN THE INTENSITY OF MELBOURNE'S URBAN HEAT ISLAND AND THE REGIONAL SURFACE PRESSURE DISTRIBUTION

C. Jon Morris, Ian SIMMONDS (both at School of Earth Sciences, The University of Melbourne, Parkville, Victoria, 3052, Australia, email: ihs@met.unimelb.edu.au)

In using urban weather records to detect global climate change one must be careful to allow for the effects of urban heat islands (UHIs) (and how these may change with time). In this study we quantify the UHI in Melbourne as the difference between the 0600 temperature within the CBD and the mean of three non-urban airport sites (all located between 16.6 and 20.5 km from the CBD, and at different points of the compass). The analysis has been performed for the period 1973-91.
The daily data are binned into 1oC 'boxes', with all those exhibiting UHI of (-1oC and > 3oC considered in two separate bins. (About 75% of the UHI values fell between 0 and 2oC, while 3.6% of days exhibited a UHI in excess of 3oC.) The composite anomalous synoptic patterns (from the NCEP reanalysis data) associated with each of these UHI bins will be shown and interpreted. Not surprisingly, the strongest heat islands in Melbourne are associated anticyclonic conditions. However, one of the interesting results to come out of this work is the composite anomalous anticyclone is not centered directly over Melbourne but is located at some distance, lying to the east and south east of Tasmania.

MC02/W/15-B2 1650

TRENDS OF CLIMATE EXTREMES IN CHINA DURING THE LAST DECADES

Chi YANG, Zhongwei Yan (both at Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029, China, email: yangchi@ihw.com.cn)

Based on the daily weather observations of 61 stations during the 1951-1997, we analyzed the trends of the climate extremes in precipitation, maximum and minimum temperatures and wind speed over China. The least square fit method and Mann-Kendall's trend test were applied to define the linear changing rates and their significance. Some nationwide significant trends were found. At most of the stations, the number of days without precipitation increased during the last decades by a few days to weeks, whereas the number of days with the least precipitation (recorded as 0 mm) decreases. There is little trend in the strength of the extreme precipitation events. The minimum temperature significantly increased by more than 1 ¡æin northern China and about 0.5 ¡æin southern China, whereas the maximum temperature decreased but not very significantly. The extreme wind speed decreased about 1 m/s throughout China. A Singular Value Decomposition analysis was performed in order to find the principal correlation modes among the changes in the different variables.

MC02/P/03-B2 1710

GLOBAL CLIMATE CANGE AND ITS EMPIRICAL DIAGNOSTICS

V.N. Adamenko (Marine Academy, 16 Kosaya Liniya, St.Petersburg, Russia); K. Ya. KONDRATYEV (Russian Academy of Sciences, Research Centre for Ecological Safety, 18 Korpusnaya St., 197110 St. Petersburg, Russia, email: nansen@online.ru)

A hypothesis that global climate warming observed during the last century had been due to anthropogenically induced carbon dioxide concentration growth provoked controversial response. In this context, general considerations have been discussed which support the viewpoint that the 'greenhouse' global warming hypothesis is doubtful. One of the strongest arguments in favour of the above hypothesis is a conclusion drawn from numerical climate modelling data that there must be an enhancement of the 'greenhouse signal' with latitude. Some results of surface air temperature (SAT) observations in the Arctic during the last 20-30 years have been discussed which demonstrate a reduction in SAT in a number of Arctic regions. Some dendro-climatic data for the last 20-30 years relevant to tree growth near the northern forest boundary have also been considered. Analysis of these data reveals that not only the conclusion about polar enhancement of climate warming is wrong but the warming itself could hardly be realistic. So it may be concluded that no non-controversial information exists that can support the hypothesis of global 'greenhouse' warming.

MC02/P/02-B2 1730

GROWING SEASONAL SYNCHRONEITY BETWEEN GLOBAL TRACE GAS LOADS AND WORLDWIDE GAS PRODUCTION?

Peter CARL (Climate Dynamics Project, c/o Forschungsverbund Berlin Hausvogteiplatz 5-7, D -10117 Berlin, Germany, email: pcarl@spclim5.wias-berlin.de)

Time-frequency analyses are presented for both the global NOAA records of atmospheric C02 and CH4 and the OGJ figures of worldwide oil and gas production. The strong CH4 growth rate anomaly of the early 90th is situated just at the common (1990-94) stagnation phase in both production records. Though decline of eastern economies and Mt. Pinatubo's eruption may be blamed, a longer-term climatic contribution is suggested from monsoon time series of the century that point to a change, at the lower-frequency ENSO timescale, in the dynamic interplay of the monsoons of both hemispheres.
Except a moderate seasonal cycle, sub- to inter-annual variability dies largely out in oil production after recovery from stagnation. In contrast, gas production maintains rich variability that is dominated by far, however, by a strong and increasing seasonal cycle. The latter shows growing yet complex coincidence with the same cycle in atmospheric methane - which itself loses much of its sub-annual variability during the 80th to become more harmonic. In parallel, the growth rate of global atmospheric methane has continuously decreased. C02 shows a similar structural evolution except for semiannual variability which increases in amplitude together with the seasonal C02 cycle. If the northern hemisphere heating period becomes more directly involved in the seasonal radiative forcing, this would not necessarily saturate together with the CH4 growth rate.

SUDDEN CLIMATE SHIFTS IN THE GLACIAL NORTH AND SOUTH ATLANTIC OCEANS

GERARD BOND (Lamont-Doherty Earth Observatory, Rt. 9W, Palisades, NY, 10964, email: gcb@lamont.ldeo.columbia.edu)

Millennial time-scale climate variability in the North and South Atlantic, revealed by radiocarbon dated surface and deep ocean proxies, exhibits complex phasing that may arise from major shifts in the ocean's thermohaline circulation. In the northwestern limb of the present-day Gulf Stream, ocean surface temperatures are strongly antiphased with respect to those to the north in the subpolar gyre. The most striking antiphased patterns occur during the North Atlantic's Heinrich events. Carbon isotopic compositions of benthic foraminifera suggest that the antiphased patterns developed at times of significant reductions in the formation of North Atlantic Deep Water. Antiphased surface temperatures in the two regions also appear in the late Holocene, and may have been associated changes in deep water formation then as well. In the South Atlantic, a series of millennial-scale ice rafting events appears to be correlated, within error of radiocarbon dating, to ice rafting events in the North Atlantic. The most robust evidence is in recurring increases in percent of volcanic glass carried on ice drifting from the Scotia Arc. The North Atlantic ice rafting events are tied to Greenland's Dansgaard-Oeschger cycles, and hence, the ice core record appears to be imprinted in the Southern Ocean. During correlatives of Heinrich events, however, the South Atlantic ocean surface warmed, thereby implying the same strong antiphasing with respect to temperature in the subpolar North Atlantic as found in the northern Gulf Stream. The antiphased patterns in the North and South Atlantic Oceans are consistent with temperature anomalies produced in coupled ocean-atmosphere GCMs by a shut down of North Atlantic Deep Water formation. In the North Atlantic the antiphased shifts result from changes in the separation point of the Gulf Stream. In the South Atlantic, they arise from changes in cross-equatorial heat transport. If antiphased climate patterns are a common product of perturbations to global thermohaline circulation, their identification in paleoclimate records provides further constraint on the role of ocean circulation in climate change.

THE GLOBAL SYNCHRONEITY OF GLACIAL-INTERGLACIAL EVENTS

A. Clement, Universite de Paris 6, LODYC, etage 4, CASE 100, 4 place Jussiieu, 75005 Paris. France. CEDEX 05. E-mail: aclod@ipsl.jussieu.fr

The global synchroneity of glacial-interglacial events is one of the major problems in understanding the link between Milankovich forcing and the climate of the late Pleistocene. In this study, we isolate a part of the climate system, the tropical Pacific, and test its sensitivity to changes in solar forcing associated with changes in the Earths orbital parameters. We use a simplified coupled ocean-atmosphere model which is run for 150,000 years, and forced with Milankovich changes in the solar insolation. This system responds primarily to the precessional cycle in solar forcing, and is capable of generating an annual mean response to the changes in the seasonal distribution of solar radiation even while the annual mean insolation is roughly constant. The mechanism responsible for the annual mean response is the interaction between an altered seasonal cycle and the El Ni\¬no/Southern Oscillation. Changes in the ENSO behavior result in a mean tropical climate change which can be relatively abrupt. The hypothesis is advanced that such a change in the tropical climate can generate a globally synchronous climate response to Milankovich forcing.

ABRUPT CLIMATE CHANGES DURING THE LAST 6 600 YEARS IN SOUTH AFRICA

PETER TYSON (Climatology Research Group, University of the Witwatersrand, Johannesburg, South Africa, email: pdt@crg.bpb.wits.ac.za)Wibjorn Karlén and Karin Holmgren (Department of Physical Geography, Stockholm University email: karlen@natgeo.su.se and karin@ natgeo.su.se)

Few high-resolution time series are available for subtropical latitudes in the southern hemisphere that permit the determination of sudden climate shifts and changing patterns of variability during the last six millennia. Recently, a quasi-decadal resolution, 6 600-year proxy climate record has been determined from a stalagmite taken from a cave in the Makapansgat Valley in northern South Africa.
The series is characterised by periods of relative stability, periods of rapid change and times when rapid changes between extreme conditions were dominant. Rapidly changing patterns of variability with time are shown to be a feature of the entire record. The most extreme and prolonged episode in the entire record is shown to have occurred in the five centuries of cooling that constituted the Little Ice Age from 1300 to1800. The depression of annual maximum temperature below the present-day 1961-1990 mean at the time of maximum cooling at 1700 was 1-2 °C. Following maximum cooling at 1700, conditions ameliorated rapidly to revert to above-normal within fifty years. Other extreme shifts in the record are shown to have occurred within a decade or two. Changes in variability with time will be illustrated by determining the decadal variability in moving two-century time periods traversing the entire 6 600-year series.
Comparison of the stable isotope record for the Makapansgat valley with a similar high-resolution stalagmite isotope data for the Cango Cave in southern South Africa and an even higher-resolution record derived from corals on the south-western coast of Madagascar reveals that the Little Ice Age was a pronounced regional event over a large area of southern Africa. The spatial extent of the abrupt changes and sudden climate …

IDENTIFICATION OF CLIMATE SUDDEN CHANGE EVENTS IN QUATERNARY SEDIMENTARY RECORD BY WAVELET TRANSFORM

Yang WANG (Lab. for Geothermics, Institute of Geology, Chinese Academy of Sciences, P.O.Box 9825, Beijing 100029, China, email: thalassa@263.net)

The previous studies on climate change in Quaternary are mostly based on classical Fourier analysis method which only provides the frequency information about climate change periods. Wavelet analysis is a powerful tool for signal processing, owing to the local feature of wavelet functions. It means the function has non-zero values in a finite range, beyond the range values

approximate fast to zero; and this range is called the window of wavelet. Making convolution of signal and wavelet function, the singularity points of signal sequence can be identified; and we can find singularity points in different time (period) scales by changing the width of wavelet's window. When we take climate record as time dependent signal sequence, sudden change points in record are singularity points. Mexican Sombrero Wavelet (MSW) is the second derivative of Gaussian Function, the convolution of signal and MSW corresponds to smoothing signal by Gaussian Function and then making two derivations. This means that sudden change points are inflection points (a kind of singularity) of convolution function. The climate change signals from a Quaternary loess sequence in Xifeng, NW China, had been processed by wavelet transform. It was found that six sudden change events occurred in 1.32, 1.11, 0.58, 0.41, and 0.16 Ma BP, and demonstrates a quasi period in scaling of ~0.4-~0.7 Ma. Thirteen sudden change events were identified on ~0.1 Ma scale, and more sudden change events were found in shorter period scales. This result reveals the hierarchical structure of Quaternary climate signals and corresponds to the fractal nature of climate system.

ON RAPID AND PROTRACTED CHANGE IN THE SOUTHERN OCEAN CIRCULATION UNDER MODERATE GLOBAL WARMING

ANTHONY C. HIRST CRC for Southern Hemisphere Meteorology CSIRO Atmospheric Research PMB 1, Aspendale, Vic., 3196 Australia William F. Budd, Dave Bi and Xingren Wu Antarctic CRC University of Tasmania GPO Box 252-80, Hobart, Tas. 7001 Australia

Recent work using the the CSIRO coupled ocean-atmosphere model suggests that certain aspects of the Southern Ocean circulation may be very sensitive to global warming. We present results from three integrations of this model where the equivalent CO2 concentration is increased according to the IS92a radiative forcing scenario from 1880 AD to (1) 2000 AD, (2) 2033 AD and (3) 2083 AD, and then held steady for several centuries at, respectively, (1) 1.5 times, (2) 2 times and (3) 3 times the 1880 level. The oceanic changes occurring at high Southern latitude in the doubled and tripled equivalent CO2 integrations are quite profound, and include an major increase in strength of the near-surface halocline and the cessation of convection and bottom water formation. In both cases, this collapsed thermohaline state continues for several centuries of stable elevated equivalent CO2 to the end of the integrations. Further, the integration featuring a mere increase in equivalent CO2 by 50 percent (approximately present day levels) produces a substantial thermohaline slow-down which lasts at least several centuries. Importantly, these changes occurring in the 1.5 times and doubled equivalent CO2 integrations develop progressively during the 21st century despite stable levels of equivalent CO2.
The sensitivity of the Southern Ocean circulation to global warming is potentially important for several reasons. Firstly, convection and thermohaline overturning are important in bringing warm, salty subsurface water into the upper mixed layer, and so a slowing of this exchange may reduce the rate of regional surface warming. Secondly, changes in the surface/deep ocean exchange rate may affect the ability of the ocean to sequester anthropogenic \co2. Thirdly, these same exchange rate changes may affect…

SUDDEN CLIMATIC CHANGE WITHIN A MILLENIAL COUPLED MODEL SIMULATION

B.G.HUNT (CSIRO Atmospheric Research, Australia, email: bgh@dar.csiro.au)

The CSIRO Mark 2 coupled global climatic model has been used to generate 1000 years of simulated climate for present conditions (i.e. constant CO2). The model has 9 vertical levels in the atmosphere and 12 in the ocean and a horizontal resolution of R21. A comprehensive land surface scheme and a dynamical sea-ice formulation are included in the model. Examination of the model output provides many examples of sudden climatic change. These changes can be simple examples of year-to-year variability,or periods of sustained (10 years or longer) climatic anomalies of opposite sign to those preceding a change. Rainfall,surface temperature and surface wind stress provide particularly good case studies for sudden climatic changes. Normally the duration of sustained changes was between 10 and 15 years,depending on the climatic variable concerned. Preferred geographical regions were easily identified. Oceanic temperature anomalies appear to play a major role in sustaining other climatic anomalies,with oceanic temperature anomalies being identifiable down to several hundred metres depth. All the sudden climatic changes in the simulation can be attributed to natural climatic variability within the model system,and as such provide possible estimates of the duration,geographical regions,frequency of occurrence and amplitude of changes which might be observable.

MC 03/E/01-B4 1150

THE IMPACT LARGE LAKES ON CLIMATE

Potemkin V.(Limnological Institute, Irkutsk, 664033 Russia, email: klimat@lin.irk.ru)

Ice-age periods and interglacials - main and the most essential changes of global climate in modern quaternary period (about 2 million years). The intensive development of paleoclimatology, the integration of extensive information from different sources, including the data from annual layers of ice cores and sediments on the bottom of lakes and seas, have allowed to receive a detailed picture of a condition of all climatic system in ice period.
According to the data obtained during research in modern lakes it is known that large, long not frozen in the winter reservoirs of middle latitudes can cause fall out of additional "lakes" snowfalls on their leeward coast. In this connection there is a supposition that the existing huge lake Mansi in Late Pleistocene (20-25 thousand years ago) on the territory of West-Siberian Lowland could be the reason of the occurrence of powerful mountainous ice-sheets in Siberia. The preliminary quantitative valuations of this effect are under discussion in this paper.

MC03/W/02-B4 1210

OCEAN CIRCULATION AND SUDDEN CLIMATIC CHANGES

Nils-Axel Mörner, Paleogeophysics & Geodynamics, S-10691 Stockholm, Sweden,
email: morner@pog.su.se

There is a strong linkage between Earth's rate of rotation – total as well as differential – and the changes in ocean surface circulation. The ocean circulation changes are, in their turn, strongly linked to the paleoclimatic evolution of the boardering land masses. This is due to the high heat-storing capacity of the oceans, the ocean/atmosphere heat flux, and the ocean/land interaction via heat transport by the winds. Consequently, we see a causal connection between Earth's rotation, oceanic circulation, ocean/atmosphere heating, atmospheric (wind) heat transport and continental paleoclimatic changes. We propose that the paleoclimatic changes on the decadal-to-millennial time scale are primarily driven by this mechanism. Observational data of changes in ocean water masses and paleoclimate are presented for the 20 Ka situation, for the "sudden" high-amplitude changes 13-10 Ka ago, for the decadal-to-century changes during the Holocene, for the last centuries' instrumental data and for the ENSO-events. This implies that the oceanic system (the ocean surface circulation system) has a much more important role than previously appriciated for the understanding of short-term changes in climate as well as in sea level. It provides a logical mechanism for the interpretation of "sudden changes in climate" as well as for globally differentiated (even opposite) responsesignals. The cold periods (or "Little Ice Ages") recorded in NW Europe in 1440-1460, 1687-1703 and 1808-1821 in approximate association with the Spörer, Maunder and Dalton sunsput minima seem all to represent oceanographic circulation changes due to rotational increases.

THE TYPICAL CONCEPTUAL MODEL OF MOIST CONVECTIVE OVERTURNING

George BRYAN (Pennsylvania State University, USA, Email: bryan@essc.psu.edu)

The typical conceptual model of moist convective overturning depicts an ensemble of individual cumulus clouds emanating from a well-mixed convective boundary layer. This model fits with the accepted notion and theoretically supported view that atmospheric overturning will be dominated by fast-growing non-hydrostatic modes, i.e., thunderstorms. However, the atmosphere sometimes overturns in a manner that resembles mesoscale slabs (or sheets) of ascending air overrunning slabs of descending air. The ascending slabs, which are typically several hundred km in length and width, are usually forced upward by a front or convective outflow layer. As a slab ascends, a substantial portion, sometimes several hundred mb deep, reaches saturation. Since the ambient environmental lapse rate is steeper than moist adiabatic, the MESOSCALE lifting and subsequent saturation of the slab results in a moist absolutely unstable layer (MAUL). If the magnitude of MESOSCALE vertical motion exceeds the magnitude of the vertical motions that result from buoyancy forcing, the atmosphere can maintain (through a process of continual creation) the MAUL. Moreover, with continued mesoscale ascent, a solid swath along the front or outflow boundary reaches saturation and the convective overturning takes the form of a highly turbulent slab instead of discrete convective cells with intervening subsaturated areas.
Evidence of slab convective overturning of MAULs was compiled using Doppler radar data and the U.S.A. sounding network. Several examples documenting this mode of overturning are presented. The results from a non-hydrostatic cloud-scale-resolution numerical simulation of an event which featured a MAUL are also presented. It is argued that adjusting our conceptual models to view mesoscale moist convective overturning as vertically expanding slabs of saturated buoyantly turbulent flow would help explain several features often observed in mesoscale convective systems. Further, it forces us to address a fundamental problem with convective parameterization in mesoscale models, i.e., that buoyant parcels sometimes follow slantwise paths and affect more than a single gridelement at a time.

MC04/W/17-B1 0940

MESOSCALE CONVECTIVE SYSTEMS IN THE TAIWAN MEI-YU SEASON

JOU, Ben Jong-Dao (Department of Atmospheric Sciences, National Taiwan University, Taipei, Taiwan, 106, email: jou@hp715.as.ntu.edu.tw)

Individual thunderstorms developed into organised thunderstorm lines (squall lines) or complex convective storms are commonly observed. The spatial scale of these convective systems is about hundred kilometers and the time scale spans from a few hours to about a day. Significant precipitation and rapid changes of wind and temperature are frequently observed at the surface stations during the passage of these storms. We call these storm systems: Mesoscale Convective Systems (MCSs). From many observational and numerical studies in the past 40 years, it is known by the meteorological community that the favourable environmental conditions for development of these storms are availability of convective available potential energy (CAPE) and pronounced vertical wind shear.
Mei-Yu period in Taiwan, i.e., May and June, is a season with transition. In this season, the cold air mass from Siberia is weakening and the warm air mass from Tropics is strengthening. The boundary of these two air masses forms a stationary front in the subtropical area, extending from south of Japan to Taiwan and southern China. Accompanying with the stationary front, a wide cloud band with embedded organized convective systems are commonly observed from satellite images. Strong interaction between Taiwan topography and the frontal system induced many interesting local weather phenomena along the coast and over the island. This paper, by using radar images, to show the precipitation patterns and evolution of the mesoscale convective systems occurred in the Taiwan area and its vicinity during the Mei-Yu season.
Four different kinds of mesoscale convective systems, i.e., mountain convection, prefrontal squall lines, frontal rainbands, and tropical convection, total 16 cases observed by the conventional and Doppler radars around the island will be discussed. Cases observed during TAMEX _Taiwan Area Mesoscale EXperiment_, i.e., data from NCAR CP4 and NOAA TOGA radars, are also included. More details will be given during the meeting.

MC04/E/10-B1 1035

WARM SEASON PRECIPITATION EPISODES IN CENTRAL NORTH AMERICA

R. E. CARBONE, J. Tuttle, L. J. Miller, S. Trier (NCAR, Boulder, CO, USA)

Our purpose is to improve the understanding and prediction of heavy precipitation episodes that result from clusters of mesoscale convective systems (MCSs). In the US, WSR-88D Level II radar data, GOES Rapid Scan satellite data, and NWS Family of Services data have been acquired over 1000 to 2500 km domains for periods of 18 to 72 h. The radar and satellite data are conditioned and gridded in a manner that preserves their native spatial and temporal

resolution (1 to 4 km; 5 to 15 min), while permitting their use for integrated analyses, retrievals, and as a basis for initializing and verifying simulations with the MM5 model. Eight precipitation episodes were selected from the 1998 warm season for diagnostic analyses and simulations. The initial analyses focus on retrieval of wind fields and condensate fields over the regional domain. Wind fields and some 1st order derivatives thereof are retrieved through harmonic Doppler techniques and auto-correlation tracking techniques using both radar and multi-spectral GOES data in addition to UHF profiler and other NWS analyses. The three dimensional condensate fields are retrieved from a combination of radar reflectivity factor and GOES cloud cover information, where emphasis is placed on (1) precipitation-sized condensate to establish diabatic effects resulting from phase change of water, and (2) the radiative effects of optically-dense, non-precipitating cloud cover. Our preliminary analyses of the 1998 episodes explore several factors including the influences of topography; the role of travelling free-tropospheric disturbances, such as fronts and mesoscale convective vortices; and the larger scale role of various planetary boundary layer convergence lines, which are well established as a major factor in convection initiation at smaller scales.

MC04/L/01-B1 1100

LONG-LIVED MESOSCALE CYCLONIC VORTICES AND THEIR ASSOCIATION WITH SUBSEQUENT DEEP CONVECTION WITHIN HEAVY PRECIPITATION EPISODES

S. B. TRIER, C. A. Davis, W. C. Skamarock, and J. D. Tuttle, National Center for Atmospheric Research, P. O. Box 3000, Boulder, Colorado USA 80307-3000

Midlevel cyclonic vortices (MCVs) generated by mesoscale convective systems (MCSs) can persist after the dissipation of deep convection, and in some cases, may focus subsequent convective development within long-lived discontinuous heavy precipitation episodes. Thus, MCV behavior may be an important aspect of the warm-season quantitative precipitation forecast problem in many midlatitude locations.
Observations taken from the modernized United States Weather Service data network have been used to assess the frequency and general characteristics of MCVs induced by MCSs. Results from the 1998 convective season over the central United States suggest that long-lived MCVs, which persist after the dissipation of the initiating MCS, are more common than previously documented. The ambient verticalshear in the path of these long-lived MCVs tends to be weaker than the shear in the path of dissipating MCSs from which no detectable MCVs were spawned. New convection was observed on the downshear flank of the MCVs (i.e. in the direction of the ambient 0.5 to 2.5 km vertical shear vector) given appropriate preexisting thermodynamic conditions (i.e.,weak convective inhibition).
Supporting numerical simulations with a primitive equation model indicate that lifting that results from the interaction of the MCV with the ambient shear produces vertical parcel displacements sufficient tosaturate portions of the lower troposphere on the downshear flank of the MCV in model environments representative of those found in the observations. In addition to confirming the importance of weak ambient shear for MCV longevity, the simulations have also illustrated the importance of internal vortex parameters such as the initial size and strength of the vortex and also its location relative to the ambient shear layer for both MCV longevity and their ability to generate subsequent convection. Additional numerical experiments that examine the interaction between convection induced by the MCV and the subsequent evolution of the MCV itself will be presented. Understanding the life cycles of MCVs is expected to improve prediction of a large class of long-lived heavy precipitation episodes.

MC04/E/09-B1 1130

SHORT-TERM FORECASTING OF SEVERE STORMS WITH A NUMERICAL MODEL AND ITS ADJOINT

Andrew CROOK, Juanzhen Sun and Tom Warner (National Center for Atmospheric Research, P.O. Box 3000, Boulder, Colorado, USA, 80307-3000, email: crook@ucar.edu)

Over the past decade we have been developing methods to initialize a numerical cloud model with Doppler radar observations for the purpose of short-term storm forecasting. The system uses the adjoint method to assimilate observations from either single or multiple Doppler radars. The goal is to produce initial conditions for the full dynamical, thermodynamical and microphysical fields that optimally fit a numerical cloud model to all available radar observations.
We have applied the adjoint method to observations of a flash flood producing storm in the Front Range of the Rocky Mountains. The storm of interest moved slowly over the Buffalo Creek, Colorado watershed producing over 75 mm of rain in less than one hour. A number of 1-2 hour forecasts of this storm have been performed starting at different times in the storm evolution. In general, the numerical forecasts outperform other methods based on persistence, extrapolation and rule-based techniques. Some of the outstanding issues and problems in short-term numerical prediction of thunderstorms will be discussed at the Conference along with future planned research.

MC04/L/03-B1 1205

PRECIPITATION AND FISH KILLS: ARE THEY RELATED?

L. J. PIETRAFESA; L. Xie (Dept. of MEAS, N.C. State University, Box 8208, Raleigh, NC 27695-8208, USA); N. E. Huang (Laboratory for Hydrospheric Processes/Oceans and Ice Branch, NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA)

Quantifying precipitation presents an important challenge, particularly as it relates to societal impacts. One such area of concern is the combination of precipitation and ensuing drainage of fresh, buoyant and often nutrient-rich water into coastal regions. Fishermen and coastal residents have long been witness to the occurrences of fish kills in river and estuary waters. Causes are often ascribed to natural environmental events which result in anoxic conditions. In recent years, fish kill occurrences have received massive public attention and political scrutiny because of the perceived increased exposure of people who are dependent upon the use and health of coastal and estuarine waters for their livelihood, eg. Fishing, agriculture and ecotourism. As an outcome of the public debate that has ensued, state and federally subsidised studies in support of determining causes, effects and solutions have been established. Albeit, to date few of these studies has focused on the time history of fish kill occurrences and their potential correlation with environmental factors. A pre-conditioning of the water environment which places the fish community at risk is a possibility. This paper looks at the documented history of fish kills, reported over eleven years in two adjacent North Carolina river estuaries in relation to several environmental factors: including precipitation, river discharge, atmospheric temperature and winds. A new empirical mode decomposition technique is used to analyse the non-linear, non-stationary time series used in the analyses. Results indicate that quantitative precipitation forecasting at river basin scales is key to coastal management strategies.

SIMULATIONS OF EXTREME EVENTS, EDUCATION AND TRAINING

MC04/W/11-B2 1400

QUANTITATIVE PRECIPITATION FORECASTING OF EXTREME PRECIPITATION EVENTS

Deborah J. ABBS (CSIRO Atmospheric Research, Private Bag No. 1, Aspendale, Vic. 3195, Australia, Email: debbie.abbs@dar.csiro.au)

The CSU Regional Atmospheric Modelling System (RAMS) has been used to model extreme precipitation events that have occurred along the steep, coastal escarpment of the Sydney-Illawarra region of south-eastern Australia. Results have been obtained at a horizontal resolution of 7 km. Two types of synoptic-scale systems have been modelled, (i) an east-coast low and (ii) an upper-level cut-off low. Both cases were associated with 24-hr rainfall in excess of 300 mm. East coast lows have been identified as the major cause of flood-producing rains on the east coast of Australia, and are characterised by heavy rainfall and strong winds. In contrast, upper-level cut-off lows are usually associated with intense thunderstorms.
For each system, simulations both with and without parameterised convection on the finest mesh have been performed. We have found that the use of an appropriate convective parameterisation scheme at these resolutions has the effect of triggering convection at both the correct location and time and produces good quanitative precipitation forecasts. In this presentation we will (a) show that a convective parameterisation scheme may need to be used at grid resolutions of the order of 10 km and (b) investigate the coupling between the convective scheme and boundary layer processes that occurs in these case studies.

MC04/W/08-B1 1425

NUMERICAL SIMULATION OF THE 28 JULY 1997 FORT COLLINS, COLORADO, FLASH FLOOD

C. Travis ASHBY (Department of Atmospheric Science, Colorado State University, Fort Collins, Colorado 80523, USA, Email: ashby@chubasco.atmos.colostate.edu); Dr. William R. Cotton (Department of Atmospheric Science, Colorado State University, Fort Collins, Colorado 80523, USA, Email: cotton@isis.atmos.colostate.edu)

The Regional Atmospheric Modelling System (RAMS) is being used to simulate the 28 July 1997 Fort Collins, Colorado, flash flood. Nested model grids are used, allowing explicit simulation of synoptic, meso and convective scale motions. The processes responsible for initiating and maintaining the quasi-stationary, flood-producing convection are investigated. The mechanisms for modulating the precipitation intensity during the event are also examined. This includes the observed acceleration of easterly winds preceding the time of heaviest precipitation. The convective bands which were observed to originate over central and north-central Colorado and propagate north-eastward over the Front Range at the time of flooding are also present in this simulation. The influence of these convective bands in intensifying the pre-existing convection over the northern foothills of the Front Range is also studied. Several experiments are being conducted to determine the sensitivity of the simulation to the initial conditions and model physics. The varying parameters in these sensitivity tests include soil moisture, topography resolution, initial cloud amount and distribution, initial wind and moisture perturbations, hydrometeor size distribution and complexity of moist thermodynamics (liquid phase only vs. mixed phase microphysics). These simulations indicate that initial cloud cover characteristics can influence storm outflow properties and storm propagation characteristics through the model surface temperature and low-level moisture fields.

MC04/W/06-B1 1450

NUMERICAL SIMULATION OF THE 16-19 OCTOBER 1994 SOUTH-EAST TEXAS HEAVY RAIN EVENT

Thomas PETROSKI, John nielsen-gammon (Texas A&M University, College Station, TX, 77843-3150, USA; email: n-g@tamu.edu)

During the period from 16 October through 19 October 1994, a mesoscale convective system developed within a weakly forced large-scale environment resulting in very heavy rainfall with subsequent widespread flash flooding that affected much of south-east Texas. Liberty, Texas, about 55 km north-east of Houston recorded 77.5 cm of rain and an area greater than the state of South Carolina received in excess of 25.4 cm of rain.
Simulations using the PSU-NCAR Mesoscale Model are conducted to explore the degree to which a high resolution model can reproduce this heavy rain event. In order to include synoptic and mesoscale features into the analysis which are important for correctly simulating a heavy rainfall event, initial conditions are generated using four dimensional data assimilation techniques. Model simulations utilise the Grell cumulus parameterisation scheme, the Reisner mixed-phase explicit scheme, and high resolution grids (i.e. 36 and 12 km). Preliminary model results show precipitation totals and distributions are very sensitive to the choice of grid resolution. The convective scheme initiates and maintains convection over much of the Gulf of Mexico even though none was occurring in the real case. Since we are interested in determining the critical mesoscale elements important for simulating a heavy rain event, future simulations will test higher grid resolutions (e.g. 4 km) over south-east Texas using only an explicit parameterisation scheme.

MC04/W/10-B1 1515

SIMULATIONS OF EXTREME PRECIPITATION EVENTS IN THE SOUTHERN UNITED STATES: SENSITIVITY TO GRID RESOLUTION

John NIELSEN-GAMMON, John Strack (Texas A&M University, College Station, TX, 77843-3150, USA; e-mail: n-g@tamu.edu)

We test the performance of the Penn State/NCAR Mesoscale Model, Version 5.2 in simulating five extreme precipitation events that occurred in the south-eastern United States during the past five years. All five events produced point totals of close to 1 m of rainfall in a short period of time, and were generally not of the same nature as the more widely studied continental mesoscale convective systems. The sensitivity of the model to grid resolution is tested by performing a large number of simulations at a wide range of resolutions using both explicit and parameterised convection. Based on preliminary results, we expect to find extreme sensitivity to explicit versus parameterised convection and fairly high sensitivity to grid resolution. We shall also explore the extent to which increases in grid resolution cause the model simulations to converge toward a particular solution.

MC04/W/16-B1 1620

IMPACT OF CHOICE OF CONVECTIVE PARAMETERIZATION ON MODEL QPF-HORIZONTAL RESOLUTION DEPENDENCE

William A. GALLUS Jr. (Iowa State University, USA, E-mail: wgalus@iastate.edu)

A workstation version of the Eta model is used to simulate three excessive rainfall events in the Central United States. The episodes reflect a wide range of meteorological situations: (i) a warm core cyclone in June 1996 generated a meso-beta scale region of excessive rainfall from echo training in its warm sector while producing excessive overrunning rainfall to the north of the warm front, (ii) a fairly typical mesoscale convective complex in July 1996 produced excessive rainfall and (iii) tornadic thunderstorms in May 1997 resulted in small-scale excessive rains. Model peak QPF sensitivity to horizontal resolution is investigated using grid spacing of 78, 39, 22 and 12 km. In addition, both the operational Betts-Miller-Janjic (BMJ) and Kain-Fritsch (KF) convective parameterizations are used. The three cases exhibit strikingly different QPF behavior as resolution is refined, and differences are shown to be related to the design of the convective parameterizations. The aggressive BMJ scheme tends to reduce the resolution dependence of QPF by preventing a significant grid-resolved component of precipitation under moist conditions with modest instability. In some cases, peak precipitation may actually decrease as resolution improves. Under the same conditions, the KF scheme promotes the grid-resolved component, resulting in large sensitivity of QPF to resolution. In the July MCS case for instance, peak QPF increased by nearly 1800% as resolution improved from 78 km to 12 km. In cases with extreme instability (such as the May 1997 case), a stronger resolution dependence occurs with the BMJ scheme; the KF scheme triggers too quickly in the strongly forced environment, with a different simulated evolution of events. The variability of results suggests that an understanding of convective parameterizations would benefit forecasters, and implies that an ensemble approach to the prediction of excessive rainfall may be of more benefit than the use of just one especially high resolution model simulation.

MC04/W/07-B1 1700

EXCESSIVE SHORT-DURATION RAINFALL FROM WARM SEASON CONVECTION

Matthew KELSCH (UCAR/COMET, USA, e-mail: kelsch@coment.ucar.edu)

Short-duration, localized excessive rainfall is among the most difficult to forecast due to the rapid storm evolution and complex storm-scale interactions involved. The storm complexes responsible for such events are often focused by terrain, pre-existing mesoscale boundaries, and meteorological boundaries generated by the storm system itself. When the precipitation occurs over hydrologically sensitive areas, such as steep terrain or small urbanized basins, severe flash flooding can result. Accurate Quantitative Precipitation Forecasts (QPF) for such events requires detailed understanding of the mesoscale processes that result in enhanced precipitation efficiency and prolonged duration over a localized area. The Cooperative Program for Operational Meteorology, Education and Training (COMET) at the University Corporation for Atmospheric Research (UCAR) in Boulder, Colorado, USA, has developed a thorough set of multimedia material for training in the hydrometeorological sciences. These materials exist in electronic form on compact discs, in Web-based material, and in an online case study library. In addition, a Hydrometeorology course as offered at the classroom facility. Participants receive presentations from experts on various topics in hydrology and meteorology. Laboratory excercises use a variety of flood events, including several warm-season events involving intense, localized precipitation. The material is designed to demonstrate the utility of mesoscale observing and modeling methodologies as well as the importance of the human forecaster in flash flood situations.

RAINFALL ESTIMATION TECHNIQUES AND GLOBAL MODEL PERFORMANCE

MC04/W/12-B2 0925

REAL TIME SATELLITE RAINFALL ESTIMATION OF HEAVY PRECIPITATION IN THE TROPICS AND SUBTROPICS - EXPERIENCE WITH AN EXPERIMENTAL/OPERATIONAL TECHNIQUE

Gilberto A. VICENTE, Rod A. Scofield (NOAA/NESDIS, Office of Research and Applications, E/NP2 4700 Silver Hill Road, Washington, DC, 20233-9910, USA, email: gvicente@nesdis.noaa.gov)

An automatic precipitation estimation technique (called the Auto-Estimator) has been developed for GOES-8/9/10 data, Vicente et al., 1998. This algorithm has being used experimentally in NESDIS for estimating rainfall from convective systems during flash flood situations for 3 years. Recently it was use by the US National Weather Service during 6 weeks in August/September on the test/operational environment. Characteristics of the Auto-Estimator include a rain rate curve based on the 10.7 micron temperature, and adjustments for cloud growth, cloud gradients, and moisture. Currently, the Auto-Estimator uses half hour data to compute 4 by 4 Km resolution real time 1-hour estimates and 3-hour totals every half hour, 6-hour totals every hour and 24-hour totals once a day. The 1-hour estimates and 24-hour totals have been archived since September/96 for sub-synoptic and mososcale analyses. The Auto-Estimator takes into account orograph and wind information and adopts cloud top satellite parallax corrections for better location and estimation of the heavy precipitation cores on the cloud system. The objective of the presentation is to show results of the NOAA/NESDIS experience in dealing with flash flood watch and warning situations using an automated rainfall estimation technique in combination with other information sources [ground observations (radar and gauges) and models (wind speed and direction, precipitable water, relative humidity)]. We will discuss the advantages and disadvantages of the automated technique in comparison with the more established manual Interactive Flash Flood Analyzer technique (IFFA, Scofield 1987) in operational use by NOAA/NESDIS US National Weather Service for the last 15 years. Attention also will be given to the use of an extension of the US version of the Auto-Estimator to South America and the possibilities for the use and implementation of the same technique for every tropical and subtropical region in the globe.

MC04/E/02-B2 0950

RADAR VALIDATION OF CONVECTIVE AND DYNAMIC PRECIPITATION FORECASTS

Anthony J. ILLINGWORTH (Department of Meteorology, University of Reading, Reading RG66 6BB, UK, email: a.j.illingworth@reading.ac.uk)

Radar is one of the most attractive means of validating quantitative precipitation forecasts because its spatial coverage is superior to that of a point rain gauge. The shortcomings of radar estimates of rainfall are well known: two of the major ones are the vertical profile of reflectivity and absolute calibration of the return power in terms of reflectivity, Z. In this paper we will indicate how corrections for vertical profile can be made by using two profiles, one for bright band and one for non-bright band cases, by using a threshold value of Z of 30dBZ at a height 1.5km above the freezing level to indicate when a bright band is absent. The two classes of profile should also provide a separation into convective and dynamic rainfall and provide validation of the contributions made by the two precipitation schemes in mesoscale forecasting models. Accurate calibration of the Z return to within 0.5Db can be provided by exploiting the redundancy of two of the polarisation parameters when observed in rain: the differential reflectivity and differential phase shift. This automatic calibration of the reflectivity values every time there is moderate or heavy rain could turn out to be one of the most powerful uses of the polarisation technique.

MC04/W/13-B2 1050

QUANTITATIVE PRECIPITATION FORECASTS BASED ON OPERATIONAL NWP MODEL PRECIPITATION FIELDS

John L. McBRIDE, E. Ebert, and K. Puri (Bureau of Meteorology Research Centre, Melbourne, Australia)

Results are presented of recent developments in operational QPF in the Bureau of Meteorology. Real-time gridded 24-hour precipitation forecasts from seven operational NWP models are verified over two large subregions of the Australian continent: the Northern tropical monsoon regime, and the south-east subtropical regime. All forecasts have been mapped to a one-degree latitude / longitude grid and have been verified against an operational daily rainfall analysis, mapped to the same grid. Verification statistics include bias score, probability of detection, false alarm ratio, root mean square error, correlation and mean absolute error. Our main measure of skill, however, is the Hanssen and Kuipers score, and its two components: accuracy for events and accuracy for non-events. The aim is to establish the current skill level in both regions as a basis for comparison with later models and longer lead-time forecasts. Results are calculated as a function of rain threshold; and a compact presentation of results is obtained through the use of phase-space diagrams, with HK score, accuracy for non-events as the three co-ordinates.
The same seven operational models are used to develop a combined model forecast, based on a weighted average of the seven models. Methods of combining include simple averaging and weighted averages based on inverse error variances. Other methods of combining forecasts are explored based on multiple linear regression and stepwise regression. We also experiment with correcting the individual models before averaging bases on errors in either rain volume or rain area. Lastly, the weights are calculated for a three month period, then recalculated at monthly intervals as a form of adaptive filter.
Other aspects of our development will be briefly described, including a graphical user interface for operational forecasters to obtain maps and line plots of analysed rain, QPF and verification statistics for all models. Also we will describe some results on the concept of verifying contiguous rain areas (or CRA's) rather than single point measures.

MC04/W/14-B2 1115

THE DIURNAL CYCLE OF PRECIPITATION IN THE ECMWF GLOBAL FORECAST MODEL: DESCRIPTION AND SENSITIVITY

D. GREGORY (ECMWF, Shinfield Park, Reading RG2 9AX United Kingdom E-mail: dgregory@ecmwf.int)

In common with many NWP and climate models, the ECMWF global forecast model has tendency to predict the onset of diurnally driven convection too early. This leads to an over prediction of precipitation before local noon over continental regions during the summer season. The early onset of convection is due to the response of the convection scheme to the rapid transition of the dry boundary layer from stable conditions during the night to an unstable profile soon after sunrise. Failure of the convection scheme to respond to longwave cooling of the mid-troposphere during the night exacerbates the problem, allows instability to build towards sunrise assisting the rapid development of intense convection.
Revision of the triggering algorithm used to diagnose the presence of convection and its impact upon the diurnal cycle of convection will be discussed. The formulation of lateral entrainment above cloud base also has an impact upon the onset of precipitating convection. A new formulation in which entrainment is linked to the buoyancy of a parcel inhibits the development of convection to a greater extent than the fixed values of the current scheme.

MC04/E/03-B2 1140

THE STUDY OF THE PRECIPITATION FORECASTS IN THE SL-AV GLOBAL NWP MODEL

Mikhail TOLSTYKH, Igor Esau (both at Institute of Numerical Mathematics, Russian Academy of Sciences, 8 Gubkina str., 117951 GSP-1 Moscow, Russia, e-mail: tolstykh@inm.ras.ru)

This work studies the quality of medium-range precipitation forecasts in the recently developed global semi-Lagrangian model SL-AV with the resolution 1.5 degrees and 28 vertical levels. The basic version of this model uses the parameterizations of subgrid-scale processes from the French operational model ARPEGE/IFS, where the convection is parameterized by a mass-flux scheme. The experimental version includes the modified Betts-Miller scheme and the modified Smith scheme for stratiform precipitations. The latter allows to take into account the variability of precipitation related with the Ns-type cloudiness. The results for the series of five-day forecasts with the basic and experimental versions of the model and their comparison with the observations are described.

MC 04/E/08-B2 1205

A NEW IDEA TO IMPROVE CHINA SUMMER PRECIPITATION FORECASTING

DONG Wenjie, Wei Zhigang (both at Lanzhou Institute of Plateau Atmospheric Physics, Chinese Academy of Sciences, Lanzhou, Gansu, 730000, P.R.China, email: dwj@ns.lzb.ac.cn)

At present, the dynamic model method and the statistical climatic method are used at flood-season precipitation forecasting. The difficulty of the dynamic method is that it is too far a way to fit an operational prediction's requirement and the limit of the statistical method is that it has no power facing the case that the muti-factors are simultaneously abnormal. By the examples to predict the precipitation of summer in 1998 in China, a new idea of the dynamical-statistical forecasting combination is found out: In the case that two or more factors are simultaneously abnormal, use the dynamical model to separate and diagnose the dependent contribution of each abnormal factor and the combing contribution of multiple abnormal factors. The EOF analysis is applied to the numerical experiment to predict summer precipitation anomalies. The main forecasting result accords with the real distribution of summer precipitation anomalies in1998 in China.

DATA ASSIMILATION, VERIFICATION AND NON-DYNAMICAL FORECAST SYSTEMS

MC04/E/01-B2 1400

EFFECTS OF MIXED-PHASE PROCESSES ON SHORT-RANGE RUC QPF

John M. BROWN, Georg Grell, Stan Benjamin, and Tanya Smirnova (NOAA/Forecast Systems Lab; 325 Broadway, Boulder, Colorado 80303 USA, Email: jmbrown@fsl.noaa.gov)

The Rapid Update Cycle (RUC) running at NCEP in the U.S. includes in its forecast model a detailed mixed-phase bulk microphysics scheme adopted from the NCAR/Penn State MM5 model. This scheme includes explicit forecasts of mixing ratios of 5 different hydrometeor species. Previous experiments showed that the inclusion of this scheme into the RUC improved QPF over that previously produced by a simple supersaturation removal. In this study, we investigate the overall effect of ice processes as well as the role of specific water-to-ice conversion processes on the 3-D structure of model-predicted precipitating systems and on the resulting QPF.

MC04/E/07-B2 1425

EFFECTS OF GOES CLOUD-TOP ASSIMILATION INTO RUC MIXED-PHASE CLOUDS ON SHORT-RANGE QPF

Stan BENJAMIN, Dongsoo Kim, Tanya Smirnova, and J. M. Brown (NOAA/Forecast Systems Laboratory, Boulder, CO 80303 USA, email: benjamin@fsl.noaa.gov)

Initial conditions of water vapor and hydrometeors are clearly critical to an accurate very short-range precipitation forecast. The Rapid Update Cycle (RUC) is a high-frequency (1-h) short-range assimilation/forecast system running at NCEP in the United States. The RUC includes a mixed-phase bulk microphysics scheme in its forecast model. At present, the RUC initializes hydrometeors by simply using the 3-D distribution of hydrometeor mixing ratios from the previous 1-h RUC forecast. Recognizing that these forecasts have significant errors resulting in large part from errors in initial conditions, FSL has begun experiments combining cloud-top pressure data from GOES with the model 1-h forecast for modified initial conditions of cloud water and ice. In this paper, we will present a study on the effects on 3-6h precipitation forecasts of this GOES cloud-top assimilation.

MC04/E/06-B2 1450

VERIFICATION OF SHORT RANGE RUC PRECIPITATION FORECASTS USING THE NCEP EXPERIMENTAL STAGE-4 HOURLY PRECIPITATION ANALYSES

Barry SCHWARTZ, Stan Benjamin (NOAA/Forecast Systems Laboratory; 325 Broadway, Boulder, CO 80303 USA, Email: schwartz@fsl.noaa.gov, benjamin@fsl.noaa.gov)

The Rapid Update Cycle (RUC) is a model that was developed at NOAA's Forecast Systems Laboratory and has been implemented operationally at the National Centers for Environmental Prediction (NCEP). The RUC has a unique role within the U.S. National Weather Service in that it is the only operational system that provides updated national scale Numerical Weather Prediction (NWP) analyses and forecasts more often than once every 6 hours. QPF forecasts from the RUC are produced hourly out to 3-h in advance, and 3-hourly out to 12-h in advance of the initial cycle run time. At NCEP an experimental real-time hourly, multi-sensor U.S. National Precipitation Analysis (NPA) was developed in the mid 1990s. Over the lower 48 states, this analysis merges approximately 2500 hourly raingauge observations obtained in real-time with hourly digital precipitation radar estimates. The NPA and the RUC give us a unique opportunity to examine frequently updated short-range QPF characteristics of an operational NWP model. Standard QPF Skill scores for 1- and 3-h accumulated RUC precipitation forecasts will be presented for part of the winter and the spring of 1999. A brief discussion of the ongoing development of the RUC and NPA systems will be included.

MC04/W/05-B2 1515

QUANTITATIVE EVALUATION OF CUMULUS PARAMETERIZATION SCHEMES IN AN OPERATIONAL MESOSCALE MODEL

Chi-Sann LIOU (Naval Research Laboratory, Monterey, CA, USA)

Three cumulus parameterization schemes: relaxed Arakawa-Schubert, Kain-Fritsch, and Kuo are evaluated within the US Navy operational model of Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS). The operational model has been run with the three cumulus parameterization schemes for 20 days in winter 98/99 over the US with two-level nested grids of 81km and 27km resolution. Equitable threat scores and biases are computed and compared among the three schemes to serve as objective measures of the quantitative precipitation forecast skills. In addition, two heavy rainfall cases, one in subtropical and the other in mid-latitude areas, are selected to examine in details the forecast skills of the three cumulus parameterizations in severe weather situations. In the case studies, 9km third-mesh grids are also included in the evaluation. The preliminary results indicate that the Kuo scheme over-predicts while the Kain-Fritsch scheme under-predicts precipitation in COAMPS.

MC04/W/09-B2 1600

THIRTY THREE YEARS OF QUANTITATIVE PRECIPITATION FORECASTING DURING THE SUMMER CONVECTIVE SEASON IN THE UNITED STATES

David W. REYNOLDS (Hydrometeorological Prediction Center, 5200 Auth Road Room 410, Camp Springs, MD 20746, USA, Email: david.reynolds@noaa.gov); Bruce Terry (Hydrometeorological Prediction Center, 5200 Auth Road Room 410, Camp Springs, MD 20746, USA, Email: bruce.terry@noaa.gov)

The HPC (Hydrometeorological Prediction Center), a service center within the National Weather Service's National Center for Environmental Prediction, has been producing quantitative precipitation forecasts for over thirty years. These are 24-hour forecasts out through 24 and 48 hours. The forecast includes a graphical depiction of isohyets using .25, .5, 1,2, 3 ... inch amounts. In addition, the HPC has been computing 6 hour QPF's since 1981 for the 6 to 12 and 12 to 18 hour period. During the past three years we have expanded the 6-hour forecast to include the 0 to 6 as well as the 18 to 24 and 24 to 30 hour forecasts. The HPC has been keeping verification scores of all forecasts since its inception, both for the 24-hour and 6-hour forecasts. Not only are these forecasts verified against observations, but are also compared to the QPF as produced by the operational NWP (numerical weather prediction) models run at NCEP. This paper will concentrate on the verification statistics for the convective season, May through August, for both the manual as well as the model forecast. As many of the more significant rainfall events during the US convective season are produced by mesoscale convective systems, by concentrating on the verification scores for the one and two inch isohyets, one can try to isolate how well the rainfall from these systems can be forecast. Year to year trends in scores will be related to either improvements in NWP or improvements in the knowledge base of the forecaster. Of special concern is the difference in skill between the 24 hour and six hour forecast amounts. As flash floods are more sensitive to rain-rate and thus the short term QPF, it will be important that the six-hour forecasts show sufficient skill as it is these values that are input to hydrologic forecast models. These results should provide the audience with the "state of the science" in QPF forecasting for convective systems, at least in the US.

MC04/E/04-B2 1625

ASSIMILATING SATELLITE AND RADAR OBSERVATIONS INTO THE ETA MODEL TO IMPROVE CLOUD AND PRECIPITATION FORECASTS

Qingyun ZHAO, Geoffrey J. DiMego, David F. Parrish, Ying Lin, Michael Baldwin, Eric Rogers, Kenneth A. Campana (Environmental Modeling Center, National Centers for Environmental Prediction, Washington, D.C. 20233, USA, Email: wd20cl@next4.wwb.noaa.gov)

To further improve the model's cloud and quantitative precipitation forecasts and to study the method of optimally using various type of data in the data assimilation, an algorithm has been developed to combine the satellite data with radar observations in the Eta Data Assimilation System (EDAS). The Real-time, three-dimensional Neph-analyses (RTNEPH) from the US Air Force Global Weather Center are used in the data assimilation procedures to indicate the cloud locations both in the horizontal and in the vertical directions. Hourly precipitation analyses derived from NEXRAD observations over the United States are also employed to retrieve the total cloud water content.
Several cases have been chosen to study the effects of the data assimilation on model precipitation forecasts. This algorithm was also continuously tested for about a month during a winter time. Results from all tests showed significant improvement in precipitation forecast during the 48-hour free forecast period.
Efforts are also being made to expand this algorithm to use more observed data resources available at NCEP, such as GOES cloud images and radar reflectivity data from NEXRAD network. As progress is being made, more interesting results from this study will come out and be represented at the conference.

MC04/L/02-B2 1650

THE MARITIME CONTINENT RAINFALL FORECASTING BY USING NEURAL ARTIFICIAL NETWORK METHOD

Joko WIRATMO (Dept. of Geophysics & Meteorology, Institute of Technology, Bandung Jl. Ganesha 10 Bandung 40132 West Java, Indonesia, email: wiratmo@geoph.itb.ac.id)

Rainfall is the main weather element with an important role in tropically maritime continent region. The rainfall cycle is controlled by many predictable and unpredictable factors. Therefore, it is not easy to forecast rainfall quantity in any specific area. At the same time, the need for an accurate quantity of rainfall is acutely felt. Learning rainfall pattern is needed to build a forecasting model. One method to recognise the rainfall pattern is neural artificial network method that is better than the statistical extrapolation techniques. The aim of this paper is to apply neural artificial network to forecast rainfall quantitatively.

MC04/E/05-B2 1715

NOWCASTS OF CONVECTIVE PRECIPITATION USING AN OBJECT-ORIENTED LIFE CYCLE MODEL OF A CONVECTIVE CELL

Andrew COOPER, Clive Pierce (Forecasting Products, UK Met. Office, London Road, Bracknell, Berkshire, RG12 2SZ, UK, email: amcooper@meto.gov.uk)

Extensive operational trials of an object-oriented convective precipitation model (or object-oriented model) have recently been completed by the UK Meteorological Office, in collaboration with the Environment Agency (responsible for flood warning in England and Wales). This Object-Oriented Model (OOM) incorporates a conceptual model of the life cycle of a shower cloud, such as might be observed in mid-latitudes. Five developmental or cell stages are recognised. These encompass the developing, mature and dissipating phases in the life of a typical convective cloud. Cell stages are distinguished on the basis of vertical instantaneous rain rate profiles, derived from multiple beam C-band radar data. The vigour or development potential of a cell may vary, accounting for variations in cell duration, the quantity of precipitation produced, and whether or not the cell can trigger daughter cell development in its mature phase.
Operational trials of the OOM have demonstrated its capability for generating reliable, very shortrange (0-3 hours ahead), high resolution (10 minute time step, 2 km resolution) precipitation forecasts during periods of airmass convection. In June 1999, the model will be implemented operationally within an automated nowcasting system known as GANDOLF (Generating Advanced Nowcasts for Deployment in Operational Land-based flood Forecasts). This system is designed to run the model when conditions suit. During periods of airmass convection, the OOM will run on a 15 minute cycle, and generate 10 minute instantaneous rain rate and 15 minute accumulation forecasts with lead times out to T+180 minutes. These forecasts may be relayed directly to Flood Warning Centres where they can be used by the Environment Agency in river flow modelling and flood prediction.
In this presentation we will review the design of the OOM and consider strengths and weaknesses revealed by the operational trials. Case study material will also be presented to demonstrate the model's behaviour.

MC05/E/01-B4 0910

UPWARD TREND IN GLOBAL INTENSE AND SUPER-INTENSE TROPICAL CYCLONE NUMBERS 1969-1997

F. P. Roberts and M. A. SAUNDERS (both at Benfield Greig Hazard Research Centre, Department of Space and Climate Physics, University College London, Holmbury St Mary, Dorking, Surrey RH5 6NT, UK, email: mas@mssl.ucl.ac.uk)

We report the results of a study of the trends in global intense (maximum sustained winds of 33ms-1) and super- intense (maximum sustained winds winds of 50ms-1) tropical cyclone numbers for 1969-1997. We also examine trends in global intense landfalling events and 'high-impact' landfalling events. We define the latter by a population density threshold of 180 people/km2. We find that the annual (and seasonal) number of intense and super-intense events have increased by 32% and 59% respectively for 1969-1997. These upward trends are significant to 99%. Over the same period, the annual number of super-intense landfalling events has increased by 57% (significant to 91%), and the annual number of high-impact landfalling events has increased by 53% (significant to 84%). Similar trends occur for 1979-1997.
We discuss possible causes for these upward increases. While artificial biases produced by inhomogenous retrieval methods may be a contributory factor, they are unlikely to have an influence on the similar upward trends found in the global number of landfalling and 'high impact' tropical cyclones.

MC05/E/04-B4 0930

LANDFALLING TROPICAL CYCLONES IN THE ATLANTIC BASIN

Jenni L. EVANS and Robert Hart (Department of Meteorology, The Pennsylvania State University University Park PA 16802 USA)

Rainfall induced damages associated with landfalling tropical cyclones are a major source of devastation in the United States. Recent climatologies of tropical cyclone rainfall impacts on the northeast United States and Canada reveal that tropical cyclones are the cause of major rainfall events every 2-3 years over most of this region. Locations, such as Boston and Cape Cod, which are particularly susceptible, with individual events every 5-6 years in which twice the normal monthly rainfall is measured as the result of a single tropical cyclone passage.
At the time that these tropical cyclones are delivering such copious rainfalls, they are often undergoing complex structural changes that are poorly understood. These may result in the system simply decaying or it may evolve toward a new, extratropical-like system. Environmental indicators that discriminate between the lifecycle of the tropical cyclone through to a hybrid or truly extratropical cyclone will be presented and a theoretical underpinning for this evolution will be elucidated here.

LONG-RANGE FORECASTING OF U.S. LANDFALLING HURRICANES

M. A. SAUNDERS and C. J. Merchant (both at Benfield Greig Hazard Research Centre, Department of Space and Climate Physics, University College London, Holmbury St Mary, Dorking, Surrey RH5 6NT, UK, email: mas@mssl.ucl.ac.uk)

MC05/W/03-B4 1030

A NEW METHOD FOR PREDICTING LAND-FALLING TROPICAL CYCLONES

Remata S. REDDY and Lail S. Hossain (Dept. of Physics, Atmospheric Sciences, and General Science, Jackson State University, Jackson, MS 39217, USA, e-mail: rsreddy@ccaix.jsums.edu) Richard L. Miller (NASA Earth System Science Office, Stennis Space Center, MS 39529, USA, e-mail: miller@Wpogate.ssc.nasa.gov)

Under the NASA/JOVE Program a study has been undertaken to investigate the ocean-atmosphere interactions over the Gulf of Mexico and their relation in the formation and development of tropical cyclones/hurricanes. Hurricane Predictive Index (HPI), a new method, has been developed for predicting the formation and development of land-falling tropical cyclones/hurricanes over Gulf of Mexico. This index characterizes the ocean-atmosphere interactions over the Marine Boundary Layer (MBL) in terms of heat, momentum, and moisture fluxes, scale height, pressure tendency, kinetic energy and instability. A positive index indicates no sign of formation of cyclones/hurricanes. A negative index indicates a significant formation and development of hurricanes. The index has been tested for the hurricane Opal which formed on October 4, 1995 over the Gulf of Mexico and made a land-falling on the same day. A strong negative index was noticed 2-3 days prior to the formation (Reddy et.al., 1998). In the present study, the index has been further tested for hurricane Roxanne which formed and developed on October 10, 1995 over the Gulf of Mexico. Satellite images of Advanced Very High Resolution Radiometer (AVHRR) Sea Surface Temperature (SST) and NOAA's buoy data from the National Data Buoy Center at Stennis are used in this study. The study has indicated a strong negative index (-0.5 to -3.0) 2-3 days prior to the formation of hurricane Roxanne. The results were in good agreement with those of hurricane Opal. This method is useful to disaster relief agencies for reducing property damage and loss of life during these events.

PLANS FOR THE USWRP HURRICANE LANDFALL PROGRAM

Russell L. ELSBERRY (Department of Meteorology, Naval Postgraduate School, Monterey, California, 93943, USA, E-mail: elsberry@met.nps.navy.mil

The United States Weather Research Program (USWRP) has adopted Hurricane Landfall as one of its three main foci. Whereas the USWRP has been in a planning and developmental stage, a major increase in funding is expected for a five-year program beginning 1 October 1999. The Hurricane Landfall program has five thrusts: (i) Improved prediction of the tracks of landfalling hurricanes; (ii) Understanding and prediction of the outer and inner wind structure; (iii) Observing and understanding the modification of the hurricane structure as the hurricane crosses the coast; (iv) Quantitative precipitation estimation and prediction during and following landfall; and (v) Understanding the socio-economic impacts of landfall. The goals and strategies in each of these thrusts will be presented.

MC05/W/02-B4 1130

EVALUATION OF CHANGES IN TROPICAL CYCLONE WARNINGS SINCE 1964

Kendal MCGUFFIE and Joanne Hall, Department of Applied Physics, University of Technology, Sydney, PO Box 123, Broadway, NSW 2007

Tropical cyclones cause considerable destruction, disruption of human activity and loss of life as they impact the coast. Over the last thirty years, forecast accuracy for tropical cyclone tracks has improved considerably. This improvement has come as a result of enhanced satellite observing systems and analysis techniques and as a result of greatly enhanced numerical weather prediction capabilities. There has, however, been little in the way of evaluation of the changes in tropical cyclone warnings issued as a result of these considerably improved forecasts. In this paper, the results of a preliminary study of forty tropical cyclones impacting the Coral Sea coast of Queensland, Australia are presented and the changes in cyclone warnings issued are evaluated. Interpretation of results from this preliminary study is not straightforward. The study was confined to the evaluation of the duration of the warning period and the linear length (measured as a straight line) of coastline warned. Preliminary results indicate slight decreases in the level of warning (time of warning and length of coastline warned) associated with cyclones in this region, although the factors influencing warnings are not restricted to meteorological factors and more work is needed to evaluate these changes.

MC05/W/01-B4 1150

NUMERICAL SIMULATIONS OF LAND-FALLING TROPICAL CYCLONES WITH A HIGH-RESOLUTION MOVABLE MESH COUPLED TROPICAL CYCLONE-OCEAN PREDICTION SYSTEM

Isaac GINIS and Clark Rowley (both at Graduate School of Oceanography, University of Rhode Island, Narragansett, Rhode Island, USA email: i.ginis@gso.uri.edu, c.rowley@gso.uri.edu)

A new coupled tropical cyclone-ocean model has been developed to study air-sea interaction under tropical cyclones. The tropical cyclone model is the GFDL/NOAA hurricane forecast model that is now in operational use by the US National Weather Service and by the US Navy. The ocean model is a new movable nested-mesh ocean model developed for air-sea interaction studies. Using a movable nested-mesh system for both the tropical cyclone and ocean models allows matching high horizontal resolutions to be maintained for the atmosphere and ocean in the vicinity of the storm. Both idealised and real-case simulations have been configured to test the performance of the coupled model and to examine the influence of the ocean coupling on the storm structure and intensity during landfall. The model is presently applied for tropical cyclone simulations in the eastern and western Pacific.

MC05/E/03-B4 1210

HOW WELL DO NUMERICAL WEATHER PREDICTION MODELS ESTIMATE ATMOSPHERIC WATER VAPOR DURING A LAND-FALLING TROPICAL CYCLONE?

Seth GUTMAN, Nicole Radziwill, Stan Benjamin, and Tracy Smith (all at NOAA Forecast Systems Laboratory, 325 Broadway R/E/FS3, Boulder, Colorado 80303 USA, Email: gutman@fsl.noaa.gov)

A brief introduction to ground-based GPS meteorology, emphasizing the ability to make accurate integrated precipitable water vapor measurements under all weather conditions, is presented. Independent GPS water vapor observations of a land-falling tropicalcyclone (Hurricane Georges) are compared with estimates of total column water vapor produced by the NOAA Forecast Systems Laboratory MAPS/RUC-2 numerical weather prediction model. The potential impact of these observations on NWP forecast accuracy of land-falling tropical cyclones is discussed.

MC05/E/06-B4 1230

STORM TIDE RISK IN TWO COMMUNITIES IN QUEENSLAND, AUSTRALIA

Ken GRANGER (Australian Geological Survey Organisation, GPO Box 762, Brisbane, Queensland, 4001, Australia, Email: kgranger.agso@bom.gov.au)

Three major storm tide events, causing loss of life and substantial damage, have been experienced along the Queensland (Australia) coast over the past 100 years. The most lethal event, on 5 March 1899, was a storm tide, reported to have reached 14.5m above sea level, which killed at least 307 people from the pearling fleet sheltering in Bathurst Bay in the far north of the state, together with possibly 100 aboriginal people on shore. On 21 January 1918 a severe tropical cyclone struck the town of Mackay on the central coast, killing 30 people, of whom at least 13 were drowned in the storm tide that reached about 5.3m above sea level. Seven weeks later, on 10 March 1918, an even stronger cyclone struck the Innisfail area, 500km to the north of Mackay, killing perhaps 100 people with as many as 60 being drowned in the storm tide that reached at least 5.6m above sea level.
Whilst the Queensland coast has been crossed by at least 80 tropical cyclones since 1918, there has, fortunately, been no repetition of these earlier tragic storm tides impacts, though there have been several near misses. Over the same 80 year period, the population of coastal settlements has grown enormously to the point where today, almost three million Queenslanders (or 86% of the total) live within 50km of the coast. As many as a quarter of these are potentially exposed to the direct impact of storm tide.
The magnitude of this risk has only recently become apparent to the current generation of disaster managers and the local governments at risk, largely as the result of research conducted under the Tropical Cyclone Coastal Impacts Program (TCCIP) - a multi-agency and multi-disciplinary research program coordinated by the Australian Bureau of Meteorology. TCCIP researchers have adopted a comprehensive risk-based approach which takes account of both the hazardous phenomena associated with tropical cyclones (wind, rain and storm surge) and the elements at risk within the community (the people, buildings and infrastructure) and their vulnerability to hazard impact. Two Queensland cities, Cairns (a major tourist destination, service and sugar growing centre with a population 125 000) and Mackay (a rural service centre and transport node with a population of 55 000), have been studied in detail, with a particular focus on their exposure to the impact of storm tide.
This paper reports on the outcomes of this storm tide risk research and describes the quantitative risk analysis and risk assessment techniques employed. Particular emphasis is given to the data collected and the geographic information systems and spatial modelling tools developed to produce information of use to local officials to develop risk reduction strategies and disaster management options.
One of the potentially life-saving outcomes of this work is the capacity to forecast inundation levels for all buildings and roads in each community well before a threatening cyclone crosses the coast. This information will greatly enhance the process of evacuation and the allocation of shelter should a storm tide, of the magnitude of those experienced historically in Queensland, were to occur today.

TITAN'S ATMOSPHERE FROM ISO OBSERVATIONS

COUSTENIS Athena (Paris Observatory, France, Email: coustenis@obspm.fr)

Observations of Titan in the thermal infrared (2.36-45.2 micron) were performed by ISO, in Jan. and Dec. 1997, with resolving powers between 1500 and 3000 in the Grating mode and up to 30000 in the Fabry-Perot mode. Two pure rotational water lines were observed for the first time using the ISO/SWS/Grating (R=2000) at 39.4 and 43.9 micron, with fluxes of about 2 Jy over a continuum of 60 Jy [1], with S/N of about 8. The flux observed can be reproduced with a constant abundance of about 0.4 ppb, or with a recent photochemical profile [2] multiplied by a factor of 0.4. This yields a water vapor mole fraction of about 10 ppb at the 400 km altitude level). The inferred water influx at Titan at 700 km of altitude is compatible with the CO2 observed abundance and similar to that found at Saturn [3]. This suggests that infalling material from Saturn rings may not be the dominant source of Saturn's water. The analysis of the 233-1500 cm-1 spectrum of ISO/SWS has provided the thermal and compositional structure of Titan on a disk-average [4]. We have also tested available vertical profiles and inferred upper limits for a few likely candidates in Titan's stratosphere (such as benzene and allene) [4]. MARS WATER ABUNDANCE BASED ON ISOTOPIC ANALYSIS

Suchita GHOSH (Department of Physics, Rajendra College, J. P. University, Chapra, Bihar 84 1301, India)

Isotopic composition of Martian water is extremely important for understanding the evolution of the planet's atmosphere. Water on Mars is present primarily as vapor in the atmosphere, adsorbed gas in the regolith, residual polar ice caps and subsurface ices. We have constructed a simple analytical model to estimate the amount of water based on the fractionation in deuterium to hydrogen (D/H) given loss of hydrogen to space and irreversible loss to the surface. Reported measurements of D/H from SNC meteorites and spectroscopic observations using Earth-based telescopes are employed to characterize the D/H evolution process. The D/H ratio in some of the SNC meteorites is found to be nearly equal to the present day value in the Mars atmosphere. This enrichment in D/H ratio is thought to reflect an interaction process involving water operating between atmosphere, regolith and rocks in SNC meteorites. Such exchange may have operated in aqueous or hydrothermal environment. The effects of replenishment of water from outgassing have also been examined. Our results show that atmospheric enrichment in D/H has occurred primarily through thermal escape of hydrogen to space. Although there is uncertainty in the interpretation of these results, they suggest a substantial loss of water to surface if Mars exchangeable global inventory of water has undergone transition from an initial large abundance to a meagre quantity at present.

MIXING HEIGHT OF THE MARTIAN BOUNDARY LAYER

Ari-Matti Harri (FMI , Vuorikatu 15A , 00101 Helsinki), Arakel PETROSYAN (IKI , Profsoyuznaya 84/32 , Moscow 117810, Russia, email: apetrosy@iki.rssi.ru)

The key features of the Martian boundary layer allow us to assume that
its role on the global-scale and meso-scale atmospheric flows in Mars are different from the one at the Earth. At first Mars has a complicated nonhomogeneous terrain making the formation of a shear driven turbulent boundary-layer easy during the night, and further, it makes boundary-layer nonhomogeneous in convective conditions. At second, all diagnostic evaluations of the Martian boundary layer height predict it not to be small in comparision of the tropospheric height. All above mentioned makes the mixing height a key parameter in the Mars atmosphere studies. In suggested presentation we discuss different prognostic models for Mars mixing height determination and predict its diurnal evolution for Viking landing sites. In our mixing height model for Mars we assume that in the morning the mixing layer is nearly neutrally stratified. Hence the height of the shear driven turbulent boundary layer in the morning is used as the initial condition to solve prediction equations for the mixing height. The main model assumption in Mars mixing modelling is that development of an unstable boundary layer is governed by same kind of similarity relations that are also applicable at the surface layer with new dimensionless characteristics connected with mixing height.

DOPPLER IMAGING OF PLANETARY ATMOSPHERES

N. MURPHY, S Gillam, E.J. Smith (Jet Propulsion Laboratory, 4800 Oak Grove Dr., Pasadena, CA 91109, USA), W. Rodgers (The Eddy Company, Apple Valley, CA 92308, USA), A. Cacciani (University of Rome 'La Sapienza', P.le A. Moro 2, 00185-Roma, Italy), W. Wild, R. Rosner (University of Chicago, Dept. of Astronomy and Astrophysics, Chicago, USA)

Typically, planetary atmospheric motions are deduced by tracing the motions of visible cloud features or by measurements from in-situ instruments. While both these techniques have provided considerable insight into the atmospheric dynamics of our planetary neighbours, they suffer from obvious disadvantages: Only visible features can be tracked and in-situ measurements are difficult to accomplish and provide limited spatial information.
We have explored an additional technique, Doppler imaging, which takes advantage of the small Doppler shifts imposed on reflected solar absorption lines by planetary atmospheric motions. These small Doppler shifts are measured using a magneto optical filter (MOF) (Cacciani and Fofi, Solar Phys. 59, 179-189, 1978) mounted on the Table Mountain 1.2m telescope. They provide a snapshot of the line-of-sight atmospheric motions and can also be used to build a synoptic map of large-scale atmospheric circulation.
We will discuss the application of this technique to the atmospheres of Jupiter, Saturn and Mars and explore its strengths and weaknesses. Using the data we have collected so far we will estimate the increased spatial and velocity resolution available via Doppler imaging with larger telescopes.

EFFECTS OF MAGNETIC FIELD ON THE DAYSIDE AND NIGHTSIDE IONOSPHERE OF MARS: SOLAR WIND - MARS INTERACTION

S.A. HAIDER (Physical Research Laboratory, Ahmedabad 380 009, India, email: haider@prl.ernet.in), S.P. Seth (Bhavan's R. A. College of Science, Ahmedabad 380 001, India) Anil Bhardwaj (Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum 650 022, India)

The magnetometer onboard Mars Global surveyor spacecraft has observed magnetic field above 100 km from the surface. This suggests that solar wind interaction with Mars is similar to that at Venus and active comets, that is, primarily an ionospheric-atmospheric interaction. To understand the solar wind - Mars interaction and its dynamical effect on the dayside and nightside ionosphere of Mars, a theoretical model is developed to study the magnetized and unmagnetized ionosphere of Mars. In the model the continuity and momentum equations are solved self consistently. Using this model the two dimensional profiles of ion and electron densities are obtained. It is found that the density decreases gradually with solar zenith angle up to 80 degree and then it drops rapidly near terminator. In the nightside region the electron densities below 150 km where 02+ is the major ion drop dramatically because of the lack of a photoionization source.

MC09/W/09-B2 Invited **1130**

OXYGEN AND OZONE PRODUCTION IN CO2-RICH PLANETARY ATMOSPHERES

Ilias VARDAVAS, Georgia Vlastou (Department of Physics, University of Crete and Foundation for Research and Technology - Hellas Heraklion, Crete, Greece)

We use a 1-D radiative-convective photochemical model for an Earth-like planet with an atmosphere consisting of nitrogen and carbon dioxide at different atmospheric pressures. The planet's atmosphere is irradiated by different levels of ultraviolet radiation. The model computes the vertical temperature and chemical composition from the planet's surface to the lower thermosphere. We show that both at low and at high CO2 pressures the production of oxygen and ozone is not significant. At pressures between 0.1 and 10 bar significant oxygen and ozone layers are formed. In addition it is found that ultraviolet flux enhancement towards Lyman-alpha reduces oxygen production. The results have important ramifications for biological evolution in CO2-rich planetary atmospheres.

MC09/W/01-B2 Invited **1200**

SEARCH FOR STRONGEST ALBEDO AND THERMAL INERTIA VARIATION INDUCED CIRCULATIONS IN THE MARTIAN ATMOSPHERE

Tero SIILI (Finnish Meteorological Institute, Geophysical Research, P.O.BOX 503, FIN-00101 Helsinki, Finland, Email: Tero.Siili@Fmi.Fi)

Modelling [1] has shown the plausibility of mesoscale circulations – albeit relatively weak – driven by variations in surface albedo (a) and/or soil thermal inertia (I). These circulations can be overwhelmed by stronger mesoscale circulations (e.g., slope winds) and large-scale flows (e.g., baroclinic disturbances). The anticorrelation of the a and I variations also tends to cause the two forcings to cancel out. For conditions conducive for observation of these circulations, as pronounced a and I variations, as high solar insolation and a season of as quiescent large-scale flows as possible are desirable. In this work a search for suitable combinations of surface areas (in the Martian equatorial and subtropical regions) and seasons has been conducted. Subsequently simulations corresponding to those regions and seasons have been been made with the Department of Meteorology / University of Helsinki 2-D Mars Mesoscale Circulation Model (MMCM). Results of the simulations are presented as well as their relevance to, e.g., the site selection of the planned European NetLander mission are discussed.

MC09/W/02-B2 Invited **1215**

WAVE DISTURBANCES FROM THE COMET SL-9 IMPACTS IN JUPITER'S ATMOSPHERE

G. SCHUBERT (Dep't Earth & Space Sciences, UCLA, Los Angeles, CA, 90095-1567 USA, email: schubert@ucla.edu); R.L. Walterscheid, D. G. Brinkman (Space Sciences Laboratory, The Aerospace Corporation, Los Angeles, CA 90009, USA)

Wave disturbances due to the Shoemaker-Levy 9 (SL-9) cometary impacts into Jupiter's atmosphere have been simulated with a fully compressible (non-hydrostatic), time-dependent, non-linear, axisymmetric, f-plane, finite difference computational scheme. Energy is released in a cylindrical region with a radius of 250 to 1000 km as suggested by models of the re-entry of impact ejecta following the initial explosion. The model produces outward moving gravity waves at stratospheric altitudes with speeds and relative amplitudes in agreement with observations. The waves emerge from a cylindrical region of alternating inflow and outflow that extends high into the atmosphere in the main region of energy release. The disturbances originate as horizontally propagating waves at the periphery of this region thereby providing an explanation for the observed large initial radius (~450-700 km) of the main ring. The model results suggest that the waves are made visible by the inflow of particulate impact debris into outward moving rings of wave horizontal convergence. The results of this study remove the necessity to invoke a stable, water-rich, wave-trapping layer in Jupiter's atmosphere in order to understand the Comet SL-9 observations of dark wave-like rings expanding radially away from the impact sites.

SCIENTIFIC INTERPRETATION OF RECENT OBSERVATIONS OF THE GIANT PLANET ATMOSPHERES: EXCITEMENT AND CAUTION

Sushil ATREYA (Dept. of Atmospheric, Oceanic and Space Sciences, University of Michigan, Ann Arbor, Michigan 48109-2143, USA, email: atreya@umich.edu), Toby Owen (Institute for Astronomy, University of Hawaii, Honolulu, Hawaii, 96822, USA)

Without a doubt, recent observations from the Infrared Space Observatory and the Galileo Probe have contributed immensely to our understanding of the composition, structure and origin of the giant planet atmospheres. At the same time, they have revealed that the interpretation of these new data, exciting as they are, requires caution. We illustrate this point with several examples, particularly those derived from the ISO observations with relevance to hydrocarbon photochemistry on the giant planets, and from the Galileo Probe as related to the composition and structure of the clouds and the origin of Jupiter's atmosphere. These

illustrations are meant to alert the planetary community of the pitfalls that can be avoided with timely work on the relevant laboratory measurements and theoretical models, especially as we embark on an ambitious set of observations of Saturn and Titan from Cassini orbiter and the Huygens probe beginning in 2004.

MC09/L/02-B2 Invited 1430

THE ATMOSPHERE OF EUROPA AND ITS EVOLUTION IN THE ENVIRONMENT OF THE JOVIAN MAGNETOSPHERE

Darrell F. STROBEL (Johns Hopkins University, Baltimore, MD, 21218, USA)

This talk will first review the observational evidence for an oxygen atmosphere on Europa based on Hubble Space Telescope observations in 1994 and 1996 (Hall et al., Nature, 373, 677, 1995; Astrophys. J., 499, 475, 1998) and for an ionosphere on Europa detected by the Galileo spacecraft radio occultation measurements. Then I will summarise the salient conclusions from the recent model of Saur et al. (J. Geophys. Res., 103, 19,947, 1998) which provides a theoretical framework to interpret the observational data.
Suprathermal torus ions with a contribution from thermal ions sputter 02 from the water ice surface and thermal torus ions remove the 02 atmosphere by sputtering. For an oxygen column density of 5 x l0^l4 cm^-2 the calculated intensities of the oxygen lines 130.4 nm and 135.6 nm produced by electron impact dissociation are in excellent agreement with the observations by the Hubble Space Telescope. Mass balance is also consistent with this column density with a net atmospheric mass loss of 50 kg s^-l. Accordingly the atmosphere has a residence time of - 2 day in the presence of ion sputtering. The exobase is approximately 70 km above the surface. The dominant heat source in the atmosphere is Joule heating with magnitude of 3 x l0^l0 W.

MC09/W/11-B2 1500

BAND MODEL PARAMETERS OF LABORATORY MEASURED METHANE BANDS AND THEIR IMPACT ON THE INTERPRETATION OF NIMS SPECTRA

Kamaljit SIHRA (University of Reading, Department of Meteorology, 2 Earley Gate, Whiteknights, PO Box 239, Reading RG6 2AU, UK, email: sws98ks@met.rdg.ac.uk); John Remedios (University of Oxford, Atmospheric, Oceanic & Planetary Physics, Parks Road, Oxford OX1 3PU); Kimberly Strong (University of Toronto, Department of Physics, 60 St. George Street, Toronto, Ontario, M5S 1A7, Canada). Simon Calcutt and Frederic Taylor (University of Oxford)

The Jovian atmosphere, in the spectral region sounded by the Near-Infrared Mapping Spectrometer (NIMS) on the Galileo spacecraft, is dominated by methane and ammonia absorption bands. In support of the NIMS/GALILEO project, laboratory measurements of methane transmittances have been obtained in the 1800-9500 cm-1 region, at an original resolution of 0.2 cm-1, for gas pressures from 0.2670 to 4965 mb and temperatures from 100 to 340 K. For the analysis of NIMS spectra, methane transmittances were degraded to 10 cm-1 and fitted using random band models, with the Goody-Voigt band model with a continuum limit term providing the best fit. The fitting errors are discussed and the uncertainty in the parameterised variables are assessed. Selected self-broadened spectra of this study were also fitted with hydrogen-broadened spectra of Strong (1992) to determine the ratio of self-to-hydrogen broadening for methane. This is important for application of these band model results to Jovian conditions. An average value of 1.40 +/- 0.07 was determined for this ratio. The band model parameters were also used in a simple radiative transfer atmospheric model to assess the impact of these spectra on the interpretation of NIMS spectral data. The implication of these results are also discussed.

MC09/W/10-B2 1515

JOVIAN ATMOSPHERIC STUDIES WITH THE GALILEO NEAR INFRARED MAPPING SPECTROMETER: AN UPDATE

F.W. TAYLOR (1), R.W. Carlson (2), K.H. Baines (2), P. Irwin (1), A. Weir (1), P. Campbell-Smith (1), S. Calcutt (1), T. Encrenaz (3), P. Drossart (3), M. Roos-Serote (3), E. Lellouch (3), and G. Orton (2).(1) Atmospheric, Oceanic & Planetary Physics, Oxford University, United Kingdom (2) Jet Propulsion Laboratory, Pasadena, USA (3) Departement Spatial (CNRS URA 264), Observatoire de Paris, Section de Meudon, email: Francef.taylor@physics.oxford.ac.uk

In its first two years of operation since arrival at Jupiter in December 1995, the Near Infrared Mapping Spectrometer on the Galileo orbiter spacecraft obtained extensive coverage of the planet, including detailed coverage of the NEB 'hot spot' region and the Great Red Spot. The status of the analysis of this data will be presented, including recent results on the abundances and variability of several minor constituents (H2O, CH4, NH3, GeH4, CH3D, and PH3) and the cloud structure and morphology.

MC09/L/03-B2 1530

IMPACT OF THE BEHAVIOUR OF THE EARTH'S INTERIOR UPON THE EVOLUTION OF THE EARTH'S ATMOSPHERE AND THE RISE OF OXYGEN

Miles OSMASTON (The White Cottage, Sendmarsh, Ripley, Woking, Surrey GU23 6JT, UK. E-mail: miles@osmaston.demon.co.uk)

At IUGG95 I outlined a new history of the Earth's internal evolution. That history can now be elaborated and its impact upon evolution of the atmosphere outlined. The story begins in the later stages of planetary accretion, with magmatic FeG being reduced by the nebular atmosphere to Fe and 'subducted' to form the core. Some of the huge amount of water thus produced (several 100 Vocean) gave the early Earth a wet mantle with a low viscosity well able to convect away the great heat. Throughout the Archaean, a low-pH ocean (topped by a shallow oxygenated water layer beneath a dense C02+N atmosphere) accumulated Fe++ in solution. At 2.Bga the ocean floor began to deepen, marking declining MOR height and mantle heat, and foreshadowing the 2.45-2.2 Ga 'hiatus' in mantle overturn seen as a gap in orogenic granitoid dates. Deepening ocean basins exposed the cratons to massive weathering. This lowered C02 and resulted in the Earth's first glaciation at 2.65Ga, followed at 2.35Ga by the Huronian glaciation during the 4km+ lowering of sea-level by the hiatus proper. During the hiatus the supply of reducing gases from MORs was shut off and oxygenic life was at last enabled to begin to win its battle against the Earth's reducing power. This resulted in deposition of uniquely vast amounts of banded ironstone formation during the 2.45-2.2Ga interval. Carbonates with a major positive excursion in deltal3C at 2.2Ga mark the florescence of oxgenic life presented with non-acid shallow seas over planated cratons as renewed MOR activity raised sea-level. Thus both the lowering of C02 in the Earth's atmosphere and the rise of oxygen stem from changes in the Earth's internal behaviour, not from biological innovation.

MC09/E/01-B2 1545

A NEW MODEL FOR THE INFRARED RADIATION OF THE MARTIAN ATMOSPHERE

Alexander KUTEPOV and Oleg Gusev (both at the Institute for Astronomy and Astrophysics, University of Munich, Scheinerstr. 1, 81679 Munich, Germany, email: aak@usm.uni-muenchen.de)

We present a new line-by-line model of the formation of the infrared radiation in the ro-vibrational bands of CO2 and CO molecules in the Martian atmosphere. The model accounts for both vibrational and rotational non-LTE, line-overlapping effects, extinction due to dust particles, effects of the ground albedo, and absorption and transformation of the near-infrared solar radiation. The number of vibrational levels and bands treated is substantially extended when compared to previous models. The collisional kinetic inputs are also updated. The model utilises the accelerated lambda-iteration technique for the solution of the system of kinetic equations and the Feautrier radiative transfer algorithm. Vibrational temperatures, radiative cooling/heating, and the limb radiances in a few spectral regions are compared with those for less sophisticated models.

MC09/W/06-B2 Invited 1630

THE VERTICAL STRUCTURE OF MAJOR METEOROLOGICAL FEATURES ON JUPITER: THE GREAT RED SPOT AND WHITE OVALS BC AND DE

Kevin H. BAINES and Robert W. Carlson (CSIRO Atmospheric Research, PMB No. 1, Aspendale, 3195, Australia. E-mail: peter.baines@dar.csiro.au)

Multi-spectral imagery of Jupiter's Great Red Spot (GRS) and two White Ovals acquired by the Galileo/NIMS are used to constrain the spatial variability of the vertical aerosol structure and the distribution of ammonia in and around these most-prominent anti-cyclonic features. All three features exhibit a high-altitude core spanning about 3/4 of their visual size when viewed with moderate absorption wavelengths, indicating a bulk elliptical, "wedding cake" shape in their overall three-dimensional cloud structure. A distinctive spiral pattern within the GRS core is seen in moderate methane and hydrogen absorption bandpasses. This pattern - which has been modelled to show a 2 km variation in cloudtop pressure within the GRS - is inconsistent with a different spiral-shaped pattern observed in ammonia-sensitive wavelengths, thus indicating spatial variability not only in the column abundance of ammonia within the GRS, but in its mixing ratio as well.
White Ovals BC and DE were observed in February 1997, just a year before their unusual merger into a single feature. At the time of these observations, the centers of the two anti-cyclones were ~16 degrees apart, separated by a complex cyclonic feature which exhibited unusual spatial variability in its appearance in images acquired at ammonia-sensitive wavelengths. In particular, the northern half of this feature has the largest ammonia column abundance seen within the environs around the white ovals, indicating unusual variability in either cloud structure/altitude and/or ammonia humidity within the cyclone.

ABRUPT CLIMATE CHANGES DURING THE LAST 6 600 YEARS IN SOUTH AFRICA

Peter TYSON (Climatology Research Group, University of the Witwatersrand, Johannesburg, South Africa, e-mail: pdt@crg.bpb.wits.ac.za); Wibjorn Karl and Karin Holmgren (Department of Physical Geography, Stockholm University, Stockholm, e-mails: karlen@natgeo.su.se and karin@ natgeo.su.se)

Few high-resolution time series are available for subtropical latitudes in the southern hemisphere that permit the determination of sudden climate shifts and changing patterns of variability during the last six millennia. Recently, a quasi-decadal resolution, 6 600-year proxy climate record has been determined from a stalagmite taken from a cave in the Makapansgat Valley in northern South Africa. The series is characterised by periods of relative stability, periods of rapid change and times when rapid changes between extreme conditions were dominant. Rapidly changing patterns of variability with time are shown to be a feature of the entire record. The most extreme and prolonged episode in the entire record is shown to have occurred in the five centuries of cooling that constituted the Little Ice Age from 1300 to1800. The depression of annual maximum temperature below the present-day 1961-1990 mean at the time of maximum cooling at 1700 was 1-2 =B0C. Following maximum cooling at 1700, conditions ameliorated rapidly to revert to above-normal within fifty years. Other extreme shifts in the record are shown to have occurred within a decade or two. Changes in variability with time will be illustrated by determining the decadal variability in moving two-century time periods traversing the entire 6 600-year series.
Comparison of the stable isotope record for the Makapansgat valley with a similar high-resolution stalagmite isotope data for the Cango Cave in southern South Africa and an even higher-resolution record derived from corals on the south-western coast of Madagascar reveals that the Little Ice Age was a pronounced regional event over a large area of southern Africa. The spatial extent of the abrupt changes and sudden climate shifts at the different widely separated sites during the Little Ice Age will be assessed. Likewise, regional differences in temporal variability will be considered.
Finally, the nature of the regional atmospheric circulation changes forcing the abrupt shifts in climate over the last few millennia, particularly during the Little Ice Age event, will be considered. It will be shown how a combination of changes occurring in both mid-latitude baroclinic and tropical barotropic circulation features, together with sea surface temperature changes within and beyond the region, modulate the regional climate on annual to millennial time scales. A framework for the validation of regional climate models will be proposed.

MC09/E/02-B2 1715

MODELING OF GRAVITY WAVE HEATING IN JUPITER'S THERMOSPHERE

Michael P. HICKEY (Department of Physics and Astronomy, 308 Kinard Laboratory, Clemson University, Clemson, SC 29634-1911, USA); Richard L. Walterscheid (Space and Environment Technology Center, The Aerospace Corporation, Los Angeles, CA 90009, USA); Gerald Schubert (Department of Earth and Space Sciences, University of California at Los Angeles, Los Angeles, CA 90095-1567, USA)

Measurements of Jupiter's upper atmosphere by the atmosphere structure instrument on the Galileo Probe revealed wave-like variations in the derived temperature profile that have been attributed to internal gravity waves. The possibility that these waves could be providing the energy required to maintain the relatively high (~ 900 K) thermospheric temperatures has been previously explored using WKB models describing gravity wave propagation. However, the observations have shown that the waves have large vertical wavelengths (~ 100 km), for which WKB analyses are not always expected to provide realistic results. In this paper we discuss the application of a full-wave model to characterise two waves observed in Jupiter's thermosphere having large vertical wavelengths. The horizontal wavelengths used are derived from published analyses. The model includes inhomogeneities due to the effects of eddy and molecular diffusion of heat and momentum, Rayleigh friction, Newtonian cooling, and the Coriolis force. The mean state required for the computations is provided by the Galileo Probe observations. The wave period required for the computations is calculated iteratively using

M

Newton's method constrained by prescribing a value of vertical wavelength at a reference altitude. Second-order wave energy terms are derived and used in the heat-flow equation to solve for the steady-state thermospheric temperatures. The whole process is repeated until convergence is achieved. We discuss the ability of the waves to maintain the high thermospheric temperatures.

ON THE STREAM VELOCITIES IN THE JOVIAN ATMOSPHERE

V.V.SHEVCHENKO, V.I.Chikmachev, S.I.Ivanov (Sternberg State Astronomical Institute, Moscow University, Universitetskii pr. 13, Moscow 119899, Russia, e-mail: shev@sai.msu.su)

It was studied the process of the dynamic development of postimpact formations in the Jovian atmosphere using results of photographic observations of Jupiter in the period of the impacts of the nucleus fragments of comet Shoemaker-Levy 9. The images were obtained by the AZT-22 telescope at the Maidanak Observatory. The structure of newly formed features was revealed, and the dynamics of their development during approximately 12 revolution periods of the planet was followed. The spatial structure of the largest details comprises a central column (plume) and a peripheral cloud of scattered ejection products. Within the accuracy of measurements carried out, the extent of the central ejecta plume remains roughly constant. The average top height of the plume over the level of the visible cloud layer is about 2500 km. The peripheral ejecta cloud is virtually at the level of the cloud layer. The tops of the central ejecta plumes have no proper motion in the latitudal direction with respect to the rotating coordinate system III. Consequently, the images of these features can serve as reference points to study the dynamics of peripheral ejecta clouds. The measurements of the extent of largest new features in longitude, made in the photographs, showed that the peripheral clouds expand predominantly from west to east with respect to longitudinal position of the central ejecta plumes. Since, according to our estimation , the peripheral clouds are localised just on the level of the surface cloud layer of Jovian atmosphere, the dynamics of the new-born features will develop under the influence of local atmospheric streams. The velocities of the streams are from zero to 40 m/s in the different latitudes. The results are compared with Galileo's data concerning the clouds dynamics in the Jovian atmosphere.

ATMOSPHERIC SCIENCE EXPERIMENT AT MARS - NETLANDER MISSION IN 2005

A.-M. HARRI 1, A. Angrilli, S. Calcutt, D. Crisp, J.-P. Pommereau, F. Forget, V. Formisano, M. Fulchignoni, R.M. Haberle, S. Larsen, V. Linkin, T. Mäkinen, A. Petrosyan, J. Polkko, H. Savijärvi, T. SIILI and J.E. Tillman. (1 Finnish Meteorological Institute, Geophysical Research, P.O.Box 503, FIN-00101 Helsinki, e-mail: Ari-Matti.Harri@fmi.fi)

ATMIS (Atmospheric and Meteorological Instrumentation System) is a versatile suite of atmospheric instrumentation to be accommodated onboard the Netlander Mission slated for launch in 2005. Four Netlanders are planned to form a geophysical measurement network on the surface of Mars. The atmospheric sciences are among the scientific disciplines benefiting most of the network concept. The goal of the ATMIS instrument is to provide new data on the atmospheric vertical structure, regional and global circulation phenomena, the Martian Planetary Boundary Layer (PBL) and atmosphere-surface interactions, dust storm triggering mechanisms, as well as the climatological cycles of H2O, dust and CO2. To achieve these goals the in situ observations made by the ATMIS sensors will be supported by extensive modelling efforts.
The ATMIS comprises sensors for the vertical profile of atmospheric pressure, temperature and density, as well as for surface pressure, temperature, wind, optical thickness and humidity. The ATMIS benefits from the heritage of instruments already built for missions as Mars-96, Huygens, Pathfinder, as well as the Mars Polar Lander. The characteristics of the atmospheric conditions and phenomena anticipated to occur at tentative NetLander landing regions, as well as the design and the predicted performance of the ATMIS are discussed.

REEXAMINATION OF THOMPSON'S MECHANISM ON THE SPHERE

Masahiro TAKAGI and Yoshihisa Matsuda (Department of Earth and Planetary Physics, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan, email: takagi@geoph.s.u-tokyo.ac.jp)

Thompson (1970) proposed a generation mechanism of a mean shear flow by the tilting instability of convection on a two-dimensional plane in order to explain the super-rotation of Venus atmosphere. In our study, Thompson's mechanism is reexamined both on the nonrotating and rotating spheres. First, two-dimensional Thompson's mechanism is reexamined. It is shown that a mean shear flow is generated not by a purely dynamical process neglecting temperature field but by a positive feedback among the mean shear flow, tilting convective motion and tilting temperature distribution. Second, a three-dimensional model is constructed in order to numerically obtain steady solutions which represent three-dimensional convection between the day and night sides on the sphere. The stability of the steady solutions is examined by linear analysis. For the case of no planetary rotation, the convection pattern is axisymmetric about a line between the subsolar and antisolar points. This convection pattern on the vertical section on the equator is very similar to that obtained in Thompson (1970). However, it is shown that this convection solution is stable. When the planetary rotation is considered, in some parameter ranges, the convection pattern is modified and restricted to the equatorial region by the Coriolis force. In this case, since the meridional flow becomes weak, it may be possible that the instability due to Thompson's mechanism takes place. However, it is found that the convection solution remains stable. These results suggest that Thompson's mechanism proposed for two-dimensional convection is not applicable to three-dimensional convection on the sphere.

MC09/E/05-B2 Poster **0930-03**

A MECHANISM OF THE SUPER-ROTATION ON THE VENUS ATMOSPHERE: MERIDIONAL CIRCULATION AND BAROTROPIC INSTABILITY

Shinichi IGA and Yoshihisa Matsuda (Department of Earth and Planetary Physics, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan, email: iga@atmos5.geoph.s.u-tokyo.ac.jp)

The Venus atmosphere at the cloud top level rotates 60 times faster than the solid part. In this study, this super-rotation is investigated in the light of the upward transport of angular momentum by meridional circulation.
First, the generation of the super-rotation by this mechanism is examined by a 2-dimensional meridional model with very large horizontal viscosity. The super-rotation with mid-latitude jet is produced for some range of parameter values. The parameter-dependency of magnitude of super-rotation is examined in detail.
Second, the origin of the assumed ``very large horizontal viscosity'' is investigated in the light of barotropic instability. In our ``barotropic'' model, meridional and vertical advections of mean zonal flow by the meridional circulation are considered. The barotropic instability occurs intermittently and produces horizontal mixing of angular momentum. Two more interesting results are also obtained. One is oscillation of magnitude of the super-rotation and the other is a dipole structure in the polar regions. The former may be related to the observed variation of zonal wind distribution. The latter seems consistent with the infrared observations, except in size.

SEARCH FOR STRONGEST ALBEDO AND THERMAL INERTIA VARIATION INDUCED CIRCULATIONS IN THE MARTIAN ATMOSPHERE

Tero SIILI (Finnish Meteorological Institute, Geophysical Research, P.O.BOX 503, FIN-00101 Helsinki, Finland, Email: Tero.Siili@Fmi.Fi)

Modelling [1] has shown the plausibility of mesoscale circulations – albeit relatively weak – driven by variations in surface albedo (a) and/or soil thermal inertia (I). These circulations can be overwhelmed by stronger mesoscale circulations (e.g., slope winds) and large-scale flows (e.g., baroclinic disturbances). The anticorrelation of the a and I variations also tends to cause the two forcings to cancel out. For conditions conducive for observation of these circulations, as pronounced a and I variations, as high solar insolation and a season of as quiescent large-scale flows as possible are desirable. In this work a search for suitable combinations of surface areas (in the Martian equatorial and subtropical regions) and seasons has been conducted. Subsequently simulations corresponding to those regions and seasons have been made with the Department of Meteorology / University of Helsinki 2-D Mars Mesoscale Circulation Model (MMCM). Results of the simulations are presented as well as their relevance to, e.g., the site selection of the planned European NetLander mission are discussed.

A REVIEW OF SUBTROPICAL ANTICYCLONES AS PART OF THE CLIMATE SYSTEM

B.J. HOSKINS (Department of Meteorology, Reading University, Berkshire, UK)

In each hemisphere the winter subtropical anticyclone belt may be described to first order as the lower tropospheric part of the region of the descending branch of the Hadley Cell. However, there are significant zonal asymmetries. In the summertime these asymmetries are dominant. The summer subtropical anticyclones are intimately connected with continental monsoon behaviour. The ITCZs occur on their equatorial flanks and radiatively important stratus on their eastern sides. They act as important drivers for oceanic motions and surface temperatures.

MC 10/E/01-B1 **0950**

THE ROLE OF MONSOONS IN THE EXISTENCE AND STRENGTH OF SUMMER SUBTROPICAL ANTICYCLONES

Mark RODWELL (Hadley Centre, UK Met Office, London Road, Bracknell, RG12 2SY, UK, E-mail: mjrodwell@meto.gov.uk); Brian Hoskins (Department of Meteorology, University of Reading, PO Box 243, Earley Gate, Reading, RG6 6BB, UK, E-mail: B.J.Hoskins@reading.ac.uk)

The subtropical anticyclones (STAs), which occupy about 30% of the earth's surface, are usually related to radiative cooling and the descending arm of the zonal mean Hadley Cell. This explanation works well for the winter anticyclone belt. However, the summer STAs are generally stronger and more longitudinally localized to the oceanic regions than in winter. We have used a global atmospheric primitive equation model to investigate the summer and winter subtropical circulations. For the winter, we find that the interaction between the zonal mean flow and orography is sufficient to reproduce the observed STAs. For the summer season, we have focused on the North and South Pacific and North Atlantic anticyclones. We suggest that the basic cause of each summer STA is the latent heating over the continental monsoon region to the east. As this monsoonal heating moves poleward to near 25 degrees latitude, it can induce descent and equatorward motion over the eastern subtropical oceans. Orography acts to localize this motion. The descending air warms adiabatically leading to an enhancement of radiative cooling and an amplification of the descent. The suppression of convection is viewed in a similar way. The equatorward motion forms part of the eastern branch of the STA, which is thought to drive oceanic upwelling, leading to cold sea surface temperatures and reinforcement of the suppression of convection. Our results also suggest that the west African monsoon plays little part in forcing the North Atlantic STA through this mechanism. Instead, the forcing comes from the Asian summer monsoon which, although more remote, extends much further north. The extent of the Andes is such that they also have an appreciable impact on the summer South Pacific STA through interaction with the zonal mean flow.

MC10/W/04-B1 **0955**

SIMULATION OF THE NORTH PACIFIC SUMMER SUBTROPICAL HIGH AND ITS SENSITIVITY

Riyu Lu and Brian J. HOSKINS (Department of Meteorology, University of Reading, PO Box 243, Earley Gate, Reading, RG6 6BB, UK)

In summer, the intensity and position of the subtropical high over the North Pacific are closely associated with the intensity and seasonal progress of the East Asian summer monsoon. Rodwell and Hoskins (Hoskins, 1996) have proposed that the North American summer monsoon is important for setting the scene for this North Pacific subtropical anticyclone.
To explore these issues further, we have used the UK Meteorological Office Unified Model, and

examined simulations with and without seasonal cycles. In the simulation without seasonal cycles (perpetual runs), the solar radiation is fixed on 1 July. The simulation with seasonal cycles captures very well both the temporal and spatial characteristics of the subtropical anticyclones, while in the perpetual runs the subtropical anticyclone over the North Pacific is simulated too far poleward. This is consistent with the proposal that the heating over the continents is important for this anticyclone. Analysis of both the seasonal cycle simulations and ECMWF re-analysis data shows that the subtropical high over the North Pacific shifts poleward in summer, whereas, the subtropical high over the North Atlantic remains at a relatively stable position. To examine the hypothesised sensitivity of the North Pacific subtropical anticyclone to the conditions on its eastward flank, simulations in which the cold sea surface temperatures near the western coast of North America are removed and in which the North American monsoon is suppressed are being performed. The results will be presented and conclusion made.

MC10/E/02-B1 1040

SEASONAL EVOLUTION OF THE SUBTROPICAL HIGH DURING ASIAN MONSOON

Hailan WANG (Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign, Urbana, IL 61801, U.S.A., e-mail: h-wang1@atmos.uiuc.edu); Mingfang Ting (Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign, Urbana, IL 61801, U.S.A., e-mail: ting@atmos.uiuc.edu)

The seasonal evolution of the subtropical Pacific high in northern summer has been found to be one of the important indicators for the East Asian monsoon onset and evolution. In this study, the dynamical mechanisms for the evolution of this high are investigated by using the GFDL general circulation model (GCM) data and the NCEP/NCAR Reanalysis. The data are divided into overlapping 30-day averages for the period April through September with a time interval of 10 days. A nonlinear stationary wave model is employed to investigate the forcing mechanisms for the seasonal evolutions of the location and intensity of the subtropical high. There is a systematic northward movement of the subtropical high from April to July in the GCM data and the NCEP/NCAR Reanalysis, and the movement is mainly related to the enhancement of heating in the tropics. A similarly significant southward movement is found from August to September. We are currently investigating the regional tropical heating centers that are most influential to the position of the subtropical high using Green's function analysis on different climatological basic states. The effect of the El nino heating on the location and strength of the subtropical high is also under investigation. The relatively long record of the NCEP/NCAR Reanalysis data set can help reveal the interannual variability of the subtropical high. The results may be useful for understanding the variability of China monsoon rainfall as well as the monsoon evolution. Some interesting differences between the GCM and the NCEP/NCAR reanalysis will be discussed. A third dataset, the ECMWF reanalysis will also be used to shed light on the credibility of the reanalysis as a prototype for observations.

MC10/E/04-B1 1105

A CLIMATOLOGY STUDY OF THE SOUTH ATLANTIC SUBTROPICAL ANTICYCLONE AND YOUR POSSIBLE INFLUENCE IN WEATHER SYSTEMS

Ester Regina Kazuko Ito and Tércio AMBRIZZI (both at Departamento de Ciências Atmosféricas, Instituto Astronômico e Geofísico, Universidade de São Paulo, Rua do Matão, 1226 - CEP 05508-900, São Paulo, SP, Brazil, Emails: esterito@model.iag.usp.br, ambrizzi@model.iag.usp.br)

An automated procedure for finding and tracking high pressure centres has been applied for mean sea level pressure data set daily for 15 years period (1981-1996) from the NCEP (National Centers for Environmental Prediction) Reanalysis to investigate the behaviour of the South Atlantic Subtropical High (SASH). The area of interest extends from 0 - 60ºS latitude and 20ºE - 70ºW longitude. We defined the climatology of the latitudinal and longitudinal variations of the high centre and analysed its function as "blocking anticyclone" and its influence in the generalcharacteristics of the atmospheric circulation. This study was first done for winter months (June, July and August), period in which the SASH is most intensified. Once defined the climatology, a case study of the anomalous winter of 1995 was studied. During this winter the SASH was anomalously intense and worked as a strong atmospheric blocking acting on the dynamic-synoptic characteristics of the South America.

MC10/W/02-B1 1130

SENSIBLE HEAT DRIVING AIR PUMP OVER THE TIBETAN PLATEAU AND THE SOUTH ASIAN SUBTROPICAL HIGH

Weiping LI and Guoxiong Wu (State Key Lab of Atmospheric Sciences andGeophysical fluid Dynamics (LASG), Institute of Atmospheric Physics, Academia Sinica,P.O. Box 2718, Beijing 100080, China, Email: lwp@lasgsgi4.iap.ac.cn)

Based upon numerical simulations by using the IAP/LASG GOALS climate model, it is shown that the downward motion in winter and upward motion in summer of the air column over the Tibetan Plateau act as an air pump. This air pump is mainly driven by the surface sensible heat flux over the plateau and is therefore named as "Sensible Heat driving Air pump"(SHAP). The pumping of the SHAP on the air at high levels pushes the atmosphere to move outward, hence forms a divergence center in summer. This, together with the strong negative vorticity forcing produced from the strong surface sensible heating over the Plateau, generates a strong South Asian Subtropical High. Through its pumping and suction on the air, the SHAP strongly regulates the activities of the atmospheric semi-permanent activity centers in mid- and high latitudes, and the monsoon systems in tropics. It is mainly the SHAP that causes the northward jump of the South Asian Subtropical High. It is also shown that in middle summer, the suction of the SHAP on the warm and moist air at low levels maintains the precipitation of the plateau area, and modulates the climate over East
and South Asia; whereas the pumping of the SHAP in the upper atmosphere can affect global climate through energy dispersion along Rossby wave trains.

MC10/W/07-B1 1155

CLOUD RADIATIVE FORCING OF THE SUBTROPICAL CIRCULATION: LINEAR CALCULATIONS

John W. BERGMAN (University of Colorado, USA, E-mail: jwb@cdc.noaa.gov)

The role of clouds for low-latitude atmospheric circulations is examined in a linearized calculation forced by diabatic heating rates. The circulation calculated from total diabatic heating, obtained from reanalysis data, determines which aspects of the calculated circulation are realistic and which are not. The role of clouds is quantified by the circulation forced by cloud radiative forcing that has been calculated in a radiative transfer model from cloud properties observed in ISCCP. In general, cloud radiative forcing contributes about 20% to the magnitude of low-latitude maritime circulations and it typically reinforces the circulation that is driven by convective latent heating. However, cloud radiative forcing has a much stronger influence in the subtropics, where it accounts for more than half of the strength of the anticyclonic flow over the eastern Pacific. Cloud radiative forcing tends to have a stronger influence in the lower troposphere than at upper levels and influences local circulations more than remote ones. In particular, cloud radiative forcing from local stratus decks is the dominant source of diabatic heating influencing subtropical circulations over the eastern oceans. Cloud radiative forcing in the subtropical stratus decks is also found to be important for seasonal variations of meridional winds over the cold tongue in the east Pacific, indicating that atmospheric cloud radiative forcing in stratus clouds is important for ocean-atmospheric coupling there.

MC10/W/01-B1 Invited 1400

BASIC DYNAMICS AND SIMULATION OF SUBTROPICALANTICYCLONE

Guoxiong WU (email: gxwu@lasgsgi4.iap.ac.cn), Yimin Liu (email: lym@lasgsgi4.iap.ac.cn)(State Key Lab of Atmospheric Sciences and Geophysical fluid Dynamics (LASG) Institute of Atmospheric Physics, Academia Sinica, Beijing P.O. 2718, 100080 China)

Based on the equation of Ertel potential vorticity, a complete form of equation of vertical vorticity tendency is developed for the study of subtropical anticyclone dynamics. In addition to those terms appearing in the corresponding classical equation, this new equation includes a term representing "internal forcing" which is associated with the thermal structure of the atmosphere and the terms representing "external forcing" associated with frictional dissipation and diabatic heating. Scaling analysis shows that the vertically non-uniform diabatic heating prevails over the horizontally non-uniform diabetic heating in the breakdown into asymmetric centers of the zonal symmetric subtropical anticyclone. A theory of thermal adaptation linking atmospheric circulation to external forcing and a new concept of "overshooting" are then proposed for the study. According to these, ascending and cold anticyclonic flow must exist in the atmospheric layers above the low-level heating even though there is no diabetic heating within these layers. It was concluded that along the subtropical belt where the Burger number is approximately unity, strong surface sensible heating can excite anticyclone to its west in the lower layer and to its east in the upper layer; whereas deep convective condensation heating can generate anticyclone to its east in the lower layer and to its west in the upper layer. This is examined by using the NCEP/NCAR reanalysis data and verified by a series of numerical experiments by using the IAP/LASG GOALS climate model.

MC10/W/03-B1 Invited 1430

IMPACTS OF SURFACE SENSIBLE HEATING ON THE FORMATION OF SUBTROPICAL ANTICYCLONE IN BOREAL SUMMER

Yimin LIU (email: lym@lasgsgi4.iap.ac.cn,); Guoxiong Wu, Ping Liu (State Key Lab of Atmospheric Sciences and Geophysical fluid Dynamics(LASG), Institute of Atmospheric Physics, Academia Sinica, Beijing P.O. 2718, 100080 China)

The mechanism linking the formation of subtropical anticyclone in boreal summer to zonaly asymmetric surface sensible heating (SH) is investigated via data diagnosis and numerical experiment. The complete form of the tendency equation for vertical vorticity development, the NCEP/ NCAR reanalysis data, and the IAP/LASG GOALS climate model are employed for the study. Based on the NCEP/NCAR data, it is shown that, in boreal summer in the Northern American region and at 500hPa, vorticity advection and beta-term in the vorticity equation are the main terms in balancing external vorticity forcing due to surface SH. Then a series of numerical experiments have been carried out. The results from idealized SH heating show that advection makes the subtropical anticyclone appear to the east of the surface sensible heating region. Whereas near the surface, beta-effect makes the subtropical anticyclone appear to its west. However, sensible heating over one single region along the subtropics only generates weak subtropical anticyclone. Only the heating over two continental regions can generate subtropical anticyclones over two oceans with intensity of reasonable extent. Further numerical simulation has proved that, continental sensible heating is essential for the formation of subtropical anticyclones over the two oceans in the lower troposphere. It also contributes to the formation of the following systems at 500hPa: the North American High, North Africa High, and the Iran High. Finally, the results from diagnosing the interannual variability by using the NCEP/NCAR reanalysis data support and verify above results.

MC10/W/08-B1 1455

SUBTROPICAL ANTICYCLONES FORCED BY ATMOSPHERIC DIABATIC HEATING

Ping CHEN (NOAA-CIRES Climate Diagnostics Center, USA Email: pc@cdc.noaa.gov)

A general formula is derived for thermally-forced atmospheric responses in a linear quasi-geostrophic beta-plane model. The analytic solutions forced by a realistic monsoonal heating resemble the observed summertime circulation in the subtropics: there is a trough (ridge) in the lower (upper) levels in the heating region; and there is a low-level anticyclone about one-to-two quarter wavelength downstream of the heating maximum. The strength of the anticyclone is proportional to the intensity of the heating and inversely proportional to the magnitude of the zonal westerly. The location of the low-level anticyclone moves eastward as the zonal westerly decreases. All these features agree with the annual cycle of the observed subtropical anticyclones. It is therefore proposed that the observed subtropical anticyclones are part of an atmospheric circulation forced by zonally asymmetric atmospheric diabatic heating rather than forced by the descending branch of the Hadley Cell.

MC10/E/03-B1 1500

ON THE ANOMALY OF THE SUBTROPICAL ANTICYCLONE OVER THE WESTERN PACIFIC IN 1998

Ping LIU (e-mail: liup@lasgsgi4.iap.ac.cn,); Yimin Liu (State Key Lab of Atmospheric Sciences and Geophysical fluid Dynamics (LASG), Institute of Atmospheric Physics, Academia Sinica, Beijing P.O. 2718, 100080 China)

In the summer of 1998, China suffered from extremely severe flood along the Yangtze River. The anomalously southward shifting of the subtropical anticyclone over the western Pacific, or SAWP in short, is pertinent to the flooding. The wind anomaly at 850hPa also shows a strong anticyclonic pattern persisting to the western Pacific Ocean. Meanwhile, the easterly near the equator is abnormally strong. The flooding and the aforementioned anomaly of the SAWP have been successfully simulated by using the IAP/GOALS climate model. A series of

numerical experiments on the mechanism are carried out mainly taking the sea surface temperature anomaly (SSTA) in the equatorial Pacific and Indian Ocean into consideration. Results show that there is strong equatorial easterly wind anomaly at 850hPa with the forcing of actual SSTA pattern. Such wind anomaly is due to the strong negative SSTA around Nino 3 area and positive one in the Indian Ocean. The results also show it is the strong anomaly of latent heat release in south-east Asia that leads to the southward shifting of the SAWP.

MC10/P/02-B1 1610

ROLES OF SUBTROPICAL RIDGE IN TROPICAL PACIFIC SST – EAST ASIN MONSOON INTERACTIONS

C.-P. Chang (email: cpchang@nps.navy.mil); Yongsheng Zhang; Tim LI (Dept. of Meteorology, Naval Postgraduate School, Monterey, CA. E-mail: li@nrlmry.navy.mil)

The interannual relationship between East Asian summer monsoon and tropical Pacific sea-surface temperatures (SST) is studied using rainfall data in the Yangtze River Valley and the NCEP reanalysis for 1951-1996. The date sets are also partitioned between 1951-77 and 1978-96 to study the interdecadal variations of this relationship.
A wet May-June summer monsoon is preceded by a warm equatorial eastern Pacific (EEP) in the previous winter and followed by a cold EEP in the following fall. In a wet year, the western Pacific subtropical ridge is stronger form the previous winter to the following fall, resulting in an 850 hPa anomalous anticyclone near the southeast coast of China. The anticyclone (1) blocks the pre-Meiyu/Meiyu fronts thereby extending the period of the stationary rainfall, (2) enhances the pressure gradient to its northwest resulting in a more intense front, and (3) warms the South China Sea surface through increased downwelling. A positive feedback may lead to an intensification of the anomalous anticyclone. This relationship is observed in both the interannual time scale within each interdecadal period and in the interdecadal scale. The SST aromalies (SSTA) change sign in northern spring and resemble a tropospheric biennial oscillation pattern during 1951-77. In 1978-96 the sign change occurs in fall and the SST pattern is of a longer time scale. This interdecadal variation appears to result from a change of the basic state. Apparently through ocean wave anticyclone starts to propagate slowly eastward in May and June towards EEP, carrying with it a cooling effect on the SST. In 1951-77 this effect is insignificant as the EEP SSTA already change from warm to cold in northern spring. In 1978-96 the EEP has a warmer mean SST. A stronger positive feedback with the Walker circulation during a warm phase tends to keep the SSTA warm until northern fall, when the eastward propagating easterly wind anomaly reaches the EEP and reserves the SSTA.

MC10/E/07-B1 1635

LOW-LATITUDE BEHAVIOUR OF ROSSBY WAVEPACKETS IN ZONALLY-VARYING BASIC FLOWS

Takeshi ENOMOTO, Yoshihisa Matsuda (both at Dept. of Earth and Planetary Physics, University of Tokyo, Tokyo 113-0033, Japan, e-mail: eno@geoph.s.u-tokyo.ac.jp)

With a non-divergent barotropic model on a sphere, a numerical study has been conducted to clarify the behaviour of Rossby wavepackets in zonally varying flows. Zonally varying basic flows with concentrated and less-concentrated westerly jets are considered to show two different mechanisms for low-latitude reflection of Rossby waves. Associated with the zonal variations of the basic state, a subtropical high exists. The subtropical high is more prominent for the basic flow with a weaker meridional shear. The position of subtropical forcing with a divergent vorticity source is varied along the latitude circle in our experiments. Wavepackets forced at the jet entrance exhibit a low-latitude reflection in the both basic states. In the basic flow with a concentrated jet, a wavepacket tends to propagate along the jet. Closer inspections, however, reveal a slight meridional propagation and an associated reflection near the shear maximum, where the stationary Rossby wavenumber squared is negative. It is considered that a reflection occurs due to a basic-state 'reflector' associated with turning latitudes. No such 'reflector' exists in the basic flow with a less-concentrated jet. A reflection in this basic flow, by contrast, occurs due to the advection of vorticity anomalies in the subtropical high. The tilt of phase lines of anomalies are changed from NE=ADSW to NW=ADSE by the clockwise flow associated with the subtropical high. Such reflections are found both in linear and nonlinear experiments. This result suggests that the nonlinear terms are less important in the critical layer of a zonally varying flow. Our results imply that the applicability of the SWW solution to upper tropospheric phenomena is questionable.
The intensity of the subtropical high in our experiments is found to be varied by the stagnated vorticity anomalies superimposed on the subtropical high. The superposition of incident and reflecting anomalies probably acts to maintain the amplitude and position of the stagnated anomalies.

EFFECT OF SSTAS OVER EQUATORIAL PACIFIC ON SUBTROPICAL HIGH OVER WESTERN PACIFIC

LONG Zhenxia (Institute of Atmospheric Physics, CAS, email: lzx@lasgsgi4.iap.ac.cn); Li Chongyin (Institute of Atmospheric Physics, CAS, email: lcy@lasgsgi4.iap.ac.cn)

LASG 9-level spectral model and IAP 2-level model have been employed to study the effect of SSTAs in equatorial Pacific on the summer subtropical high over western Pacific. Positive or negative SSTAs with different duration (Similar to the SSTA distribution during the years next to El Nino or La Nina) over equatorial eastern Pacific are prescribed. Anomalous subtropical high is defined as the difference between anomalous experiment and control experiment. The results suggest that the anomalous subtropical high shows insensitive to the details of SSTAs in equatorial Pacific. The insensitivity is independent of model. Furthure analyses suggest that the atmospheric internal dynamic process may be responsible for the insensitivity of anomalous subtropical high to the details of SSTA in equatorial Pacific. For example, the weakened intraseasonal oscillation may be responsible for the insensitivity during the warm event. This result will change the traditional theory with which the summer subtropical high over western Pacific can be predicted based on the SSTAs over equatorial Pacific.

LOCAL HADLEY CELL, LOCAL WALKER CELL AND SUBTROPICAL CELL

Ming XU (Department of Atmospheric Science, Lanzhou University, Lanzhou, China, New address: Graduate Department, Beijing Meteorological College, Beijing, 100081, China)

The relationship of subtropical cell and local Hadley cell and local Walker cell is still an unsettled problem. In this paper, the indexes of local Hadley cell, local Walker cell and subtropical cell are defined. By using these indexes, the relationship of subtropical cell and local Hadley cell, subtropical cell and local Walker cell are diagnosed. The results show, local Hadley cell and local Walker cell play distinct roles in different subtropical cells. In Southern Hemisphere, subtropical cells are mainly affected by local Hadley cell. However, in Northern Hemisphere, subtropical cells are affected by both local Hadley cells and Walker cells. Subtropical cell in Southern Hemisphere seems like trade wind system, while in Northern Hemisphere it seems like monsoon system. The mechanism that local Hadley cell and local Walker cell influence subtropical cell is also discussed.

LONG-TERM CLIMATIC SIMULATIONS

Introduction 0830

N. de NOBLET (LSCE, Saclay, France)

MC11/E/18-B3 Invited 0850

INFLUENCE OF CO2 THRESHOLDS IN THE RESPONSE OF THE LLN CLIMATE MODEL TO THE ASTRONOMICAL FORCING

André BERGER, Marie-France Loutre (Université catholique de Louvain, Institut d'Astronomie et de Géophysique G. Lemaître, 2 Chemin du Cyclotron, B-1348 Louvain-la-Neuve, Belgium, e-mail: berger@astr.ucl.ac.be)

The LLN 2-D northern hemisphere climate model has been used to reconstruct the long-term climatic variations over the Quaternary Ice Age. Sensitivity analyses to the astronomically-driven insolation changes and to the CO2 atmospheric concentration have been performed. In particular, an atmospheric CO2 concentration decreasing linearly from 320 ppmv at 3 Myr BP (Late Pliocene) to 200 ppmv at the Last Glacial Maximum was used to force the model in addition to the insolation. Under such condition, the model simulates the intensification of glaciation around 2.75 Myr BP, the late Pliocene-early Pleistocene 41-kyr cycle, the emergence of the 100-kyr cycle around 900 kyr BP, and the glacial-interglacial cycles of the last 600 kyr. Using a reconstructed CO2 concentration over the last 600 kyr from a regression based upon SPECMAP, it has been shown that stage 11 and stage 1 request a high CO2 to reach the interglacial level. The insolation profile at both stages and modelling results tend to show that stage 11 might be a better analogue for our future climate than the Eem. Sensitivity analyses have also demonstrated that CO2 thresholds do control the response of the LLN climate model to the orbital forcing. Between 4 and 3 Myr BP CO2 must exceed 450 ppmv to prevent ice sheets to develop, in particular at about 3.8 Myr BP. The mid-Pleistocene transition between the 41 kyr and 100 kyr periodicities is associated to CO2 values lower than 240 ppmv. Over the last 200 kyr, CO2 threshold values depend upon the global climate itself. The global warming expected over the next centuries require to study deeply periods during which temperature and CO2 higher than to-day, e.g. the late Pliocene.

MC11/W/03-B3 0930

AN ATMOSPHERE-MIXED LAYER OCEAN MODEL'S RESPONSE TO ORBITAL VARIATIONS OVER THE PAST 120,000 YEARS

Charles JACKSON (Program in Atmospheric and Oceanic Sciences, Princeton University, Princeton, New Jersey 08542, email: csj@gfdl.gov); Anthony Broccoli (Geophysical Fluid Dynamics Laboratory/NOAA, Princeton University, Princeton, New Jersey 08542, email: ajb@gfdl.gov)

The atmosphere's response to variations in Earth's orbital configuration over the past 120,000 years is considered using a 9 layer R15 atmospheric general circulation model coupled to a static mixed-layer ocean and dynamic/thermodynamic sea ice model. The large computational cost of simulating the equilibrium response to orbital variations over this long time period is reduced by accelerating orbital variations by a factor of 30 which can be justified by the relatively short response time of the atmosphere-mixed layer ocean system. Of interest are the internal processes by which the model adjusts to temporally and spatially varying insolation. The response for any given location should include factors that are local as well as remote, immediate as well as long term. The advantage of the present model experiment over equilibrium simulations with fixed orbital parameters is that it can produce the time evolving response to the complete spectrum of orbital variations. In so doing, the nature of model processes can be illustrated by the way they filter or translate a given variation in radiative forcing to model climate. Model results will also be compared to various paleoclimate records. Similarities obtained from these comparisons can be helpful in diagnosing the degree to which the observed record can be understood in terms of the physics of an atmosphere-mixed layer ocean model given one of the known variations in palaeoclimate forcings.

MC11/P/02-B3 0950

SIMULATIONS WITH THE WATER ISOTOPE SUB–MODEL OF THE GISS AND THE ECHAM ATMOSPHERIC GENERAL CIRCULATION MODELS: RESULTS FROM 7 TIME SLICE CALCULATIONS FROM THE RECENT HOLOCENE TO THE LAST GLACIAL MAXIMUM

G.HOFFMANN1, R.Koster2, G.Delaygue1, M.Werner3, Jjouzel1 ,(1. Lab. Des Sciences du Climat et de l'Environnement, CEA/CNRS, Gif sur Yvette, France, 2. NASA, GSFC, Greenbelt, Maryland, USA, 3. MPI f.Meteorologie, Hamburg, Germany)

Since long time the isotopic composition of water (180,D) is used to quantitatively estimate past temperatures. In mid and high latitudes a strong relationship has been found between the isotopic composition of modem precipitation and the corresponding mean temperature. The basic assumption for using the water isotopes in paleo climatology now is the equivalence between this spatial isotope-temperature gradient and the temporal gradient at a fix location. The spatial relation serves then as a modem analogue for the temporal gradient subsequently applied on temporal series of reconstructed isotopic composition of precipitation. For the application of this modem analogue method to be valid several preconditions must hold, e.g. an approximately constant contribution of vapour from different source regions or a constant seasonality of precipitation under even completely different climate conditions such as the last glacial maximum (LGM). Recently new results came up that imply that this assumption, i.e. the equivalence of the spatial and the temporal gradient, is not valid at least for Greenland ice cores. Different and independent methods using borehole temperatures or trace gases enclosed in the ice showed that the temporal isotope-temperature gradient most probably is overestimated by about 50% (modern spatial gradient over Greenland. 0.69%°/°C, estimates

based on borehole temperatures: 0.33-0.36%°/°C).
GCMs coupled with a water isotope sub-model are in principal perfectly suited to address this problem. They take into account for example atmospheric circulation changes, varying source conditions or changes in the seasonality of precipitation for calculating the isotopic composition of precipitation under different climate conditions. The model experiments done until now showed only a slight diminution of the temporal gradient (Control-LGM) over Greenland compared to the calculated spatial gradient. In all other regions the analogue method was justified by GCM simulations. For testing the robustness of these results we perfon-ned a set of time slice calculations with two of the above mentioned GCMS, the GISS model (in its high resolution version of 4°*5° degrees) and the ECHAM4 model (T30 resolution). These time slice calculations were done in time steps of 3kyrs through the entire Holocene to the last glacial maximum, 21kyr BP. The computed gradual changes of the temporal versus the spatial isotope-temperature gradients are discussed in terms of the continuously increasing glacial conditions at high latitude regions of both the northern and the southern hemisphere.

MC11/E/17-B3 1010

THE ROLE OF SEA-LEVEL AND VEGETATION IN THE ASTRONOMICAL THEORY OF PALAEOCLIMATES

BERGER, André, Dutrieux A., Loutre M.F. (Université catholique de Louvain, Institut d'Astronomie et de Géophysique G. Lemaître, 2 Chemin du Cyclotron, B-1348 Louvain-la-Neuve, Belgium, email: berger@astr.ucl.ac.be)

Sensitivity experiments have been made over the last glacial-interglacial climatic cycle using the Louvain-la-Neuve 2-dimension Northern and Southern hemispheres climate model. The continental ice volume was simulated for the last 122 kyr in response to changes of both the insolation and CO2 atmospheric concentration. The sensitivity of such a response to sea level changes and to the taïga-tundra - snow albedo feedback indicates that the 100-kyr cycle cannot be sustained if these processes are not taken into account.

MC11/W/06-B3 1100

THE ROLE OF THE THERMOHALINE CIRCULATION IN THE INITIATION OF GLACIATION

Zhaomin WANG, Lawrence A. Mysak (Department Of Atmospheric and Oceanic Scienecs McGill University 805 Sherbrooke West Montreal Quebec H3A 2K6 Canada email: Zhoamin@whale.meteo.mcgill.ca)

We present a new coupled atmosphere-ocean-sea ice-land surface model for long-term climate change studies which incorporates the seasonal cycle. The three major ocean basins, the Antarctic Circumpolar Current region and the major continents are resolved.
The model components are coupled together using flux adjustments (for heat and fresh water) in order to first simulate the present day climate. The major features of this simulation are consistent with observations and the general results of GCMs. In a global warming (cooling) experiment, the thermohaline circulation (THC) in the North Atlantic Ocean is weakened (intensified) mainly due to the increased (reduced) moisture transport to the northern high latitudes and warming (cooling) in the high latitudes of the North Atlantic.
Lastly, the coupled model is employed to investigate the initiation of glaciation by slowly reducing the solar radiation and increasing the planetary emissivity, only in the northern high latitudes. When land ice is growing, the THC in the North Atlantic Ocean is intensified, resulting in a warm subpolar North Atlantic Ocean, which is in agreement with the observations of Ruddiman and McIntyre. The intensified THC maintains large land-ocean thermal contrast at high latitudes and hence enhances land ice accumulation, which is consistent with the rapid ice sheet growth during the first 10 ka of the last glacial period that was observed by Johnson and Andrews. We conclude that a cold climate is not responsible for a weak or collapsed THC in the North Atlantic Ocean; rather we suggest that increased fresh water or massive iceberg discharge from land is responsible for such a state.

MC11/W/08-B3 1120

ATMOSPHERE-CRYOSPHERE INTERACTION FROM EEMEAN TO HOLOCENE CLIMATE SIMULATIONS WITH A COUPLED AGCM-ICE SHEET MODEL

G. VETTORETTI, W. R. Peltier (both at Dept. of Physics, University of Toronto, Toronto, Ontario, M5S 1A7, Canada); N. A. McFarlane (Canadian Climate Centre for Modelling and Analysis, University of Victoria, Victoria, British Columbia, V8W 2Y2, Canada)

Atmospheric-Cryospheric interaction in the earth system is fundamental to the long-term dynamical evolution of global climate. A series of simulations of climate state at key epochs within the last glacial cycle have been performed using the CCCma atmospheric general circulation model (AGCM). The focus in this paper will be upon investigations of the Last Glacial Maximum (LGM) at 21 000 years before present (21 Kyrs BP) and post Eemean Glacial Inception (117 to 112 Kyrs BP). The AGCM has also been asynchronously coupled to a much simpler Energy Balance-Ice Sheet Model (ISM/EBM) to connect the AGCM hydrological cycle and atmospheric energy balance with the dynamics of the ISM/EBM.
We will demonstrate that the resolution of the T32 AGCM cannot adequately capture the detailed mass-balance along the ablation zones of the Laurentide ice complex at LGM. Also, changes in the LGM northern hemisphere stationary wave patterns over Eastern Canada reveal an increased cold southerly geostrophic air flow being driven directly to the southern lobes of the Laurentide ice sheet which extended into the New England region of the United States at LGM. An AGCM sensitivity study of post Eemean Glacial Inception was conducted with modified orbital parameters, orography and model surface hydrology. To adequately resolve the initial evolution of the glacial cycle over many thousands of years, we have coupled the AGCM to the ISM/EBM in order to simulate the evolution of continental scale glacial advance during the last interglacial. We will demonstrate that this combination provides an opportunity to determine ice sheet mass balance over periods which the AGCM alone could not simulate given current computational restraints.

MC11/W/05-B3 1140

THE CLIMATE-ICE SHEET INTERACTIONS IN A SIMPLE CLIMATE MODEL

Lawrence A. MYSAK, Zhaomin Wang (Department Of Atmospheric and Oceanic Scienecs, McGill University, 805 Sherbrooke West, Montreal, Quebec, H3A 2K6, Canada. E-mail: Mysak@zephyr.meteo.mcgill.ca; Zhoamin@whale.meteo.mcgill.ca)

A zonally averaged ice sheet model used by Gallee et al. has been coupled to a simple climate model, which incorporates an energy-moisture balance atmospheric model, a zonally averaged ocean model of Wright and Stocker, a zero-layer thermodynamic sea ice model and a simple land surface model. The ice sheets are initiated by reducing the solar insolation and planetary emissivity in the northern high latitudes.
The ice sheets grow rapidly during the first 10 ka due to the strong thermohaline circulation (THC) in the North Atlantic and very small lateral discharge of ice mass. However, during this stage, the climate in the northern high latitudes is only cooled down slightly and ice sheets cannot advance southward easily. On the other hand, if the planetary emissivity is reduced globally, which can mimic the drop of the concentration of carbon dioxide and water vapor after the initiation of glaciation, the ice sheets may extend southward significantly. Also, the weakening of the THC due to the large ice mass discharge leads to the southward advance of sea ice and a significant cooling of the climate.
Since there exist two flow regimes (steady flow and rapid ice mass discharge) of ice sheets, the ice mass discharge to the ocean is suddenly increased once the ice flow reaches a critical value. This causes the drop of ice volume and weakens the THC. The weak THC leads to the advance of sea ice, which cools down the climate further and slows down the growth of ice sheets. When the large ice mass discharge stops, the THC is restored and the sea ice cover retreats. Then the ice sheets grow relatively rapidly and the critical situation is reached again, which causes another large ice mass discharge.

MC11/L/03-B3 1200

TWO-WAY AGCM-ISM COUPLING

Christophe GENTHON and Catherine Ritz (both at Laboratoire de Glaciologie et Géophysique de l'Environnement, CNRS, BP96, F-38402 Saint Martin d'Hères Cedex, France,
E-mail: genthon@glaciog.ujf-grenoble.fr)

Coupling an Atmospheric General Circulation Model (AGCM) and an Ice Sheet Model (ISM) poses sharp constraints on the AGCM computing efficiency. Because the climate of ice sheets is very sensitive to resolution, low resolution is not an acceptable option.
We use a stretchable-grid AGCM to reach reasonable resolution (about 300km) where major ice sheets develop during an ice age at affordable computing cost. Asynchronous coupling is nevertheless inescapable. Because the topography of the ice sheets can significantly evolve between two coupling steps [O(1000 years)], interpolation in time of the atmospheric forcing must be done. Simulations of the atmosphere of an ice age with different ice sheet topographies have been performed, from which simple parameterizations of temperature and mass balance at the surface of ice sheets will be developed. After testing the equilibrium of the ice age ice sheets by fully (two-way) coupling the atmospheric and ice models, a full deglaciation will be covered. Results available at the time of the symposium will be presented.

MC11/E/12-B3 1220

THE NORTHERN HEMISPHERE ICE COVER SIMULATED WITH A COUPLED CLIMATE-SYSTEM MODEL

Reinhard CALOV, Andrey Ganopolski, Martin Claussen (all at Potsdam Institute for Climate Impact Research, PO Box 60 12 03, D-14412 Potsdam, Germany, Email: calov@pik-potsdam.de)

We study the temporal evolution of the northern Hemisphere's ice sheets through the last glacial cycle with special emphasis on the inception of glaciation and deglaciation using the climate-system model CLIMBER-2 (CLIMate and BiosphERe model) coupled to the polythermal ice-sheet model SICOPOLIS (SImulation COde for POLythermal Ice Sheets). CLIMBER-2 is a coarse resolution climate-system of intermediate complexity. It describes the atmosphere, sea ice, ocean, and the biosphere. The polythermal ice sheet model SICOPOLIS simulates the time-dependent extent of thickness, velocity, temperature, water-content and age for grounded ice sheets. The bedrock responds to the load of the ice through the buoyancy forces of the asthenosphere. SICOPOLIS provides CLIMBER-2 with the temporal change of orography and areas of land and ice sheets. Inversely, the climate characteristics (air temperature and humidity, long-wave and short-wave radiation, precipitation) on the coarse grid of CLIMBER-2 are used to calculate the energy and mass balance on the fine grid of SICOPOLIS accounting for the orography on the fine grid. The only external forcing for CLIMBER-2 are the Milankovitch insolation and the atmospheric CO2-concentration.
The validation of the new coupled model CLIMBER-2/SICOPOLIS shows, in particular, that the modeled present-day surface mass balance and precipitation of Greenland are in good agreement with observations, and that the modeled northern Hemisphere's ice cover at LGM corresponds to the geological findings. Here, we study the role of different factors for the inception of glaciation (at 115 kyr BP) and deglaciation (after 21 kyr BP) of the northern Hemisphere. These factors are in particular the oceanic transport, the sea ice, the vegetation, the atmospheric dust and the flow properties of ice. Furthermore, we compare the importance of these factors for glaciation and deglaciation.

MODELLING THE LAST GLACIAL MAXIMUM CLIMATE: STATUS AND UNCERTAINTIES

Sophie PINOT, Sandy P. Harrison , Gilles Ramstein

Simulations of the last glacial maximum (LGM) have been performed within the Palaeoclimate Modelling Intercomparison Project (PMIP) using atmospheric general circulation models (AGCMs) with both prescribed (CLIMAP) sea-surface temperatures (SSTs) and with SSTs computed using a mixed-layer slab ocean. The simulations use the same boundary conditions for CO2, insolation, and ice sheet extent and height, in order to determine which responses are model-dependent. Evaluations of these simulations have been made using offline vegetation (BIOME 3.5), in order to facilitate comparison with global data sets of pollen-based reconstructions of vegetation patterns. Although all of the models simulate generally colder and drier conditions at the LGM, the global comparisons show that they underestimate the degree of cooling and drying shown by the data. A more quantitative evaluation of the simulated climates can be made using new reconstructions of the temperature lowering at the LGM across the tropics. The simulations with prescribed CLIMAP SSTs underestimate the observed tropical cooling. However, three models with computed SSTs (CCM1, CCC2 and UKMO) simulate a mean annual cooling consistent with the terrestrial reconstructions. Two of the models produce a rather uniform cooling across the tropics; only the UKMO model simulates the spatial patterning in the cooling shown by pollen-data from lowland tropical areas and alkenone-based estimates of SSTs. A sensitivity experiment in which the simulated

SSTs field from the UKMO experiment was used to drive an AGCM (LMD5) shows that it is possible to reconcile marine and terrestrial estimates of the tropical cooling at the LGM. The implausibility of uniform tropical cooling is confirmed by sensitivity experiments with an AGCM asynchronously-coupled to an ocean general circulation model which show that the eastern tropical Pacific must be at least 2°C colder than the western tropical Pacific in order to explain the observed 3-dimensional structure of the tropical ocean.

MC11/E/05-B3 1440

CLIMATE-VEGETATION FEEDBACKS DURING THE LAST GLACIAL MAXIMUM

SAMUEL LEVIS (National Center for Atmospheric Research, PO Box 3000, Boulder CO 80307-3000, USA, Email: slevis@ucar.edu) Jonathan A. Foley (Climate, People and Environment Program, University of Wisconsin, Madison WI 53706, USA) David Pollard (Earth System Science Center, Pennsylvania State University, University Park PA 16802, USA)

We operate the fully coupled GENESIS-IBIS climate-vegetation model with last glacial maximum boundary conditions (~21000 years before present). We find that grasslands and tundra largely replace temperate and boreal forests primarily due to colder and drier simulated conditions. Also, mainly due to reduced plant productivity under lowered CO2 concentrations, tropical and subtropical forests retreat and C4 grasses advance. These shifting vegetation patterns produce significant climatic feedbacks when isolated from the radiative effects of lowered CO2 on this epoch's climate. In particular, a positive feedback process which depends on the difference in albedo between tundra and forest regions results in additional middle and high latitude cooling. On the other hand, sparser vegetation cover in the tropics and subtropics results in significant decreases in the evapotranspiration, leading to warmer and drier conditions in these regions when compared to the simulation results without vegetation feedbacks. These results, and particularly the changes in vegetation cover simulated for the tropics and subtropics, are supported by some observational reconstructions but refuted by others. Progress must be made in the reconstruction of palaeobotanical maps for the tropics, in order to evaluate model results such as these.

MC11/E/02-B3 1540

CONTINENTAL BIOSPHERE CARBON STORAGE AT 21KYR

Dr. Caroline ROELANDT (Max Planck Institute for Biogeochemistry, Tatzendpromenade 1a, D-07745 Jena, Germany, e-mail: caroline.roelandt@bgc-jena.mpg.de)

An integrated land-surface biosphere model: ALBIOC (ALbedo - BIOsphere - Carbon), which simulates the potential distribution of vegetation, terrestrial carbon storage and land-surface properties, as a function of climate, has been applied to estimate changes in the continental biosphere carbon storage at 21kyr (the Last Glacial Maximum).These experiments were made using 17 atmospheric general circulation model simulation done within the Palaeoclimate Modelling Intercomparison Project (PMIP). The simulated vegetation patterns are compared with vegetation reconstructions based on pollen- and macro-fossil data from the BIOME6000 project. The simulated carbon storage values compare well with previous estimate of LGM carbon storage.

MC11/E/04-B3 1620

COMPARISON OF VEGETATION DISTRIBUTIONS AND TERRESTRIAL CARBON BUDGETS RECONSTRUCTED FOR THE LAST GLACIAL MAXIMUM WITH FOUR DIFFERENT BIOSPHERE MODELS

Louis FRANCOIS (1), Dominique Otto (1), Jed Kaplan (2), Pierre Friedlingstein (3), Caroline Roelandt (2), Gilles Ramstein (3), Nathalie de Noblet (3), Pierre Warnant (1), Colin Prentice (2) (1 Laboratoire de Physique Atmosphirique et Planitaire, Universiti de Lihge, Lihge, Belgium, e-mail: francois@astro.ulg.ac.be) (2 Max-Planck Intitut fur Biogeochemie, Jena, Germany) (3 Laboratoire des Sciences du Climat et de l'Environnement, Uniti mixte de Recherche CEA-CNRS, Gif-sur-Yvette, France)

Model reconstructions of vegetation distribution and carbon sequestration in the land biosphere at several key periods in the past have been attempted in recent years by many research groups. These reconstructions are based upon the use of biosphere models forced with climatic outputs from general circulation models. This methodology applied to the Last Glacial Maximum (LGM) provides results which vary significantly from one reconstruction to the other. The question can thus be raised whether this variability in the results are mainly due to the use of different biosphere models or to the different climate reconstructions adopted in these studies. In order to answer this question, an intercomparison of biosphere models forced with a common set of climate reconstructions is necessary. Such a work has been initiated in the frame of the "Paleo-Carbon Cycle Modelling Intercomparison Project (PCCMIP)", a sub-project of the "Paleoclimate Modelling Intercomparison Project (PMIP)". Here, we present some preliminary results obtained with four biosphere models participating in this project: BIOME3, CARAIB, ALBIOC and SLAVE. These models differ widely from each other. The first two use a mechanistic description of photosynthesis and stomatal regulation and predict the biome distribution from a physiologically-based approach in which the net primary productivities of different plant functional types are compared. ALBIOC also incorporates a mechanistic model of photosynthesis and provides a detailed formulation of land surface processes. SLAVE simulates biome distribution in a more simple way, but has the advantage of including a nitrogen cycle. These biosphere models are forced with a common subset of the LGM climatic reconstructions available within PMIP. The predicted vegetation distributions, carbon fluxes (e.g. the net primary productivity) and stocks are compared. Some results regarding the 13C biospheric changes between the LGM and pre-industrial times are also presented.

MC11/E/13-B3 1640

GLOBAL SIMULATIONS OF THE EFFECTS OF LOW ATMOSPHERIC CO2 ON VEGETATION PROCESSES WHICH AFFECT ATMPOSPHERIC ENERGY TRANSFER AND CARBON CYCLING

SA COWLING (Climate Impacts Group, Lund University, S223 62 Lund, Sweden. (tel) +46 (0)46 222 3132, (email: Sharon.Cowling@planteco.lu.se)

Atmospheric CO2 during the last ice-age was between 35 and 50% lower than today, and was probably an important modifier of glacial vegetation. Global modelling experiments using a biogeography-biochemical vegetation model (BIOME3) and palaeoclimate reconstructions from an atmospheric general circulation model (NCAR-CCM1) will be used in a two-by-two factorial design to test the independent and interactive effects of climate and CO2 on leaf area index (LAI), net primary production (NPP) and vegetation distributions at the Last Glacial Maximum (LGM). Regional differences in the sensitivity of vegetation to low atmospheric CO2 is expected, with sub-tropical vegetation predicted to show the greatest response. Low CO2 increases stomatal conductance, which in turn can lower plant water-use efficiency (WUE, ratio of photosynthesis to transpiration) and augment plant water stress. The contribution of LGM climate and LGM CO2 in altering plant-water relations will be quantified by comparing combinations of simulations, and implications for feedbacks on atmospheric energy transfer and carbon cycling will be addressed.

MC11/E/16-B3 1700

DUST SOURCES AND DEPOSITION DURING THE LAST GLACIAL MAXIMUM AND CURRENT CLIMATE: A COMPARISON OF MODEL RESULTS WITH PALEODATA FROM ICE CORES AND MARINE SEDIMENTS

Natalie MAHOWALD (Department of Meteorology, Stockholm University, S-106 91 Stockholm, Sweden. Now at Donald Bren School of Environmental Science and Management, University of California, Santa Barbara, CA 93106, USA.); Karen E. Kohfeld (Dynamic Palaeoclimatology, Lund University); Margareta Hansson (Department of Meteorology, Stockholm University); Yves Balkanski (Laboratoire des Sciences du Climat et de l'Environnement); Sandy P. Harrison (Dynamic Palaeoclimatology, Lund University); Colin Prentice (Max Planck Institute for Biogeochemistry); Michael Schulz (Institute for Inorganic and Applied Chemistry, University of Hamburg); Henning Rodhe (Department of Meteorology, Stockholm University)

Mineral dust aerosols in the atmosphere have the potential to affect the global climate by influencing the radiative balance of the atmosphere and the supply of micronutrients to the ocean. Ice and marine sediment cores indicate that dust deposition from the atmosphere was on average 2-20 times enhanced (depending on location) during glacial periods. Differences in atmospheric dust loadings between the last glacial maximum (LGM) and Holocene might therefore have contributed to climate change on glacial-interglacial time scales. As a first step to addressing this possibility, we have used a terrestrial biosphere model (BIOME3), a simpledust source model, and an atmospheric transport model (TM3) in an attempt to simulate the dust cycle in the atmosphere for current and last glacial maximum climates, as simulated by an atmospheric general circulation model (ECHAM3). We obtain a 2.5-fold higher dust loading in the entire atmosphere and a 20-fold higher loading in high latitudes, relative to present. Based on a compilation of atmosphere-to-surface dust flux estimates for LGM and present in marine sediment and ice cores, we show that the simulated flux ratios are broadly in agreement with observationsboth in the high latitudes and elsewhere; differences between the modelled and observed deposition nevertheless suggest that further improvements in the simple dust model could be made. Changes in atmospheric transport alone do not produce such a large increase in dustiness at the LGM in thismodel, although enhanced transport can account for some specific geographic features of the marine dust record. The simulated increase in high-latitude dustiness depends on the expansion of unvegetated (potential dust source) areas, especially in the high latitudes and in central Asia,caused by a combination of increased aridity and low atmospheric [CO2]. The existence of these dust source areas at the LGM is supported by pollen data and loess distribution in the northern continents, and by geochemical sourcing of LGM dust in polar ice cores. These results point to a role for vegetation feedbacks, including climate effects and physiological effects of low [CO2], in modulating the atmospheric distribution of dust.

MC11/L/02-B3 1720

SENSITIVITY TO THE SSTS FORCING IN PALEOCLIMATE SIMULATIONS

Isabelle MARSIAT, Paul J Valdes (Department of Meteorology, University ofReading, Whiteknights, PO Box 243, Reading. RG6 6BB UK, e-mail: marsiat@met.rdg.ac.uk)

The role of prescribing Sea Surface Temperature in paleoclimate atmospheric simulations has been investigated by comparing GCMs experiments using different SSTs data sets as well as coupled atmosphere/oceanic mixed layer models. We found that the SST forcing is as important as the ice sheet orographic forcing. Changes in the SSTs and sea ice margin generate different patterns of zonal assymetries in the atmospheric circulation that are responsible of reorganisation of heat and moisture transport, leading to important variations of northern hemisphere regional climates. Sensitivity experiments have been carried over to isolate the individual role of North Pacific and North Atlantic SSTs.

MC11/W/04-B3 1740

PRESENT DAY AND LAST GLACIAL MAXIMUM OCEAN THERMOHALINE CIRCULATION INA ZONALLY AVERAGED COUPLED OCEAN-SEA ICE-ATMOSPHERE MODEL

H. BJORNSSON, and L.A. Mysak, Department of Atmospheric and Oceanic Sciences, McGill University, Montreal Canada, H3A 2K6

Using a simple three-basin zonally averaged ocean model coupled to an energy moisture balance atmospheric model and a thermodynamic sea ice model we investigate the stability of the thermohaline circulation during the last glaciation.
First we determine whether the model can be used to simulate the ``present day'' climate conditions, and following that we spin the model up for the conditions resembling those of the last glacial maximum (LGM). In the first case, the model has an ocean ``conveyor belt'' (thermohaline) circulation in which the overturning in the North Atlantic is slightly more than 15 Sv.
Two methods are used to spin up the model to the LGM climate. First, a cool state is obtained by running the coupled model with a reduced model greenhouse effect and increased albedo, but without making any explicit changes to the hydrological cycle. In the second method, the model is directly set up for LGM conditions, in a manner similar to the method used to simulate the present day climate. In both cases the computed LGM sea surface temperatures are reasonable, but only in the second case a is realistic ocean thermohaline circulation obtained.
The LGM conveyor belt circulation is stable and no self-sustained millennial-scale oscillations are present. The absence of these oscillations in this model and their presence in other models are discussed, and it is suggested how ocean modelling results combined with paleoceanographic data might be used to determine whether the glacial conveyor indeed exhibited such oscillations.

CLIMATE OF THE LAST GLACIAL MAXIMUM (21,000 YEARS AGO)

MC11/E/06-B4 0900

A PERIODICALLY-SYNCHRONOUSLY COUPLED ATMOSPHERE-OCEAN GENERAL CIRCULATION MODEL (ECHAM-LSG) FOR SIMULATION OF PALEOCLIMATES

LORENZ, S. J. and Paul, A. (University of Bremen, Postfach 330440 D-28334 Bremen, Germany, e-mail slor@palmod.uni-bremen.de)

For modelling past climates, boundary conditions at the atmosphere-ocean interface are not generally available on a global scale. Coupled atmosphere-ocean general circulation models (GCM) have the potential to make these boundary conditions superfluous. Synchronously

coupled GCMs have been developed for studying anthropogenic greenhouse warming with a typical simulation time of 200 years. Due to the long response time of the deep ocean this is too short for simulating an equilibrium state of the atmosphere-ocean system. In order to reduce the computing time the method of periodically-synchronous coupling is applied to the coupled ECHAM-LSG GCM. In this method, short periods of synchronous coupling alternate with long ocean-only periods. Our application on paleoclimatic time scales enables an integration over some thousand model years within a reasonable computing time. We present stationary states of the ocean-only model and the coupled atmosphere-ocean GCM forced by modern and paleoclimatic boundary conditions. The ocean model simulation of the last glacial maximum at about 20,000 years B.P. exhibits a weaker and shallower Atlantic conveyor belt circulation. The next step is a simulation of the glacial climate with the coupled model. Resultant global data sets at the atmosphere-ocean interface can be used for an independent comparison to the CLIMAP data set.

MC11/E/14-B4 0920

ARE DEEP DECOUPLING OSCILLATIONS OF ATLANTIC THERMOHALINE CIRCULATION THE CAUSE OF DANSGAARD-OESCHGER CYCLES: MODEL RESULTS VS. PALEOCEANOGRAPHIC DATA

Michael SCHULZ(1), Shirley van Kreveld(1), Michael Sarnthein(1) and Simon,Jung(2), (1)Institute for Geosciences, University of Kiel, Olshausenstr. 40, D-24118 Kiel (2)Institute of Earth Sciences, Free University, De Boelelaan, 1085, NL-1081 HV Amsterdam

Based on model experiments it has been postulated that thermohaline circulation of the Atlantic Ocean may exhibit self-sustained oscillations on centennial to millennial time scales (Winton, 1993; 1997). These deep decoupling oscillations are not a feature of the coupled ocean-atmosphere system, but are solely due to internal ocean dynamics. Depending on model parameters, the periodicity of these oscillations ranges from approximately 700-4000 years, and thus includes the periodicity of the Dansgaard-Oeschger (D-O) oscillations (1450 years). To test whether this model is capable of explaining the D-O oscillations, we compare model predictions with paleoceanographic data from the North Atlantic. We use a simple box model of the Atlantic Ocean to simulate the deep decoupling oscillations. This model predicts temperature variations of the subsurface water in the North Atlantic by about 3-5°C over the course of an oscillation. In contrast, benthic oxygen isotope as well as Mg/Ca data from the North Atlantic indicate only an average temperature change of approximately 2 °C during a D-O cycle. Furthermore, the model predicts steady warming of subsurface water masses in the North Atlantic during the cold phase of a D-O cycle. This is at variance with our data, which clearly depict a warming of the subsurface water during the warm phase of a D-O cycle. Hence, we regard it as unlikely that deep decoupling oscillations are a suitable mechanism to explain the observed D-O oscillations. We will discuss alternative modeling approaches, which predict temperature variations during D-O cycles, which are consistent with the paleoceanographic record.

PANEL DISCUSSION 0940

HOW IMPORTANT IS THE INITIALIZATION OF FRESHWATER INPUTS TO THE CORRECT SIMULATION OF THE COUPLED OCEAN/ATMOSPHERE SYSTEM AT THE LGM?

Bette OTTO-BLIESNER, NCAR.

CLIMATE OF THE MID-HOLOCENE (6,000 YEARS AGO)

MC11/E/15-B4 Invited 1045

MODEL UNCERTAINITIES IN SIMULATING MID-HOLOCENE CLIMATES

Paul J VALDES and Buwen Dong (Department of Meteorology, University of Reading, Whiteknights, PO Box 243, Reading. RG6 6BB UK, email: P.J.Valdes@reading.ac.uk)

The mid-Holocene climate of North Africa has received much recent attention. GCM simulations have suggested that changes in ocean circulation and land surfaces have played a major role in climate change in this region. We will present results from a number of simulations using the UGAMP GCM with different land surface conditions, sea surface temperatures and different model parameterisation schemes. The results show that all contribute towards increased monsoon strength during the mid-Holocene although the changes remain smaller than implied by palaeodata. The results will also be used to help interpret the PMIP simulations.

MC11/E/07-B4 1125

MID-HOLOCENE GREENING OF THE SAHARA, WITH THE HELP OF FEEDBACKS FROM THE TERRESTRIAL BIOSPHERE

Nathalie DE NOBLET, Pascale Braconnot, Sylvie Joussaume and Olivier Marti (Laboratoire des Sciences du Climat et de l'Environnement, Unite mixte de Recherche CEA-CNRS, Bat. 709 / Orme des Merisiers , 91191 Gif-sur-Yvette, FRANCE, email: noblet@lsce.saclay.cea.fr)

One characteristic of the Mid-Holocene climate (6000 years ago) is the enhanced seasonal cycle of insolation in the northern hemisphere. As a result, African and Asian monsoons are strongly increased and accompanied, in northern Africa, by the so-called 'greening' of the Sahara. Pollen data are indeed showing that moisture-demanding vegetation types were present in now arid regions. Simulations of the mid-Holocene climate carried out within the Paleoclimate Modelling Intercomparison project (PMIP) demonstrated that Atmosphere General Circulation Models (AGCMs), using fixed present-day SSTs and land-surface characteristics, are unable to explain the intensity of the observed signal in northern Africa in response to the sole prescribed change in orbital forcing. Feedbacks from the ocean and the biosphere, to name only the most important ones, may therefore be required to reconcile models and data. We will present results from simulations of increasing complexity to test the role of feedbacks from the terrestrial biosphere in the Mid-Holocene climate simulated by the LMD1 AGCM. In the first and simplest one, desert in the Sahara is replaced by a prescribed combination of xerophytic woods/scrub and warm grassland, in agreement with vegetation reconstructed using pollen data. The second simulation uses an interactive biosphere, i.e. the BIOME1 model is asynchronously coupled to our AGCM while SSTs are still fixed to present-day conditions. In the third and more complex simulation, the AGCM is also being coupled, synchronously, to a three-dimensional oceanic model.

MC11/E/19-B4 Invited 1145

STABILITY ANALYSIS OF THE CLIMATE-VEGETATION SYSTEM WITH THE CLIMBER-2 MODEL

Victor BROVKIN, Martin Claussen, Andrey Ganopolski, Claudia Kubatzki, and Vladimir Petoukhov. (Potsdam Institute for Climate Impact Research, PO Box 601203, D-14412, Potsdam, Germany, Email: victor@pik-potsdam.de)

The interaction among different compartments of the climate system can lead to multiple steady states which evolve during the history of the Earth system. While the existence of multiple steady states in zero- and one-dimensional climate models is rather certain, the multistability phenomenon is interesting to analyse with geographically explicit models of the climate system. We concentrate our efforts on the interaction between climate and vegetation and analyse the system dynamics with assistance of a climate system model of intermediate complexity CLIMBER-2. It includes a 2.5-dimensional dynamical-statistical atmosphere model; a multi-basin, zonally averaged ocean model including a sea ice model; a surface parameterization scheme based on BATS; and a terrestrial vegetation model, VECODE, based on the continuous bioclimatic classification. Vegetation is described as a composition of plant functional types (trees and grasses), and the equilibrium vegetation cover depends only on climate. VECODE estimates changes in vegetation structure and the terrestrial carbon cycle in response to climate change, and the model has been validated globally for present-day climate. Oceanic carbon cycle is represented by models of inorganic carbon uptake and marine biota.
We perform a series of transient runs of the coupled climate-vegetation model from the early Holocene to present day under the external forcing of the Milankovich insolation. The two main candidates for multistability regions are: near-ocean subtropical deserts like the Sahara where precipitation-vegetation feedback is quite significant, and high latitude land regions where interaction between forest cover and air temperature is amplified by sea ice-albedo feedback. While conceptual models point to the possibility of mulistable equilibria in both geographical regions, the experiment results in a unique stable equilibrium. However, we see a rather abrupt change from a vegetation covered Sahara in the mid-Holocene to the present-day desert Sahara. At the high latitude region, we obtain a slow retreat of the treeline from the northwards extended position in the mid-Holocene to the present-day boundary. The biogeochemical feedback through the carbon cycle plays a stabilising role in the system dynamics.

MC11/W/01-B4 1205

A GREEN PLANET VERSUS A DESERT WORLD: ESTIMATING THE MAXIMUM EFFECT OF VEGETATION ON THE ATMOSPHERE

Klaus FRAEDRICH, Axel Kleidon, and Frank Lunkeit (Meteorologische Institut, Universitaet Hamburg, Bundesstr. 55, D-20146 Hamburg, Germany, email: fraedrich@dkrz.de)

The effect of vegetation extremes on the general circulation is estimated by two atmospheric GCM simulations using global desert and forest boundary conditions over land. The difference between the climates of a 'green planet' and a 'desert world' is dominated by the changes of the hydrological cycle, which is intensified substantially. Enhanced evapotranspiration over land reduces the near surface temperatures; enhanced precipitation leads to a warmer mid- and upper troposphere extending from the subtropics (induced by ITCZ, Monsoon and Hadley cell dynamics) to the mid-latitudes (over the cyclogenesis area of NH storm tracks). These regional changes of the surface water and energy balances, and of the atmospheric circulation have potential impact on the ocean and the atmospheric greenhouse: The ocean is reduced to the prescribed annual cycle of the sea surface temperatures, which are associated with the present day climate. Therefore, both 'green planet' and 'desert world' are expected to generate a net heat exchange between ocean and atmosphere which does not balance in the climatological global average. This global imbalance amounts to a loss of 0.6 10**15 W for the oceans in a desert world and a gain of 1.2 10**15 W on the 'green planet'. The atmosphere and its implied CO2-induced greenhouse warming may be substantially influenced by a 'green planet'. The near surface cooling (associated with a more stable troposphere) reduces the greenhouse effect.

MC11/E/01-B4 1225

THE ROLE OF VEGETATION IN CLIMATE INTERACTION AND INTERANNUAL VARIABILITY IN SHAPING THE AFRICAN SAVANNAH

NING ZENG and David Neelin, Dept. of Atmospheric Sciences and Inst. of Geophysics and Planetary Physics Univ. of California, Los Angeles

Using a coupled atmosphere-land-vegetation model of intermediate complexity, we explore how vegetation-climate interaction and internal climate variability might influence the vegetation distribution in Africa. When the model is forced by observed climatological sea surface temperature (SST), multi-equilibrium states are found in the climatically sensitive zones, namely, the Sahel and southern Africa. Depending on the initial condition, these regions can settle on either a forest-like or a desert-like vegetation cover. When forced by interannually varying SST that corresponds to observed wet and dry years in the Sahel, these stable equilibria are driven toward an intermediate grass-like vegetation due to the nonlinearity in the coupled system. In comparison with the traditional view of vegetation as a mere response to environmental conditions, our results suggest a new mechanism involving vegetation playing an active role in shaping the subtropical savanna ecosystem and modifying the regional climate.

CLIMATE OF THE MID-HOLOCENE (6,000 YEARS AGO).

MC11/E/11-B4 1400

PAIN - THE PALAEO-ARCTIC INITIATIVE

Jed O. KAPLAN 1, and Nancy Bigelow 2 (1Max Planck Institute for Biogeochemistry, Jena, Germany) (2Alaska Quaternary Center, University of Alaska Fairbanks, Fairbanks, AK, USA)

Many recent studies have shown the high sensitivity of arctic ecosystems to climate change, especially with respect to short-term melting of permafrost soils and the consequent release of CO2 and CH4 to the atmosphere. Over longer time scales changing climate in the high-latitudes has had significant impact on the distribution and productivity of vegetation with important feedbacks to the ocean-atmosphere system. The Palaeo-Arctic Initiative (PAIN) is an informal, multidisciplinary project to quantify both vegetation changes though the past and simulate those changes using coupled biosphere and circulation models. This approach of parallel data synthesis and model development allowed us to validate and improve both reconstruction methods and the model results in an efficient way. The activity has three main components, 1. Assembling floristic and physiological information regarding the present distribution of vegetation in the Arctic, 2. Determining the extent and timing of vegetation changes in the arctic since the Last Glacial Maximum (LGM) mainly through use of the pollen record, and 3. Modelling vegetation changes through time with a biosphere model driven by GCM output. We made pollen-based reconstructions of Arctic vegetation during three important time slices: at the LGM, 6000 yr. BP. and in the present day using the widely applied biomisation technique. The modern biomisation was calibrated to a new map of potential natural vegetation for the Arctic. The vegetation map was also used in the development of a new version of the biosphere model driven by present-day mean climatology. Results indicate that reconstructing regional vegetation history from the pollen record is difficult. Several indicator genera are not well represented in the Arctic pollen record. We applied a novel approach to the biomisation method to extract important distinctions in vegetation type. The model successfully simulated the range of different Arctic vegetation types observed today.

However, under different climate regimes, changes in Arctic vegetation were not possible to simulate with the simple, time-slice coupling performed here. Substantial feedbacks between the vegetation and the atmosphere-ocean system may be responsible for the model's inability to match the pollen-based reconstruction.

PANEL DISCUSSION 1420

THE LAND-SURFACE IS MORE THAN VEGETATION.

Sandy HARRISON,MPI Jena.

Thursday July 29 PM

MC11/E/10-B4 1500

THE CLIMATE OF 6000 YEARS BP IN NEAR-EQUILIBRIUM SIMULATIONS WITH A COUPLED AOGCM

Uwe MIKOLAJEWICZ and Reinhard VOSS (Max-Planck Institut fuer Meteorologie, Bundesstr 55, D-20146 Hamburg, Germany email: mikolajewicz@dkrz.de, reinhard.voss@dkrz.de)

One focus point for application of complex models in palaeoclimate studies is the time slice 6000 years before present. Most of these studies have been performed using uncoupled atmosphere general circulation models (AGCMs) forced with insolation and CO2 concentration of the mid-Holocene and prescribing present-day sea surface temperatures (SSTs) and sea-ice distributions. First results from coupled atmosphere-ocean general circulation models (AOGCMs) with identical CO2 and insolation forcing, however, show a marked effect of resulting SST changes on the atmospheric circulation. We have performed a set of coupled AOGCM simulations to investigate the impact of insolation and CO2 changes including a control run with present-day forcing. In one simulation, both, insolation and CO2 forcing were applied. In a second run the mid-Holocene CO2 forcing and modern insolation were prescribed. The 000 years length each to permit the ocean circulation to adjust to the changes in forcing. In order to derive an estimate of the error induced by the use of present-day SST fields, corresponding uncoupled AGCM experiments have been performed. In the coupled runs the insolation and CO2 changes lead to an decrease of the global mean near surface temperature of 0.3 K after 1000 years. Regarding only the CO2 changes the cooling is 0.5 K. Where as the cooling dominates in most regions, the high northern latitudes show a warming in connection with a reduced ice coverage and intensified thermohaline circulation of the Atlantic. Cooler tropical SSTs lead to a weaker monsoon response compared to the uncoupled simulations.

MC11/E/09-B4 1520

THE AFRICAN MONSOON AND THE GREEN SAHARA 6000 YEARS AGO: INFLUENCE OF OCEAN-ATMOSPHERE FEEDBACKS IN A COUPLED MODEL

Olivier MARTI, Pascale Braconnot, Nathalie de Noblet, Sylvie Joussaume Laboratoire des Sciences du Climat et de l'Environnement, CEA Saclay, DSM/LSCE, F91191 Gif sur Yvette Cidex, France. Email: olivier.marti@cea.fr.

6000 years ago, the insolation at the top of the atmosphere was characterised by an enhanced seasonal contrast in the Northern hemisphere. African and Asian monsoons were stronger than today, and pollen and lakes data show that in Africa the vegetation was covering the Sahara, suggesting a northward extension of the summer monsoon. Simulations of the Paleoclimate Modelling Intercomparison Project (PMIP) with atmosphere general circulation models qualitatively reproduce this humidification of the Sahara, but underestimate the magnitude of the change. Part of the mismatch could therefore be attributed to the neglected feedbacks from ocean and vegetation. To study the impact ocean on climate of this period, we have used of the IPSL coupled ocean-atmosphere model. It significantly improves the simulation of the African monsoon, which reacts to an increased land-sea temperature contrast. For the 6000 years ago simulation, only the orbital parameters have been changed and set to those of this period, compared to a coupled control simulation. As observed in ocean sediment cores, the simulated sea surface temperature (SST) changes between 6 kyears and present are small. However, the changes of SST seasonality in the Atlantic has a large impact on monsoon seasonality and amplitude, and of the northward migration of the intertropical convergence zone over Africa. The relative role of changes in atmospheric heat fluxes and in oceanic heat transport on the SST show that ocean dynamic plays a major role, through the change of Ekman layer heat transport within the tropics and subtropics. We discuss the relationship between the change of atmospheric circulation (trade winds) and oceanic one.

MC11/E/08-B4 1540

MODES OF ATMOSPHERIC CIRCULATION AND THEIR CONNECTIONS TO NORTHERN HEMISPHERE TEMPERATURE AND PRECIPITATION DURING THE MID-HOLOCENE

Bette L. OTTO-BLIESNER (National Center for Atmospheric Research Address: P.O. Box 3000 Boulder, CO 80307 USA Association: E-mail: ottobli@ncar.ucar.edu Phone: 303-497-1723 Fax: 303-497-1348)

Analyses of instrumental data quantify the roles of two circulation modes, the North Atlantic Oscillation (NAO) and the Southern Oscillation (SO). in explaining regional temperature and precipitation anomaly patterns over North America, Europe, and the North Atlantic. Their roles in explaining interannual to decadal variabilty during the mid-Holocene is investigated using the fully coupled atmosphere-land-ocean-sea ice model developed at the National Center for Atmospheric Research. The results show prominent Northern Hemisphere teleconnections for the North Atlantic Oscillation but reduced teleconnections for the Southern Oscillation.

MC11/W/07-B4 1630

A COUPLED MODEL EXPERIMENT OF THE MID-HOLOCENE OPTIMUM

WEBER, N., KNMI (P.O. Box 201, 3730 AE De Bilt, The Netherlands. E-mail: weber@knmi.nl)

A coupled atmosphere-ocean model of intermediate complexity (ECBilt; Opsteegh et al., 1998) is applied to the simulation of the mid-Holocene Optimum at 6000 BP. At this time, which was identified by PMIP as a key period for evaluating model performance, the seasonality of insolation was enhanced compared to present-day values. The computational efficiency of ECBilt makes it feasible to perform simulations in coupled mode over time periods of the order of thousands of years. In ECBilt the enhanced summer insolation gives rise to warmer summer temperatures over the NH continents and an enhanced hydrological cycle, consistent with PMIP results for atmosphere-only models. The response in ocean temperature and salinity is small. However, the ocean overturning circulation shows a marked response with a decreased intensity in the Atlantic ocean and an increased overturning in the Pacific domain. The mechanism for this Atlantic-Pacific connection is described. The ocean response evolves during the integration, due to the long adjustment times of the deep ocean. The associated sensitivity of the atmospheric response to the length of the integration (as well as the averaging period) is discussed. As the Holocene insolation is characterised by enhanced seasonality over large time periods the present results might have implications for transient model experiments.

MC11/W/02-B4 1650

THE PRESENT-DAY AND HOLOCENE CLIMATES SIMULATED WITH MOBIDIC

Philippe TULKENS (email: ptulkens@astr.ucl.ac.be); Marie-France Loutre (email: loutre@astr.ucl.ac.be); Michel Crucifix (email: crucifix@astr.ucl.ac.be); Thierry Fichefet (email: fichefet@astr.ucl.ac.be);Andre Berger (email: berger@astr.ucl.ac.be)

MoBidiC is a zonally averaged climate model in which a quasi-geostrophic atmosphere model is coupled to a three-basin (latitude-depth) ocean-sea-ice model. The main continental ice sheets are also represented. The atmospheric component of MoBidiC contains an interactive representation of the hydrological cycle based on meridional transport of moisture and zonal redistribution of precipitation. The sea-ice model enables to represent explicitly the climatic effect of ice formation and ablation and their consequences on the ocean circulation. The interconnected ocean basins allow this model to simulate the main thermohaline circulation processes. MoBidiC is designed for long-term climate simulations and has a low computational cost.
We present temperature, precipitation and ocean circulation patterns simulated for the present-day climate. Despite shortcommings in the representation of atmospheric dynamics and in the distribution of ocean salinity, the values obtained are realistic. Then we discuss a first palaeoclimatic application of the model: the climate of the Holocene is simulated forcing the model with the variations of CO2 and insolation over that period.

MONCRIEFF (National Centre for Atmos Research, USA)

MI04/L/04-B1 0840

A STATISTICAL EQUILIBRIUM THEORY FOR CUMULUS CONVECTION

GEORGE C. CRAIG (University of Reading, UK)

Cumulus parameterization is based on the assumption that, in a convecting atmosphere, the ensemble of cumulus clouds is in some sort of equilibrium with the large-scale forcings that destabilize the atmosphere. The various closure hypotheses in parameterization schemes predict mean properties of the ensemble, but in the absence of a complete statistical theory, it is impossible to determine when these mean properties will be achieved in the atmosphere.
In this talk, cumulus convection will be considered from the point of view of equilibrium and non-equilibrium statistical mechanics. A theory will be presented for an ideal convective ensemble ("ideal" implying that the clouds do not interact). The theory will reduce to a standard closure hypothesis (boundary-layer quasi-equilibrium) for the mean properties of the ensemble, but will also make predictions for the distribution of convection in space and time. Fundamental results from statistical mechanics, including the fluctuation-dissipation theorem and the Curie symmetry principle, will be used to identify limits on the parameterizability of cumulus convection and to propose new observational tests.

MI04/W/32-B1 0900

IDEALIZED SIMULATIONS OF RADIATIVE-CONVECTIVE EQUILIBRIUM

Adrian TOMPKINS (Max Planck Institute for Meteorology, email: Tompkins@dkrz.de Tompkins@dkrz.de)

Cloud resolving models have been used previously to examine bulk statistics of deep convection in long-term simulations of radiative-convective equilibrium. Here we focus on highly resolved deep convection, with statistics based on individual cloud units, tracing cloud volumes, cross-sectional areas, and transport properties in a pseudo-Lagrangian fashion. The sensitivity of such properties to 'external' factors such as large-scale temperature and humidity profiles and boundary layer properties will be examined, using a domain large enough to continuously contain an ensemble of deep convective clouds, and with a horizontal resolution of 400m to attempt to resolve some of their internal structure.

MI04/W/13-B1 0915

RADIATION AND SURFACE ENERGY BUDGETS SIMULATED BY NCAR CLOUD-RESOLVING MODEL AND COMMUNITY CLIMATE MODEL

Xiaoqing WU (Email: xiaoqing@ucar.edu) and Mitchell W. Moncrieff (National Centre for Atmos Research, Mesosacle and Microscale Met., Boulder, USA, Email: moncreif@ncar.ucar.edu)

The representation of cloud systems and the simulation of sea surface temperature (SST) are two major uncertainties in coupled ocean-atmosphere general circulation models (GCMs). Clouds affect the ocean-atmosphere system through their influence on the earth radiation budget and the surface energy budget, momentum flux and precipitation. In order to improve

the representation of physical processes in the coupled GCMs, a comparison of cloud properties, radiative properties and surface energy budget is conducted using the NCAR cloud-resolving model (CRM) and community climate model (CCM3). CRM that combines evolving large-scale observations with cloud-scale models has shown great potential for producing realizations of tropical cloud systems and dynamically consistent cloud-scale datasets. The model-produced data can be quantitatively evaluated against various independent data sources, such as satellite radiative fluxes, albedo, cloud radiative forcing, surface heat fluxes, radar rainfall data, among others. The results show that the successful representation of cloud systems is of great importance for models to realistically simulate the radiative fluxes and surface energy budget. It suggests that the ocean-atmosphere coupling may be down to mesoscale and cloud-scale processes. The dynamically consistent cloud properties and surface forcing provide valuable long-term datasets for improving the parameterization of cloud radiative properties and understanding the role of clouds in the coupled ocean-atmosphere system.

MI10/W/25-B1 0930

CIRRUS CLOUD PROPERTIES DERIVED FROM AN EXTENSIVE RECORD OF SURFACE-BASED SENSOR DATA

Gerald G. MACE, (Uni of Utah Email: mace@atmos.met.utah.edu); E.E Clothiaux and T.P Ackerman, (Penn State University)

In the efforts toward improved characterization of cloud-related processes in global models two genaeral trains of thought have emerged.
One approach is to use global data sets to characterise the influence of clouds on the energy budget and then to parameterise the infra-red physical processes in the models.
The canonical example of this is the use of Earth Radiation Budget Experiment (ERBE) data to validate the top of atmosphere energy budget of most general circulation models. Another equally viable approach that is now emerging is to use highly detailed extended time observations of a single vertical column to characterise the statistics of the physical processes that occur within that column and then to compare the statistics of the observations to those predicted by a global model. We have been active in this latter approach largely through the analysis of Atmospheric Radiation Measurement Program data. We are in the the process of developing new and implementing already ppublished cloud retrievals schemes on the operational cloud radar data streams available from the various ARM sites . At the conference we will present the lattest results of this effort. Specifically, we will explore the statistical distributions that are now emerging from this undertaking regarding cirrus and boundary layer clouds and our ongoing to coompare theses distributions to predictions by the ECMWF model.

MI04/L/13-B1 0945

CIRRUS DETRAINMENT-TEMPERATURE FEEDBACK

DAVID NEELIN and Chia Chou (Dept. of Atmospheric Sciences, UCLA, Los Angeles, California, USA)

To unravel the role of cirriform clouds in climate change, it is important to distinguish among the relationships of different high cloud types to large-scale atmospheric dynamics. While cirrostratus and cirrocumulus (CsCc) have a clear relation to deep convective sources, the ensemble behavior of cirrus is more subtle. An empirical relation is found between cirrus fraction and deep cloud top temperature that points to detrainment temperature as a dominant factor governing tropical and subtropical cirrus. This cirrus-detrainment-temperature (CDT) relation provices a target for modelers, and suggests an additional cloud-climate feedback. As surface temperatures warm, detrainment temperatures cool as deep cloud top height increases. The CDT relation implies that cirrus fraction increases. Because cirrus are optically thinner than CsCc, the competition between longwave feedbacks and cloud albedo feedbacks leads to a hypothesized positive climate feedback by cirrus fraction.

MI10/W/15-B1 1000

LONG TERM CLOUD AND RADIATION MEASUREMENTS IN THE TROPICAL WESTERN PACIFIC

Charles N. LONG, James Mather, and Tomas P. Ackerman (Pennsylvania State University Department of Meteorology University Park, PA, USA 16802)

The tropical western Pacific region is characterized by high sea surface temperatures and frequent deep convection. It also plays an important role in the global atmospheric circulation, acting as a driver for mass and energy export into higher latitudes. The US Department of Energy Atmospheric Radiation Measurement (ARM) Program has recently installed two Atmospheric Radiation and Cloud monitoring Stations (ARCS) in the area. The first ARCS was installed in September-November of 1996 on the island of Manus, Papua New Guinea. The second ARCS has more recently become operational as of November, 1998, on the island of Nauru. This paper describes the instrumentation included with each ARCS deployment, focusing on the capabilities of these instruments in the quantification of cloud properties and the study of cloud effects on the surface energy budget. Each ARCS includes standard surface meteorological instrumentation (pressure, temperature, RH, winds, etc.) as well as radiometers to measure the complete surface radiative energy budget. Additional instrumentation, including balloon borne radiosondes, measures properties of the atmospheric state. Instruments, especially at Nauru, particularly suited to measure cloud properties include a lidar, a millimeter cloud radar, a whole sky radiance and cloud instrument, a microwave radiometer, a narrow field of view 10 micron radiometer, and an Infrared Fourier Transform Interferometer. With these instruments, we can observe vertical (lidar and cloud radar) and horizontal (sky imager) distributions of clouds over the site. With the microwave radiometer and the infrared instruments we can determine column water vapor and liquid water amounts, and cloud optical properties. The ARCS combination of active and passive sensors gives a comprehensive view of the cloud field over each site, and measurements of the effect at the surface. The ARM program intends to operate these two, and other, ARCS sites for at least a 10 year period. We will present examples of retrieved cloud properties and the attendant effect of clouds on the surface radiative energy budget from the first six months of data collected at the Nauru site, and a comparison with over two years of data collected at the Manus site.

MI04/W/34-B1 1045

RADAR STATISTICS IN TROPICAL PACIFIC CLOUD FIELDS

Brian MAPES (NOAA-CIRES Climate Diagnostics Center, Boulder, CO USA 80303-3328, email: bem@cdc.noaa.gov)

Shipborne Doppler radar data from several month- long cruises in the equatorial Pacific have been analyzed by binning the observations in a coarse cylindrical grid. This analysis reduces the data volume tremendously, allowing nimble exploration. The cylindrical coordinate system respects the perverse nature of radar data, and facilitates quantiative use of single Doppler data. Reflectivity, wind, and horizontal wind divergence statistics from unprecedentedly large samples of Pacific precipitating cloud fields are presented. Systematic differences between radar- derived and sonde-derived winds indicate the vertical flux of horizontal momentum.

A MULTISCALE NUMERICAL SIMULATION OF A HIGH LATITUDE CLOUD SYSTEM

M.K.YAU (Department of Atmospheric and Oceanic Sciences, McGill University, Montreal, Quebec, Canada H3A 2K6, email: yau@rainband.meteo.mcgill.ca)

In this study, the cloud system associated with the 30 September 1994 Arctic low which passed over the southern Beaufort Sea area of northern Canada is simulated using the Canadian Mesoscale Community Model (MC2) in a one-way nested mode. The model utilizes simultaneously a cumulus parameterization scheme and an explicit microphysics scheme to simulate the evolution of the larger-scale flows over the coarser-mesh domain (20km grid size). Over the fine-mesh domains at a grid size of 5km and 2 km respectively, the storm is resolved with the explicit scheme containing prognostic equations for cloud water, ice, rainwater, snow and graupel. The model is initialized with the Canadian Meteorological Center (CMC) analysis and is integrated for 36 h which covers the development stage and the mature stage of the storm.
As verified against various observations and the best analysis, the model captures reasonably well many of the fine-scale structures of the cloud system associated with the storm, including the cloud head, the banded cloud features, and the warm frontal clouds. In particular, the model reproduces the observed dry slot at the front edge of the storm. The effects of the frontal circulation, sublimation, horizontal shear and conditional symmetric instability in the evolution of the cloud system are also investigated.

NONLINEAR KELVIN WAVES AND INTRASEASONL OSCILLATIONS IN THE EQUATORIAL

HAN-RU CHO (Department Of Phyics University Of Toronto Toronto Ontario Canadam5s 1a7 FAX: 416-978-8905 e-mail: cho@physics.utoronto.ca)

Equatorial Kelvin wave-CISK has been proposed as the possible mechanismto explain equatorial intraseasonal oscillations. This paper will discuss certain nonlinear aspects of Kelvin wave-CISK propagation. This study is motivated by the fact that if one adopt the so called "CISK arameterization", then, as pointed out by a number of authors, CISK is an essentially nonlinear process which is nonlinear even in the small amplitude approximation.
Since Kelvin wave is a none-dispersive wave, its solution can be obtained from the method of characteristics. In applying the methods we find that CISK process doesn't exist in Kelvin waves. In other words, Kelvin waves with cumulus heating is always stable. This is the central conclusion of this paper. Furthermore we found another problem with the so called "CISK parameterization". In the trailing edge of the cloud region, we show that discontinuity will develop. Because of the so called "CISK parameterization" we show the discontinuity begin to appear at the initial time. Furthermore, we will show that the discontinuity in the cloud heating parameter introduced in the so called "CISK parameterization" is imcompatible with the "jump condition". A jump condition is what we must have when a discontinuous solution is applied to a conservation law.
In the leading edge of the cloud region the solution of the wave will involve the so called "rarefacton wave".A method used to drive a rarefaction wave will also be discussed.

MI04/E/19-B1 1130

ORGANISED DEEP CONVECTION AND ITS RELATION TO SST AND HUMIDITY

C. A. BABU and P. V. Joseph (Department of Atmospheric Sciences, Cochin University of Science and Technology, Cochin - 682 016, INDIA)

We have examined the relationship of SST and humidity at 850 hPa level with organised deep convection over tropical Indian Ocean and Western Pacific Ocean. SST is obtained from COADS data set and humidity field is from NCEP data set while HRC data set as derived by Garcia (1985) is used to represent deep convection. SST and HRC data sets are monthly mean values during the period 1971 to 1986 and humidity field is from 1979 to 1986, averaged over 4 deg. latitude X 4 deg. longitude squares. The response of convection to SST is of two types : one the TROUGH type and the other the SUBSIDENCE Type. In The Equatorial Convective Cloudiness Maximum(ECCM) area convection is large (HRC 4-6 days/month) and occurs with SST in the range 28 to 30 C. To the north and south of the ECCM, convection is feeble (HRC less than 2 days/month) due to the subsidence zones associated with the descending limb of tropical Hadley circulation and in these areas convection increases with SST in the range 26 C to 29 C.
Decrease in convection above 29 C is also noticed as found by Waliser (1993). Another component examined is the response of convection to SST over the ECCM cloud band during January and February (Austral summer) over the Australian Seas, Indian Ocean and in the equatorial central Pacific. Trough type pattern occurs over the Australian Seas and other two areas show Subsidence type pattern with high HRC values. This can be interpreted due to sinking motion associated with the Walker circulation with rising motion over the Australian Seas. The response of convection to SST in El Nino case is also discussed. Humidity - convection results indicate that humidity at 850 hPa has influence in organised deep convection.

MI04/L/12-B1 1145

STATISTICAL ANALYSIS OF THE MAXIMUM VERTICAL WIND VELOCITY IN THE WESTERN PACIFIC

Philippe NAVEAU and Mitch Moncrieff (National Centre for Atmos Research, Mesosacle and Microscale Met., Boulder, USA, Email: moncreif@ncar.ucar.edu)

To model the atmospheric characteristics of mesoscale clouds system in the Western Pacific, a variety of simulated numerical models has been generated and studied in the past. One important output from these models is the time series of the maximum vertical wind velocity on the domain. Our data constitutes of two different sets of observations. The first set is generated by a two-dimensional, two-nested Cloud Resolving Model (CRM) with a large outer domain (4500 * 30 km) initialized by an idealization of December 1992 westerly wind burst in the Tropical Oceans Global Atmosphere Coupled Ocean-Atmosphere Research Experiment region (TOGA COARE). The second set of observations is generated by a different two-dimensional CRM initialized by a thermodynamic sounding typical of those observed during TOGA COARE but with different idealized wind profile (for more details see Wu and Moncrieff (1995) and Liu and Moncrieff (1997)).
A key aspect in this study is the relationship between the maximum vertical wind velocity and two distinct regimes, highly organized squall-line-like convection and less organized non-squall cloud clusters. Applying the statistical theory of extreme values, we first analyze the

statistical distribution of the maximum vertical wind velocity as a mixture of two Generalized Extreme Distributions. Since the maximum vertical wind velocity time series is not stationary, we develop then a stochastic model that takes into account the non-stationary temporal dependence and the regime type dependence. Our stochastic model can be describe like a random game with two players, and can reproduce the different regimes, squall-lines, non-squall lines cluster and scattered. We show that the behaviour of the maximum vertical wind velocity can be simulated by using few parameters. These parameters are set according to the behaviour of the cloud system that you want to reproduce.

A COMPREHENSIVE TREATMENT OF CLOUDS AND CONVECTION FOR USE IN A REGIONAL CLIMATE MODEL

Colin G. JONES, Ulrika Willen, Markku Rummukainen & Anders Ullerstig (Rossby Centre, SMHI, Norrköping SE601 76 Sweden)

The SWECLIM program has as a goal to model climate change in the NORDIC region, over the next 50-100 years. To achieve this the High Resolution Limited Area Model (HIRLAM) is being developed into a Regional Climate Model (RCA), incorporating an atmospheric component, 3D model of the Baltic Sea and a sophisticated treatment of the surface and subsurface hydrology. For climate change experiments the RCA is commonly run at a resolution between 20-80km. Crucial to these climate integrations is an accurate treatment of the water cycle. In particular, precipitation and cloud cover/content and its radiative interaction. The HIRLAM model contains a detailed parameterisation of cloud microphysics and formation, due to Sundqvist(1988,1993). The treatment of convection is less detailed, being a Kuo type scheme. In an attempt to improve the representation of convection in the RCA, the Kain-Fritsch convection parameterisation has been implemented. This scheme was designed specifically for mesoscale applications. Amongst other features, it contains a CAPE based closure, a trigger function controlling the onset of convection in an unstable atmosphere and both moist updrafts and downdrafts. Cloud water is a prognostic quantity in the RCA, water detrained from the convective updrafts and downdrafts is passed to the cloud microphysics parameterisation for cloud formation and may also interact directly with the resolved dynamics. This talk will outline the impact of the Kain-Fritsch scheme on simulations with the RCA on both synoptic forecast timescales through to multi annual climate timescales. Key parameters analysed include precipitation, cloud cover/content and its radiative interaction and the overall water budget of the atmosphere.

PARAMETERIZATION AND LARGE-SCALE MODELLING

MI04/W/24-B1 1400

A PARAMETRIZATION OF CLOUD AND PRECIPITATION OVERLAP FOR USE IN GENERAL CIRCULATION MODELS

Christian JAKOB (1) and Stephen A. Klein (2); (1) European Centre for Medium-Range Weather Forecasts (2) Geophysical Fluid Dynamics Laboratory/NOAA

Global Circulation Models (GCMs) have generally treated only the radiative impacts of vertically varying cloud fraction by use of a cloud overlap assumption. In a recent study Jakob and Klein (1999) have attempted to evaluate the importance of the ``cloud macrophysics", i.e., the treatment of cloud cover and its vertical overlap, for the parametrization of microphysical processes. They used a simple microphysical scheme as it is implemented in the current ECMWF model to show that a more detailed treatment of cloud fraction and its overlap can lead to large differences in the parametrized precipitation and evaporation rates. The method they employed was to subdivide each model grid box in a number of smaller boxes and solve the cloud microphysics parametrization for each of the sub boxes individually after applying a cloud overlap assumption. This method increased the runtime of the ECMWF model by about 20 %. Given the large uncertainties in both the microphysical parametrization themselves and in the description of the cloud overlap it seems inadequate to apply their ``sub-grid precipitation scheme" directly in a GCM. However, it can also be argued that the use of a complex microphysical parametrization, which undoubtedly also increases model cost enormously, is not useful before addressing the cloud and precipitation overlap issues. This paper describes a simple parametrization that tries to address the problems raised in JK99 without significantly increasing the model cost. The basic idea of the parametrization is to divide the precipitation flux in each grid box into a cloudy and a clear-sky part. That division together with a description of the area coverage of each of the flux components and their overlap captures the main features of the sub-grid precipitation formulation of Jakob and Klein (1999) at a much reduced cost. Results from both climate simulations and forecasts will be presented to demonstrate the impact the new treatment has on the ECMWF model simulations.

MI04/E/09-B1 1420

ASSESSING CLOUD OVERLAP ASSUMPTIONS USING LARGE EDDY MODEL RESULTS

Jon PETCH, John Edwards and Mike Gray (UK Met Office, London Rd, Bracknell, Berks, RG12 2SZ. e-mail: jpetch@meto.gov.uk)

A Large Eddy Model (LEM), using a horizontal grid length of 2 km and a domain size of 256 km, has been run for 6 days of the TOGA-COARE Intensive Observational Period (IOP). 2-D and 3-D simulations have been carried out to give detailed temperature, moisture, cloud and radiation fields. A radiation scheme from a climate model has then been run on the domain average fields and compared to the heating rates calculated within the LEM. Sensitivities to the cloud overlap assumption used in the climate model radiation scheme are presented. Further sensitivities to the treatment of precipitation sized hydrometeors in the radiation schemes are also shown.

MI04/E/15-B1 1435

IMPROVEMENT OF CUMULUS-SCALE PARAMETERIZATION IN A TROPICAL CYCLONE MODEL

Tomoe NASUNO and Masanori Yamasaki (Department of Earth and Planetary Physics, Faculty of Science, University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo, 113-0033, Japan, email: nasuno@atmos0.geoph.s.u-tokyo.ac.jp, yamas@atmos0.geoph.s.u-tokyo.ac.jp)

It is important to treat cumulus convection properly in tropical cyclone models. Especially, the significance of expressing mesoscale organized convection(MC), which is known as a basic component in TC rainband (Yamasaki,1983), has been emphasized(Yamasaki,1986). In the present study a new non-hydrostatic 10km grid model inclouding cumulus-scale parameterization is constructed, based upon Yamasaki(1986). At present axi-symmetric model is used for understanding and results are evaluated in comparison with cloud resolving case (1km grid).In order to express MC cloud water and rainwater are predicted following Yamasaki(1986). Cumulus-scale heating is included by Kuo's(1965) method, different from Yamasaki(1986). Water vapor consumed as cumulus-scale condensation is converted to cumulus-scale cloud water, and cumulus-scale cloud water and rainwater are also treated as predictable variables. By including cumulus-scale effects convection grows to high levels and maintains with intense rainfall, and decays within several hours as cold pool develops. Tropical cyclone scale circulaion gradually develops through continuous formation of MC. The life cycle of MC and development of the tropical cyclone qualitatively express the main characteristics of the cloud-resolving case and consistent with observational facts.

MI04/W/20-B1 1450

A PARAMETERIZATION OF CONVECTIVE CLOUDS FOR LARGE-SCALE MODELS

RONI AVISSAR, Yongqiang Liu and Chris Weaver (Department of Environmental Sciences, Rutgers University, 14 College Farm Road, New Brunswick, New Jersey 08901-8551, USA, email: avissar@gaia.rutgers.edu)

To develop a parameterization of shallow convective clouds and precipitation induced by land-surface processes in large-scale atmospheric models, a set of simulations was performed with a high-resolution 3D atmospheric model. Results indicate that landscape discontinuities could significantly affect the timing of onset of clouds, and the intensity and distribution of precipitation. In most cases, landscape discontinuities enhance precipitation. Current parameterizations of clouds and precipitation in atmospheric models do not account for such effects. Similarity theory was used to develop such a parameterization. For this purpose, Buckingham Pi Theory, a systematic method for performing dimensional analysis, was used to derive a set of dimensionless groups, which describes the large-scale atmospheric background conditions, the spatial variability of surface sensible heat flux, and the characteristic structure of the landscape. These dimensionless groups were used to calculate the coefficients of a Chebyshev polynomial, which represents the self similar vertical profiles of dimensionless mesoscale heat fluxes obtained for a broad range of large-scale atmospheric conditions and different landscapes. The numerous 3D numerical experiments performed to evaluate this similarity relationship suggest that the parameterization provides reasonable results.

MI04/W/01-B1 1505

TOWARDS PARAMETRIZING CONVECTIVE MOMENTUMTRANSPORTS BY ORGANISED CONVECTION

D. GREGORY and M.Miller (ECMWF, Shinfield Park, Reading RG2 9AX, United Kingdom Email: dgregory@ecmwf.int)

In recent years several schemes for representing convective momentum transports have been incorporated into GCMs, differing in their treatment of the across-cloud pressure gradient which plays an important role in determining the vertical variation of updraught horizontal momentum. At ECMWF, the convection scheme represents the pressure gradient through enhanced horizontal mixing (Miller, personal communication), while the scheme in use at the UK Met. Office uses aparametrization with dependency upon verticals hear and cloud mass flux (Gregory et al, 1997).
Further analysis suggests that a combination of the two approaches may provide a more accurate parametrization of the pressure gradient. The various approaches are contrasted in the ECMWF convection scheme for cases of shallow and both unorganised and organised deep convection using results from CRM simulations. Comments will also be made regarding the ability of the combined approach to represent "up-gradient" transports associated with organised convection through use of the "lateral mixing" component of the pressure gradient formulation.

MI04/L/11-B1 1520

DYNAMICAL MODELS OF MOMENTUM TRANSPORT BY ORGANIZED CONVECTION

Mitchell W. MONCRIEFF (National Center for Atmospheric Research, Boulder, CO 80307-3000, USA email: moncrief@ucar.edu)

Convective momentum transport (CMT) is categorized in terms of two regimes; namely, i) down-gradient flux and ii) up-gradient flux as paradigms for organized transport in constant shear and in jet-like mean flow, respectively. Archetypal models are derived, as the term implies, as the simplest possible representation of momentum flux, simple enough to be applied in mass-flux-based parameterization.
These dynamical models represent the total momentum flux rather than the eddy flux associated with the standard Reynolds-averaging principle on which standard convective parameterization is based. This concept and the modeled momentum fluxes are evaluated against transports derived from fine-scale simulations of organized convection. The entraining plume used in convective parameterization is argued to be an inappropriate model of CMT by organized flows. This points to shortcomings in its (universal) application in convective parameterization. Finally, it is suggested how existing parameterization methods for CMT should be modified, at least to test the impact of organized fluxes in global models if not as a fundamental concept.

MI04/W/33-B1 1535

PARAMETERIZATION OF THE INTERACTION BETWEEN CUMULUS CONVECTION AND THE SUBCLOUD LAYER

A. Pier SIEBESMA (European Centre for Medium-Range Weather Forecasts, Shinfield Park, Reading, RG29AX, England. email: siebesma@ecmwf.int.) and Roel Neggers (Royal Netherlands Meteorological Institute, P.O. Box 201, De Bilt AE3730, the Netherlands. Email: neggers@knmi.nl.)

It is well known that the roots of cumulus convection reside in strong convective plumes that originate from the surface layer. Yet, in large-scale weather and climate models it is still common practice to parameterize the dry boundary layer and the cloud layer separately. This results in unwanted overlaps between the schemes and double counting of the transport mechanisms. It also has the additional disadvantage that it requires extra boundary conditions for the convective fluxes at cloud base, which is usually referred to as the closure problem. To overcome these problems a mass flux parameterization is proposed and analysed for strong thermals in the convective boundary layer. Lower boundary conditions can be formulated using the surface layer similarity theory. By subsequently solving updraft equations for vertical velocity, temperature and moisture, this parameterization estimates the non-local convective transport of heat and moisture by strong thermals in the sub-cloud cloud layer that transform into cumulus updrafts in the cumulus cloud layer above the level of condensation (LCL). This way the closure problem is simply shifted to the surface layer and the interaction of cumulus convection with the sub-cloud layer is established in a natural way. The parameterization scheme is tested and developed using Large Eddy Simulation (LES) results and its impact is evaluated using the ECMWF model.

MI10/W/21-B1 1620

INTERACTIONS BETWEEN CLOUD MICROPHYSICS AND CUMULUSCONVECTION IN THE CSU GENERAL CIRCULATION MODEL

Laura D. Fowler and David A. Randall (Department of Atmospheric Science Colorado State University Fort Collins, CO 80523, e-mail: laura@slikrock.atmos.colostate.edu)

In the Colorado State University General Circulation Model (CSU GCM), cumulus detrainment of cloud water and cloud ice is the only coupling between convective and large-scale condensation processes. This one-way interaction from the convective to the large-scale environment parameterizes, in a highly simplified manner, the growth of horizontally spreading anvils at the tops of narrow cumulus updrafts. The reverse interaction from the large-scale to the convective environment through which large-scale cloud water and cloud ice can modify microphysical processes occurring in individual convective updrafts is presently missing.
In the EAU cup parameterization of convection, large-scale water vapor, cloud water, and cloud ice are let to enter the sides of the convective updraft, and be lifted to the top of the cloud. As the different water species are being lifted, cloud microphysical processes are taking place, removing excess supersaturation in the form of cloud water and cloud ice, and converting excess cloud water and cloud ice in the form of precipitation of rain and snow. The partitioning between cloud water and cloud ice, and that between rain and snow are based on temperature, as in the EAUliq parameterization of large-scale cloud microphysical processes. As in the CONTROL parameterization of convection, cumulus precipitation of rain is assumed to instantaneously fall to the surface. In contrast, the treatment of the cumulus precipitation of snow varies, from assuming that snow completely detrains at the top of cumulus towers, to assuming that snow falls through the updraft and melts, or to assuming that snow falls outside of the updraft and may evaporate. Differences between climate simulations obtained with the EAUcup and CONTROL parameterizations of convection are discussed. Emphasis is given on the impact of the treatment of the precipitation of snow formed by convection on the simulated climate. The importance of parameterizing a two-way interactionw between convective and large-scale condensation processes is emphasised.

MI04/W/17-B1 1635

ATMOSPHERIC GENERAL CIRCULATION MODELS: CAN SEASONAL AND LATITUDINAL CHANGES OF CLOUD-RADIATIVE FORCING BE USED TO VALIDATE CLOUD- CLIMATE FEEDBACK?

Robert D. CESS (Marine Sciences Research Center, State University of New York, Stony Brook, NY 11794-5000, email: cess@atmsci.msrc.sunysb.edu)

Seasonal and latitudinal changes in cloud-radiative forcing at the top of the atmosphere have been evaluated from 18 atmospheric general circulation models. These same models have been used to evaluate cloud-climate feedback for one type of climate-changes simulation. These two separate studies thus provide a means of addressing the question as to whether seasonal and latitudinal changes of cloud-radiative forcing can be used to validate cloud-climate feedback.

MI04/E/08-B1 1650

STUDY OF CLOUD PARAMETERIZATIONS AND THEIR INTERACTION WITH CONVECTION IN AN OPERATIONAL NWP MODEL

Qingyun ZHAO, Thomas L. Black, and Song-You Hong (Environmental Modeling Center, National Centers for Environmental Prediction, Washington, D. C. 20233, Email: wd20cl@next4.wwb.noaa.gov)

A package of cloud and precipitation parameterization schemes has been incorporated into the National Centers for Environmental Prediction (NCEP) Eta Model for testing. This package combines the operational Eta Model cloud parameterization scheme (Zhao and Carr, 1997, Zhao et al., 1997) with the precipitation physics package developed by Hong et al. (1998). The schemes in this package are designed with different levels of sophistication in microphysics for different model configurations and/or for different reaearch and operational purposes. Currently, there are three cloud and precipitation schemes in this package. The CLD2 scheme contains only one prognostic variable, cloud water/ice mixing ratio, and is basically for uses in large-scale NWP models and GCMs. This scheme has been in operational use in the Eta Model at NCEP since 1995 and is being incorporated and tested in the NCEP MRF Model. The CLD3 scheme contains two species of hydrometeors, namely, cloud water/ice and rain/snow, and is designed to improve the cloud and precipitation forecasts in the mesoscale Eta Model where model resolution is high and the horizontal advection of precipitation (rain and snow) is important due to the small model grid size. The CLD5 is the most sophisticated scheme in this package and has four prognostic variables: cloud liquid water, cloud ice, rain and snow. This scheme is developed for the future uses for the Eta Model with very high model resolution. The CLD3 and CLD5 schemes have been tested with the NCEP Regional Spectral Model (Hong et al., 1998). The whole package is coded with a plug-in ability for easy uses with other models and it is easy to switch from one cloud scheme to another without changing the model codes. The objectives of this research are to study the effects of cloud parameterization with different schemes on the model's cloud and precipitation forecasts and to learn how cloud parameterization interacts with convection. For this purpose, tests with all these cloud parameterization schemes have been carried out with the same model configuration. Preliminary results show that a simple scheme sometimes performs better than complicated ones in a large-scale model. Experiments have also been performed with and without cloud microphysics in the model's convective parameterization. Studies of these experiments are underway and results will be represented at the Symposium.

MI04/E/27-B1 1705

IMPACTS OF CONVECTION PARAMETERS ON CLIMATE SIMULATIONS USING THE ARIES GCM

Julio T. BACMEISTER (University Space Research Association, 7501 Forbes Blvd #206, Seabrook, MD 20706-2253 USA e-mail: bacmj@janus.gsfc.nasa.gov); Max J. Suarez (Code 913, NASA Goddard Space Flight Center, Greeenbelt, MD 20771 USA)

Results from multi-year simulations at 2.5x2 degree resolution using the ARIES GCM are shown. ARIES includes a relaxed Arakawa-Schubert scheme (RAS) to represent the effects of atmospheric convection. We examine the climatological impact of several physical processes represented in RAS , including the efficiency of precipitation conversion and re-evaporation, and the existence of "triggers" for convection. Large impacts are found when rain-re-evaporation is included. Persistent errors in the model's global precipitation, such as the existence of a "double ITCZ" are reduced or eliminated. Interactions between RAS and a new prognostic liquid water scheme for ARIES will also be discussed.

RADIATIVE TRANSFER AND CLOUD FIELD MORPHOLOGY

MI10/E/03-B2 0930

CLOUD SPATIAL STRUCTURE AND 3D RADIATIVE TRANSFER

ROBERT F. CAHALAN (NASA/Goddard Space Flight Center, Greenbelt, MD 20771 USA)

Cloud radiative properties are sensitive to drop size and other parameters of cloud micro-structure, but also to cloud shape, spacing, and other parameters of cloud macro-structure, including internal fractal structure. New information on cloud structure is being derived from a variety of cloud radars, and angoing field programs such as DoE/ARM are improving the measurement and modelling of physical and radiative properties of clouds. A parallel effort is underway to improve cloud remote sensing, especially from the new suite of EOS-AM1 instruments which will provide higher spectral, spatial resolution, and/or angular resolution.
Key parameters for improving pixel-scale retrievals are cloud thickness and photon mean-free-path, which together determine the scale of "radiative smoothing" of cloud fluxes and radiances. This scale has been observed as a change in the spatial spectrum of Landsat cloud radiances, and was also recently found with the Goddard micropulse lidar, by searching for returns from directions nonparallel to the incident beam. "Offbeam" Lidar returns are now being used to estimate the cloud "radiative Green's function", G, which depends on cloud thickness and may be used to retrieve that important quantity. G is also being applied to improving simple IPA estimates of cloud radiative properties. This and other measurements of 3D transfer in clouds, coupled with Monte Carlo and other 3D transfer methods, are beginning to provide a better understanding of the dependence of radiation on cloud inhomogeneity, and to suggest new retrieval and parameterization algorithms which take account of cloud inhomogeneity.
An international "Intercomparison of 3D Radiation Codes" or I3RC, program is beginning to coordinate and evaluate the variety of 3D radiative transfer methods now available, and to make them more widely available. Information is on the Web at: http://climate.gsfc.nasa.gov/I3RC. Input consists of selected cloud fields derived from data sources such as radar, microwave and satellite, and from models involved in the GEWEX Cloud Systems Studies. Output is selected radiative quantities that characterize the large-scale properties of the fields of radiative fluxes and heating. Several example cloud fields will be used to illustrate.

MI04/E/26-B2 0950

THE RETRIEVAL OF CIRRUS CLOUD MICROPHYSICAL AND BULK PROPERTIES USING RADIANCE DATA FROM THE MULTI-SPECTRAL AND DUAL-VIEWING ALONG TRACK SCANNING RADIOMETER

Sarah K. WATTS (Department of Atmospheric, Oceanic and Planetary Physics, Oxford University, Parks Road, Oxford OX1 3PU, UK, Email: swatts@atm.ox.ac.uk); Anthony J. Baran (Satellite Soundings, UK Meteorological Office, Email: ajbaran@meto.gov.uk); Philip D. Watts (Rutherford Appleton Laboratory Email: p.d.watts@rl.ac.uk); Mark J. Webb (Hadley Centre, UK Meteorological Office, Email: mjwebb@meto.gov.uk Ping Yang, Department of Atmospheric Sciences, University of California, Email: yang@atmos.ucla.edu)

The Along Track Scanning Radiometer (ATSR-2) instrument on the ERS-2 platform has multi-spectral and dual look capabilities providing the means for retrieving cirrus cloud parameters such as optical depth, crystal effective size and estimates of crystal habit and ice water path. In the retrieval scheme, cloud is modelled as a single, homogeneous layer, specified by the single scattering albedo, the optical depth and the scattering phase function. Assuming a particular crystal shape (or habit), it is usual to assume the geometric optics approximation in calculating crystal optical properties and single scattering phase function. The limitations of the geometric optics method are well known. However, in this paper we present retrievals based on the Finite Difference Time Domain (FDTD) method. The FDTD method is exact and has been used to calculate all crystal optical properties and single scattering phase functions for hexagonal plates, hexagonal columns, bullet rosettes and complex aggregates at the wavelengths of 0.55, 0.87, 1.6 and 3.7 microns.
Selected tropical and mid-latitude cirrus cases are presented. For these cases we use the dual-view geometry of ATSR-2 at 0.87 microns to to estimate the dominant crystal habit, thereby testing the FDTD predictions of the scattering phase functions representing the various crystal habits. The 0.55, 1.6 and 3.7 micron ATSR-2 channels are used to retrieve the bulk optical depth and crystal effective diameter (De), and these two independent retrievals allow the estimation of ice water path (IWP). Preliminary comparisons of retrieved De and IWP will be made with the UK Meteorological Office HadAM4 model predictions of ice water path for selected case studies in the tropical Pacific.

MI10/W/06-B2 1005

A STATISTICALLY BASED PARAMETERIZATION OF SHORTWAVE CLOUD RADIATIVE FLUXES OF INHOMOGENEOUS MIXED PHASE CLOUDS

Andreas MACKE, Ronald Scheirer, and Lueder v. Bremen (Institute for Oceanography,University of Kiel, Duesternbrookerweg 20, D-24105Kiel, Germany, email: amacke@ifm.uni-kiel.de)

Shortwave (SW) cloud radiative fluxes and radiance fields for inhomogeneous mixed-phase clouds have been calculated by means of a Monte Carlo radiative transfer model. Single scattering properties of water droplets, ice, snow and graupel particles, as well as raindrops are considered as realistically as possible. Furthermore, scattering and absorption at the spatially inhomogeneous distributions of dry airand water vapour is taken into account. Cloud geometries and cloud microphysical properties have been obtained from a large number of mesoscale cloud model results and various cloud radar measurements. The calculated SW albedo, transmission, and absorption differ considerably from those obtained by a homogeneous plane-parallel cloud idealisation. These qualitatively well known deviations have been quantified with respect to bulk cloud physical properties such as cloud height, cloud liquid water, cloud ice, and cloud top temperature. First results of a principal component analysiscorrelating the radiative fluxes ith the most relevant bulk properties will be discussed. These statistically based parameterisation of solar broadband cloud radiative properties provides a promising tool to improve cloud radiation schemes in atmospheric circulation models.

MI10/W/05-B2 1020

USING MEASUREMENT-BASED THREE-DIMENSIONAL CLOUD DEPICTIONS IN NUMERICAL WEATHER PREDICTION

Donald C. NORQUIST, (AFRL/VSBE, c/o AFWA/DNX, 106 Peacekeeper Dr, Offutt AFB, NE 68113-4039 USA; Telephone: 402-232-8282, Fax: 402-294-2892, E-mail: Donald.Norquist@afwa.af.mil)

Mesoscale and global-scale numerical weather prediction (NWP) models are now predicting near-future distributions of clouds in three-dimensions. In most cases, the prognostic cloud variable is cloud water content in both ice and liquid states. Unfortunately, initialization of such predictions have lagged behind the mechanics of the predictions themselves. Modellers find themselves having to use less than adequate means to initialize the cloud water content, usually either with a zero state or a previous forecast. This is because direct cloud water measurements, unlike other NWP prognostic variables, are not available. What are widely available are the "observed" cloud quantities like fractional cloud coverage and cloud top temperature. Satellite imagery processing algorithms have been developed to estimate additional quantities, such as cloud top altitude, cloud emissivity, cloud optical depth, and cloud type. What is needed is a way to convert these observed or derived cloud properties based on satellite imagery into cloud water content that can be used to initialize NWP models. In this project, we have placed aircraft-borne in situ cloud particle measurements, ground-based cloud radar measurements, and satellite observed and derived cloud properties in three-dimensional grids. The in situ and radar measurements were used to derive cloud water content which were place in grid cells on grids synoptic with satellite imagery from a geostationary satellite. The imagery-based cloud properties were also placed in the gridin their respective locations. From these grids, co-located and synoptic grid values of cloud water content and observed/derived satellite-based cloud properties were matched to derive empirical relationships for the former as a function of the latter. These relationships were tested on subsequent days of field experiment data to evaluate their effectiveness in estimating cloud water content from the satellite-based cloud properties. We plan to use the relationships as a module in a cloud water analysis procedure to convert satellite imagery data to cloud water estimates that, in correcting a mesoscale NWP model prediction of cloud water, can result in realistic initial cloud water conditions for a subsequent model prediction. Three-dimensional cloud data grids and empirical cloud water - cloud property relationships will be shown at the conference.

MI10/W/01-B2 1035

FRACTAL ANALYSIS OF AN UPPER TROPICAL TROPOSPHERIC CIRRUS SHIELD AND OF AN ARCTIC POLAR STRATOSPHERIC CLOUD

Adrian TUCK (NOAA Aeronomy Laboratory, 325 Broadway, Boulder CO 80303-3328, USA, email: tuck@al.noaa.gov); Susan Hovde (CIRES/NOAA Aeronomy Laboratory, 325 Broadway, Boulder CO 80303-3328, USA, email: hovde@al.noaa.gov)

The ER-2 high altitude research aircraft made over 200 flights in the lower stratosphere between 90N and 72S, with some penetrations into the upper tropical troposphere between 1987 and 1997. Here, we describe a fractal analysis using the Hurst exponent measure H to examine the cirrus shield associated with tropical cyclone Jason over the Gulf of Carpentaria 19870208. We show that all variables measured (CN, water vapor, total water, ice saturation mixing ratio, temperature, pressure, horizontal wind speed and direction, vertical wind speed, ozone and NOy) are fractal, with cases of random (H=0.5), persistent (H>0.5) and anti-persistent (H<0.5) self-affine behaviour. It is shown that total water shows a value of H indicating that it was subject to a process which was variable on small scales and which did not operate on the other measured variables; gravitational settlement is suggested as a viable candidate. In the case of a polar stratospheric cloud over Scandinavia on 19890124, the relative dispersion measure is used in conjunction with H to examine the behaviour of the above variables plus the particle number densities in the 0.50-0.55 and 0.55-0.60 micron size bins. We argue that at the edge of the cloud the measures show variabilities in certain of the observables which correlate with the particle number densities in the former range but not the latter, yielding insight into how the processes are related. In neither tropical or polar case would it have been possible to deduce the relationships among variables without using the measures.

MI04/W/14-B2 1120

CLOUD MODULATION OF ZENITH SKY OXYGEN PHOTON PATHLENGTHS OVER BOULDER COLORADO: MEASUREMENTS VS. MODEL

Robert PORTMANN, Susan Solomon, Ryan Sanders and John Daniel (NOAA Aeronomy Lab, 325 Broadway, Boulder, CO, USA, email: portmann@al.noaa.gov); Ellsworth Dutton (NOAA Climate Monitoring and Diagnostics Lab, 325 Broadway, Boulder, CO, USA)

Cloudy sky average photon path lengths were measured using the 628nm gamma band of oxygen on many days over Boulder, Colorado using a zenith looking spectrograph. These photon pathlengths show very large variations as the cloud field overhead evolves. They are compared with detailed line-by-line model calculations based on the HITRAN database and the DISORT radiative transfer code. Clouds are modeled as temporally varying in optical depth but uniform vertically and horizontally, with cloud top and bottom heights estimated from radar and ceilometer data. Reasonable agreement between the measured and modeled pathlengths is obtained when the cloud optical depth is retrieved from broadband flux measurements taken at a nearby location (approximately 2 km distant). Thus, the relationship between the cloud scattering induced reflection (which dominates changes in the broadband flux at the ground) and enhanced photon pathlengths is usually (surprisingly) well modeled by current plane parallel radiative transfer codes, at least when cloud cover is relatively uniform. The implication of these results to the "anomalous absorption" problem are discussed.

MI04/W/28-B2 1135

SURFACE RADIATION BUDGET AND CLOUD COVER DIURNAL PATTERN MODEL

Oleg POKROVSKY (Main Geophysical Observatory, Karbyshev str.7, St.Petersburg, 194021, Russia, e-mail: pokrov@main.mgo.rssi.ru)

Surface radiation budget (SRB) variables are not synoptically observed or input daily as a boundary condition into global models. SRB data sets could be used to identify systematic errors and to improve land surface and boundary layer parametrization for global models. This study is prompted by the need to investigate the climatology of surface variables diurnal cycles. The solar terms are the dominant terms during daytime and in summer. It is difficult to calculate the SRB to sufficient accuracy in global forecast and climate models. Many of models underestimate the absorption or reflection of solar radiation in atmosphere , either by clouds or aerosol, that are poorly modeled with the results that they overestimate the incoming solar radiation at surface. Proposed method bases on "fuzzy" logic approach, aiming the maximization of intercluster distances under the minimum of each cluster scattering measures. A basis for our researches were hourly observational data for several sites of North-West region of Russia for 1984-93. Diurnal cycle of total solar downward radiation in summer is the most significant due to amplitudes. The obtained results on average diurnal cycle in clusters suppose the simple interpretation. The upper curve corresponds to conditions of clear sky, and lower one to overcast cloud cover. Intermediate curves correspond to conditions of a fractional cloud cover, which can vary during a day. Results of empirical classification of a day time cycle of cloud cover, presented in climatological works , are closely linked with our conclusions. The complete set of classes changes from 3 in the winter up to 6 in the summer. To substantiate the interpretation of classification results parallel calculations of day time distribution of downward SW radiation for the latitude 60° and height of the Sun, adequate to the middle of an appropriate month of the year, were performed. The calculations were carried out on the base of the Delta-Eddington approximation technique for one-layer cloud model, with optical thickness equal to 30, the single scattering albedo was equal to 0.99 and asymmetry factor of the phase function g=0.85 . Bi-diurnal SRB patterns also are considered. Main result of this research is not only study of non-stationary diurnal and multidiurnal oscillations (modes), but also the definition of elementary neural network for modeling diurnal cycles and multidiurnal patterns of SRB.

TEMPORAL VARIABILITY OF CUMULUS CLOUD FIELD SPATIAL DISTRIBUTIONS OVER TEXAS

U. S. NAIR and R. M. Welch (Department of Atmospheric Sciences, University of Alabama in Huntsville, Global Hydrology and Climate Center, 977 Explorer Avenue, Huntsville, AL 35899 USA. E-mail: nair@atmos.uah.edu)

The spatial arrangement of clouds within cumulus cloud fields has been an area of considerable controversy. The majority of studies in this area have been conducted using SKYLAB, LANDSAT and AVHRR satellite imagery. GOES satellite imagery shows significant temporal variation in the spatial arrangement within cumulus cloud fields. For a four month period of time, cumulus cloud fields over Texas are identified using an automated cumulus cloud detection scheme. Then forindividual cloud fields, the morphological features and spatial arrangements within cumulus cloud fields are examined as a function of time and atmospheric properties. The spatial arrangements within cloud fields are analyzed using the nearest neighbor distance cumulative distribution function. The interaction between clouds within the cloud field are examined using the radial cloud number density function. The general pattern observed is that cloud fields tend to be clustered during the early stages of growth. As the cloud fields mature, their spatial distributions tend towards randomness, but with some tendencies towards regularity. During later stages of cloud field development the spatial distributions tend towards randomness and some clustering. The Colorado State University Regional Atmospheric Modeling System (CSU RAMS) is used to model the cloud fields for a few selected days. The modeled cloud fields are compared against the satellite observed cloud fields.

AUTOMATIC DETERMINATION OF DAYTIME AND NIGHTTIME CLOUD FRACTION

Dave SOWLE (Mission Research Corporation, P. O. Drawer 719, Santa Barbara, CA 93102, email: sowle@mrcsb.com); Tim Tooman (Sandia Corporation, Livermore CA, email: tooman@ca.sandia.gov); Sean Moore (Mission Research Corporation, P. O. Drawer 719, Santa Barbara, CA 93102, email: moore@mrcsb.com)

The Atmospheric Radiation Measurements Program of the U. S. Department of Energy developed a Whole Sky Imager. This instrument measures absolute atmospheric radiance with approximately 0.3-degree resolution between zenith and 2-degrees below the horizon. Copies of the instrument are deployed over a wide geographical area. An objective of the instrument is to provide automated cloud fraction measurements at ten-minute intervals, or more frequently, over the complete diurnal cycle continuously for periods up to decades. Our daytime algorithm compares measured radiance in blue, red, and near infrared bands to those calculated for a pristine clear sky. Comparing measured to calculated band radiance allows classification of each pixel as clear, aerosol burdened, or cloudy. Thus resolution is approximately 0.3-degrees. Results were calibrated against known sky conditions.
Our night-time algorithm has resolution of tens of degrees, rather than tenths of degrees. It compares, for a specific set of bright stars, the difference between stellar and nearby sky radiance to that measured on a night known to be clear. The portion of sky represented by a particular star is then classified as clear, thin clouds, or thick clouds.

MI10/W/08-B2 1220

VALIDATION OF CUMULUS CLOUD PARAMETERIZATIONS FOR LONGWAVE RADIATION CALCULATIONS

Robert G. ELLINGSON, Dejiang Han and Zhaohui Cheng (Department of Meteorology, University of Maryland, College Park, MD 20742, email: bobe@atmos.umd.edu)

Measurements at the Atmospheric Radiation Measurement (ARM) program site in Oklahoma, USA have been used to estimate many characteristics of small cumulus clouds, including the effective cloud cover, actual cloud cover, and aspect ratio. Different parameterizations of the longwave radiative effective cloud fraction have been tested by comparing observations with calculations from several different parameterizations using observed cloud variables as input.

The results show agreement to within about 10% between observed and estimated effective cloud fraction for absolute cloud fractions less than about 50%. Such errors result in longwave flux uncertainties of a few Watts per sq. m. Reductions of the errors below this level require refinements in the specification of the cloud spatial and size distributions.

RADIATIVE TRANSFER AND CLOUD FIELD MORPHOLOGY

MI10/E/06-B2 1400

PARAMETRISATION OF FLUX RADIATIVE TRANSFER THROUGH LOW CONVECTIVE CLOUD LAYERS.

Ofer Yaron and Joachim H. JOSEPH (Dept of Geophysics and Planetary Sciences, TAU, Tel- Aviv 69978, Israel, e- mail: yoya@jupiter1.tau.ac.il)

We present in this study a parameterisation of cloud optical depth in terms of the multifractal parameter C1. This parameterisation makes it possible to include the 2D characteristics of a Stratocumulus layer cloud into a 1D plane- parallel radiative transfer model. Our study was based on a 2D Monte Carlo simulation of the flux radiative transfer that used a 1D bounded cascade model to represent a fractal, inhomogeneous cloud layer. The simulations were carried out for a range of the C1 parameter determined from analysis of digital cloud field images and a range of typical optical depths. The resulting albedos as a function of average optical depth, C1 and solar zenith angle were linked with those obtained from a delta-Eddington approximation for a plane- parallel layer. This linkage made it possible to define- for use in the plane parallel case- effective optical depths that depend on C1, for any given average optical depth of the cloud layer.

ABSORPTION OF SOLAR RADIATION BY THE CLOUDY ATMOSPHERE: FURTHER INTERPRETATIONS OF COLLOCATED AIRCRAFT MEASUREMENTSROBERT

D. CESS and Minghua Zhang (both at Marine Sciences Research Center, State University of New York, Stony Brook, NY 11794-5000, email: cess@atmsci.msrc.sunysb.edu); Francisco P. J. Valero, Shelly K. Pope, Anthony Bucholtz and Brett Bush (all at Atmospheric Research Laboratory, University of California, San Diego, Scripps Institution of Oceanography, 0221, La Jolla, California 92093-0221, email: fvalero@ucsd.edu); Charles S. Zender (National Center for Atmospheric Research, P. O. Box 3000, Boulder, CO 80307, email: zender@ncar.ucar.edu); John Vitko, Jr. (Sandia National Laboratory, Org. 8102, P. O. Box 969, 7011 E. Avenue, Livermore, CA 94551-0969, email: john_vitko@sandia.gov)

We have extended the interpretations made in two prior studies of the aircraft shortwave radiation measurements that were obtained as part of the Atmospheric Radiation Measurements (ARM) Enhanced Shortwave Experiments (ARESE). These extended interpretations use the 500 nm (10 nm bandwidth) measurements to minimize sampling errors in the broadband measurements. It is indicated that the clouds present during this experiment absorb more shortwave radiation than predicted by clear skies and thus by theoretical models, that at least some (less than 20%) of this enhanced cloud absorption occurs at wavelengths less than 680 nm, and that the observed cloud absorption does not appear to be an artifact of sampling errors nor of instrument calibration errors.

MI10/W/16-B2 1435

A STUDY OF CLOUD GEOMETRY EFFECTS ON ATMOSPHERIC SOLAR ABSORPTION

Qiang FU, M.C. Cribb, (both at the Department of Oceanography, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada. Email: qfu@atm.dal.ca), and H.W. Barker (Atmospheric Environment Service, Downsview, ON, Canada)

A 3D broadband solar radiative transfer scheme is formulated by integrating a Monte Carlo photon transport algorithm with the Fu-Liou radiation model. It is applied to fields of tropical mesoscale convective clouds and subtropical marine boundary layer clouds; they were generated by a cloud resolving model. The effects of cloud geometry on the radiative energy budget are examined by comparing the full resolution Monte Carlo results with those from the independent column approximation (ICA) which applies the plane-parallel radiation model to each column. We also investigate the effects of cloud geometry on the absorption of solar radiation by black carbon aerosol and a water vapor continuum.

MI04/W/35-B2 1450

THE ABSORPTION OF SOLAR RADIATION BY THE ATMOSPHERE AS DETERMINED USING CONSISTENT SATELLITE, AIRCRAFT AND SURFACE DATA DURING THE ARM ENHANCED SHORT-WAVE EXPERIMENT (ARESE)

Francisco P. J. VALERO, Shelly K. Pope, Anthony Bucholtz Atmospheric Research Laboratory, Center for Atmospheric Sciences, Scripps Institution of Oceanography, University of California, San Diego, 9500 Gilman Dr, La Jolla, Ca 92093-0242 Patrick Minnis, NASA Langley Research Center, David R. Doelling, AS&M, Inc., Hampton, Virginia

Radiometric data sets acquired during the ARESE experiment using simultaneous measurements from five different, independent platforms (GOES 8 geostationary satellite, ER-2, Egrett and Twin Otter aircraft and surface) are analyzed for consistency. It is found that a very robust data set can be built on the basis of the observations from these multiple platforms. The aircraft data are further analyzed to determine atmospheric absorption of solar radiation applying the flux divergence method, and the GOES 8 and surface data are combined to determine the relationship between top of the atmosphere albedo and surface transmittance. The results of the aircraft data analysis and the GOES 8 versus surface analysis are in excellent agreement. It is found that there is strong evidence for excess absorption by the atmosphere in the presence of clouds, compared to model estimates, and that such excess absorption increases with cloud amount. These results are in agreement with recent findings that are the subject of some controversy, but here an exceptionally robust data set that brings together totally independent observations (satellite, surface and aircraft) is used.

MI10/E/07-B3 1505

SPATIAL-TEMPORARY VARIATIONS OF TOTAL CLOUDINESS OVER THE GEORGIAN TERRITORY

Avtandil Amiranashvili, VAZHA AMIRANASHVILI, Tengiz Gzirishvili (all at the Institute of Geophysics of Georgian Academy of Sciences, 1, M. Aleksidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com); Kukuri Tavartkiladze (Institute of Geography of Georgian Academy of Sciences, 12, M. Aleksidze Str., Tbilisi 380093, Georgia)

The results of investigations of total cloudiness (G) and its variations from 1936 to 1991 over the Georgian territory are presented. With this purpose data of 46 meteorological stations on mean monthly values of G were analysed.
Mean annual, cold and warm season, January and July distribution maps of total cloudiness values on the Georgian territory in the mentioned time period are presented. Mean monthly trends of G are studied from 1936 to 1991 and peculiarities of total cloudiness variations for various regions of Georgia are reveal ed. Maps of variations of G in the mentioned months and seasons are composed.
In Georgia in the cold season and on the average per year small negative trends of G are observed: decrese in 1991 in comparison to 1936 by 5% and 0.9% in Western Georgia and by 5% and 1.8% in Eastern Georgia correspondingly. In the warm season small positive trends are characteristic for the whole Georgian territory: increase by 2.8% in 1991 in Western Georgia and by 1.9% in Eastern Georgia.
For a number of stations and certain months variations of total cloudiness in the mentioned period are quite considerable and range from +67% (station Dmanisi, August) to -31% (station Jvari Pass, February).

MI10/E/14-B2 1520

UNBOUNDED CASCADE MODELS OF CLOUD FIELDS AND THE ANOMALOUS RADIATIVE ABSORPTION

D. SCHERTZER, M. Larchevêque (LMM, CNRS UMR 7607, Case 162, Université P.&M. Curie, Paris, France, 4 Pl. Jussieu, 75252 Paris Cedex 05, France); S. Lovejoy (Physics dept, McGill University, 3600 University St., Montréal, Québec, H3A 2T8, Canada); C. Naud (Space and Atmospheric Physics, Blackett Laboratory, Imperial College London SW7 2BZ)

We first clarify the reasons to consider unbounded cascade models of cloud fields, rather than bounded cascade models. Second, we show that this distinction is extremely important for radiative transfer studies, in particular to explore the question of the atmospheric anomalous absorption. The difference between the two types of models is related to the fundamental distinction between the fields (e.g., velocity , temperature, liquid water content) and the corresponding turbulent fluxes (e.g., energy flux, scalar variance flux). In the case of the bounded cascade models, one tries to use a rather standard model of flux, i.e., a multiplicative cascade process, for the concentration field itself. As it does not yield smooth enough statistics, one is compelled to introduce an ad-hoc bounding operation step-by-step. Not only is the physics soon lost , since fluxes are no more defined, but so is the logical coherence of cascades: the bounding breaks down the scaling of the cascade process! There is no need to proceed this way: the difference of scaling and smoothness between fields and fluxes is easily taken into account by a fractional integration, as done in multifractal Fractionaly Integrated Flux (FIF) models. Furthermore, keeping the direct contact with physics of turbulence is indispensable to understand and quantify the anomalous absorption in an apparently nearly perfect scattering case. Indeed, the case of perfect scattering corresponds to the rather naive 'external' solution of a singular perturbation problem. On the contrary, the 'internal' solution estimates the effect of the thin but primarily important 'boundary layers' where occur most of the increase of the 'effective' absorption which is quite larger than the 'bare' absorption coefficient . We present the internal solutions of the FIF models.

MI10/E/01-B2 1535

CLOUD TOP HEIGHTS AND WINDS FROM STEREO METHODS USING ATSR DATA

R M DUNDAS, J P Muller and C Vogt (Geomatic Engineering, University College London, Gower Street, London WC1E 6BT, UK, Email: rdundas@ge.ucl.ac.uk

Clouds considerably influence the radiation interaction between the surface and space. Satellite images offer the possibility of obtaining cloud top heights over a large area using techniques such as Stereo. Stereoscopic methods require two images of the same geographical area from two different view angles. The resulting parallax between the two images of an observed feature is then proportional to its height. These techniques will be applied to data from the dual view Along Track Scanning Radiometer, (ATSR) and evaluation will include a comparision with brightness temperature derived cloud top heights, a comparision of cloud free heights against a ground terrain model and ground based 94GHz radar measurements. Winds will also be derived.

MI10/W/17-B2 1620

CLOUD-FIELD VARIABILITY DURING CLARA: ACTIVE INSTRUMENT SIGNALS

DAVID P. DONOVAN, A.C.A.P. Van Lammeren, A. Feijt (Royal Netherlands Meteorological Institute (KNMI), Postbus 201, 3730 AE, De Bilt, The Netherlands, Email: donovan@knmi.nl)

The degree of cloud variability has obvious implications with regards to cloud remote sensing. By combining measurements made with different instruments in principle it is possible to extract much more information than is the case by using each instrument in isolation. However, in the real world, different instruments may have different footprints and sampling rates as well there may be some spatial and/or temporal separation between the measurements made by the different sensors. Hence, it is necessary to know to what extent two spatially and/or temporally separated soundings may be meaningfully compared. further complicate matters, the degree of signal variability in space and time depends not only on the physical variability of the cloud field itself but also on what exactly a given instrument is measuring.
During the CLARA (CLouds And RAdiation) campaigns carried out in 1996 in the Netherlands a large number of co- located lidar and radar cloud soundings were carried out. In addition, two nearly identical lidar systems were operated within 4 km of each other so the CLARA data can be used to explore cloud variability by comparing the spatially separated data as well using standard spectral analysis techniques on the single instrument lidar and radar data.
In this presentation, an overview of the temporal and spatial cloud signal variability encountered during CLARA is presented. In addition, the difference in the behavior between the lidar and radar signals will be explored with the aid of a simple analytic model linking the lidar and radar signals to fluctuations in the physical state of the clouds themselves.

MI10/W/20-B2 1635

INVESTIGATION OF THE TWO-DIMENSIONAL SECOND ORDER STRUCTURE FUNCTION OF SATELLITE-RETRIEVED OPTICAL DEPTH AND EFFECTIVE RADIUS

Gregory M. LEWIS (Institute of Applied Mathematics, University of British Columbia, Vancouver, BC, V6T 1Z4, Canada, Email: lewis@math.ubc.ca); Philip H. Austin (Atmospheric Science Programme, University of British Columbia, #217 Geography, Vancouver, BC, V6T 1Z2, Canada, Email: phil@geog.ubc.ca).

We investigate the scaling behaviour of satellite-retrieved optical depth and cloud top effective radius in marine stratocumulus clouds found over the eastern Pacific Ocean and the Southern Ocean near Tasmania. Using the algorithm of Nakajima and Nakajima, the optical depth and

effective radius are inferred from radiance measurements made by the AVHRR (Advanced Very High Resolution Radiometer) on board four NOAA polar orbiting satellites. The second order structure functions of twenty-five scenes are examined. Many of the isotropic structure functions indicate a possible scale break at a spatial scale of approximately 10km. However, when the two dimensional structure functions are calculated, it is found that many of the scenes are characterized by their anisotropy, indicating that in some cases the isotropic structure function may not be the appropriate scaling function. The structure function averaged over all scenes still exhibits anisotropy and the scale break is still seen (although it seems clearer that it is a transition between two different scaling regimes). The possibility that the scale break is a result of the anisotropy will be discussed. We will also contrast the scaling and anisotropy of the raw data versus the transformed data. We find that although the isotropic structure functions are similar there is a marked change in the anisotropy. This is expected since the anisotropy due to external variables, in particular the dependence of reflectivity on solar zenith angle, has been corrected for in the transformed data. We will also investigate the sensitivity of the scaling with domain size.

MI10/W/13-B2 1650

A GCM PARAMETERIZATION OF BIMODAL SIZE SPECTRA FOR ICE CLOUDS

D.L.Mitchell, (Desert Research Institute, Atmospheric Sciences Centre, P.O.Box 60220, Reno, Nevada, 89506 USA. E- mail: mitch@dri.edu)

As the global radiation budget is sensitive to the effective radius assumed for water clouds, so also it is sensitive to the effective diameter (De) assumed for ice clouds. While many GCMs assume an effective radius for ice clouds around 30 μm, De is known to vary due to changes in size distribution with temperature by over an order of magnitude.
Based on existing field measurements of size spectra from 10 frontal cloud studies, ARM, FIRE and SUCCESS cirrus case studies, 7 tropical cirrus clouds and 8 other mid-latitude cirrus flights, a scheme was formulated by which the small and large particle modes of the observed bimodal size distribution could be estimated as a function of temperature and ice water mixing ratio (or IWC), as provided by a GCM.
The size distribution slope of both modes was related to temperature, where size spectra were averaged over horizontal transects exceeding 5 km, which eliminated much variability. To calculate the bimodal spectra, the total IWC needed to be partitioned between both modes. The IWC for each mode was calculated from measured spectra, and the resultant partitioning was well described solely in terms of the slope (or mean length) of the large particle mode. Hence, by only knowing temperature and the total IWC, the complete bimodal size spectrum can be estimated, which agreed reasonably well with measured leg-averaged spectra having the same temperature and IWC.

MI10/E/10-B2 1705

THE MULTIFRACTAL CONTINUUM IN RAIN AND CLOUDS FROM 0.2MM TO 5000KM

S. LOVEJOY, N. Desaulniers-Soucy, J. D. Stanway, (all at Physics dept, McGill University, 3600 University St., Montréal, Québec, H3A 2T8, Canada) D. Schertzer (LMM, case 162, Universite P. et M. Curie, 4 pl. Jussieu, Paris F-75252 Cedex 05, France)

Using stereophotography of rain drops and large numbers of satellite and ground based cloud images, we empirically examine two key assumptions of classical meteorology and rain/cloud physics. We first investigate the standard homogeneity assumptions used for modelling drop growth, aggregation or the interpretation of radar reflectivities from rain or snow. This standard "continuum" hypothesis for the hyrdrometeors implies that particle size distributions can be well defined independently of the measurement volume/scale. On the contrary, over the accessible range (ª0.2mm to 2m) we find multiscaling statistics with an inner scale very close to the mean inter particle distance; the continuum is multifractal. The second key assumption we investigate is that at scales of roughly 10km (the vertical pressure scale) there is a "meso-scale gap" in the (horizontal) spectrum seperating the small scales (assumed to be isotropic homogeneous 3-D turbulence) and the large scales (assumed to be the corresponding 2-D turbulence). On the contrary, by analyzing nearly a thousand visible and infra red cloud images from geostationary (GMS), polar orbiting (NOAA 12, 14, SPOT) satellites as well as ground based images (roughly 100 times more data than that used on any comparable study) over the range 5000km to ª50cm we found (as predicted by the unified scaling model), a) that the scaling is well respected over the entire range (there is no "meso-scale gap"), b) We obtain the first direct evidence for multiplicative cascades and direct estimates of the outer scale (ªplanetary scale), c) the radiance fields are indeed very close to what is expected for universal multifractals. In the latter, the infinite hierarchy of exponents (e.g. dimensions/codimensions) is described by only three universal exponents which we estimate.

MI04/L/21-B2 1720

RADIATIVE TRANSFER THROUGH FAIR-WEATHER CUMULI

Paquita ZUIDEMA (Program in Atmospheric and Oceanic Sciences, University of Colorado-Boulder, Boulder, CO USA 80309-0311, email: zuidema@monsoon.colorado.edu) and Frank Evans

The two-dimensional radiative transfer behavior of ten fair-weather cumulus clouds observed by cloud radar in the equatorial Pacific is examined. A recently-introduced radiative transfer approximation, the tilted independent pixel (TIP; Varnai and Davies, 1998) is evaluated. TIPA is similar to the independent pixel approximation except that TIPA evaluates the optical depth columns as seen tilted towards the Sun rather than vertically-projected optical depth columns. Major results are:
• TIPA captures the two-dimensional domain-averaged albedo quite well at all Sun angles, performing much better than IPA.
• Most of TIPA's successful perfomrnace can be attributed to its use of the apparent cloud fractio as seen by the Sun.
• 2D-TIPA albedo differences under low Sun vary with optical depth and with cloud shape details related to the cloud aspect ratio. This differs from what is seen in Varnai and Davies (1998).
• Knowledge of the mean cloud optical depth and aspect ratio, when utilized within TIPA, is often enough information with which to successfully capture the true domain-averaged albedo.
The results are thought to apply to many tropical fair-weather cumuli although more work needs to be done to establish the representativeness of the cloud radar-derived cloud sample. This study extends Varnai and Davies' (1998) work by examining more realistic clouds with a different range of optical depths and aspect ratios than is present within the cloud fields utilized by Varnai and Davies' (1998).

MI10/W/18-B2 1735

ESTIMATION OF FRACTIONAL SKY COVER FROM BROADBAND SW RADIOMETER MEASUREMENTS

Charles N. LONG and Thomas P. Ackerman., (Penn State University Dept. of Meteorology. John J. DeLuisi, NOAA ARL Surface Radiation Research Branch. E-mail: long@essc.psu.edu)

One of the greatest uncertainties in global climate change research is the changes, if any, in cloud amount and the resultant effect on global radiative energy balance. Only satellites afford the global coverage needed to study cloud amount on a global scale. However, as with other satellite-derived variables, the accuracy of satellite cloud fraction retrievals must be verified with surface measurements. Previous comparisons have in large part depended on surface observer reports, which include temporal and spatial mis-matches and observer subjectivity that add uncertainty to the comparison.
Our previous work has provided a means to infer the effect of clouds on the downwelling SW irradiance at the surface. We have now additionally developed a technique to infer fractional sky cover from the same surface broadband global and diffuse SW measurements. While the absolute accuracy of these sky cover retrievals depends on the particular division of clear sky - cloudy sky boundary, comparisons with NOAA/ARL/Surface Radiation Research Branch (SRRB) Hemispheric Sky Imager data suggest the retrieved sky cover values are accurate to better than an RMS Standard Deviation of 0.1. The retrieval method does not appear to be system or location dependent. Comparisons of three independent surface radiation measurement systems collocated at the Atmospheric Radiation Measurement (ARM) Program site near Lamont, OK yield RMS standard deviations better than 0.04 for retrieved sky cover. Thus, this method affords a consistent, non-subjective estimation of fractional sky cover at high temporal resolution for use in verifying satellite derived cloud fractions, and provides both SW cloud effect and sky cover for climate change studies.
We present details of the method, as well as comparisons with sky cover measurements and collocated retrievals to illustrate accuracy and precision. Examples of retrieved SW cloud effect and sky cover will be included, along with analysis and comparison of multi-year time series using ARM Southern Great Plains and Tropical Western Pacific, and SRRB SURFRAD data.

EFFECT OF CIRRUS CLOUDS ON LONGWAVE OUTGOING RADIATION IN THE FAR INFRARED

C.NAUD, J. E. Russell and J. E Harries (both Space and Atmospheric Physics group, Imperial College, London SW7 2BZ, email: j.e.russell@ic.ac.uk, j.harries@ic.ac.uk)

We have performed simulations of the impact of cirrus clouds on radiances at the top of the atmosphere, and on atmospheric heating rates in the far infrared region from 100 to 1000 cm-1. Using a high resolution data base for the atmospheric gases optical properties, and a multiple scattering radiative transfer scheme, we look at the effect of changes in parameters such as the shape and size of ice crystals, and the height and ice water content of the clouds. We show that cirrus clouds have a strong effect on the reduction of the outgoing radiation in the far infrared, this part of the total infrared spectrum contributing to nearly 20% of the overall reduction. Calculation of the atmospheric heating rates shows that ice clouds cool the atmosphere at their top and heat the atmosphere below compared to clear sky conditions. This effect is enhanced for higher heights of clouds, and, by comparing different shapes of ice crystals, we show that spheroids (distorted spheres) have a bigger effect than spheres for a same cloud ice water content. The main consequence is that cirrus clouds warm the troposphere and cool the stratosphere in the far infrared, whereas they warm the local atmosphere in the window region.
We used these calculations to study the effect of changes in the global cirrus cloud amount on the local atmospheric heating rates and the relation to changes in upper troposphere and lower stratosphere temperatures, for a variety of shapes and size distributions of ice crystals. Using NCEP data for changes in temperature trends and ISCCP data for cirrus trends, we consider whether these changes are compatible with each other given our calculations of the radiative effect of any change in clouds.

PRECIPITATING CONVECTIVE CLOUD SYSTEMS

MI04/W/26-B3 0830

AN OVERVIEW OF PROFILER OBSERVATIONS OF TROPICAL PRECIPITATING CLOUD SYSTEMS

Kenneth S GAGE (NOAA Aeronomy Laboratory, Boulder, CO 80303; email: kgage@al.noaa.gov); Warner L. Ecklund and Christopher R. Williams (University of Colorado/CIRES, Boulder, CO 80309; 303-497-5322; e-mail: wecklund@al.noaa.gov; chris@al.noaa.gov)

During the past decade Doppler radar profilers that operate at 915 MHz were developed at the NOAA Aeronomy Laboratory and are now in widespread use primarily for wind measurement in the lower troposphere. The profilers are also very sensitive to hydrometeors and can be very useful tools for precipitation studies. During the TOGA COARE field campaign, these profilers were utilized for wind and precipitation measurements at four island sites and on two research ships. Following TOGA COARE the Aeronomy Laboratory developed an S-band (2835 MHz) profiler that is about 20 dB more sensitive to hydrometeors than the 915 MHz profiler.
This paper presents an overview of observations and analyses of the structure and evolution of precipitating cloud systems over the western Pacific region obtained during COARE and subsequent field campaigns including the Maritime Continent Thunderstorm Experiment (MCTEX) that took place near Darwin Australia in November - December 1995 and the Combined Sensor Program (CSP) that took place in the vicinity of Manus Island, Papua New Guinea in March 1996. The latter two campaigns utilized collocated 915 MHz and S-band profilers which have been intercompared to unambiguously separate backscattering from hydrometeors and atmospheric turbulence.
Profiler observations yield time height cross-sections of equivalent reflectivity, Doppler velocity and spectral width that illustrate the evolution of precipitating clouds systems. In the presence of precipitating clouds back-scattering from hydrometeors is dominant and the Doppler velocity provides a measure of the fall velocity of hydrometeors. The vertical structure of these parameters has been used to classify the precipitating cloud systems into several different categories. These observations document the prevalence of deep anvil cloud systems over the Pacific warm pool region. These optically thick clouds are present up to 25% of the time. While precipitation occurs at the surface less than about 10% of the time.

MI04/W/09-B3 0850

RAINFALL AND RADIATIVE HEATING RATE ESTIMATES FOR TOGA COARE

RICHARD H. JOHNSON and Paul E. Ciesielski (Department of Atmospheric Science, Colorado State University, Fort Collins, CO 80523, USA, email: rhj@vortex.atmos.colostate.edu)

Atmospheric heat and moisture budgets are used to determine rainfall and radiative heating rates over the western Pacific warm pool during TOGA COARE. Using the COARE bulk flux algorithm to estimate surface evaporation over the Intensive Flux Array (IFA), the IFA moisture budget-derived average rainfall for the 120-day Intensive Observing Period (IOP) is 8.2 mm/day. However, for a smaller area within the IFA comprising the rain-mapping domain of the

TOGA and MIT radars, the atmospheric budget for the 101-day radar deployment yields a much smaller value, 5.2 mm/day. This estimate agrees well with the independent radar rainrate estimate of 5.4 mm/day. Further analysis indicates that the TOGA and MIT radars were located within a relatively dry region of the IFA and their deployments were during relatively dry periods of the IOP.
Computation of the vertically integrated net radiative heating rate as a residual from the heat and moisture budgets yields an IFA-IOP average of -0.31 C/day. This net cooling rate is smaller than many previous estimates for the Tropics, but is within the range of independent COARE estimates based on radiation models and observations. This small value may arise from decreased longwave emission to space due to abundant cirrus over the warm pool and may also reflect some short-wave absorption by cirrus.

MI04/L/02-B3 0905

A COMPARISON OF COARE RADAR OBSERVATIONS WITH AN NCAR 2-D CLOUD RESOLVING MODEL

Scott J. CARPENTER,(Colorado State Uni, Fort Collins co80523, USA,
Email: Rhj@vortex.atmos.colostate.edu); Steven A. Rutledge, Xiaoqing Wu, and Mitchell W. Moncrieff

A two-dimensional cloud resolving modeling study was performed at NCAR for a 39-day period (5 December 1992 through 12 January 1993) during the Tropical Ocean Global Atmosphere (TOGA) Coupled Ocean-Atmosphere Response Experiment (COARE). The study was motivated by the need to study the complex coupling of processes over climatically key areas as well as the need to quantify the collective effects of cloud systems which will help to improve future parameterizations for general circulation models (GCMs). The work presented here was performed to test the consistency of the model output with the observed radar data from the MIT and TOGA Radars which were stationed on the R/V John V. Vickers and PRC ship Xiangyonghang No. 5, respectively.The model's convective response to the overall forcing was analyzed by comparing model simulations and radar observations of rainfall rate distribution, diurnal rainfall rate signals, and reflectivity characteristics. The forcing data originated from numerous other platforms in operation during COARE (radiosondes, buoys, etc.) and was added to the model at six hour intervals. The model output condensate mixing ratios were used to derive reflectivity values using reflectivity to liquid water content relationships (Z-M relationships), so that a direct comparison with radar reflectivities could be performed. The model derived rainfall rate data was compared to the rainfall rate files prepared from the combined TOGA and MIT radars using cumulative and percent frequency distributions. Initial results indicated that the model and radar results were in agreement for rainfall rates near 10 mm/hr. About 0.5% of the radar and model grid points had rainfall rates greater than 10 mm/hr. The model overestimated the areal coverage of smaller rainfall rates (between 10 mm/hr and 0.1 mm/hr) by between 0.5% and 1.5%, and underestimated areal coverage for rainfall rates greater than 10 mm/hr. The later fact is probably due to the model's inability to resolve the short lived, narrow, very intense convective cells which produced very heavy precipitation.
The TOGA-COARE radar data set has also shown that there exists a trimodal distribution of convective echoes, with peaks at heights typical of cumulus, cumulus congestus, and cumulonimbus. Analysis of whether or not this cloud-resolving model (CRM) can simulate the trimodal distribution of convective echoes is ongoing.

MI10/E/08-B3 0920

THE COMPARISON OF MICROWAVE BRIGHTNESS TEMPERATURES SIMULATED BY A 3-D CLOUD-RESOLVING MODEL WITH OBSERVATIONS

Philip R.A. BROWN and David C. Jones (Meteorological Office, London Road, Bracknell, RG12 2SZ, UK, email: prabrown@meto.gov.uk, dcjones@meto.gov.uk)

Recent intercomparisons of both 2- and 3-d cloud-resolving models (CRMs) on cases of tropical convection observed during the TOGA-COARE experiment have shown that they can produce widely-differing vertical profiles of hydrometeors, particularly in the widespread ice anvil region. It is in this part of the cloud system that most of the radiative heating is generated, hence the models indicate differing feedbacks between convection, cloud and radiation. It is of great importance to the use of such CRMs for cloud parametrization development to determine whether their simulated hydrometeor profiles are realistic.
Microwave brightness temperatures measured by aircraft and/or spaceborne instruments have been used to retrieve the total ice and liquid water paths, using both statistical and physically-based retrieval methods. The latter do, however, usually rely on some a priori knowledge or assumption of the relative vertical distribution of ice hydrometeor species. In the present study, we use the Eddington approximation for plane-parallel radiative transfer to calculate the upwelling microwave brightness temperatures over clouds simulated by a 3-d cloud-resolving model, which has a 1.25 km grid spacing in the horizontal. The simulated brightness temperatures are then averaged over the instaneous field of the view of the simulated observing instrument. The primary aim is to examine the sensitivity of modelled brightness temperatures to changes in the vertical hydrometeor profiles caused by changes to the model's microphysics parametrization scheme. We then examine whether the available aircraft and spaceborne microwave observations of the case are able to distinguish between the model simulations and give guidance as to which is generating the most realistic ice and water cloud distributions. We also consider the uncertainties introduced by the representation of the strongly structured hydrometeor fields by a plane-parallel radiative transfer model.

MI04/E/28-B3 0935

UNDERSTANDING HECTOR: THE DYNAMICS OF ISLAND THUNDERSTORMS

Andrew CROOK (National Center for Atmospheric Research P.O. Box 3000, Boulder, CO, USA, 80307-3000, email: crook@ucar.edu)

Hector is the name given to a thunderstorm complex that develops over the Tiwi Islands just north of mainland Australia during the wet season. The regular occurrence of the storms over isolated, basically flat, terrain make the islands an excellent testing ground for observational and modeling studies. The thunderstorm complex is particularly suitable for studies which include convection initiation, microphysical development, electrification, radiation, and convectively-generated gravity waves.
In this study we will examine the convective response to changes in the large-scale thermal forcing provided by the islands. A model of the large-scale forcing is first developed by solving the linear equations for flow past an isolated heat source. The model predicts that the maximum convergence occurs along a narrow band in the downwind half of the heat source. The dependence of the convergence strength on a number of features such as flow speed and direction is then examined.
The predictions of the linear model are then tested in a nonlinear, cloud-resolving, model. The nonlinear model simulates a number of features such as sea-breezes, gust fronts and moist convection that are not captured by the linear model. Nevertheless, the dependence of convective strength on the large-scale flow predicted by the linear model is borne out by the nonlinear simulations. However, one major difference is that the storms generally do not form along a band in the downwind half of the island but rather at a point where that band intersects a cold pool formed by the moist convection. We end with a discussion on the controversial question of whether or not the sea breezes from opposite coastlines collide.

MI04/L/16-B3 0950

MECHANISMS RESPONSIBLE FOR THE DEVELOPMENT AND MAINTENANCE OF LONG-LIVED SQUALL LINES

TAKEMI

The mechanisms responsible for the development and maintenance of long-lived squall lines in dry environments are investigated through two-dimensional numerical experiments by using a nonhydrostatic cloud model. The squall-line environments are characterized by a low convective available potential energy (CAPE), low moisture content, and a high level of free convection (LFC), which are based on observations of a squall line over an arid region in China. Although these environments seem to be unfavorable for the development of convective systems, a long-lived squall line is simulated in the environment of a well-mixed moisture profile within a deep, mixed boundary layer. During the mature stage of this simulated squall line, the air parcels originating in the upper part of the mixed layer ahead of a surface cold-air pool are lifted to the upper troposphere. On the other hand, the air parcels originating in the lower part of the mixed layer are forced to go rearward, never reaching the upper levels. The low pressure just above the surface cold pool plays an important role in determining these parcel trajectories. The sensitivity experiments in which the mixed-layer height and vertical profile of moisture within the mixed layer are varied illuminate the mechanisms for the development and maintenance of the simulated squall lines in the dry environments. First, the presence of a deep mixed layer is indispensable for the squall-line development. Second, a moisture profile that is nearly constant with height is favorable for the long-lived squall lines, although the CAPE value for the surface air parcel is small (250 J/kg). In this moisture condition, air parcels in the upper part of the mixed layer have moderate CAPE values of 50-150 J/kg, and the differences between the source levels of these parcels and their LFCs are very small. These parcels are easily lifted to their LFCs without experiencing substantial inhibition of convection, thus releasing their CAPE. The vertical distribution of CAPE values in the mixed layer is very important for the squall-line maintenance in dry environments. Another sensitivity experiment in which the mid-to-upper level vertical shear of horizontal winds is varied shows that upper-level shear plays an important role in characterizing the structure and longevity of squall lines. The upper level shear is necessary for the development of vigorous squall lines.

MI04/W/23-B3 1035

A NONHYDROSTATIC NUMERICAL MODELING STUDY OF MESOSCALE CONVECTIVE SYSTEMS ALONG THE BAIU FRONT OVER KYUSHU, JAPAN ON 17 JULY 1988

Zhe-Min TAN (1) Kozo Nakamra (2) Tokao Takeda (Frontier Research System for Global Change, Institute for Global Change Research), (2) Ocean Research Institute Tokyo University) & (Institute of Hydrosperic-Atmospheric Sciences Nogoya University)

Numerical simulations and the analysis of observational data are employed to understand the structure and development of meso-scale convective systems along the Baiu front over Kyushu, Japan on 16 July 1988. The National Center for Atmospheric Research (NCAR) / The Pennsylvania State University (PSU) Mesoscale Model Version 5 (MM5) was used to simulate 24h on a 30-km domain with 10-km and 3.33-km nests. The model includes microphysics with cloud, rains, snow/graupel; ice processes on all domians' resolved scales. The Grell cumulus parameterization scheme is adopted only on the 10-km and coarser domains.
In the relatively coarse horizontal resolution (e.g. 10-km), the numerical simulation has captured the major features of observed convective systems development very well. The sensitivity experiments are done to isolate the effects of topography, latent heat release and sea surface temperature. The results showed that the latent heat release plays the key role for the development of convective system along the Baiu front. Using of the cloud-resolving 3.33-km resolution model investigated the organization and maintenance of rainband in this event. The results showed that structure and evolution of rainband are closely related to the large-scale forcing and different choices of subgrid-scale convective parameterization for a coarse domain.

MI04/W/03-B3 1050

THE MODEL SIMULATION OF AN ISOLATED CUMULONIMBUS CLOUD WHICH MOVES ALONG A VALLEY

Mladjen CURIC, Dejan Janc and Vladan Vuckovic (Institute of Meteorology, University of Belgrade, Yugoslavia)

In the summer season the isolated severe hail clouds are often formed on the western portion of the Western Morava valley named Zlatibor plateau which mean height is approximately 1 km (Western Serbia). They move roughly from WNW to ESE direction. The environmental wind of the mean troposphere is nearly parallel with valley direction, while the low-level air motion is in the opposite direction to the cloud motion. The basic purpose of this study is to simulate the development of such hail cloud which occured in the Western Morava valley by help of the ARPS three-dimensional mesoscale model with improved hail microphysics and local orography. The model simulation shows that a cloud came down from a plateau to the valley. A strong downdraft of the cold air occurs since the land slopes down to a valley. The warm air motion toward the mountainside is amplified due to the forced lifting of a warm air above the cold air and the local low pressure. Further, the strong updraft in the front side of the cloud occurs and after that the hail appears on the ground. The cold air spreads out in a valley direction. The model simulation clearly shows the gust front formation in front of the main cloud, whose height oscillates with time. This is fairly illustrated by the patterns of the reflectivity factor in x-y plane whose maxima values are concentrated in the valley area. As a consequence of such cloud processes, the hail produced on the ground has the hailstreaks form separated about 10 km.

MI04/W/06-B3 1105

THE DEPENDENCE ON GRID RESOLUTION OF NUMERICALLY SIMULATED CONVECTIVE CLOUD SYSTEMS USING ICE MICROPHYSICS

Scott A. BRAUN, Wei-Kuo Tao, Stephen E. Lang, and Bradley S. Ferrier (NASA/GSFC, Code 912, Greenbelt, MD 20771, USA)

As model resolution increases from scales >10 km to scales on the order of a few kilometers, the representation of cloud processes shifts from cumulus parameterizations to grid-resolvable bulk microphyics. It is not uncommon these days to see mesoscale models run with fine grids of about 4-10 km for storms such as fronts, squall lines, and hurricanes. Bulk cloud microphysical parameterizations that include detailed ice microphysics (e.g., common 3-ice class schemes) were designed for models using high-resolution (<1 km) grids. An important question that remains to be addressed is to what extent models with grid sizes > 1 km can represent cloud structures obtained with higher resolution grids using common ice

microphysical parameterizations? In this study, we compare simulations from 2-D models of convective cloud systems using 1-, 2-, and 4-km grids and show how the cloud and circulation structures change as resolution is decreased. Implications for mesoscale modeling will be discussed.

MI04/E/13-B3 1120

DYNAMICS OF THUNDERSTORMS EMBEDDED WITHIN THE SHEAR FLOW

R.B.ZARIPOV. (Department of Meteorology and Climate, Geographic Faculty, Moscow State University, Vorobjovi Gori, 119899 Moscow, RUSSIA, email: pressman@rhmc.mecom.ru)

The impact of horizontally homogeneous large-scale flow on the dynamics of thunderstorm is studied numerically with the use of three-dimensional Cb cloud based on the anelastic equations. The cloud and precipitation microphysics in the liquid and ice phases is parametrized. The interaction of several thunderstorms is achieved by posing the periodic boundary conditions at the side walls. The series of numerical experiments with different wind hodographs: plane-parallel and veering flows have been performed. The influence of different velocity profiles on the internal cloud dynamics is studied in terms of kinetic energy, vorticity, helicity and the other flow characteristics. The analysis of production (and sink) of vorticity and helicity is presented. The results of this study agree qualitatively with those obtained in the previous works for the cases of isolated thunderstorms. The mayor difference is that in the case of interacting clouds the effects of basic flow helicity are less pronounced than in the case of isolated storm, particularly in terms of storm longevity.

MI04/W/22-B3 1135

WHAT CAN WE LEARN ABOUT CLOUD PROCESSES FROM A SIMPLE MODEL?

Olaf STILLER (Uni of Reading, Dept of Meteorology, Earley Gate, RG6 6BB, UK, Email: o.stiller@reading.ac.uk); and George C. Craig

The parametrisation of cloud processes is a delicate task due to the lack of understanding of the basic dynamics comprising mixing processes and momentum transport. Experimental data are limited and not always conclusive and also numerical investigations are difficult due to the systems complexity and often obscurred by the large number of parameters involved in a realistic representation of moist processes. Using the large eddy model of the British Meteorogical office to investigate the dynamics of single clouds (updrafts) we have extracted a largely idealised version of the model which possesses basic features of the full model but has fewer parameters and thus permits a more systematic analysis facilitating conclusions concerning cause and effect of the observed phenomena. The idealised model has a drastically simplified microphysics which still includes condensation and re-evaporation of cloud water but the parametrisation of rain is reduced to the fact that the content of cloud water has an upper limit above which the water is irreversibly taken out of the system. The saturation value of water vapour is taken to depend only on height and to decrease linearly with height. As a consequence a sounding with a constant dry lapse rate also possesses a constant moist lapse rate. To investigate mixing processes we are considering situations where the height reached by the updraft is entirely determined by mixing processes. This means we consider a sounding which is neutral with respect to moist convection. In particular we find that a dryer atmosphere enhances mixing and decreases the the height reached by the updraft. This can be explained by the increased release of negative buoyancy from re-evaporation processes which enhances the vortices responsible for the mixing. Similarities and differences of the model dynamics and those from simulations with the full large eddy model are discussed.

MI04/C/MI06/W/10-B3 1150

RELATIONSHIPS BETWEEN THE MICROSTRUCTURE OF CONVECTIVE CLOUDS AND THEIR RAINFALL PRODUCTION

Daniel ROSENFELD (Atmospheric Sciences, The Hebrew University, Jerusalem, Israel. email: daniel@vms.huji.ac.il); William L. Woodley, Woodley (Weather Consultants, Littleton, Colorado Bernard A. Silverman, Meteorological Consultant, Englewood, CO, USA)

Radar tracking and aircraft measurements of nearly 400 convective clouds during 5 years over northwestern Thailand provided for each cloud the following information: (1) the extent of warm rain processes, indexed into three categories; (2) the integrated rainfall in time and space; (3) maximum echo top height. Analysis of the rain production as a function of precipitation echo top height and warm rain index revealed that:1.Clouds with tops smaller than 10 km precipitate more than 10 times as much rainfall with active coalescence as compared to clouds with little coalescence. 2. Clouds with tops taller than 10 km (i.e., deep Cb) precipitate 3.5 times as much as clouds with little coalescence. All the results are statistically highly significant. Some of the ramifications of these findings are: Mainly anthropogenic aerosols, such as biomass burning smoke and air pollution cause the lack of coalescence, in the study area as elsewhere, as has been shown by Rosenfeld and Lensky (BAMS, 11/1988). That means a very large impact detrimental impact of these aerosols on rainfall. That has major climatic, economical and sociological implications, which must be brought to the front of the attention of the climate change community.

MI04/W/02-B3 1205

A LAGRANGIAN MODEL FOR THE BAROCLINIC GENESIS OF MESOSCALE VORTICES

Robert Davies JONES (National Severe Storms Lab., NOAA, Norman, OK 73069 USA, email: bobdj@nssl.noaa.gov)

Baroclinically generated mesoscale vortices play vital roles in the genesis of near-ground mesocyclones, jets of strong surface winds and tornadoes in supercell and bow-echo storms. An analytical Lagrangian model is based on the decomposition in inviscid isentropic flows of vorticity into barotropic and baroclinic components. The model is tested by showing that it correctly predicts the formation of baroclinic lee vortices in stratified flow over hills. It is then used to show that air on the left (right) side of a cool downdraft in an unstably stratified environment acquires cyclonic (anticyclonic) baroclinic vorticity during descent. The cyclonic spin is greatly amplified if the air on the left side passes out of the downdraft along the ground into an updraft. This scenario explains many observed features of severe storms, and leads to the conclusion is that the rain curtains associated with hook-shaped appendages to radar echoes are the insigators (not just passive indicators) of tornadoes.

MI04/P/01-B3 1220

LIDAR SOUNDING OF LOW AND MIDDLE LEVEL CLOUD PROPERTIES OVER A TROPICAL STATION

P.C.S. DEVARA, P.E. Raj, R.S. Maheskumar, K.K. Dani and Y. Jaya Rao (Indian Institute of Tropical Meteorology, Pune 411 008, India, email: devara@tropmet.emet.in)

Clouds in the lower part of the atmosphere play vital role in pollution transfer and boundary layer and radiative processes, Unlike the clear air, cloud medium generates strong lidar return signals which can be used for the purpose of cloud parameterisation involving ceiling and base heights, and the location of discontinuities (layer clouds). The fine-scale variations in scattered signal strength in the sub-cloud air, layer and polarisation characteristics provide more insight into the structure and composition of clouds. These measurements at multiple laser probing wavelengths offer more reliable means to study cloud evolution and microphysics. Shallow clouds generally allow penetration of low power laser beams and hence both cloud base and top height measurements ate possible. In the case of high dense clouds, the corresponding parameters can be determined in the lower part of the cloud without regard for the influence of multiple scattering effects.
The bistatic, continuous wave, Argon-ion lidar system at the Indian Institute of Tropical Meteorology (IITM), Pune (18°32'N, 73°51'E), India has been used to study the base heights (above ground level) of clouds over the station during 1986-1993. Subsequently, this lidar was equipped with an optical polariser to enlarge the scope of cloud studies. In this paper, cloud base and top heights, multi-layer cloud structures, interface between cloud condensation nuclei in the sub-cloud- layer and in the vicinity of cloud base and depolarisation characteristics studied from the data archived during 1997-1998 together with the cloud lidar database built with the observations collected during the past 12-year period from October 1986 through September 1998 are presented.

PBL, SHALLOW CONVECTION AND NONPRECIPITATING LAYER CLOUDS

MI04/L/06-B3 1400

GENERATION OF MESOSCALE FLUCTUATIONS IN CONVECTIVE ATMOSPHERIC BOUNDARY LAYERS

Peter G. DUYNKERKE and Harm J.J. Jonker (Princetonplein 5,3584 CC Utrecht,The Netherlands Tel: 31 30 2532909, Fax: 31 30 2543163 Email: P.G.Duynkerke@phys.uu.nl)

The goal of this study is to obtain a better understanding of the generation of mesoscale fluctuations in different types of convective (buoyancy driven) atmospheric boundary layers. To this end we will use Large Eddy Simulations (LES) with a domain size large enough to accommodate mesoscale fluctuations, but with a resolution fine enough to resolve the three-dimensional turbulence structure. Moreover we will use observations of GATE and ASTEX to illustrate our findings.
The research on the generation of mesoscale fluctuations has until now mainly focused on investigating the effect of diabatic heat sources, associated with clouds, such as radiative cooling at cloud top and latent heat release. Recently (Jonker et al, 1999; http://www.phys.uu.nl/~hjonker) we have shown that in a clear convective boundary layer (without diabatic heat sources) passive scalars can possess significant mesoscale fluctuations, while at the same time the dynamics (velocity and temperature fields) do not show fluctuations on the mesoscale.
First we will investigate why passive scalars in the dry convective boundary layer (CBL) become dominated by mesoscale fluctuations, while the dynamics does not. Since the dry CBL can be regarded as the most elementary but still relevant boundary layer, we will endeavour to fundamentally understand the mechanism of mesoscale generation in this case. Next, we will step by step increase the complexity of the boundary layers, by including radiative cooling, and latent heat effects and studying their separate effect on mesoscale generation. Finally, we will consider the cloudy boundary layer, where all these processes simultaneously play a role.
The methodology will consist of spectrally decomposing the variances of the turbulence variables in the LES model into a microscale and mesoscale contribution, and determining the budget terms (sources and sinks) of the separate evolution equations in the numerical model.

MI04/E/12-B3 1420

IMPROVED STRATOCUMULUS SIMULATION IN A CLIMATE MODEL

Andrew C BUSHELL (Hadley Centre, London Road, Bracknell, Berks., RG12 2SY, UK.)

Cloud simulations in Atmospheric General Circulation Models (AGCMs) result from a combination of the chosen physical parametrization for cloud with the dynamical structure of the local environments in which the cloud parametrization activates. In particular, stratocumulus is highly sensitive to the state of the atmospheric boundary layer, and the main regions of persistent stratocumulus, off the coasts of Namibia, Peru and California, are generally recognized by AGCM modellers as problem areas.
Current developments to the Meteorological Office Unified Model (UM) include the introduction of a new dynamical core, which has been tested in a research AGCM with a state-of-the-art package of physical parametrizations, including a new boundary layer scheme. This offers a rare opportunity to examine the behaviour of the main stratocumulus regions in an alternative dynamical realization for which the model physics is kept as far as possible constant. It will be shown that this leads to a much improved representation of stratocumulus.

MI10/W/07-B3 1435

ON THE ESTIMATION OF ENTRAINMENT IN SHALLOW AND DEEP CONVECTION D.

GREGORY (ECMWF, Shinfield Park, Reading RG2 9AX,United Kingdom Email: dgregory@ecmwf.int); H.J.Jonker and A.P.Siebesma (KNMI, De Bilt, AE 3730, The Netherlands Email: jonker@knmi.nl and siebesma@knmi.nl)

A key parameter in the mass flux approach to convective parametrization is the lateral entrainment rate, which determines the rate of mixing of an ascending parcel with environmental air. Although mass flux schemes are now in wide use this parameter remains poorly defined, although recent LES and CRM studies have provide insight into both its magnitude and vertical variation in several cases of deep and shallow convection. Considering the vertical velocity equation of an up draught a formulation for entrainment is suggested, emphasising the effect of entrainment upon the vertical kinetic energy budget of an ascending parcel rather than on the mixing of thermodynamics quantities. The success of the approach depends upon estimating the vertical velocity within the cloud up draught. An approximate form of the vertical velocity equation for use in simple cloud models is suggested, including a parametrization of the vertical pressure gradient in terms of shear and net inflow and outflow. Comparison is made to the vertical kinetic energy budget derived from LEs and CRM simulations.
The formulation gives reasonable estimates of entrainment rates for both shallow and deep convection compared to LES and CRM simulations. The entrainment rate is sensitive to the environmental profile and may allow convective parametrization schemes to be more sensitive to situations (such as a dry middle troposphere) where deep convection is inhibited.

MI04/W/31-B3 1450

A NEW PARAMETERIZATION OF THE PBL

Bjorn STEVENS (Max Planck-Institut fur Meteorologie & University of California, Los Angeles, Email: stevens@dkrz.de)

We present a new parameterization of the planetary boundary layer. Although still general, the parameterization has been developed tobetter address the physics of subtropical stratocumulus clouds. Thus it contains an explicit representation of boundary layer depth and entrainment, and is formulated to perform adequately on coarse (order 250 - 500m) vertical grids.
The main conceptual distinction of this model is its explicit specification of a bulk entrainment rate, following the work of the European Center (Beljaars and colleagues) and the GEWEX cloud systems studies (GCSS) working group one, and the use of profile reconstruction. Profile reconstruction allows for air in an intermediate layer (diagnosed to contain the top of the PBL) to be partitioned into PBL air and free-tropospheric air, on the basis of the properties of adjacent layers. In the limit of smooth profiles above the inversion, and strong forcing, the method allows one to diagnostically track the depth of the boundary layer as it moves through a coarse grid, and thus maintain very high accuracy at very coarse resolution. Key additional features that provide resolution independence are the formal coupling of the PBL model to the large-scale advection and radiative forcing in a way that is consistent with the profile reconstruction. That is we show that spurious grid-scale-dependent effects are only eliminated if radiative and advective tendencies are applied in a manner consistent with the dynamic and numerical assumptions of the PBL model.
Single column results will be shown comparing the performance of the model with both large-eddy simulation, and measurements of stratocumulus taken during the DYCOMS experiment. Preliminary results, with the model implemented in the ECHAM GCM will also be presented.

MI04/E/18-B3 1505

A NON-LOCAL PARAMETRIZATION OF BOUNDARY LAYER MIXING WITH EXPLICIT ENTRAINMENT AND ITS IMPACT ON CLOUD SIMULATIONS IN THE UKMO UNIFIED MODEL

A.P.LOCK, A.R.Brown, M.Bush, A.L.M.Grant, G.M.Martin, R.N.B.Smith, (UK Meteorological Office, London Road, Bracknell, RG12 2SZ, UK; email: aplock@meto.gov.uk)

Accurate representation of boundary layer clouds is essential in all forecast models, from short term mesoscale forecasts to global climate simulations. A realistic representation of boundary layer mixing is crucial to the simulation of such clouds. In the Unified Model's current boundary layer scheme, the local Richardson number profile determines the calculated mixing coefficients within the boundary layer. Studies have shown that turbulent fluxes between the boundary layer and the freeatmosphere cannot be represented accurately by such a scheme. A new boundary layer mixing scheme, which includes non-local turbulent mixing, an explicit parametrisation of cloud-top entrainment, and diagnosis and treatment of decoupled boundary layers, has been tested in different configurations of the Unified Model. One of the main benefits is in allowing a specific diagnosis and treatment of different cloudy boundary layer types, extending the basic stable/unstable separation to recognising well-mixed, decoupled and cumulus-capped boundary layers. Results from the mesoscale model show better discrimination between layer cloud and convective cloud in the boundary layer in unstable conditions. In the climate model (where this scheme is introduced along with increased vertical resolution below 600 hPa), the tendency for the boundary layer to be excessively shallow in the sub-tropical stratocumulus regions is reduced, although cloud amounts remain underestimated. The treatment of decoupling allows the transition between stratocumulus and trade cumulus to be represented realistically.

ATMOSPHERIC BOUNDARY LAYER DEPTH EVALUATION USING A GCM AND AVHRR CLOUD DATA

A.MATHIEU (Centre d'Etude des Environnements Terrestre et Planetaire (CETP), 10-12 av. de l'Europe 78140 Velizy, France, Email: nne.mathieu@cetp.ipsl.fr); G.Seze (Laboratoire de Meteorologie Dynamique LMD), Paris); A.Weill (CETP); H.Giordanni (Meteo-France CNRM/GMGEC, Toulouse); H.Dupuis (Departement de Geologie et d'Oceanographie, Bordeaux)

We propose a method to compare Marine Atmospheric Boundary Layer height as determined from a GCM and corresponding information as retrieved from AVHRR satellite cloud analysis over oceanic mid-latitudes. We use the Holtslag et al. (J. of Climate, 92) algorithm and the French Met GCM : RPEGE.
First, a cloud classification of AVHRR images is used to discriminate low level Strato-Cumuli, from which are derived cloud top temperature fields. Secondly, from the GCM output, we determine the MABL altitude. The temperature correspondence between the two fields is worked out to evaluate the ability of the GCM to give realistic characteristics of the MABL. The method is applied to the SEMAPHORE experiment, hold in sept-Nov 1993 over the Azores basin (North. MidAtlantic) using ARPEGE re-analysed with the SEMAPHORE observations. The advantage to use a combined information of GCM with relatively good surface information but poor determination of the cloud layer and remote sensing with relatively accurate data is demonstrated.

HEAT AND MOISTURE BUDGETS IN STRATOCUMULUS AND TRADE CUMULUS REGIMES: SYNOPTIC AND DIURNAL VARIABILITY

Paul E. CIESIELSKI, Wayne H. Schubert, and Richard H. Johnson, (Department of Atmospheric Science, Colorado State University, Fort Collins, Colorado 80523, USA, email: paulc@tornado.atmos.colostate.edu)

Rawinsonde data collected from the Atlantic Stratocumulus Transition Experiment (ASTEX) are used to investigate the mean and temporal characteristics of large-scale heat and moisture budgets for a two-week period in June 1992. During this period a large apparent heat sink and apparent moisture source are observed near inversion base (around 1500 m) which resulted from evaporation of cloud droplets which detrained near this level. Analyses from other budget studies such as BOMEX (Barbados Oceanographic and Meteorological Experiment) show that similar convective signatures (i.e., low-level apparent moistening and cooling) occur in a wide variety of regimes when trade-wind type inversions are present. The vertical eddy flux of moist static energy over the ASTEX domain (centered at 33N with an average sea-surface temperature of 19.4 C) is about half that observed in the undisturbed trade-wind regime of BOMEX (centered at 15N with an average sea-surface temperature of 28.1 C). The apparent heat source, apparent moisture sink and convective flux of moist static energy over ASTEX are strongly modulated on a synoptic time scale by the passage of fronts and by fluctuations in the subsidence rate associated with changes in the strength and position of the subtropical high. The influence of mid-latitude distinguishes this region from trade-wind and tropical regimes. We will also examine the diurnal variability of large-scale motion fields over ASTEX and compare these results to other regions in order to deepen our understanding of why regional phase and amplitude differences exist in the diurnal cycle.

MI10/W/11-B3 1615

IMPROVEMENTS IN THE REPRESENTATION OF STRATOCUMULUS IN THE ECMWF MODEL

Joao TEIXEIRA, Anton Beljaars, Christian Jakob and Pier Siebesma (ECMWF, Shinfield Park, Reading, RG2 9AX, UK, email: teixeira@ecmwf.int)

It has been recognized for many years that clouds play a fundamental role in the climate system. Stratocumulus, in particular, have a strong influence on the global climate due to its impact on the Earth's radiation budget. This implies that the ability to represent stratocumulus in global models in a realistic way is a crucial scientific issue in climate modelling. Comparisons of the ECMWF Re-Analysis stratocumulus with observations have shown that the model largely underestimates the observed stratocumulus clouds. This problem can have serious negative consequences in the ocean surface fluxes produced by the model. Other diagnostic studies based on the NWP model or the single-column version of the ECMWF model also point on the same direction. An improved boundary layer vertical resolution configuration has been tested at ECMWF. The first studies were performed using the single-column model, and they have shown that the stratocumulus clouds and the transition to cumulus clouds is better captured with the increased resolution. In long integrations, the new configuration improves the cloud cover, liquid water path, surface shortwave radiation and the net surface flux over the stratocumulus areas. A major impact of the improved resolution is also seen in the thermodynamic structure of the boundary layer profiles: the new resolution has sharper inversions and the inversion heights are closer to the observations. One of the missing processes in the ECMWF model is the vertical turbulent mixing of cloud variables, that is only partially done by cloud top entrainment. A parametrization for the turbulent mixing of cloud variables is shown to have a positive impact on the simulation of stratocumulus. Improvements in the representation of stratocumulus due to the introduction of a revised parametrization for the evaporation of precipitation are also discussed.

MI04/W/12-B3 1630

SIMULATION OF THE CLOUD-TOPPED BOUNDARY LAYER WITH A SINGLE-COLUMN MODEL

Jean-Christophe GOLAZ (Department of Atmospheric Science, Colorado State University, Fort Collins, CO 80523, USA, email: golaz@tofu.atmos.colostate.edu); William R. Cotton (Department of Atmospheric Science, Colorado State University, Fort Collins, CO 80523, USA, email: cotton@isis.atmos.colostate.edu)

Accurate representation of boundary layer clouds in large-scale models remains a formidable task. Single-column models, which can be viewed as isolated columns from a large-scale model, offer the ability to develop parameterizations without the complexity of the full model. A single-column model for simulating the cloudy boundary layer is presented. The model offers different turbulence parameterizations including several low order closure schemes as well as a plume decomposition. A microphysical scheme is also included, making it possible to simulate liquid and mixed-phase precipitation processes and their influence on the cloudy boundary layer.
The model has been applied to different marine boundary layer regimes such as stratocumulus, cumulus and cumulus under stratus. Sensitivity to sea surface temperature and drizzle is explored. It is, for instance, shown that for a stratocumulus-topped boundary layer, evaporation of drizzle can produce a two-layer structure by stabilizing the subcloud layer with respect to the cloud layer. This stabilization does not necessarily lead to a decoupling of the boundary layer.

CLOUD, AEROSOL AND BOUNDARY LAYER EVOLUTION MEASURED DURING THE ACE-2 LAGRANGIAN EXPERIMENTS

D.W.JOHNSON, S.Osborne and R.Wood (Meteorological Office, Meteorological Research Flight, Building Y46, DERA, Farnborough, Hants GU14 6TD, UK.)

On three occasions during June and July 1997 as part of the Aerosol Characterisation Experiment (ACE-2), "smart" balloons and PFC tracers were released into the boundary layer off the Portuguese coast. On each occasion the balloons were tracked for up to two days using instrumented aircraft as they were advected south westwards in the trade winds towards the Canary Islands. Results will be presented of the analysis of the measurements made on the UK Meteorological Research Flight C-130 aircraft which describe how the cloud conditions, aerosol characteristics and boundary layer thermodynamics and dynamics evolve with time.
The three Lagrangian experiments showed a great deal of diversity in the cloud and aerosol characteristics encountered and in particular how the aerosol evolved within the boundary layer. The boundary layer was always relatively deep and highly structured in the vertical with a well mixed surface layer decoupled from the cloud layer. In the first Lagrangian the airmass had originated from the centre of the Atlantic and was unpolluted. In the other two Lagrangians anthropogenic sources over western Europe had considerably polluted the air parcel. The influence of the boundary layer structure on the cloud, and the feedback between the cloud microphysics and the aerosol characteristics will be detailed.

MI04/E/05-B3 1700

DEVELOPMENT OF A PARTIALLY CLOUDY BOUNDARY LAYER

J.D. PRICE (Met. Research Unit, Cardington, Beds, MK42 0SY, UK)

A case study of a partially cloudy boundary layer consisting of cumulus and stratocumulus is presented, and the main dynamical processes responsible for its evolution are identified. Measurements were made with the UK Meteorological Office tethered balloon facility which was located in Hampshire, Southern England, during the Doppler Radar Observation Project, September 1998.
Results show fair weather cumulus formed during the morning and quickly overdeveloped into patches of stratocumulus. A characteristic of this day was a relatively weak capping inversion, which allowed a significant amount of encroachment/entrainment to occur. Between 1100 and 1400GMT this was calculated at 102kgm-2. The ratio of entrainment to encroachment was found to be 0.5.Data show, together with a simple model, that entrainment of warm air into the upper part of the boundary layer significantly increased the stability there and caused a reduction in the cloud area.

MI10/W/19-B3 1715

TEST OF THE VOLUME-OF-FLUID METHOD ON MARINE BOUNDARY LAYER CLOUDS

C.-Y. J. KAO, Y. H. Hang, J. M. Reisner, and W. S.Smith (Earth and Environment Sciences Division, Los Alamos National Laboratory, Los Alamos, NM 87545, USA. E-mail: kao@lanl.gov)

The impact of using grid-averaged thermodynamic properties (i.e., neglecting their sub-grid variability due to partial cloudiness) to represent forcings for condensation or evaporation has long been recognized. In particular, numerical difficulties in terms of spurious oscillations and/or diffusion in the vicinity of a cloud-environment interface have been encountered in most of the conventional finite-difference Eulerian advection schemes. This problem is equivalent to the inability of models to accurately track the cloud boundary within a grid cell, which eventually leads to spurious production or destruction of cloud water at leading or trailing edges of clouds. In this paper, we employ a specialized technique called "Volume of Fluid" (VOF) method to better parameterize the subgrid-scale advection process that accounts for the transport of material interfaces. VOF also determines where the partial cloudiness actually sits within a grid box. Consequently, relevant microphysical parameterizations in mixed cells can be consistently applied in "cloudy" and "clear" regions. We have incorporated the VOF technique in a two-dimensional hydrodynamic model to simulate the diurnal cycle of the marine stratocumulus-capped boundary layer. The fidelity of VOF to advection-condensation processes under a diurnal radiative forcing is assessed by comparing the model simulation with data taken during the ISCCP FIRE observational period as well as with results from simulations without VOF. Our study shows that the VOF method indeed suppresses the spurious cloud boundary instability and supports a multi-day cloud evolution as observed. For the case without VOF, the spurious instability near the cloud top causes the dissipation of the entire cloud layer within a half of a diurnal cycle.

MI04/E/29-B3 1730

ON TOP-HAT REPRESENTATION OF TURBULENCE STATISTICS IN CLOUD-TOPPED MARINE BOUNDARY LAYER: A LARGE-EDDY SIMULATION

Shouping WANG (Universities Space Research Ass, 977 Explorer blvd, Huntsville AL 35806, USA Email: wangsx@vmcs.msfc.nasa.gov)

Large-eddy simulation is used to study top-hat parameterizations of second- and third-order scalar statistics in cumulus and stratocumulus cloud-topped boundary layers (CTBLs). Although the top-hat parameterizations based on commonly used conditional sampling methods is a useful approach to modeling the vertical fluxes in the simulated CTBLs, it fails to realistically represent the scalar variances. The reason is because the common sampling methods are based at least in part on the sign of vertical velocity, but not the sign of scalars, and because scalars and velocity are not perfectly correlated such methods cannot guarantee uniqueness of the sign of the scalar fluctuations in each individually defined plume. The cancellation between the positive and negative fluctuations induced by the physical processes such as cloud-top entrainment, radiative cooling, small-scale mixing between the different plumes considerably reduces the top-hat contribution to the variances, but has significantly less effect on the fluxes. For the vertical velocity-scalar related third-order moments, the top-hat model gives reasonable estimates for the cumulus CTBL; but not for the stratocumulus CTBL. These differences between the two CTBLs are explained by structural differences (tied to circulation differences in the two CTBLs) in their respective joint probability density functions of vertical velocity and various scalars.

MORPHOLOGY OF LOW CONVECTIVE CLOUD FIELDS

Joachim H. JOSEPH and Ofer Heyman (Dept. of Geophysics and Planetary Sciences, Tel- Aviv University, Tel- Aviv 69978, Israel, email: yoya@jupiter1.tau.ac.il)

Morphological and fractal analysis of digital, spectral images, acquired from air- planes during the SCAR-B mission at different times of day, has been carried out for the purpose of supplying detailed data on the structure of low- level convective cloud fields. Morphological and fractal characteristics of clouds as well as holes in clouds have been derived and are compared. The morphological characteristics have been applied to develop two new parameters- the "Stratiformity" and the Maximal Area/Median Area ratio. These can be used for an automatic discrimination between low- level convective cloud types.

MICROPHYSICAL PROCESSES AND UPPER-TROPOSPHERE CLOUDS

MI04/E/25-B4 0930

ESTIMATION OF THE PARTICLE SIZE DISTRIBUTION IN TROPICAL CIRRUS CLOUDS - HOW IMPORTANT ARE SMALL PARTICLES?

C. Martin R. PLATT (Department of Atmospheric Science, Colorado State University, Fort Collins, CO, 80523.); R. T. Austin (Department of Atmospheric Science, Colorado State University, Fort Collins, CO, 80523.); S. A. Young, CSIRO, Atmospheric Research, P. Bag 1, Aspendale, VIC, 3195, Australia); D. L. Mitchell (Atmospheric Sciences Center, Desert Research Institute, P.O. Box 60220 Reno, NV 89506); Stephen M. Sekelsky (Dept. of Electrical & Computer Engineering, University of Massachusetts, Amherst, MA 01003)

Recent ground-based remote sensing observations have shown that small particles are prevalent, and sometimes dominant, in cold tropical cirrus near the tropopause. These clouds are found to have significant infrared optical depths, but, because of their small particle size, even higher visible solar optical depths. Combined lidar, radar and infrared radiometric observations provide the opportunity to deduce an effective particle radius. Particle sizes in the small-particle range are inferred from lidar-IR radiometer observations, whereas the larger particle range is inferred from combined lidar and millimeter radar data. A set of such data obtained in the Maritime Continent Thunderstorm Experiment (MCTEX) on the Tiwi Islands, Northern Australia in November-December, 1995, included cirrus clouds with temperatures covering the range from -80C to -20C. In some of the higher cloud decks, the millimeter radar could not detect any returns. The lidar-radiometer technique then indicated small particles in the 1 micron to 20 micron range. In the warmer cloud decks, the millimeter radar easily detected most of the cloud (except near cloud top) and the lidar-radar method was able to give effective radii. The methods require an assumption of a particle size distribution. Three models are employed here to assess the sensitivity of the method to such assumptions. The importance of the very high cold clouds of small particles to the radiation budget is discussed.

MI10/W/04-B4 0950

ON THE MAINTENANCE OF HIGH TROPICAL CIRRUS

M.T.BOEHM (Dept of Meteorology, Pennsylvannia State University, 503, Walker Building, University Park, PA 16802. USA,. email: boehm@essc.psu.edu)

Observations reveal that cirrus clouds are ubiquitous in the tropics and therefore significantly impact the radiation budget in this region. Numerical studies are conducted using a two-dimensional cloud resolving model with explicit microphysics to study the processes that lead to the maintenance of tropical cirrus. In particular, radiative destabilization is investigated as a possible maintenance mechanism. It is found that, despite significant differences in the cloud dynamics among the simulations performed, the model is unable to maintain a cloud against the processes of sedimentation and evaporation under the assumed environmental conditions, leading to the conclusion that radiative destabilization is not able to maintain tropical cirrus. It is hypothesized that maintenance requires a source of large-scale upward motion.

MI04/E/23-B4 1005

NUMERICAL SIMULATIONS OF DROP SPECTRA EVOLUTION IN TROPICAL CONVECTIVE CLOUDS OVER LAND AND SEA

Lester ALFONSO, Daniel Martínez (Instituto de Meteorología, A.P. 17032, La Habana 17, Cuba, email: finubes@met.inf.cu); Alberto A. García (Centro de Investigación y Estudios Avanzados del I.P.N., A.P. 14740, México D.F.); Carlos A. Pérez (Martínez (Instituto de Meteorología, A.P. 17032, La Habana 17, Cuba, email: finubes@met.inf.cu)

A one dimensional cloud model with detailed microphysics was used to simulate the evolution of drop spectra in tropical convective clouds. The model considers the processes of activation, condensation, coalescence, break-up, deposition and advection. Two types of cloud base activated droplet spectra were used, corresponding to clouds developing over land and sea. These droplet spectra were measured in young cloud bases over the central part of Camaguey, Cuba and over the Caribbean Sea, near the Camaguey coast, respectively. As initial environmental conditions, a sounding of the Camaguey rawinsond stations was used. Sub-cloud layer sounding data were modified for the simulations over sea. Comparisons were made between modeled and experimental raindrop spectra.

MI04/W/21-B4 1020

DO ICE NUCLEATION RATES DEPEND ON CRYSTAL SHAPE?

D.l. MITCHELL (Desert Research Institute, Atmospheric Sciences Centre, P.O. Box 60220, Reno, Nevada, 89506, USA, email: mitch@dri.edu)

A snow growth model based on an analytical solution to the ice particle number density equation to date has been tested against 9 case studies with consistent favorable agreement between observed and predicted mean particle size and number concentration, N. The model physics for diffusional growth predicts N to be very sensitive to crystal habit. This can be understood if nucleation rates depend largely on the level of supersaturation, Si. In the absence of water droplets, Si depends on the surface area of the size distribution. Cloud regions characterized by crystals with low surface area-to-volume ratios tend to develop higher Si than regions characterized by higher ratios, and the higher Si is, the higher is N. This reasoning was tested in a parcel model, which predicted N in the isometric crystal regime (-7 to -11 C) to be 2 to 7 times greater than N in the dendritic regime. While this assumes no droplets, other detailed microphyical modeling indicates cloud droplets are generally rapidly depleted through riming within snowbands, leaving Si governed by the ice phase. In another test, size spectra predicted by the snow growth model were compared with those from a frontal cloud where enhanced N was attributed to the rime-splintering mechanism. The snow growth model, which implicitly includes the above physis but no rime splintering mechanism, successfully reproduced the observed height evolution of size spectra and N.

MI04/E/04-B4 1035

VALIDATION AND IMPROVEMENT OF STRATIFORM CLOUD FRACTION PARAMETERISATION IN GCMS USING AIRCRAFT DATA

Robert WOOD, Paul R. Field, Doug Johnson, Stephen Cusack, Mark Webb, Gill Martin, Roy Kershaw and Damian Wilson (United Kingdom Meteorological Office, London Road, Bracknell, UK, email: robwood@meto.gov.uk)

Cloud fraction is an important parameter in global circulation models (GCMs) as it can affect both the surface radiation balance and the production of precipitation. The majority of cloud schemes currently used in GCMs diagnose cloud fraction as a function of grid-box mean relative humidity. Results are presented of an attempt to validate several diagnostic cloud fraction schemes with aircraft data collected using the Meteorological Research Flight C-130 aircraft in both warm and cold stratiform cloud. It is shown that one of the most commonly used schemes results in a substantial underprediction of cloud fraction. A scheme based upon a fit to the aircraft data is tested in the UK Meteorological Office Unified Model and results in a significant improvement in the prediction of cloud fraction especially in the stratocumulus sheets over the oceans to the west of continents. The scheme also results in an improvement to the TOA short-wave radiation in these regions and, through feedback, produces boundary layers with more realistic inversion heights and specific humidities.

MI04/E/11-B4 1120

ICE PARTICLE NUCLEATION IN AN A DIABATIC PARCEL MODEL

Richard COTTON, Doug Johnson (The Met. Office, Meteorological Research Flight, Y46, DERA Farnborough, Hants, GU14 0LX, UK, email: rcotton@meto.gov.uk)

Ice particle production by the processes of homogeneous freezing and heterogeneous nucleation in orographic cirrus clouds is studied using a simple adiabatic ascending air parcel model. Case studies being used in the GEWEX Cloud System Study (GCSS) WG2 have been used to initialise this model and results will be shown here. Homogeneous freezing rates in the model are based on Jeffery's (1997) formulation, which matches with observed rates, modified according to the solution effect. Different parametrisations of the heterogeneous nucleation processes have been incorporated into the model and sensitivity studies have been carried out. The model initial conditions are:
100 cm-3 CCN H2SO4 particles, lognormally distributed 0.02 - 1.0um radius, a range of updraught velocities 0.04, 0.2, 1.0 ms-1, warm case model run starting at -40 C (height 8.3km, pressure 340mb), and cold case model run starting at -60 C (height 13.4km, pressure 170mb).

MI04/E/27-B4 1135

ICE CLOUD DIABATIC PROCESSES AND MESOSCALE STRUCTURE IN FRONTAL ZONES

R.M.FORBES (Joint Centre for Mesoscale Meteorology (UK Met Office), University of Reading, Reading, RG6 6BB, UK. email: rmforbes@meto.gov.uk)

Ice cloud can have a significant dynamical effect through the sublimation of precipitation that may be important in determining mesoscale structure in frontal zones. Observations from FASTEX, a major observational campaign over the North Atlantic, are used to investigate this relationship. The FASTEX dataset includes airborne Doppler radar data, in situ observations from aircrafts, and series of dropsondes which are objectively analysed on isentropic surfaces to form vertical cross sections along the aircraft track. Information regarding heat and moisture budgets will be derived from the observational data, and implications for the representation of diabatic processes in a numerical model will be discussed.

MI04/E/22-B4 1150

A CIRRUS CLOUD MODEL WITH EXPLICIT MICROPHYSICS

Ken-ichi MARUYAMA, Naomi Kuba (Institute of Global Change Research, @frontier.esto.or.jp, N.Kuba: kuba@frontier.esto.or.jp); Ryosuke Nakamura (Information Processing Center, Kobe University, Japan, email ryosuke@komadori.planet.sci.kobe-u.ac.jp); Yasushi Fujiyoshi (Institute of Low Temperature Science, Hokkaido University, Japan, email: fujiyo@stellar.lowtem.hokudai.ac.jp, Frontier Research System of Global Change); Takao Takeda (Institute for Hydrospheric-Atmospheric Sciences, Nagoya University, Japan, email: takeda@ihas.nagoya-u.ac.jp , Frontier Research System for Global Change)

It is well known that cirrus clouds play an important role in the radiative heat balance of the earth. Since their radiative properties critically depend on microphysical properties, we are developing a new cirrus model that explicitly calculates such microphyical processes as nucleation of cloud condensation nuclei, nucleation of ice nuclei, condensational growth/ evaporation of droplets, growth/sublimation of ice crystals due to accretion, freezing of droplets and stochastic collection between ice crystals and droplets. To simulate the stochastic collection process rigorously, the Monte Carlo algorithm (Gillespie,1975) is used for calculation of collection and coalescence of ice crystals. Although this calculation technique takes much more CPU-time than other conventional schemes (e.g., Berry and Reinhardt,1974, Bott, 1998), this model can produce realistic development of ice crystals within cirrus clouds. In addition our model can describe the growth processes of individual ice particles and simulate the shapes of aggregates by applying a cluster formation model.

MI10/E/09-B4 1205

A COMPARISON BETWEEN ISCCP CLOUD OPTICAL DEPTHS AND VALUES ESTIMATED FROM IN-SITU AIRCRAFT DATA FOR CIRRUS CLOUDS OBSERVED DURING FIRE-II

Samantha SMITH (Columbia University,2880 Broadway, New York, NY10025, USA, email: ssmith@giss.nasa.gov); Anthony D. DelGenio (NASA Goddard Institute for Space Studies,2880 Broadway,New York,NY10025,USA)

The results of a comparison between ISCCP retrieved optical depths and FIRE-II in-situ aircraft measurements are presented. Conditions must be examined closely to omit cases with underlying cloud and to choose a satellite scene representative of the aircraft flight region. Comparison is very good for well-sampled homogeneous cirrus layers when cloud fraction is accounted for, with locally averaged ISCCP optical depth values within 4 to 9% of the in-situ derived values. Locally averaged ISCCP optical depths differ from in-situ values by up to 70% for inhomogeneous cloud fields (optical depth standard deviation greater than 4), although individual pixel values may give better agreement if that part of the cirrus happens to be similar to that sampled by the aircraft. Conditions that change in time cause even more problems. Although individual histograms of in-situ ice water contents are not necessarily the same shape as the ISCCP optical depth histogram, their overall behavior with cloud fraction is the same. At low cloud fractions the histograms peak at the highest measurable value. At larger cloud fractions the distributions are wider, tending towards a Gaussian shape. The standard deviations of the ISCCP optical depths are proportional to the average values, as for in-situ ice data.

MI04/E/16-B4 1220

THE EFFECTS OF EMBEDDED CONVECTION ON THE PARAMETERISATION OF LAYER CLOUD

T.W. CHOULARTON, K.N. Bower and J. Cardwell (Department of Physics, UMIST, P.O.Box 88, Manchester M60 1QD, UK, email: t.w.choularton@umist.ac.uk)

A model of the microphysical development of a nimbostratus cloud with embedded convective cells has been developed. The cloud model contains a full description of mixed phase cloud microphysics including droplet growth, ice nucleation, ice crystal growth by vapour diffusion, riming and aggregation. The model is used to predict the precipitation rate from the cloud as a function of time and the ice and liquid water contents as a function of position and time in the cloud. The results are compared with a similar model but using the parameterised cloud microphysics developed at the UK Meteorological office by Wilson and Kershaw. The results of both these model runs are then compared with a single column cloud model which does not resolve the embedded convection but in which the total water flux into the cloud is the same as the models. The paper will comment on the results of this intercomparison and the implications for treating such clouds in Global Climate Models. The work is supported by the UK Meteorological Office.

CLOUD MICROPHYSICAL PARAMETERIZATION: VARIABILITY IN THE DERIVED RELATIONSHIPS

G.A. ISAAC and I. Gultepe (Cloud Physics Research Division, Atmospheric Environment Service, Toronto, Ontario, M3H 5T4, Canada, e-mail: george.isaac@ec.gc.ca and ismail.gultepe@ec.gc.ca)

This study shows uncertainties in cloud parameterizations using observations collected during Canadian field projects conducted in the 1980s to 1990s. Microphysical and dynamical measurements were collected by instruments mounted on National Research Council aircraft. Observations represent various cloud types including both maritime and continental stratus, at mid and high latitudes. Models use relationships which have parameters such as liquid water content (LWC), ice water content (IWC), total particle concentration (aerosol, ice, and droplets), temperature, vertical air velocity, and particle size. In parameterized equations, the following concepts have been used: 1) continental clouds have higher concentrations than maritime clouds, 2) droplet number concentration increases with particle concentration and decreasing droplet size, 3) LWC and IWC decreases with altitude, 4) ice crystal number concentration increases with decreasing temperature, and 5) increasing vertical air velocity results in large number concentrations. Most of the earlier relationships were based on observations collected during the 1950s-70s. In earlier studies, scale effects for averaging were not considered, and breaks in the clouds were ignored. The results from this study will be used to show the variability and profiles of cloud microphysical parameters, and the importance of vertical air velocity on number concentration. Also, comparisons with ice crystal number concentration-temperature relationships will be summarized, and their importance to model results will be discussed.

IMPROVED IN SITU OBSERVATIONS OF CLOUD PARTICLE CHARACTERISTICS AND IMPLICATIONS ON CLOUD MICROPHYSICS AND RADIATION

R. Paul LAWSON (SPEC Incorporated, 5401 Western Ave., Suite B, Boulder, CO 80301, USA, email: plawson@specinc.com)

A new airborne device, the cloud particle imager (CPI), records high-resolution (2.3 um) digital images of cloud particles "on the fly" as they pass through the instrument sample volume. The CPI now makes it possible to study the detailed structure of ice crystals and discriminate them from water drops in clouds. The CPI is a sophisticated instrument that has been carefully designed to provide extensive information on cloud particle characteristics. In addition to high-resolution images, the CPI sizes the particles in real-time, records particle detection sensitivity, arrival time, transit time, dead time, total particle count and several other critical parameters. Analysis of data recently collected by the CPI in Arctic stratus, mid-latitude cirrus, and organized convection in Texas and Florida, suggests the presence of very high (5,000 - 10,000 per liter) concentrations of small ice particles in some of these clouds. In the outflow of convective clouds, regions of exceptionally high ice particle concentration are located in juxtaposition with regions with substantially lower concentrations. The visual characteristics of the ice particles in the two adjacent regions are noticeably different. The particles found in high concentrations generally show evidence of riming and contain pockets with high concentrations of small particles. Regions with lower particle concentrations are usually more faceted, showing less evidence of riming and fewer small particles. When the high concentrations of small particles are detected, they are typically found to be inhomogeneously distributed in small clusters. If the clusters of small particles are real, (i.e., not artifacts of the sampling process) they would have previously gone undetected by conventional digital imaging probes and undercounted by scattering probes. In this paper we compare data from the CPI with measurements from the conventional imaging and scattering probes. The likelihood that clusters of small particles exist, their possible origins, the impact on cloud microphysics and radiation are considered.

LABORATORY STUDIES OF AEROSOLS AND ICE FORMATION IN CIRRUS

Paul J. DEMOTT (Department of Atmospheric Science, Colorado State University, Fort Collins, CO, USA 80523-1371, Email: pdemott@lamar.colostate.edu)

The role of aerosols in catalyzing ice formation in clouds, an indirect pathway to altering cloud properties that potentially affect climate, is poorly understood. This area of study is receiving renewed interest world-wide and nowhere is this more evident than in laboratory studies of cirrus ice formation. Cirrus ice formation is often envisioned as a straightforward process involving the freezing of haze particles composed of binary solutions of water and sulfuric acid or ammonium sulfate. Some observations do exist to support the view that cirrus ice formation is primarily by homogeneous freezing nucleation and on this basis a number of numerical studies have investigated the expected relationships between aerosol properties, thermodynamics and ice formation. Nevertheless, the fundamental hydration and freezing behaviours of liquid aerosol particles have not been well documented and there are a host of potential complexities involved under cirrus conditions. First, there are many ways that the cloud nuclei may arrive at cirrus levels or be modified along the way, so there are many potential compositions to be investigated. It is certain that secondary phase transition behaviours of aerosol particles also impact cirrus formation and there may be additional kinetic limitations to a problem that is often viewed thermodynamically. Finally, there are several alternate pathways to ice formation in cirrus, including all the hypothesized heterogeneous ice nucleation mechanisms. This presentation will highlight recent advances in understanding that have been obtained through laboratory studies of ice formation on aerosol particles under cirrus conditions. These new research results provide guidance for theoretical developments, focused field study, and parameterization of ice formation processes for numerical cloud models. This contribution updates a recent textbook contribution in this rapidly evolving research area.

EVOLUTION OF BIMODAL ICE SPECTRA

Paul R. FIELD, Doug Johnson (United Kingdom Meteorological Office, London Road, Bracknell, UK, email: prfield@meto.gov.uk)

Frontal clouds were sampled with the UKMO C-130 research aircraft. The aircraft advected with the wind and descended from cloud top to cloud base with an average descent rate close to the average fall speed of the observed ice crystals. The ice crystal size spectra from 5 descents exhibited very similar evolutions: a mode formed at small crystal diameters and high concentrations migrated to larger diameters and lower concentrations with increased depth from cloud top. Quantitative relations for the observed evolution of bimodal ice size spectra and conclusions about the relative importance of aggregation and diffusional growth processes will be presented.

IS THE DETAILED PATTERN OF SNOW ACCUMULATION OVER ANTARCTICA PREDICTED BY GLOBAL MODELS?

Tom LACHLAN-COPE, Russell Ladkin and Steven Leonard (British Antarctic Survey, High Cross, Madingley Road, Cambridge CB3 0ET. email: t.lachlan-cope@bas.ac.uk)

M

During the 1998/99 summer a series of 10m firn cores were taken in a traverse inland from the coast in the Bryan Coast area of Antarctica. The annual accumulation was determined from these cores using the Electrical Conductivity Method (ECM) in the field using a new portable ECM instrument developed for this project. The results give a detailed picture of how the accumulation varies with height during 1997and 1998. The results are compared with the annual precipitation, over the same period, given by the UK Met Office operational forecast model, the ECMWF operational model and a Lagrangian version of the UK Met. Office single column model.
A detailed comparison of the accumulation will show any gross errors in the parameterisation of clouds and precipitation processes in numerical models. Some thought is given to possible differences between the precipitation predicted and the accumulation measured, in particular the effect of blowing snow will be considered.

THE DYNAMICS OF HAIL PROCESSES IN THE KAKHETI REGION OF GEORGIA IN 1967-1998

Vazha AMIRANASHVILI, Avtandil Amiranashvili, (Institute of Geophysics of Georgian Academy of Sciences, 1, M. Aleksidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com); Muraz Bakhsoliani (Main Department of Hydrometeorology and Environmental Monitoring of Georgia,); Nodar Begalishvili (Institute of Hydrometeoroly of Georgian Academy of Sciences); Kukuri Tavartkiladze (Institute of Geography of Georgian Academy of Sciences)

An analysis of the hail processes from 1967 to 1998 in the Kakheti Region of Georgia is carried out, where untill 1989 hail suppression activities were conducted.
Within the period of activities af the hail suppression service (1967-1989) positive trends of the following chracteristics of hail processes were detected: the number of hail-dangerous clouds exposed to the modification, the part of protected territory inflected by hail per 100%, the expected number of hail cases, the actual number of hail cases.
Within the same period a negative trend of hail suppresion efficiency was detected, which on the average amounted to 80%. The part of protected territory inflected by hail per 100% in 1967-1989 amounted on the average to 0.44%. After the cancelation of the hail suppression activities in19901998 this value rose up to 2.9% versus 2% before the launching of the activities.
Thus, within the last decade in Kakheti an intensification of hail processes has taken place. It is supposed that one of the reasons of this represents the regional climate change and increase of the anthropogenic air pollution. In the nearest future it is planned to renew the hail suppression activities and the above factors should be taken into account for a more precise development of the hail clouds modification methodology.

CHARACTERIZATION OF CIRRUS CLOUD PROCESSES USING A CLOUD RESOLVING MODEL WITH AN ADVANCED RADIATIVE TRANSFER SCHEME

Angela BENEDETTI and Graeme L. Stephens (Department of Atmospheric Sciences, Colorado StateUniversity, Fort Collins, CO 80523, Email: angela@moa.atmos.colostate.edu, stephens@langley.atmos.colostate.edu)

The understanding of ice cloud properties and their sensitivity to different atmospheric conditions is very important for the proper parameterization of such clouds in forecasting models, from mesoscale to the global scale. A two-dimensional cloud resolving model, including dynamical and microphysical processes, is coupled with an advanced radiative transfer model to simulate cirrus clouds. The latter is computationally extremely efficient, deriving its speed by an approximate, robust perturbation technique developed at CSU. The fields provided by the cirrus model are ice water content, crystal number concentration, radiative fluxes, heating rates and vertical velocities. Analysis of these fields will provide insight into the variables that play important roles in the evolution of cirrus clouds. The results of these simulations will also be compared against benchmarks to determine the accuracy and integrity of the cirrus model.

IMPROVED NUMERICAL MODELING OF THE LIFECYCLE OF A THUNDERSTORM CELL BASED ON OGURA - TAKAHASHI'S MODEL

Sohaila Javanmard (Department of Agricultural Meteorology, Faculty of Agriculture, Kyushu Uniersity, Hakozaki, Fukuoka 812-8581, Japan, email: jbjp8scp@mbox.nc.kyushu-u.ac.jp); JAVAD BODAGHJAMALI (Department of Physics, Faculty of Science, Kyushu Uniersity, Hakozaki, Fukuoka 812-8581, Japan, email: jbjp8scp@mbox.nc.kyushu-u.ac.jp); Golamali Kamali(IR of Iran Meteorological Organization, Meradj Ave., email: Tehran@13185-361, Islamic Republic of Iran)

Ogura-Takahashi's numerical modeling of the life cycle of a thunderstorm has been improved in microphysical processses, specially in autoconversion of cloud droplets to form raindrops, as well as in glaciation of raindrops to form hail and fall velocities of raindrops and hail. The results of the improved modeling are shown that the rainfall intensity became much heavier with using the Kessler's bulk parameterization. Besides, the second peak of rainfall intensity disappeared with using the Bigg's freezing probability of supercooling water, and also the rainfall intensity became much heavier and sharper withusing the Lin et al's bulk parameterization for fall velocities of the rain and hail in comparing to the Ogura-Takahashi's original model. THe rainfall profile has much similarities to the observations. The modified Ogura-Takahashi's model can be useful not only for the construction of mesoscale cloud model including clouds and precipitation, but also for the study of the seeding effect on rain evolution.

ONE-DIMENSIONAL NUMERICAL CLOUD NODEL STUDY ABOUT THE EFFECTS OF ICE MULTIPLICATION AND ICE NUCLEI CONCENTERATION ON PRECIPITATION

Javad BODAGHJAMALI (Department of Physics, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812-8581, Japan, email: jbjp8scp@mbox.nc.kyushu-u.ac.jp); Sohaila Javanmard (Department of Agricultural Meteorology, Faculty of Agriculture, Kyushu Uniersity, Hakozaki, Fukuoka 812-8581, Japan, email: jbjp8scp@mbox.nc.kyushu-u.ac.jp); Golamali Kamali(IR of Iran Meteorological Organization, Meradj Ave., email: Tehran@13185-361, Islamic Republic of Iran)

The effects of ice multiplication and variation of natural ice nuclei concenteration on rain evolution and precipitation have been studied by using a time-dependent, one-dimensional numerical cloud model. The dynamics and thermodynamicsof the model is according to Ogura-Takahashi's cloud model. Six forms of water substance (water vapor, cloud water, cloud ice, rain, snow, and hail) have been simulated. The model utilizes the "bulk water" microphysical parameterization technique acording to Lin et al's bulk parameterization. When ice multiplication was used, model produced more intencse rainfall peak and precipitation efficency reached to 24%. Besides, when ice nuclei concenteration was increased about 1000 times of standard value, rainfall intensity peak appeared 8 minites earlier and precipitation efficiency reached to 13%.

NUMERICAL MODELING OF LOW LEVEL HORIZONTAL PENETRATION OF LIQUID CARBON DIOXIDE SEEDING IN SUPERCOOLED CLOUD IN NORTHEN KYUSHU OF JAPAN

JAVAD BODAGHJAMALI(Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812-8581, Japan, e-mail: jbjp8scp@mbox.nc.kyushu-u.ac.jp) Norihiko Fukuta(Department of Meteorology, University of Utah, Salt Lake City, Utah, USA, e-mail: nfukuta@..)Sohaila Javanmard, Yoshinori Suzuki, Kouji Nishiyama and Kenji Wakimizu (all at Faclty of Agriculture, Kyushu University, Hakozaki, Fukuoka 812-8581, Japan) Golamali Kamali (IR of Iran Meteorological Organization, Meradj Ave., Tehran 13185-361, Ilamic Republic of Iran)

In order to achieve effective modification of supercooled clouds, Fukuta (1996) formulated a new seeding method which avoids the problems associated with dry ice and silver iodide seedings and maximizes the seeding reactions involved. The method causes RETHIT (Roll-up Expansion of Twin Horizontal Ice-crystal Thermal) process followed by FILAS (Falling-growth Induced Lateral Air Spreading) process, with a low level horizontal penetration seeding of liquid carbon dioxide (LC). The two-dimensional and time-dependent numerical modeling of the LC seeding method has been carried out for standard atmosphere, where the cloud base temperature and the thickness of cloud were 0 C and 3 km, respectively, in one of our previous work. In this paper, the above mentioned model has been performed to test the feasibility of precipitation enhancement by LC seeding in Northern Kyushu of Japan (Fukuoka). The sounding data of the Fukuoka on 4 November 1998 is used to test the seeding effect. The cloud base and cloud top temperatures are -12 C and -22 C, respectively, and the thickness of cloud is about 2 km. The modeling results of microphysics and dynamics interactions of LC seeding effect shows that the seeded ice crystal thermal has arrived the cloud top in 11 minutes and the amount of precipitation at the ground is obtained about 1.0 mm which is about the maximum releasable precipitation of the supercooled cloud with liquid water content of 0.5 gram per cubic meter and 2000 m thick.

MODELLING THE FORMATION AND GROWTH OF ICE SNOWFLAKES IN DEEP LAYER CLOUD

J. CARDWELL, T.W. Choularton (Physics Department, UMIST, P.O. Box 88, Manchester, M60 1QD,UK) and P.R. Field (Meteorological Research Flight, DERA, Farnborough, Hants)

The UK Meteorological Office C-130 aircraft made measurements in a deep layer cloud of the evolution of the ice crystal and snowflake spectrum from cloud top down to cloud base. A detailed microphysical model has been used to investigate the contribution of the range of physical processes to the evolution of the ice crystals. Comparison of the model and observations shows that: a. The initial ice crystal spectrum grows and descends fro cloud top. This can be explained by the known mechanisms of primary nucleation and growth by vapour diffusion. b. Aggregation is required to explain the ice crystal spectrum lower down in the cloud. The results suggest that aggregation is more important at low temperatures than previously thought. c. A mechanism of secondary ice particle production is required to explain the large number of small ice particles observed at all levels below cloud top. This is consistent with laboratory studies of the fragmentation of ice crystals during evaporation.

DETECTION OF VERTICAL FINE STRUCTURES IN THE FREE ATMOSPHERE

Takashi CHUDA, Ryuji Kimura, Hiroshi Niino (Ocean Research Institute, University of Tokyo, 1-15-1 Minamidai, Nakano-ku Tokyo, 164-8639, Japan, email: chuda@ori.u-tokyo.ac.jp)

Using raw insonde data with vertical resolution of about 10 m, we have detected vertical fine-structures of temperature and specific humidity between 1 and 8 km MSL. An average vertical scale of these structures is about 300 m. Mean amplitudes of temperature and specific humidity are 0.4 K and 0.4 g/kg, respectively, which are significantly larger than the accuracy of the sensors, where the fine-structures of temperature and specific humidity are defined as deviations from running means.
In most fine-structures, perturbations of temperature and specific humidity have a significant negative correlation: For 167 vertical soundings obtained in Kyushu island in the southern part of Japan during the summer of 1996, more than 90 percents of those had negative correlation. To assess the generality of these features found for the soundings in Kyushu, additional studies were made for rawinsonde soundings in different seasons and in different districts of Japan. Most of the soundings exhibited similar features of the fine-structures of temperature and specific humidity. Thus, it is considered that these are common features that exist in the troposphere. Such fine-structures of specific humidity seem to be consistent with occasional observations of cap clouds with multiple layered structure over an isolated mountain.

RADIATION-INDUCED DYNAMICS IN ARCTIC STRATUS CLOUDS

Dietmar FREESE and Joerg Hartmann (Alfred Wegener Institute, 27515 Bremerhaven,Germany, email: dfreese@awi-bremerhaven.de)

To study the interaction between radiation, cloud microphysics and dynamic processes, the experiment REFLEX III (Radiation and Eddy Flux Experiment) was conducted in summer 1995 in the European Arctic north of Svalbard. It was shown that radiative cooling at the top of a stratus cloud deck can lead to a dynamic formation of cell structures within the entire stratus layer.
Airborne measurements were taken of the three wind components, of the temperature and humidity, of the solar and of the terrestrial irradiance and of the particle spectra on flights through the stratus cloud cover over sea ice. Results from measurement on 27 July 1995 are presented, when a stratus cloud was at first shielded by a higher altocumulus cloud. The lower cloud then drifted into a region without higher clouds leading to the onset of radiation cooling at the top. Complex cell structures formed in the stratus layer due to radiative cooling and are visualised by a tomography method.

THE EFFECT OF INHOMOGENEOUS SUPERSATURATION HISTORY ON THE DROPLET SPECTRA IN STRATOCUMULUS CLOUDS

Sarah L. IRONS (Department of Physics, UMIST, Manchester, UK, email: sarah@sneezy.phy.umist.ac.uk); Peter R. Jonas (Department of Physics, UMIST, Manchester, UK, e-mail: peter.jonas@umist.ac.uk)

This work is concerned with the impact of a turbulent updraught on the nucleation processes and droplet spectral evolution within stratocumulus cloud. It has previously been shown that turbulent variations in the updraught result in fluctuations of supersaturation. Fluctuations in the updraught velocity cause local values of the supersaturation which may be much larger than those occuring in a cloud experiencing a constant vertical velocity equal to the mean of the fluctuating updraught. This leads to increased droplet nucleation as well as enhanced growth rates for pre-existing droplets in the regions of higher than average updraught. The effect is investigated using an explicit microphysical model which has been developed to simulate a marine stratocumulus cloud deck. It is shown that while the fluctuations give rise to local variations in droplet concentration, effects on the development of the mean droplet spectrum are however limited due to the short vertical scale over which the velocity fluctuations are correlated.

FREEZING OF CLOUD DROPS ON THE GRAUPEL SURFACE - THEORETICAL STUDY

Tzveta KASSABOVA (Department of Meteorology and Geophysics, Sofia University, P.O.Box 44, Sofia 1164, BULGARIA, email: rumypm@phys.uni-sofia.bg) and Martin Kassabov (Department of Mathematics, Yale University, 276 Prospect Str., #211, New Haven, CT 06511, USA)

A new approach to the freezing process of water droplets on the graupel surface is proposed. The model takes into account the influence of the freezing of droplets on the temperature inside the graupel. The surface temperature of the graupel is a parameter in the Mackline & Payne (1967) equation. Its change during the freezing process brings an additional heat flow in the original equation. The impact of droplets size, cloud temperature and liquid water content on freezing time of cloud droplets and on graupel surface temperature will be discussed. References: Macklin W. C. and G. S. Payne, 1967, Quart. J. Roy. Meteor. Soc., 93, 195 _

A LONG-TERM ANALYSIS OF THE GLOBAL CLOUD MICROPHYSICS DERIVED FROM AVHRR DATA

Kazuaki KAWAMOTO and Teruyuki Nakajima (Center for Climate System Research, University of Tokyo, Meguro-ku, Tokyo, 153-8904, Japan, e-mail: kawamoto@ccsr.u-tokyo.ac.jp)

An algorithm is developed for determining the@cloud optical thickness and effective particle radius (the cloud microphysics) simultaneously on a global scale using AVHRR (Advanced Very High Resolution Radiometer) multi-spectral radiance data. In the algorithm, the treatment of thermal radiation in Nakajima and Nakajima (1995) is improved by reformulating the thermal emission in the atmospheric layers. At the same time, the look-up table for thermal emission is parameterized in terms of the effective water vapor path in order to include the effect of various vertical water vapor profiles. This algorithm has been applied to four-month (Jan., Apr., Jul. and Oct.) data to generate the annual-mean global distributions of the cloud optical thickness and effective particle radius for every 0.5 (deg.) x 0.5 (deg.) box in a -60 (deg.) to 60 (deg.) latitudinal region. Various features of the cloud optical thickness and effective particle radius such as the ocean-land contrast and the altitude dependence are obtained. Moreover, a long-term analysis of the cloud microphysics from 1985 to 1994 has been performed. We have obtained a result that the effective particle radius decreased gradually both over ocean and land during this period. As one of the major reasons, we like to suggest an increase of anthropogenic aerosols originating from industrial production and biomass burning.

CONCERNING TO IDENTIFICATION OF THUNDER CLOUDS

T. G. Salukvadze, N. V. KHELAIA, E. I. Khelaia Nodia (Institute of Geophysics, Academy of Sciences of Georgia Georgia, Tbilisi 380093 Aleksidze str. 1)

The investigation of radar observations on several hundred convective clouds to overwhelm thunder phenomena, with the aim to express the modeling possibilities on atmospheric electrity processes have been carried out. From date archives of many years radar observations on hail and thunder clouds, that had been carried out on Alazany Valley in East Georgia, were selected such clouds, the evolution of the parameters of which was tracked by their natural development. According this the following 8 radar and aerological parameters have been used: Hm km – the radioecho height maximum above sea level; tHm (c- – the temperature in the free atmosphere over the Hm level; h-/h+ - the ratio radio-echo thickness of the part of cloud that is above zero isothermal (h-) level on that isothermal height, that is above place level (h+);Hzm km – the radar reflectivity locations height maximum above sea level;tHzm (c- the temperature of the free atmosphere on the Hzm level;(h km – the increased reflectivity thicknesser zones that are placed above zero isotherm's level;t(h (c- the temperature in the free atmosphere on the level of the upper bound; lgzm- the logarifm of maximum radar reflectivity. The distribution curves for the values of were found where rain and thunderstorm clouds separate unambiguously. The informativeness of all parameters according to Makhalanobisis distance was estimated.

TROPOSPHERIC STATIC STABILITY AND CONVECTIVE RAINFALL IN CAMAGÜEY, CUBA.

Daniel MARTINEZ, Lester Alfonso, and Ieng Jo (Instituto de Meteorologia, A.P. 17032, La Habana 17, Cuba, Email: finubes@met.inf.cu)

Convective available potential energy (CAPE), stability indices, moisture and wind shear related magnitudes were calculated from 413 afternoon soundings of the Camagüey rawinsond station, located in the Central-Eastern part of Cuba. These and other magnitudes, derived from a simple stationary cloudy parcel model with lateral entrainment were related with 24 hour mean and maximum rainfall for a dense rain gauge network centered in the rawinsond station. Regression and discriminate analysis techniques were applied. Positive correlation was found between rainfall and moisture related parameters. If inter-seasonal variations are considered, slightly positive correlations are obtained between rainfall and static stability parameters, which becomes negative if only rainy season soundings are included. The results are discussed on the base of cloud physics arguments based on data and numerical modeling results.

SHALLOW CONVECTION IMPACT UPON MEDIUM-RANGE NUMERICAL WEATHER FORECASTS

Gueorgui V. MOSTOVOI and Elena D. Astakhova (Hydrometeorological Centre of Russia, Bol'shoi Predtechensky per., 9-13, Moscow, 123242, Russia, email: most@rhmc.mecom.ru)

The description of a new parameterization scheme of shallow convection (SC) and results of numerical experiments, carried out with the help of an operational version of Russian Hydrometeorological Centre spectral model (T40L31 sigma model) are presented . Experiments were carried out for estimating the impact of a new SC scheme on the model performance for 6-day forecasts. The scheme takes into account the terminal size and deformation of a small cumulus cloud during its life cycle. Therefore in comparison with other schemes based on a parcel method it is more adequate for reproducing thermodynamic structure of small clouds. Influence of the new parameterization scheme of SC upon large-scale thermodynamic fields is assessed. Sample estimations of the model skill for some meteorological elements are considered. They allow to note existence of clear tendency toward small improvement of 850 hPa geopotential height and air temperature forecasting quality for 6-day period at the expense of SC parameterization. Noticeable positive responce of forecast skill is observed in the tropics. The quality of surface pressure forecasts remains about the same everywhere. Influence of SC parameterization upon spatial distribution of precipitations in midlatitudes is discussed for few individual forecasts.

PARAMETERIZATION SCHEME OF SHALLOW CONVECTIVE CLOUDS BASED ON TWO-DIMENSIONAL NUMERICAL MODELLING

Gueorgui V. MOSTOVOI (Hydrometeorological Centre of Russia, Bol'shoi Predtechensky per., 9-13, Moscow, 123242, Russia, email: most@rhmc.mecom.ru)

The parcel concept based on one-dimensional, steady-state cloud models is widely used in atmospheric convection (AC) parameterization schemes. These models are generally restricted to the prescribed cloud geometry and neglect some important features relating to the spatial structure of the AC. The current research is carried out to refine a parcel method taking into account the terminal size and deformation of a small cumulus cloud during its life cycle. Numerical experiments with nonhydrostatic two-dimensional shallow AC model with fine spatial resolution of 30m aimed for simulation of a cumulus cloud evolution represent a necessary framework for the parcel method improvement. Model thermodynamical variables are: the liquid water potential temperature and the total moisture content (TMC) mixing ratio. AC is initiated by the overheated dome-like area in the form of a semicircle placed at the bottom boundary on a central axis of the model domain. The initial thermodynamic profiles, chosen for numerical experiments, reflected various conditions of large-scale stratification for small cumulus development in the tropics and midlatitudes. A quasi-conservative property of the TMC mixing ratio is taken into account to track displacements of atmospheric layers in the course of AC and to consider the composition of the cloudy air from the viewpoint of air parcel history. Peculiarities of cumuli life cycle revealed in numerical experiments form a basis for the proposed parameterization scheme of small cumulus clouds in large-scale atmospheric models. A comparison with other parameterization methods is done. The scheme provides more adequate estimation for a cloud top height and thermodynamic parameters.

CHARACTERISTICS OF THE VERTICAL AND HORIZONTAL DISTRIBUTION OF CLOUDS FROM LITE OBSERVATIONS

Kathleen A. POWELL (NASA Langley Research Center, MS 475, Hampton, VA 23681 USA, email: k.a.powell@larc.nasa.gov) David M. Winker (NASA Langley Research Center, MS 475, Hampton, VA 23681 USA, email: d.m.winker@larc.nasa.gov)

Clouds play a major role in determining the Earth radiation budget. The feedback between clouds and the climate system are not well understood, however. This is due in part to the limitations of passive satellite sensors for observing thin and multi-layer clouds and for measuring characteristics such as cloud height and the 3-D spatial organization of cloud. The Lidar In-space Technology Experiment (LITE) was flown on Space Shuttle mission STS-64 in September 1994. High vertical resolution, high sensitivity, the ability to observe multi-layer clouds, and near-global coverage provide a unique dataset for the study of cloud distribution. As an example of the information available from LITE, preliminary results on cloud brokeness and on the characteristics of the overlap of multilayer clouds are presented. These results have implications for the design of satellite sensors for observing clouds and can be used to test the validity of cloud parameterizations in global climate models.

A SIMPLE MODEL OF CIRRUS HORIZONTAL INHOMOGENEITY AND CLOUD FRACTION

Samantha SMITH (Columbia University,2880 Broadway,New York, NY10025, USA, email: ssmith@giss.nasa.gov); Anthony D. DelGenio, (NASA Goddard Institute for Space Studies,2880 Broadway,New York,NY10025,USA)

A simple model of horizontal inhomogeneity and cloud fraction in cirrus clouds has been formulated on the basis that all internal horizontal inhomogeneity in the ice mixing ratio is due to variations in the cloud depth, which are assumed to be Gaussian. The use of such a model was justified by the observed relationship between the normalized variability of the ice water mixing ratio (and extinction) and the normalized variability of cloud depth.
Using radar cloud depth data as input, the model reproduced well the in-cloud ice water mixing ratio histograms obtained from horizontal runs during the FIRE-II cirrus campaign. For totally overcast cases the histograms were almost Gaussian, but changed as cloud fraction decreased to exponential distributions which peaked at the lowest nonzero ice value for cloud fractions below 90%. Cloud fractions predicted by the model were always within 28% of the observed value. The predicted average ice water mixing ratios were within 34% of the observed values. This model could be used in a GCM to produce the ice mixing ratio probability distribution function and to estimate cloud fraction. It only requires basic meteorological parameters, the depth of the saturated layer and the standard deviation of cloud depth as input.

USING LEM TO INVESTIGATE THE DYNAMICS OF SINGLE CLOUDS

STILLER (Address not available at time of going to press)

The parametrisation of cloud processes is a delicate task due to the lack of understanding of the basic dynamics comprising mixing processes and momentum transport. Experimental data

are limited and not always conclusive and also numerical investigations are difficult due to the systems complexityand often obscurred by the large number of parameters involved in a realistic representation of moist processes. Using the large eddy model of the British Meteorogical office to investigate the dynamics of single clouds (updrafts) we have extracted a largely idealised version of the model which possesses basic features of the full model but has fewer parameters and thus permits a more systematic analysis facilitating conclusions concerning cause and effect of the observed phenomena. The idealised model has a drastically simplified microphysics which still includes condensation and reevaporation of cloud water but the parametrisation of rain is reduced to the fact that the content of cloud water has an upper limit above which the water is irreversibly taken out of the system. The saturation value of water vapour is taken to depend only on height and to decrease linearly with height. As a consequence a sounding with a constant dry lapse rate also possesses a constant moist lapse rate. To investigate mixing processes we are considering situations where the height reached by the updraft is entirely determined by mixing processes. This means we consider a sounding which is neutral with respect to moist convection. In particular we find that a dryer atmosphere enhances mixing and decreases the height reached by the updraft. This can be explained by the increased relea se of negative buoyancy from reevaporation processes which enhances the vortices responsible for the mixing. Similarities and differences of the model dynamics and those from simulations with the full large eddy model are discussed.

ON SIMULATING INTRASEASONAL OSCILLATIONS IN A GCM

G.K.WALKER, Y.C.Sud, K.-M. Lau (Laboratory for Atmospheres, NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA), and D.A.Randall (Colorado State Univeristy, Fort Collins, CO, USA)

One of the least understood phenomenon of tropical motions is the interaction among physical and dynamical processes that cause intra-seasonal oscillations commonly known as Madden-Julian Oscillations, or MJOs. Only a few general circulations models (GCMs) were able to simulate decent MJOs in the Atmospheric Model Inter-comparison Project (AMIP I). A few GCMs that had decent MJOs in one version lost them in another so-called improved version; consequently considerable diagnostic and model development research is necessary to understand the processes that affect MJOs. Such research not only would help to understand MJOs, but also would enable modelers to improve tropical moist processes in GCMs. The GLA GCM in AMIP I, which is a version of the GEOS GCM with an improved physical package, had fairly decent MJOs. In this research, we show how several changes in moist convection, rain-evaporation, and downdraft parameterizations would influence simulation of MJOs. The investigations are in the form of sensitivity studies in which the influence of inclusion or removal of the above noted physical processes on MJOs is examined. Our preliminary results show that elimination of a physical process leads to slow degradation of MJOs. In this way, simulation of MJOs is ultimately related to realistic simulation of vertical heating profiles and depth of moist convection. The details of the episodic structure and intensity of convection is also identified.

LAND USE AND TERRAIN IMPACTS ON CLOUD FIELD DEVELOPMENT ON THE CARIBBEAN SLOPE OF COSTA RICA AND NICARAGUA

R. M. WELCH, R. O. Lawton and U.S. Nair

It has long been hypothesized that landscape changes alter regional climates, but direct evidence has been lacking. Analaysis of satellite imagery acquired during the Central American dry season reveals that the trade wind cumulus cloud fields over the Caribbean slope of northern Costa Rica and adjacent southern Nicaragua are influenced by several classes of terrain features and by human land use practices. In Costa Rica, deforestation of the southern margins of the Lloanura de Tortuguero, the Llanura de San Carlos and the Llanura de los Guatusos began in the 1950s but expanded rapidly on the northern margins in the 1970s and has continued until the present. Social conditions in southeastern Nicaragua have limited agricultural expansion in that time frame, so that area remains forested, as do tracts protected within the Costa Rican Parque Nacional de Tortuguero and the Regugio de Fauna Silvestre de Barro Colorado. Twenty years of Landsat imagery shows that deforestation and establishment of a mixed agricultural landscape in Costa Rica is associated with significantly decreased cumulus development. Indeed, many images show complete suppression of cloud development over deforested areas, while nearby forested regions are covered by trade wind cumulus.

NAST-I: AN AIRBORNE DEMONSTRATION OF FORTHCOMING SATELLITE CAPABILITIES FOR HIGH SPECTRAL RESOLUTION INFRARED REMOTE SENSING OF WEATHER AND CLIMATE VARIABLES

William L. SMITH (NASA Langley Reasearch Center, Mail Stop 401, Bldg 1250, 21 Langley Blvd. Hampton, VA 23681 USA, email: bill.1.smith@larc.nasa.gov Tel: 757-864-5380, Fax No: 757-864-8197)

The NPOESS Airborne Sounder Testbed-Interferometer (NAST-I) is a new high spectral resolution (0.25cm-1) and high spatial resolution (2.6 km at nadir and 3.6 X 5.2 km at 45 degrees) scanning (46 km swath) Fourier Transform Spectrometer flying on NASA high altitude (~20 km) ER-2 aircraft. The NAST-I has been flown during several field measurement campaigns to provide experimental observations needed to finalize the specifications and to test proposed designs for future satellite instruments, particularly the Cross-track Infrared Sounder (CrIS) set to fly on the National Polar-orbiting Operational Environmental Satellite System (NPOESS). The data are also being used to test and validate forward radiative transfer models and retrieval algorithms designed for the upcoming launch of the EOS-PM platform Advanced Infrared Sounder (AIRS) and the METOP Infrared Atmospheric Sounding Interferometer (IASI). The NAST-I instrument provides new and exciting observations of the mesoscale structure of the atmosphere and the Earth's surface. The fine scale thermodynamic characteristics of tropical cyclones (Hurricane Bonnie and Hurricane Georges, Atlantic Basin 1998 Hurricane Season) and extra-tropical storm systems have been observed to date. The detailed horizontal structure of ocean, and land, surface temperature and spectral emissivity features can be observed with high accuracy afforded by a high spectral resolution and precision of the radiance measurements. The spatial resolution and scan geometry of this instrument enables observation of the fine spatial structure of cloud radiation and implied cloud microphysical properties. The NAST-I instrument provides atmospheric sounding measurements with an unprecedented vertical and horizontal resolution. Surface and atmospheric remote sensing results obtained during several airborne measurement campaigns have already provided provide a glimpse of the advanced global remote sensing capabilities which will soon be realized from meteorological satellites.

MI06/L/04-B1 0950

AN INSTRUMENT FOR GRADIENT FIELD MAPPING IN WEATHER SYSTEMS

Dr. William E. SHARP, ITT Aerospace Communications, Fort Wayne, IN 46801, 219-451-6147, email: wesharp@itt.com. Dr Mark Abrams, ITT Aerospace Communications, Fort Wayne, IN 46801, 219-451-6822, email: mcabrams@itt.comSevere

Storm formation occurs in the boundary regions between airmasses with very different temperatures, pressures, water content, and aerosol loading. Severe storm tracking and forecasting utilizes the discontinuities in observed fields and gradient fields to diagnose and forecast the formation, evolution, and motion of severe storms. Heat islands, super-regional pollution, and rain shower formation are each the result of temporal and spatial gradients present in the atmosphere. Diagnosing and forecasting such event requires an ability to map atmospheric gradients and discontinuities in real-time on micro to meso-scales in the atmosphere.A new measurement concept, the Geostationary Severe Storm Imager (GSSI), is described which demonstrate a class of autonomous event identification, monitoring and tracking sensor. The GSSI combines high spatial resolution (0.5-1 km) imaging with high spectral resolution (0.25 cm-1 across the mid infrared 3-10 microns) in time intervals of a few seconds. This electronically programmable infrared camera combines a large-format focal plane array with a Fourier transform spectrometer and builds on currently fielded airborne demonstration systems and an instrument concept in development for the Next Generation Space Telescope (NGST). The GSSI concept is revolutionary in several aspects: 2-10 fold increase in spatial resolution, 2 fold increase in spectral resolution, 30 fold increase in temporal resolution; in combination the measurement concept would require a 100-600 fold increase in telemetry bandwidth without a new approach to imaging. GSSI breaks this paradigm with a new approach to hyperspectral imaging. Four innovations enable this measurement concept: GSSI will: (a) directly observe the gradient fields, (b) Nyquist sample the image, (c) have Multi-channel detection of gradient regions, and (d) have an autonomous targeting and tracking system that identifies, subsets, and follows regions with significant discontinuities (i.e., regions where severe storms, toxic pollution, heat islands, or rain/thunderstorms will form). An analysis of the excellent spectral data and images from an airborne experiment demonstrates the utility of the GSSI concept.

MEASURING ATMOSPHERIC WATER VAPOR, TEMPERATURE AND GEOPOTENTIAL USING SATELLITE OCCULTATION OBSERVATIONS NEAR 22 GHZ

E. Robert KURSINSKI, Thomas Yunck (Both at Jet Propulsion Laboratory, California Institute of Technology, Pasadena CA 91109, Email: Rob.Kursinski@jpl.nasa.gov), Benjamin Herman, Dasheng Feng (Both at Institute of Atmospheric Physics, University of Arizona, Tucson, AZ 85712)

Atmospheric water plays fundamental roles in energy transfer, atmospheric circulation and defining the continental biosphere via precipitation. Accurate predictions of weather and changes in climate require detailed knowledge of the distribution of atmospheric water in clear and cloudy conditions, at sufficient spatial and temporal scales over the entire range of climatic conditions. Observations must capture aspects of the distributions from which to infer the mechanisms and predict how they will change in a changing climate. In particular, both specific and relative humidity are needed to infer the processes involving water phase changes and moisture advection.

Spacecraft radio occultations near 22 Ghz can address many of these objectives as well as improve knowledge of temperature and geopotential on a global scale. The concept is to make occultation measurements near the 22 Ghz water line of both propagation delay and absorption to derive the wet and dry density structure of the atmosphere in a limb viewing geometry. Recovery of dry density versus height yields hydrostatic pressure versus altitude or equivalently the geopotential of pressure surfaces. Estimated specific humidity accuracy is ~1 to 2% in the lower and middle troposphere and 3 to 5 ppm in the upper troposphere. Relative humidity can be estimated at the few percent level through much of the troposphere. Profiles of cloud liquid water will be derived as well. Temperatures with sub-kelvin accuracy and geopotential heights accurate to ~10 m or better should extend from near the surface to ~60 km altitude.

The presentation will discuss the measurement and retrieval concept, estimated accuracy and plans for development of this system.

FIELDS OF NO2 AND O3 TOTAL CONTENT: MEASUREMENTS, VALIDATION, NUMERICAL SIMULATION

Yuriy M. TIMOFEYEV, Dmitriy, V. Ionov, Vladimir, V. Ionov (St.Petersburg State University, Ulyanovskaya 1, St.Petersburg-Petrodvorets, 198904 Russia, e-mail: tim@troll.phys.spbu.ru).
Nikolay F. Elansky, Aleksandr S. Elokhov, Alexandr M. Gruzdev, Oleg V. Postylyakov (Institute of Atmospheric Physics RAS, Pyshevsky per. 3, Moscow, 109017 Russia, e-mail: Nikolai@selansky.home.bio.msu.ru). Igor L. Karol, Vladimir Zubov, Arkadiy M. Shalamyansky(Main Geophysical Observatory, Karbysheva 7, St.Petersburg, 194018 Russia, e-mail: ozon@peterlink.ru). Eugene Rozanov, M. Schlesinger (University of Illinois, S.Gregory Ave 105, Urbana, IL 61801 USA, e-mail: rozanov@atmos.uiuc.edu). John P. Burrows (University of Bremen, Bibliothekstr. 1, Bremen,330440 Germany, e-mail: burrows@gome3.physik.uni-bremen).

Information on global fields of the O3 and NO2 content is retrieved from the GOME satellite measurements of reflected and scattered solar radiation in UV and visible spectral ranges. Data of ground-based Russian network are used for estimating the quality of the satellite measurements. Russian network of ground-based measurements of atmospheric gaseous constituents by optical methods is characterized. Accuracy of measuring the O3 and NO2 column amount and the methods of device calibration and interpretation of measurement data are clarified. Comparison of the GOME O3 and NO2 data with network measurements over the 1996-1998 period is carried out for North-West and Central Russia. Systematical deviations between the GOME satellite and M-124 ozonometer ground-based measurements are revealed. Comparisons of the M-124 and the TOMS data testified to a high accuracy of ground-based measurements. Essential deviations are also observed between the NO2 total column amount retrieved from the GOME and ground-based measurements. Possible sources of the mismatches revealed has been analyzed. Some examples of comparing the O3 and NO2 satellite and ground-based measurements with the results of numerical modeling the total content by the global three-dimensional model are given.

THE MOISTURE CONTENT OF MID-LATITUDE WEATHER SYSTEMS IN THE NEW ZEALAND REGION FROM GPS PRECIPITABLE WATER AND GMS-5 SATELLITE IMAGERY

James MCGREGOR (School of Earth Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand, Email: mcgregor@vuw.ac.nz); Mark Falvey (School of Earth Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand, Email: mfalvey@gamma.gns.cri.nz)

Video animations of infrared and upper tropospheric water vapour channel data from the Geostationary Meteorological satellite, GMS-5 satellite reveal the passage of a number of interesting mid-latitude weather systems in the vicinity of New Zealand during February - March 1997. The water content of the atmosphere during these events is examined in detail using GMS-5 satellite data, GPS Total Precipitable Water data and rainfall data from the New Zealand Climate database (CLIDB). Comparisons are also made to six hourly data derived from European Centre for Medium Range weather Forecasting (ECMWF) global analysis fields. In this study we pay particular attention to mesoscale variations in the moisture observed in the GMS water vapour channel and its relationship to short term temporal variations in the GPS PW time series at four stations around the NZ region. By combining the upper tropospheric information of the GMS data with the total column information provided by GPS-PW, we also obtain a greater insight into the vertical distribution of moisture content of the various weather systems.

RETRIEVAL OF HUMIDITY PROFILES FROM GMS-5 DATA USING BAYESIAN DISCRIMINATION AND REGRESSION

Niels BORMANN, Crispin J. Marks, James A. Renwick (NIWA/VUW Centre of Excellence, PO Box 14 901, Kilbirnie, Wellington, New Zealand/Aotearoa, email: n.bormann@niwa.cri.nz)

We describe and characterise a statistical method to estimate humidity profiles based on data from the Geostationary Meteorological Satellite (GMS-5). The method incorporates data from all four GMS channels (0.6*mu*m, 6.7*mu*m, 11.5*mu*m, 12.5*mu*m), and it is developed for the New Zealand region, i.e. for an oceanic midlatitude environment with very few conventional observations. Results from the validation of the retrievals are discussed and compared to results from other algorithms based on similar satellite data (e.g. Garand 1993).
The retrieval method uses various predictors derived from atmospheric background fields and scenes of the satellite data, and it is based on clustering and cluster-specific regression models for standard pressure levels, similar to Garand 1993. Clustering allows the separation of different physical regimes similar to cloud-classification, and we use multivariate Bayesian discrimination to distinguish between the clusters (e.g. Uddstrom and Gray 1996). The algorithm is developed by collocating 33 months worth of radiosonde profiles with satellite data. The algorithm shows significant skill in estimating humidity profiles. The retrievals are better for upper levels (700hPa and above) due to contributions of the 6.7*mu*m channel, though poorer at lower levels as these are often obscured by clouds in the satellite data. The Bayesian approach allows the identification of poorer retrievals and can be used to significantly improve the algorithm performance. We highlight the benefits and limitations of the scheme with a view to assimilating the retrievals into a regional numerical model.

MI06/W/22-B1 1200

THERMODYNAMIC PROFILING OF THE LOWER 10-20 METRES OF THE ATMOSPHERIC MARINE BOUNDARY LAYER USING HIGH SPECTRAL RESOLUTION INFRARED INTERFEROMETRY

BJ Osborne, MJ LYNCH (Remote Sensing and Satellite Research Group, School of Physical Sciences, Curtin University of Technology, GPO Box U1987, Perth WA 6845, Australia, email: posbornebj@cc.curtin.edu.au); RO Knuteson (Space Science and Engineering Center, University of Wisconsin-Madison, 1225 W. Dayton Street, Madison, WI 53706, USA)

This paper will describe the information content of high spectral resolution infrared radiance observations in the 15 micron region, for the purpose of retrieving near-surface marine boundary layer air temperature and temperature profiles. Using atmospheric transmittance models and radiometric data from the Marine Atmospheric Emitted Radiance Interferometer (MAERI), the potential for down-looking sounding of temperature from ship deck altitude is assessed. Factors impacting such retrievals, such as spectral selection, the sea surface emissivity, reflected downwelling radiation and instrument specifications will also be discussed.It is anticipated that such profiles may be useful estimators of ocean heat flux. Preliminary investigations comparing MAERI-derived air temperature with an in-situ sensor and the response of temperature profiles to ocean heat flux will be discussed.

ATMOSPHERIC BOUNDARY LAYER DEPTH EVALUATION USING A GCM AND AVHRR CLOUD DATA

A.MATHIEU (Centre d'Etude des Environnements Terrestre et Planetaire (CETP), 10-12 av. De l'Europe 78140 Velizy, Email: anne.mathieu@cetp.ipsl.fr); G.Seze (Laboratoire de Meteorologie Dynamique (LMD, Paris); A.Weill (CETP, Velizy); H.Giordani (Meteo-France CNRM/GMGEC, Toulouse); H.Dupuis (Departement de Geologie et d'Oceanographie, Bordeaux)

We propose a method to compare Marine Atmospheric Boundary Layer (MABL) height as determined from a GCM and corresponding information as retrieved from AVHRR satellite cloud analysis over oceanic mid-latitudes. We use the Holtslag et al.(J.of Climate,92) algorithm and the French Met GCM : ARPEGE. First, a cloud classification of AVHRR images is used to discriminate low level Strato-Cumuli, from which are derived cloud top temperature fields. Secondly, from the GCM output we determine the MABL altitude. The temperature correspondence between the two fields is worked out to evaluate the ability of the GCM to give realistic characteristics of the MABL. The method is applied to the SEMAPHORE experiment, hold in sept-nov 1993 over the Azores basin (North. MidAtlantic) using ARPEGE re-analysed with the SEMAPHORE observations. The advantage to use a combined information of GCM with relatively good surface information but poor determination of the cloud layer and remote sensing with relatively accurate data is demonstrated.

GROUND - BASED OBSERVATIONS OF O3, CO2, NO2, H2O AND VISIBLE SPECTRAL IRRADIANCE OVER EURASIA CENTRAL PART

Vladimir N. Aref'ev, Nikita Ye. Kamenogradsky, Felix V. Kashin, Vladimir K. Semyonov, Valery P. Sinyakov, Konstantin K. VISHERATIN (all at Institute of Experimental Meteorology, SPA "Typhoon", Obninsk, Kaluga region, 82 Lenina Avenue, Russia, email: typhoon.meteo.ru)

Since 1979, regular carbon dioxide, water vapor, total ozone, nitrogen dioxide and visible spectral irradiance measurements have been made over central part of Eurasia (42.6 N, 76.7 E, 1650 m above see level). The instrumentation and measurements procedures are outlined, and results from 1979-1998 are discussed. The daily as well as monthly averages have been examined to find the trends and other statistical characteristics. The trend values are 6.1% (carbon dioxide), 11% (water vapor), -4.0% (total ozone), 4.3% (nitrogen dioxide) and 4.7% (visible spectral irradiance) per decade. The spectral analysis of the obseravations have been used to obtain the periodical oscillations and the comparisions are made with variations of the solar activity and quasi-biennial oscillation (QBO).

NOAA GROUND-BASED GPS WATER VAPOR DEMONSTRATION NETWORK

Seth GUTMAN, Kirk Holub, and Nicole Radziwill, (all at NOAA Forecast Systems Laboratory, 325 Broadway R/E/FS3, Boulder, Colorado 80303 USA, Email: gutman@fsl.noaa.gov)

An overview and status report on the Forecast Systems Laboratory's efforts to develop a GPS water vapor demonstration network for NOAA is presented. This project was initiated to evaluate the engineering and scientific bases of ground-based GPS meteorology, as well as the utility of ground-based GPS observations for improved weather forecasting and climate monitoring. An increased number of observations are needed to assess the impact of these data on short-term weather forecast accuracy in a timely manner. As a consequence, FSL plans to expand the demonstration network to about 200 sites in the next 3-5 years. Some examples of data acquired by the network are presented.

HIGH RESOLUTION SOLAR SPECTROMETR FOR RETRIEVAL OFTROPOSPHERIC WATER VAPOR: FIRST RESULTS AND COMPARISONS

Bernd SIERK(Institute of Geodesy and Photogrammetry, Swiss Federal Institute of Technology (ETH), ETH-Hoenggerberg 8093 Zurich email: bernd@geod.ethz.ch); Stefan V. Florek and Helmut Becker-Ross(Institute of Spechtrochemistry and Applied Spectroscopy Rudower Chaussee 5, 12489 Berlin, Germany); Beat Bürki, Lars Kruse and Hans-Gert Kahle (Institute of Geodesy and Photogrammetry, Swiss Federal Institute of Technology (ETH), ETH-Hoenggerberg 8093 Zurich)

Based on previous studies of Differential Optical Absorption Spectroscopy (DOAS) using solar radiation, we developed a field spectrometer which is specially designed to measure water vapor in the troposphere. The Solar Atmospheric Monitoring Spectrometer (SAMOS) is capable of monitoring single absorption lines of H2O in the visible and near infrared spectral region (600-900 nm). The high resolution of the instrument allows accurate
retrievals of columnar precipitable water. In addition we investigate the possibility to derive information on vertical humidity profiles. The distribution of molecules along the line of sight towards the Sun determines the shape as well as the total absorption of each individual line. Simulation studies show that profile information can be retrieved from the spectra, provided spectral line parameters are known and simple models of pressure and temperature profiles are assumed. In addition to the instrumental design we will present results from a field campaign carried out on Hawaii. The water vapor retrievals from SAMOS-data will be compared with those from radiosondes, microwave radiometers and Global Positioning System (GPS) receivers.

CHARACTERISTICS OF THE VERTICAL AND HORIZONTAL DISTRIBUTION OF CLOUDS FROM LITE OBSERVATIONS

Kathleen A. POWELL (NASA Langley Research Center, MS 475, Hampton, VA 23681 USA, email: k.a.powell@larc.nasa.gov) David M. Winker (NASA Langley Research Center, MS 475, Hampton, VA 23681 USA, email: d.m.winker@larc.nasa.gov)

Clouds play a major role in determining the Earth radiation budget. The feedbacks between clouds and the climate system are not well understood, however. This is due in part to the limitations of passive satellite sensors for observing thin and multilayer clouds and for measuring characteristics such as cloud height and the 3-D spatial organization of cloud. The Lidar In-space Technology Experiment (LITE) was flown on Space Shuttle mission STS-64 in September 1994. High vertical resolution, high sensitivity, the ability to observe multilayer clouds, and near-global coverage provide a unique dataset for the study of cloud distribution. As an example of the information available from LITE, preliminary results on cloud brokeness and on the characteristics of the overlap of multilayer clouds are presented. These results have implications for the design of satellite sensors for observing clouds and can be used to test the validity of cloud parameterizations in global climate models.

CLOUD COVER OBSERVED SIMULTANEOUSLY FROM POLDER AND METEOSAT

Genevieve SEZE(1),Claudine Vanbauce(2), Jean-Claude Buriez(2), Frederic Parol(2),Pierre Couvert(3); (1)Laboratoire de Metorologie Dynamique du CNRS; (2)Laboratoire d'Optique Atmosphrique Universite des Sciences de Lille; (3)Laboratoire de Modelisation du Climat

The POLDER instrument that was aboard the Japanese ADEOS platform between August 1996 and June 1997, is designed to the global observation of the polarization and directionality of the sunlight reflected by the earthatmosphere system. The cloud detection from POLDER takes advantage of the original capabilities of the instrument (spectral polarization and directionality). This cloud scheme uses 5 threshold tests based on pressure, reflectance, polarized reflectance, spectral variability. The results of the POLDER cloud detection scheme are compared to those of the LMD dynamical clusrtering method applied to visible and infrared METEOSAT data and local spatial variability of these two parameters. Special focus is given to the detection capabilities of the two kind of measurements for cloud situations such as small cumulus, thin cirrus. Is shown also the interest of combining the two kind of measurements to improve the indentification and separation of cloud types such as low clouds, middle clouds , multi-layer clouds, thick cirrus, high convectif clouds, is shown. Results of this comparison will give some insight on the behavior of the International Satellite Cloud Climatology (ISCCP) built mainly from visible and infrared measurements.

THE NATURE OF ARCTIC CLOUD SYSTEMS

D. HUDAK, B. Currie, R. Stewart, and V. Kezys (Atmospheric Environment Service, 14780 Jane Street, King City, Ontario L7B 1A3 Canada. E-mail: David.Hudak@ec.gc.ca Telephone No: 905-833-3896,x242 Fax No: 905-833-0398)

The Mackenzie GEWEX Study (MAGS) represents the Canadian contribution to the international GEWEX effort. It involves a coordinated series of process, remote sensing, and modelling studies within the Mackenzie River Basin, a high latitude, cold region climate system. The McMaster University IPIX radar, a portable X-band, polarized, Doppler radar with high sensitivity, was deployed in the middle of the basin at Fort Simpson, NT, as part of the remote sensing studies on MAGS. The role of the IPIX radar was to take the necessary observations that will contribute to i) the quantification of the atmospheric component of the hydrological cycle; ii) the development of new observing techniques that combine surface and satellite based sensors; and iii) the improvement in regional climate models. To that end, a series of observational campaigns each lasting about three weeks took place during the fall, winter and spring of 1998/99.
Preliminary analyses included extended time height representations of radar intensity and vertical Doppler velocity for cloud systems that originated in both the Pacific and the Arctic Oceans from each of the three seasons. The descriptions of these cloud systems included the degree of layering, the cloud top height, and an assessment of their horizontal homogeneity and predominant precipitation formation mechanism. This information was combined with AVHRR data from the NOAA polar orbiting satellites to characterize the typical cloud systems. These findings were compared with objective analysis fields from the Canadian Meteorological Centre Global Environmental Multiscale model. An assessment of the ability of the model to replicate the essential features of these systems was then made.
An improved understanding of these cloud systems and the role they play in the global climate system is expected to be derived from this study.

ANALYSIS OF ERRORS IN RETRIEVALS OF CLOUD OPTICAL THICKNESS AND DROPLET SIZE IN 3-D CLOUD FIELDS

K-S KUO and R. M. Welch, Department of Atmospheric Science, University of Alabama in Huntsville

Cloud optical thickness and droplet size are retrieved from satellite imagery by assuming that plane-parallel approaches are valid. However, broken cloud fields produce reflected radiances which are significantly different from those produced by the plane-parallel assumption. The 3-D Picard Iterative method is used to simulate the radiances produced by broken cloud fields. Then cloud optical thickness' and droplet sizes are retrieved from these radiance values using the standard plane-parallel retrieval scheme. Resulting cloud optical thickness' are underestimated from the true values, while droplet sizes are overestimated. Results will be shown for a number of cloud field simulations in terms of cloud size, cloud cover and cloud aspect ratios. Even with these cloud property retrieval errors the important question is to what extent the resultant radiative fluxes from the cloud field are altered. To answer this question, radiative fluxes derived from the retrieved values are compared with those fluxes derived from the actual cloud properties. It is found that significant errors (in W/m2) occur in broken cloud fields.

THE IMPACT OF ADVANCED TOVS DATA ON NUMERICAL WEATHER PREDICTION

Caroline POULSEN, Andrew Collard, Paul Dibben, Steve English, Peter Rayer, Richard Renshaw, Andrew Smith, (all at UK Met. Office, London road Bracknell, RG12 2SZ)

Radiance observations measured by infrared and microwave radiometers on polar-orbiting satellites are used by assimilation schemes of numerical weather prediction models to provide a more accurate three-dimensional analysis of temperature and humidity in data sparse regions. In May 1998 the Advanced TOVS instrument was launched on NOAA-15 as a replacement for the TOVS system which had operated on a succession of NOAA satellites since 1978. The Advanced Microwave Sounding Unit is the main difference between Advanced TOVS and TOVS. It has twelve temperature sounding channels, three humidity sounding channels and five window channels which can also provide information on lower tropospheric water vapour. The main purpose of the Advanced Microwave Sounding Unit is to provide temperature and humidity information in cloudy areas. The observed brightness temperatures have been compared with brightness temperatures calculated using the numerical weather prediction model background (a short range forecast). This has shown we can model these channels very accurately, typically achieving standard deviations of the difference between observed and modelled brightness temperatures of 0.2-0.5K for mid tropospheric channels. The radiances have been assimilated into a 3DVAR assimilation scheme in the form of retrievals generated using a 1DVAR method. The direct assimilation of the radiances themselves has also been tested. The differences between observed and modelled brightness temperatures and the results of the assimilation experiments will be presented.

NEURAL NETWORK BASED SATELLITE SCATTEROMETER FORWARD AND INVERSE MODELS

Dan CORNFORD and Ian T Nabney (Neural Computing Research Group, Aston University, Aston Triangle, Birmingham B4 7ET, UK, Email: d.cornford@aston.ac.uk)

Satellite scatterometer forward sensor models, relating wind vectors over the ocean to the backscatter measurements, such as CMOD4, are generally based on highly parameterised statistical models. Even the physically based models, such as VIERS-1, are significantly calibrated from observational data. We propose an alternative, dual approach to the retrieval of scatterometer winds. We describe the development of a hybrid forward model, which combines the physical knowledge incorporated in CMOD4 with the flexibility of neural networks. A Bayesian framework is adopted to train the networks accounting for the 'input noise' on the Numerical Weather Prediction (NWP) model wind vectors and this significantly improves the model. However, inversion of forward models is generally computationally expensive. We show how neural network based methods can be used to create local, direct inverse models. We compare the results of local wind vector retrieval from our forward and direct inverse models with those from CMOD4. We then indicate an appropriate framework for the use of the local models for wind field retrieval and contrast the results of wind field retrieval with local wind vector retrieval.

THE SURFACE AND ATMOSPHERIC RADIATION BUDGET: VERTICAL PROFILES OF FLUXES RETRIEVED BY CERES FOR JANUARY 1998

Fred G. ROSE (A.S.&M., Suite 300, 1 Enterprise Parkway, Hampton VA 23666, Email: f.g.rose@larc.nasa.gov), Thomas P. Charlock (NASA Langley Research Center, Mail Stop 420, Hampton, Virginia 23681, USA, Email: t.p.charlock@larc.nasa.gov), and Jean-Jacques Morcrette (ECMWF, Shinfield Park, Reading, Berkshire, England, Email: pam@ecmwf.int)

The surface and atmospheric radiation budget (SARB) has been retrieved by applying a variational analysis which incorporates broadband CERES data at the top of the atmosphere (TOA), temperature and humidity profiles from ECMWF, cloud optical properties from the VIRS imager, and the Fu-Liou radiative transfer code. The analysis constrains (adjusts) surface temperature, humidity profile, aerosol optical depth, cloud top altitude, cloud fractional area, cloud optical depth, surface albedo, and the TOA broadband fluxes. The initial cloud properties were retrieved with Minnis' technique, which uses numerous VIRS pixels within the larger CERES footprints. Our broadband radiative transfer calculations are iterated at each footprint. The analysis to date covers January 1998 for 35N-35S.SW and LW fluxes were retrieved and archived at the surface, 500 hPa, 200 hPa, 70 hPa, and TOA. The ensemble mean adjustments produced mean reductions of 0.192 K in skin temperature, 0.006 cm in precipitable water, 0.002 in surface albedo, 0.006 in aerosol optical depth, 0.821 in cloud optical depth, 1.527 K for cloud top temperature, and 0.01 in cloud fraction. The first results were biased. We are revising our algorithm to reduce the biases.
One revision incorporates the CERES broadband LW and 8-12 micron window channels, making separate adjustments for upper and lower tropospheric humidity. Results with the revised algorithm will be shown at IUGG.

VALIDATED SURFACE RADIATION INFERRED FROM METEOROLOGICAL SATELLITE DATA

Franz H. BERGER (Dresden University of Technology, Institute of Hydrology and Meteorology, Piennerstr. 9, D-01737 Tharandt, Germany. email: berger@forst.tu-dresden.de)

For episodes (with periodes up to two months) within a few experiments in Europe, like BALTEX, RESMEDES, LITFASS and MAP, meteorological satellite data could be analysed. The analysis of NOAA-AVHRR and Meteosat data included a detailed cloud classification, the determination of cloud optical properties, and the computation of surface radiation. Concerning the surface radiation all radiation components could be inferred. The analysis of surface radiation as well as of cloud optical properties is based on an inverse remote sensing

technique, where intensive calculations of atmospheric radiative transfer could be carried out in advance. These calculations consider all relevant atmospheric (temperatur and humidity profiles, aerosol content in the PBL) and geometrical (solar zenith angle, satellite viewing angle) conditions.
After the computation of surface radiation from remotely sensed data, different validation with ground based observations could be done. And this validation show a general slight underestimation of the inferred satellite radiation with respect to the ground based measurements. More detailed results (correlation, variances) will be given. Thus, diurnal variations of surface radiation for the experiment periods will be presented, which show the influence of individual clouds on the surface fluxes. A comparison with modelled surface radiation, carried out with the regional model REMO, will close this contribution.

A STUDY OF RELATIONSHIP BETWEEN SATELLITE DERIVED CLOUD PROPERTIES AND PRECIPITATION.

Muloshi, Department of Meteorology, P.O.Box 30200, Lusaka 10101, ZAMBIA, Telefax: (+260-1) 251889, E-mail: zmd@zamnet.zm

The satellite sub-system constitutes a part of the WWW Global Observing System. Information is received from near- polar orbiting and geostationary satellites. Current observations from these satellites provide information about the most important meteorological elements, such as cloud and wind fields, location of precipitation areas and their intensity and components of radiation balance just to mention a few. The information received from these satellites by interpreting images have been important to meteorologists and have proved to be of immense value to operational weather forecasting, agro-meteorological research and many other environment monitoring applications.At Zambia Meteorological Department, one of the application of the satellite information is in rainfall estimation by correlating Cold Cloud Duration (CCD) information at a given threshold temperature on daily or 10 days basis with observed rainfall measured using standard rain gauge. This is more useful in areas which are not accessible or the density of the standard rain gauge is very low.This paper presents a statistical analysis of the relationship between CCD values in hours and measured rainfall (mm) at 10 meteorological stations in Zambia. The data studied is for the three decades of November to April for a period of four years (1992 - 1996).The correlation method employed in this study revealed a significant positive value of r = 0.99 for all the stations. The result seems to suggest that a strong relationship exists between the CCD images and rainfall. Least square regression shows that the increase in the amount of CCD values at a given temperature threshold corresponds to an increase in rainfall.

PRINCIPAL COMPONENT ANALYSIS FOR RAINDROPS AND ITS APPLICATION TO THE REMOTE SENSING OF RAIN

JONATHAN MEAGHER(MS 300-227, Jet Propulsion Lab, 4800 Oak Grove Drive, Pasadena, CA 91109-8099,USA, email: meagher@radar-sci.jpl.nasa.gov)Ziad Haddad(MS 300-227, Jet Propulsion Lab, 4800 Oak Grove Drive, Pasadena, CA 91109-8099, USA, email: zsh@titan.jpl.nasa.gov)

In the problem of inverting remote-sensing measurements of rain, current representations of the raindrop size distribution (DSD) suffer crucially from the expedient but unjustified and empirically ill-fitting assumption that the distribution has a known closed-form shape.Indeed, statistical tests for goodness of fit have repeatedly failed to support the assumption that the sampled drops are consistent with a Gamma or lognormal distribution. The Gamma and lognormal fits are especially bad when large drops occur, and in cases where the DSD exhibits peaks at two or more drop diameters. This produces biases in subsequent estimates of the rain.Yet fitting the DSD with a closed form expression does conveniently reduce the entire description of the rain to the knowledge of two or three parameters. One approach to obtain such a description without bias would be to discretize the range of drop diameters and use as DSD variables the numbers of drops in each discrete size bin. The drawback is that this requires a few dozen parameters to characterize a DSD. Grouping adjacent size bins into single variables is counter-productive since it drastically increases the resulting error. Using a "principal-component" analysis, we identify those four linear combinations of the equivalent-liquid-water in the drop size bin which embody the essential description of the DSD. Moreover, being eigenvectors of the covariance matrix, these four arameters are mutually uncorrelated.This characterization of DSDs using four parameters appears quite robust. The results obtained using a ground distrometer did not differ significantly from those obtained using airborne probes, in spite of the vastly different measurement uncertainties, implying that this description can be used for rain aloft and near the surface. Moreover, the horizontal autocorrelation shows that three of the four variables can be assumed constant on small spatial scales.

THE EVOLUTION OF AVHRR-DERIVED TEMPERATURES OVER BOREAL LAKES FROM BREAKUP TO FREEZE-UP

Normand Bussières (Climate Processes and Earth Observation Division, Climate Research Branch, Environment Canada, 4905 Dufferin St., Downsview, Ontario, Canada, M3H 5T4, Normand. email: Busières@ec.gc.ca)J. Ian McPherson (Flight Research Laboratory, Institute for Aerospace Research, National Research Council Canada, Room 223, Building U-61, Ottawa, Ontario, Canada, K1A 0R6, email: Ian.Macpherson@nrc.ca)

Thermal IR observations were extracted from NOAA AVHRR satellite data over the period from April 1st, 1994 to August 31st, 1994. These were collected in order to set up the lake temperature boundary conditions for a land surface model. The IR temperatures were calibrated and atmospherically adjusted for the intervening atmosphere. For each of these days, polar stereographic scenes of temperatures were generated for a 1000 km by 1000 km rectangular region extending from about 111oW, 60oN over the Northern part of the Canadian Province of Alberta to about 97oW, 50oN in Southern Manitoba. The average daytime variance of the daily AVHRR-based water surface temperature estimations under cloud-free conditions is 2 oC. Independent aircraft data confirms the validity of the AVHRR-based temperature estimates. There are 134 water bodies of area larger than 100 km2. The temperature cycle over these water bodies can give an accurate estimation of break-up date, which can serve to complete other types of data sources like passive microwave observations of the larger lakes.

STUDY OF VERTICAL VELOCITIES WITH THE MU RADAR MULTIBEAM/INTERFEROMETRY OBSERVATIONS

N.KAWANO, M. Yamamoto and S. Fukao (Radio Atmospheric Science Center, Kyoto University, Uji, Kyoto 611-0011, Japan, Email: kawano@kurasc.kyoto-u.ac.jp)

Atmospheric radar observations are useful for the wide height range and continuous observations. The Doppler technique is utilized as a standard technique. However, there are reports of possible errors of vertical velocities determined as Doppler velocities in a vertical beam if turbulent layers are tilted. It is also reported that such error in the vertical velocity could be corrected by measuring the tilt angle of turbulent layers with the interferometry technique. Based on some more data from the multibeam/interferometry observations with the MU radar, behavior of the vertical velocity fields and its relationship to such anisotropic scattering layers will be discussed.

ESTIMATIONS FROM SYNERGY OF ACTIVE AND PASSIVE MICROWAVE SENSORS ONBOARD TRMM

Peter Bauer German Aerospace Center, Linder Höhe, 51147 Köln, Germany phone: (+49) 2203 601 2995, fax: (+49) 2203 68309, email: peter.bauer@dlr.de

New rainfall retrieval was developed aiming at optimization of accuracy and computer efficiency considerations to be applied to the Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI) and the Precipitation Radar (PR) over oceans. The technique involves single sensor retrievals and their combination to provide the retrieval accuracy introduced by the PR on the narrow swath (220 km) and its transfer to the TMI-retrievals on the broad swath (760 km). For the PR-estimates the TRMM standard product 2A25, i.e., rainrate profiles, were used. The TMI-component is based on extensive, three-dimensional radiative transfer simulations through various cloud systems obtained from dynamical cloud models which form the database for the inversion procedure. The retrieval comprises (1) the deconvolution of the TMI 10.7 GHz channel to provide better surface resolution and signal dynamic range; (2) the inclusion of local estimates of surface conditions (SST, near-surface wind speed) and zenith angle; (3) the derivation of additional parameters such as effective sensing altitude where retrieval accuracy is maximized; (4) the non-linear calibration of TMI- by PR-estimates on a unified resolution across the narrow swath; (5) the calibration of TMI-estimates on the wide swath; (6) application to case studies as well as large data amounts allowing climatological analyses. The outline of the algorithm and its major features as well as some aspects of database generation will be presented. Various inversion principles such as multiple linear regressions, a neuronal network, and database search routines are intercompared. The algorithm performance is demonstrated by examples from TRMM data covering various meteorological situations and geographical regions. Major error sources seem to be introduced by the database rather than the retrieval procedure. Particle size distributions, ice microphysics, and inhomogeneous particles are candidates which require attention when better algorithm performance is sought.

A COMBINED SATELLITE INFRARED AND PASSIVE MICROWAVE TECHNIQUE FOR ESTIMATION OF SMALL SCALE RAINFALL OVER THE GLOBAL TROPICS AND SUBTROPICS

MARTIN TODD (School of Geogrpahy, University of Oxford, Mansfield Road, Oxford, OX1 3TB,U.K, email: martin.todd@geog.ox.ac.uk) Dominic Kniveton (Department of Geography, University of Leicester, Univesity Road, Leicester, UK, email: drk5@le.ac.uk)

The accurate estimation of rainfall at small spatial and temporal scales (0.5 degree or less/daily and below) presents problems for satellite based methods. Passive (PMW) and active microwave (rain radar) algorithms are able to provide accurate estimation of instantaneous rainrates, but the poor temporal sampling of low earth orbiting satellites makes them most suitable for estimation over longer periods of perhaps a month. In contrast, infrared (IR) satellite algorithms benefit from the high temporal sampling of geostationary satellites, but IR radiances from cloud tops have only a weak, indirect relationship with surface rainfall. Accordingly, many simple IR algorithms rely on the effects of scale averaging to improve accuracy.
Whilst global satellite (and merged) precipiation products at monthly/2.5 degree resolution are now routinely available, there is an absence of rainfall information at smaller scales, over extended periods for the globe as a whole. There are numerous applications in climatology where accurate information of this kind would be invaluable. Only since 1996 have daily/1 degree satellite IR products using the Goes Precipitation Index been archived. Here we introduce a technique which combines the information content of both satellite IR and PMW data. Rainfall estimates are produced at the high temporal frequency of the IR data using rainfall information from the PMW data. The technique first uses coincident instantaneous PMW and IR observations over a 1 month period to calculate at each 0.5 degree grid cell (a) an optimum IR temperature threshold to identify rainfall and (b) the conditional rainrate. These variables are then applied to each hourly IR slot over the entire month period. Unlike existing IR algorithms therefore the IR threshold and rainrate parameters are spatially and temporally variable. The results of a validation exercise are presented.

CORRECTION OF RADAR SURFACE RAINFALL ESTIMATES FOR THE EFFECTS OF THE VERTICAL PROFILE OF REFLECTIVITY USING TYPICAL SHAPE FUNCTIONS

Warren Gray and Michael Uddstrom (National Institute of Water and Atmosphere, PO Box 14 - 901,Wellington New Zealand, Email: w.gray@niwa.cri.nz)

As the distance from the radar increases, so does the height at which radar samples rainfall. Variations in the relationship between these observations aloft and the rain rate at the ground need to be accounted for if good estimates of surface rain rate are to be formulated. A hypothesis was formed that a few typical shapes can describe the variations in the vertical profile of reflectivity and that these shapes are useful in estimating the surface rain rate. An archive of radar volume scan information was formed from data interpolated on to 10 constant height levels at 250m intervals. The heights were chosen so that the melting layer always lay at height level 6. Five typical shape functions (TSF) classes were found in the vertical profile of reflectivity archive. Bayesian equations were formulated that related the observations aloft to the shape class. Linear equations were found which relate the observations aloft to surface reflectivity for each TSF class. The results showed that 62% of the dependent sample was

correctly classified into its TSF class. This approach increased the variation of the surface reflectivity explained by observations aloft from 59.5% to 77.4%. An assessment of the skill of the surface rainfall estimate was also produced.

NEW METHODS FOR RETRIEVAL OF RAINFALL RATE WITH SSM/I DATA

Daren LU,Haibing Sun,Jianchun Bian, Hongbin Chen, Jinli Liu, Mingzhen Duan,(Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029,CHINA, e-mail: ludr@sun.ihep.ac.cn)

Space-borne microwave (MW) remote sensing of rainfall distribution with multi-channel radiometers has been proved as a powerful tool in past decade, in particular with DMSP's SSM/I and recently TRMM data. Similar instruments but with different channel combinations, such as ADEOS-II/AMSR are being developed. Although there have been several schemes used for research and operational application, improvement of retrieval accuracy is still an important subject. As part of a NASDA project for ADEOS-II/AMSR retrieval algorithm development and Chinese National High-tech R&D program for space Technology, we proposed two kinds of retrieval algorithms for rainfall rate over ocean and land with SSM/I data. The first kind of algorithm is based on probability pairing method, in which three different retrieval rain indices composed with different combination of SSM/I's channels are used as pairing indices with surface rainfall rate data provided by NASDA, Japan. Three different empirical rainfall rate- rain index relationship are produced. The second kind of algorithm is based on the method of self Organization feature Mapping(SOM), a kind of artificial neural network(ANN). SSM/I data and co-located surface rainfall data are put into SOM and clustering procedure is self-trained. After training, 154 clustering centers are formed and for each cluster a regressive relationship between retrieved rainfall rate and SSM/I data is established. In this paper, these two kinds of algorithm are briefly reviewed with their developments and validation. Comparison of these retrieved methods and with other published methods are discussed.

TRMM PRECIPITATION RADAR (PR) GROUND VALIDATION USING GROUND BASED DATA FROM JAPAN

Riko OKI, Kinji Furukawa and Misako Kachi (Earth Observation Research Center (EORC), National Space Development Agency of Japan (NASDA), 1-9-9 Roppongi Minato-ku, Tokyo 106-0032, Japan, email: riko@eorc.nasda.go.jp)

The Precipitation Radar (PR) on the Tropical Rainfall Measuring Mission (TRMM) satellite is the first space-borne precipitation radar that can observe the three-dimensional structure of rainfall over the tropics. Ground validation of the PR using ground based data from Japan and its results are presented in this paper.
In the Ishigaki-Miyako Campaign Experiment for TRMM (IMCET), several simultaneous observations were conducted by the PR and Japan Meteorological Agency (JMA) 's ground-based radars. Horizontal and vertical patterns of radar reflectivities obtained by those different radars agreed well. In addition to the radar reflectivity, estimated rain rates are compared with rain rates estimated from ground-based radar and rain gauges. Rain rates estimated by the standard algorithm (2A25) appear to be reasonable in spatial patterns, compared with rain rates obtained from JMA's Radar-AMeDAS and AMeDAS rain gauges. To compare AMeDAS rain gauges and 2A25 rain rates, both data were averaged in 0.5 degree by 0.5 degree boxes respectively. A seasonal dependency of rain intensity estimated by 2A25 is found. That is, in winter PR rain rates are higher than rain gauges, however the 2A25 algorithm seems to estimate rain rate lower than rain gauges especially in summer. In winter, there is a possibility that estimated rain rates were affected by bright bands. Also a comparison of rain amount in climatological sense will be reported.

A MICROPHYSICALLY BASED IR NIGHTTIME METHOD TO DELINEATE RAINFALL IN CLOUDS WITH TOPS WARMER THAN 245K

ITAMAR M. LENSKY, Atmospheric Science, The Hebrew University, Jerusalem, Israel. email: itamarl@cc.huji.ac.il ; Daniel Rosenfeld, Atmospheric Science, The Hebrew University, Jerusalem, Israel. email: daniel@vms.huji.ac.il

The Tropical Rainfall Measuring Mission (TRMM) data have been used for developing and validating a microphysically based method to delineate precipitating clouds with tops that are warmer than the temperature at which much ice and thus precipitation always develops in optically thick clouds. That temperature threshold is 245K. Optically thick clouds with colder tops have been identified as precipitating by the currently available VIS/IR methods. The existence or lack of precipitation processes near the top of the clouds is inferred from the 3.7 micron emissivity of their tops. Clouds with small particles have low emissivity. Such clouds also typically are devoid of precipitation forming processes. An algorithm, based on the 3.7, 10.8 and 12.0 micron channels of the TRMM VIRS (Visible IR Scanner) is using that principle to delineate the precipitating clouds.
That algorithm was developed as part of the package for the Global Imager (GLI) onboard the ADEOS-2 satellite, for NASDA. Therefore, the algorithm is named hereafter the "GLI" algorithm. Results of the GLI rain algorithm were validated against the actual measurements of precipitation by the TRMM precipitation radar (PR). The performance was compared to that of the TRMM microwave imager (TMI) rainfall delineation.
The GLI algorithm detected significant amount of precipitation that the TMI missed, especially over land in the mid-latitude, but not exclusively. The GLI algorithm correctly detected non-precipitating microphysically continental clouds over sea, which the TMI falsely identified as precipitating. This was found often over the Mediterranean Sea. The added microphysical information from visible/IR sensors, in both day and nighttime, is potentially valuable for cloud radiative and precipitation parameterization, and for improvement of rainfall measurements from space.

COMPARISON OF ECMWF MODEL CLOUD COVER WITH RADAR DERIVED VALUES

Robin Hogan (Department of Meteorology, University of Reading, UK; email: R.J.Hogan@reading.ac.uk), Christian Jakob (ECMWF, Reading, UK), Anthony Illingworth (Department of Meteorology, University of Reading, UK)

Clouds represent one of the major uncertainties in climate modelling. The limited resolution available to global climate models means that clouds cannot be resolved explicitly and it is necessary for some estimate of the sub-gridscale fluctuation of cloudiness to be included in radiative transfer calculations. However there is little physical basis behind the diagnosis of cloud cover from prognostic model variables, and errors in model radiative fluxes are often blamed on poor model cloud cover. It is therefore vital for climate simulations that this parameter can be calculated accurately. Previous attempts to validate the cloud cover in the ECMWF model have used AVHRR data to estimate the total cloud cover for a model gridbox through the whole depth of the atmosphere, but there is clearly a need for vertically-resolved observations of cloud cover to be used to perform the validation at each model level. In this study, ECMWF cloud cover is compared with that derived by three active instruments located at Chilbolton, England, for a month-long period. Throughout most of the depth of the atmosphere one of two cloud radars (operating at 35 and 94 GHz) is used, but in the lowest 500 metres where ground clutter and leakage from the transmit pulse can be a problem, we use data from a lidar ceilometer.

MI06/W/28-B2 0950

PROFILING CLOUD LIQUID WATER BY COMBINATION OF A CLOUD RADAR AND A PASSIVE MICROWAVE RADIOMETER

Ulrich LOEHNERT (Meteorologisches Institut der Universitaet Bonn, Auf dem Huegel 20, 53121 Bonn, Germany, Email: uloeh@uni-bonn.de) Andreas Macke (Institut fuer Maritime Meteorologie Kiel, Duesternbrooker Weg 20, 24105 Kiel, Germany, Email: amacke@ifm.uni-kiel.de)

To derive cloud liquid water profiles (LWC) a combination of a cloud radar and a passive microwave radiometer is proposed. A cloud radar can measure radar reflectivities (Z) with an accuracy of -30 dBZ in 10 km distance, but conventional algorithms for LWC based on Z alone show errors of up to an order of one magnitude. Collocated measurements of integrated cloud liquid water (ILW) (10 - 20 % relative accuracy) with a dual-channel microwave radiometer can, together with a cloud radar, provide a constrained estimate of the LWC profile. Previous studies of the Z-LWC relation have used eitherfixed or statistically varied drop size distributions. In this work a 1.5-dimensional dynamic cloud model is used to investigate the dynamical dependencies of the Z-LWC relationship. The spectral model, which calculates drop size spectra prognostically, allows a detailed study of the statistics of the Z-LWC relationship concerning height and time, which can prove valuable in algorithm development. Difficulties arise in mixed-phase clouds and precipitation, where scattering and attenuation become difficult to handle. First collocated measurements of the 95 GHz polarimetric cloud radar MIRACLE (GKSS, Geesthacht, Germany) and corresponding values of ILW of the dual-wavelength (20/30 GHz) RESCOM radiometer (Institute for Marine Sciences Kiel, Germany), which are currently being recorded, will be shown.

LIDAR/RADAR REMOTE SENSING OF CLOUD PARTICLE EFFECTIVE RADIUS DURING CLARA

DAVID P. DONOVAN, A.C.A.P. Van Lammeren, H.R. Bloemink, A. Feijt (Royal Netherlands Meteorological Institute (KNMI), Postbus 201, 3730 AE, De Bilt, The Netherlands)

During 1996 three intensive cloud measurement campaigns were carried out in the Netherlands. The CLARA (CLouds And RAdiation) program was headed by the Royal Netherlands Meteorological Institute (KNMI) and involved participation from several other Dutch institutions and universities. During CLARA, cloud measurements were obtained using a ground-based 3 GHz radar system, several lidar systems, microwave and IR radiometers as well as an aircraft mounted FSSP particle size probe. The goal of the CLARA program was mainly to investigate the radiative effects of the clouds using the data obtained from the various diverse instruments.
It is well known that the scattering pro perties per unit mass for cloud particles can be well represented in terms of their effective radius. Since lidars and radars operate at very different frequencies they are capable of providing complementary information which may be used to infer the effective radius of the sampled cloud particle size distribution. In this presentation, a new procedure for determining effective radii profiles using a combination of microwave radar and near-infrared lidar measurements is outlined. Several examples of the application of this procedure to cloud measurements made during the CLARA campaigns are presented and compared to the results of in-situ FSSP-100 airborne particle probes.

REMOTE SENSING AND AIRCRAFT OBSERVATIONS OF PHASE AND SIZE OF PARTICLES DURING FIRE-ACE

I.GULTEPE, and G. A. Isaac (both at Atmospheric Environment Service, Cloud Physics Res. Div., Downsview, Ontario, M3H 5T4, Canada, e-mail: ismail.gultepe@ec.gc.ca and george.isaac@ec.gc.ca); R. Hoff, and K. Strawbridge (both at Atmospheric Environment Service, Air Quality Proc. Res. Div., Downsview, Ontario, M3H 5T4, Canada, e-mail: ray.hoff@ec.gc.ca and kevin.strawbridge@ec.gc.ca); D. L. Michell (Desert Research Institute, Reno, NV 89506, USA, e-mail: mitch@dri.edu); A.Macke (Institut fuer Meereskunde, Abt. Maritime Meteorologie, Duesternbrooker, Weg 20, 24105, Kiel, Germany, e-mail: amacke@ifm.uni-kiel.de)

In this study, observations collected during the First International Satellite Cloud Climatology Project (ISCCP) Regional Experiment -Arctic Cloud Experiment (FIRE-ACE) which took place over the Arctic Ocean during April 1998 were utilized. Measurements from aircraft microphysical probes, an Arizona radiometer, a LANDSAT simulator, a simultaneous upward/downward lidar with depolarization capability, and LANDSAT were used to understand phase separation, and particle size estimation in the Arctic clouds. Five individual cases, representing different microphysical characteristics, were analyzed. Each case had either mixed phase or one phase. Cases of liquid phase were mostly observed when aircraft were over the leads or polynya. Aircraft microphysical data obtained by the hot-wire probes, Rosemount icing detector, the Particle Measuring Systems (PMS) forward scattering spectrometer probe (FSSP) and 2 dimensional cloud (2D-C) probes indicated water and ice regions. Using information from different channels e.g. near infrared (1.6 and 2.21) and visible channel (0.83) in the various remote sensing platforms, particle size and phase of the particles were obtained. Near-infrared channels have lower reflectance compared to those of visible channels. Arizona radiometer, LANDSAT simulator, and lidar observations showed the open water surfaces that were likely the source of warm and moist air. Results showed that in-situ cloud microphysical information obtained using various platforms were comparable with those of the remote sensing platforms. Theoretical calculations using a Monte-Carlo radiative transfer model will also be made for further validation of the observations, and summary of the results related to climate change studies will be given.

AEROSOL AND CLOUD PROCESS STUDIES USING AIRBORNE LIDAR OBSERVATIONS OF STRATOSPHERIC CLOUDS - NEW TECHNIQUES AND FUTURE APPLICATIONS

KENNETH S. CARSLAW (Environment Centre, University of Leeds, Leeds LS2 9JT, UK. E-mail: carslaw@lec.leeds.ac.uk). Th. Peter, A. Tsias, T. Trautmann, B.P. Luo (Max Planck Institute for Chemistry, Mainz, Germany) M. Wirth, W. Renger (Deutsche Forschungsanstalt fur Luft- und Raumfahrt, Oberpfaffenhofen, Germany)

Lidar observations can yield detailed optical information, such as backscatter ratio and depolarisation properties, of atmospheric aerosols and clouds. However, it is often difficult to convert such measurements into microphysical information, such as particle sizes, which are needed to validate atmospheric models.
We describe a technique for probing polar stratospheric clouds with dual wavelength airborne depolarisation lidar, combined with optical and microphysical model simulations, which can yield detailed information on the evolution of individual cloud elements. The technique has so far been restricted to stratospheric aerosols and clouds, but could also be applied to thin cirrus. The technique is based on quasi-Lagrangian observations of small scale clouds (i.e, with the aircraft heading parallel with the wind at the level of the cloud). Microphysical properties of the clouds, such as particle sizes, aerosol growth and ice nucleation conditions, are then derived by combining an optical simulation of the lidar signal with a microphysical model in an iterative procedure.
We have so far appiled this new technique to interpret measurements made with the DLR OLEX lidar on board Transall and Falcon aircraft during two Arctic ozone and aerosol campaigns. Our interpretation of lidar data has yielded unprecedented information on polar stratospheric cloud properties. Important results include a determination of ice particle number densities in mother-of-pearl clouds and the first determination of the supercooling required to form such clouds.

MULTIWAVELENGTH LIDAR OBSERVATIONS OF THIN CLOUDS AND AEROSOLS

SATYANARAYANA. M., Ramakrishna Rao. D, Mohankumar., S.V., Presennakumar. B., Sreelatha. P. and Veerabuthiran. S. (Atmospheric Lidars Branch, Space Physics Laboratory, Vikram Sarabhai Space Centre, Trivandrum - 695 022, India, email: spl_vssc@vssc.org)

This paper describes a pulsed monostatic high resolution Multiwavelength Lidar (MWL) system designed and developed for use in detailed scientific studies on clouds, atmospheric aerosols, ozone and temperature variations (upto 70 km) at a tropical station Trivandrum (Geog. Lat. - 8.6øN, Geog. Long. - 77øE) India. Nd:YAG laser is the main transmitting source operating at wavelengths 1064 nm, 532 nm, 355 nm and 266 nm with a pulse energy of about 600 mJ at 532 nm. The backscattered signals are received using a 500 m Cassegrain telescope. To obtain usable data upto 70-80 km, both the analog and photon counting modes of data acquisition have been incorporated in the system. Further, the PC based Data Acquisition System (DAS) has a two step digitization scheme with 8 bit resolution and a maximum sampling rate of 100 MSPS in the analog mode. The MWL system can also be used in the polarization lidar mode by using suitable polarizers in the receiving system. Scientific observations on the simultaneous measurement on aerosols and thin clouds made for about 15 days spread over 3 months using the above system will be described. A new lidar inversion technique developed for obtaining extinction coefficient of both aerosols and clouds will be presented. Preliminary results on the characteristics of clouds and aerosols at this tropical coastal station are presented.

USE OF DIFFERENT PHASE FUNCTIONS TO RETRIEVE THE POLDER DIRECTIONAL OPTICAL THICKNESS

M. DOUTRIAUX-BOUCHER, J.-C. Buriez, L. C.-Labonnote, G. Brogniez (Laboratoire d'Optique Atmospherique, Universite des Sciences et Technologies de Lille, Villeneuve d'Ascq, France, e-mail: mdoutri@loa.univ-lille1.fr) A. J. Baran (UK Meteorological Office, Bracknell, Berkshire, England)

POLDER uses an original concept to observe clouds and their properties.Angular reflectance measurements obtained from the POLDER instrument are used to retrieve, for each scene, the cloud visible optical thickness. POLDER also has a capability to distinguish between liquid and ice clouds from polarisation measurements. The algorithm presently used to retrieve cloud properties can be improved. Especially, in the present version of the algorithm, cloud optical thickness is calculated assuming the cloud is composed of 10 micrometer droplets, without distinction between liquid and ice clouds. However, it is well known that the droplet size distribution may vary and that the single scattering properties of ice crystals differ substantially from those of liquid droplets. We test here the scattering phase functions of several cloud particle models, such as 5 micrometer cloud droplets, ice polycrystals, hexagonal monocrystals as well as a synthesised phase function fitted from aircraft observations, in order to retrieve ice cloud properties using the POLDER algorithm. We show that the directional cloud optical thickness measured by POLDER is very dependent on the cloud particle models chosen for the inversion.

HIGH RESOLUTION INFRARED SPECTRA OF ICE CLOUDS

R. J. Bantges, J. E. Russell, J. D. Haigh and C. Naud (All at Space & Atmospheric Physics, Blackett Laboratory, Imperial College, London SW7 2BZ, UK, email: r.bantges@ic.ac.uk)

High spectral resolution top of atmosphere brightness temperatures have been simulated in the infrared (600-2500cm-1) for an absorbing, emitting, multiple-scattering cirrus cloud placed in a realistic atmosphere. Single scattering properties of the ice crystals were calculated using Mie theory for spheres, ray-tracing optics for hexagonal columns and T-matrix method for spheroids. The sensitivity to a variety of assumptions concerning the cirrus cloud properties, (ice crystal sizes, shapes and size distributions) has been studied. Comparisons between simulations and data obtained from the High resolution Interferometer Sounder have been made. A statistical method has been applied to the simulated spectra to highlight wavelength combinations which may be used to exploit the retrieval of cirrus cloud properties from data anticipated from the next generation of spaceborne high resolution spectrometers, such as the Infrared Atmospheric Sounding Interferometer, due for launch on METOP-I in 2003.

MI06/W/19-B2 1230

OBSERVED EFFECTS OF CLOUD DROPLET CONCENTRATION ON ALBEDO FOR LOW-LEVEL CLOUDS USING SATELLITE DATA

Qingyuan Han(1), William B. Rossow(2), Joyce Chou(1) and R. M. Welch(1) (1)Department of Atmospheric Science, University of Alabama in Huntsville (2)NASA Goddard Institute fro Space Studies, New York, NY

This study presents retrieved effects of enhanced cloud droplet concentration on cloud albedo for low-level clouds on a near-global scale using ISCCP data. A new parameter, column cloud susceptibility, is introduced so that no assumptions of constant liquid water content and cloud geometrical thickness are required in the retrieval. This greatly reduces the uncertainties caused by these approximations. The results show that the cloud albedo sensitivity to the percentage change of cloud droplet concentration is more than two times larger than predicted by model calculations based on the assumption of constant liquid water path. Regions close to and within most continents are already saturated, so that cloud albedo is insensitive to cloud droplet changes. The derived relationships such as column susceptibility and column drop concentration, column susceptibility and cloud albedo, and the distribution of column susceptibilty can be used as a basis for model studies and guidance for selection of future field campaigns.

A STUDY OF THE DIURNAL CYCLE OF OLR WITH IMPLICATIONS TO ERBE AND CERES ANALYSES

ROBERT G. ELLINGSON, and Mamadou Ba (Department of Meteorology, University of Maryland, College Park, MD 20742, email: bobe@atmos.umd.edu)

A multi-spectral outgoing longwave radiation (OLR) estimation technique is being applied to GOES sounder data to study the diurnal cycle of OLR. Currently, all satellite-based OLR estimation techniques require the use of models of the diurnal cycle in order to estimate time-averaged OLR from any scene. In this study we use July 1998 hourly GOES sounder radiance observations with the Ellingson et al. (1994) multi-spectral OLR estimation technique to determine the instantaneous, daily- and monthly- averaged OLR from 100 square km scenes over North America and the adjacent Gulf of Mexico. The instantaneous data are compared with collocated data from the TRMM/CERES and NOAA-14 HIRS to establish the instantaneous accuracy of the multi-spectral estimation techniques for homogeneous scenes. The time-averaged data are used to estimate the accuracy of the ERBE/CERES and HIRS diurnal cycle models as applied to daily- and monthly -averaged products at different spatial resolutions. The presentation will concentrate on the effects of the uncertainties in the diurnal models on monthly-average OLR products at different spatial resolutions.

OUTGOING LONGWAVE RADIATION AND CLOUD RADIATIVE FORCING OF THE TIBETAN PLATEAU

WENYING SU, Jietai Mao, Fei Ji, Dept of Geophysics, Peking University, LSSR, Beijing, 100871

In this paper two years'GMS5 satellite data are analyzed to study the monthly mean outgoing longwave radiation (OLR) and the cloud radiative forcing (CRF) of the Tibetan Plateau. A method was developed to compute the OLR by using radiative transfer model DISORT together with the radiosonde profile of the Tibetan Plateau. Since the location of the Tibetan Plateau is nearly out of the effective observational range of the GMS5 satellite, the regression results of GMS5's split-window channels and the water-vapor channel are corrected by using simultaneous retrieved results from TOVS. The correlation coefficient between them is 0.8426. During winter season the OLR distribution exhibits low value over the Tibetan Plateau but high value for areas off the Tibetan Plateau and during summer season the OLR of the southern part is smaller than that of the northern part. The temporal resolution of GMS5 data which is one hour and can help us to study the diurnal variations of OLR. The diurnal variations of OLR are affected by diurnal cycles of cloud amount and surface temperature. The relief of the Tibetan Plateau is very high and the radiative heating is intense after sunrise, so the OLR is much influenced by the surface and reaches maximum soon after sunrise. But for the emergence time of minimum OLR it is varied. The monthly mean clear-sky components of OLR and albedo are obtained from the ISCCP cloud detection algorithm. The CRF over the Tibetan Plateau is negative most of the time which means the CRF is dominated by cooling effects and the distribution pattern is mainly determined by the shortwave CRF component. While the CRF to the southern and the northern of the Tibetan Plateau is different, it shows obvious annual variations which demonstrates heating effects in summer-autumn season and cooling effects in winter-spring season.

DATA ASSIMILATION

MI06/W/32-B2 1610

NEURAL NETWORKS AS A GENERIC TOOL FOR RETRIEVAL ALGORITHM DEVELOPMENT AND DIRECT ASSIMILATION

Vladimir KRASNOPOLSKY (EMC/NCEP/NOAA, 5200 Auth Rd., Camp Springs, MD 20746,USA, Email: kvladimir@ncep.noaa.gov)

Retrievals (geophysical parameters derived from the remote sensing satellite measurements) are used by operational meteorology, for assimilation into atmospheric and oceanic models, etc. Two different ways of producing retrievals from satellite remote sensing data are discussed. Variational retrievals (direct assimilation) use data assimilation systems of atmospheric or oceanic models to produce fields of retrieved geophysical parameters. Forward models (FM) which convert geophysical parameters into satellite measurements are required for variational retrievals.
Traditional retrievals use retrieval algorithms, which approximate the transfer functions (TF) of various satellite instruments, to convert satellite data into geophysical parameters.TFs can be estimate theoretically or/and empirically from observed or simulated data. Direct assimilation requires simple and fast FMs, whereas existing FMs are often too complex and slow. Because

both FM and TF can be considered as continuous mappings, and neural networks (NNs) are well suited to approximate continuous mappings, they can provide accurate mathematical models for a broad class of FMs and TFs. NN FMs are simple and fast, they are well suited for using in direct assimilation. NNs can also be used for accelerating existing FMs. A NN tutorial and approach to solving the forward and retrieval problems in satellite remote sensing are presented. NN are also well suited for multi-parameter retrievals, which advantages vs. single-parameter retrievals are discussed.
Recently developed NN SSM/I retrieval algorithm, which retrieves wind speed, W, columnar water vapor, V, columnar liquid water, L, and SST, using only satellite data, and NN SSM/I FM, which generates SSM/I brightness temperatures given W, V, L, and SST, are used for illustration. New NN TF and FM are compared with physically based and other empirical TFs and FMs.

MI06/E/08-B2 1630

A ONE DIMENSIONAL VARIATIONAL SCHEME FOR THE SIMULTANEOUS RETRIEVAL OF TEMPERATURE AND HUMIDITY INFORMATION FROM GPS RADIO OCCULTATION REFRACTIVITY PROFILES.

S.B.HEALY, Numerical Weather Prediction, Meteorological Office, Bracknell, Berkshire, United Kingdom, RG12 2SZ.

A one dimensional variational (1dvar) scheme for the simultaneous retrieval of temperature and humidity information from GPS radio occultation (RO) refractivity profiles will be outlined. The method combines information contained in the measurements with a priori (or background) data in statistically optimal way, in order to find the most probable atmospheric state. It will be demonstrated, using both simulated and real easurement data, that the "water vapour ambiguity" inherent in more conventional RO inversion techniques is resolved with this approach. Comparisons with alternative "sub-optimal" water vapour retrieval methods will be presented. Furthermore, it will be shown that the measurements can also provide significant surface pressure information.

ASSIMILATION OF SATELLITE DATA AND OBJECTIVE ANALYSIS

Willy S Goma, Zambia Meteorological Department, P.o Box 310095, Lusaka 15301, Zambia. Fax: (260)-1-251889 E-mail: zmd@zamnet.zm

Although Zambia lies entirely within the tropics , its weather is influenced to a large extent by the migratory synoptic systems of the southern mid-latitude (Mumba et...1984). During the wet season the main weather system responsible for rainfall occurrence in Zambia as a whole is the Inter-tropical Convergence Zone. In this regard Forecasting had continued in the past to be a problem in Zambia especially when it came to forecasting climatic anomalies e.g drought, floods and weather associated with synoptic features such as Angolan Low and easterly waves. Since most of the practical forecasting was mostly subjective, little progress had occurred. This was due to lack of upper air data from Zambia. As such we were relying on upper air data from our neighbouring countries. Secondly, it was due to lack of computing facilities. However, since then automation has been introduced in the department. The main weather systems considered in this discussion are the Inter-tropical Convergence Zone (ITCZ) and frontal systems in the Atlantic and the Indian Oceans. The satellite images and the corrosponding surface charts have been examined for similarities in position of the above mentioned weather systems. The objective of this paper is to examine satellite images and try to incorporate the inherent details into charts that have been objectively analysed and these charts may be either (a) the ECMF forecast data or (b) the real time surface chart. In the case of ECMF products it is important to find out if a link exits between the forecast position of the synoptic systems and that of the satellite image together with the actual real time surface charts depicted at a given time.

MI06/W/01-B2 1710

ASSIMILATING SATELLITE MEASUREMENTS OF CLOUD COVER IN THE REGIONAL ATMOSPHERIC MODEL SYSTEM (RAMS)

ISMAIL YUCEL, W. James Shuttleworth, and James Toth (all at Department of Hydrology and Water Resources, University of Arizona, Tucson, 85721, AZ, USA, Email: yucel@hwr.arizona.edu)

The goal of this study is to provide an improved, high-resolution regional diagnosis of three of the important controls on the land surface energy and water balance, namely the downward shortwave and downward longwave surface radiation fluxes, and precipitation. Cloud cover is a key parameter linking and controlling these three terms. An automatic procedure was developed to derive high resolution (4km X 4km) fields of fractional cloud cover from visible band, (GOES series) geostationary satellite data using a novel tracking procedure to determine the clear-sky composite image. In our initial data assimilation studies, the surface shortwave radiation fluxes calculated by RAMS were simply replaced by the equivalent estimated values obtained by applying this high-resolution satellite-derived cloud cover in the University of Maryland (UMD) GEWEX/SRB Model. However, the cloud cover simulated in RAMS remained unchanged and this lead to inconsistencies in areas modeled by RAMS as being cloud-free. Specifically, the modeled downward longwave fluxes retain their relatively low, clear-sky values rather than assuming higher values appropriate to cloud covered areas. In semi-arid areas such as Southern Arizona--the area used in this study--the difference in longwave radiation between cloud-free and cloud-covered areas can exceed 100 watts per square meter. A further important inconsistency is that RAMS can generate precipitation where the sky is clear. It was recognized that the UMD GEWEX/SRB Model and RAMS both use essentially identical descriptions of atmospheric radiative transfer. To diagnose shortwave radiation, both models use a multidimensional lookup table which is precalculated for fixed intervals of cloud optical depth, solar zenith angle, spectral band, total ozone and water vapor absorption, and both models assume the same relationship between optical depth and vertically integrated cloud water/ice. Recognizing these similarities, our research then focused on exploring the feasibility of directly assimilating cloud cover into RAMS by converting the measured fractional cloud cover (via cloud optical depth) into vertically integrated cloud water/ice. The potential advantages of this approach are that, not only is the surface solar radiation field better estimated, but RAMS may also be better able to diagnose the true spatial pattern of longwave radiation and precipitation. However, the procedure is complicated by the need realistically to distribute the cloud water/ice within the vertical profile for each modeled grid square. This paper describes our progress towards directly assimilating satellite-derived cloud cover into RAMS and validating the model-calculated surface fields against field data.

EXPERIMENTS ON THE ASSIMILATION OF TROPICAL CONVECTIVE RAINFALL ESTIMATES IN THE UKMO GLOBAL FORECAST MODEL

MARK RINGER (U.K. Met. Office, Bracknell RG12 2SZ, U.K.)

Results are presented from a set of experiments which aim to test the impact of assimilating satellite-derived estimates of tropical convective rainfall in the U.K. Met. Office's global numerical weather prediction model. The rainfall estimates are derived from infrared brightness temperatures using three different methods. The data are assimilated using a latent heat nudging method currently used in the UKMO's operational mesoscale model. Latent heating profiles are calculated by considering the condensational heating within the model physics step. Increments to the potential temperature are then derived within the assimilation scheme, based on a scaling of the profiles by the ratio of the observed and model first-guess rainfall rates. The aim is to cause the model to adjust so that the diagnosed rainfall rate agrees more closely with the observations. The practical considerations involved in applying this technique (e.g. the optimal spatial resolution of the observations) are briefly discussed.
The impacts of assimilating the rainfall data on the model analyses and forecasts are then examined. Independent validation data sets from SSM/I, CERES and TRMM are used for this purpose. Particular attention is focussed on the location of rainfall events, the sensitivity of the technique to the choice of the rainfall estimation method and the effects on model spin-up time. A brief comparison with other assimilation experiments currently being undertaken at the UKMO is presented.

SIGNATURE OF CLIMATE CHANGE IN ATMOSPHERIC CIRCULATION-REGIME FREQUENCIES

T.N.PALMER (ECMWF, Reading, UK), S.Corti and F. Molteni (CINECA, Bologna, Italy)
E-mail: tim.palmer@ecmwf.int

Based on analyses of mid-tropospheric geopotential data, evidence is presented that trends in northern hemisphere climate over recent decades can be explained by changes in the frequency of preferred nonlinear naturally-occurring circulation regimes. These results support a nonlinear paradigm that the climatic response to anthropogenic forcing may project principally on the dominant patterns of natural climatic variability, even though such natural variability may be manifest predominantly on timescales much shorter than that of the imposed forcing.

MI11/E/08-B5 0900

CLIMATIC INTRA-DECADAL QUASI-CYCLES AND THEIR NONLINEAR EVOLUTION

Igor I. MOKHOV (A.M.Obukhov Institute of Atmospheric Physics RAS, 3 Pyzhevsky, Moscow 109017, Russia, email: mokhov@omega.ifaran.ru)

Global climate system is considered as a dynamics system with potential attractors of the cyclic behaviour in the interannual evolution. The diagnostics of intra-decadal quasi-cyclic features in the temporal series of different thermodynamical and dynamical climatic characteristics is performed. Analysis of phase portraits and their changes during the last century displays the nonlinear effects of a general increase of amplitudes with an increase of periods, in particular for quasi-biennial (QBO) and quasi 5-year period (QFO) oscillations of global surface air temperature (GSAT), El-Nino/ Southern Oscillation (ENSO) characteristics and zonal wind in the equatorial stratosphere. The applicability of adiabatic invariants for climate dynamics system is estimated using models of an oscillator with slowly evolving period and a system of two coupled oscillators (TCO). In particular, the dependence of the QBO amplitude on its period for zonal wind in the lower equatorial stratosphere is quite well approximated by the power function with the power index close to 1/2 as it follows from adiabatic invariant theory. The TCO model is used for interpretation of relative variations of QBO and QFO peaks in spectra of the NH surface air temperature during last decades. In some cases there are significant differences between amplitude-period relation following from observations and from quasi-adiabatic model results. The general tendency of the QFO period decrease of GSAT under global warming during last century is exhibited.This effect is related to El-Nino-like phenomena. The displayed nonlinear dynamics and tendencies of its change can effect the resonance properties of the system (particularly in the case of the QBO realization as a parametric resonance phenomenon) and its variability.

MI11/W/07-B5 0915

SENSITIVITY ANALYSIS OF THE CLIMATE OF A CHAOTIC SYSTEM

J.A. HANSEN (1,2) and M.R. Allen (1,3) (1) Rutherford Appleton Laboratory, Space Science Department, Chilton/Didcot, OXON, OX11 0QX, UK, (2) Mathematical Institute, University of Oxford, Oxford, OX1 3LB, UK, (3) Department of Physics, Clarendon Laboratory, Parks Road, Oxford, OX1 3PU, UK.

The dominant source of uncertainty in climate prediction is likely to be model error, in contrast to the exponential growth of uncertainty in initial conditions which dominates short-range forecasting. A formal treatment of uncertainty in model structure remains virtually impossible, but parametric uncertainty can, at least in principle, be addressed through ensemble predictions varying model parameters. The challenge is to determine which parameters must be varied to span the range of possible forecasts with a limited ensemble. Model linearisation techniques have proved useful in the analysis of initial-condition uncertainty, but the utility of the conventional approach in the analysis of parametric uncertainty is limited by the exponential growth of perturbations in state space. For long enough trajectories, linear uncertainty growth in both fast and slow manifold processes can become too large to be useful. Extendible methodologies to address the issues of linearisation optimisation time and multiple time-scales are demonstrated.

MI11/E/01-B5 0930

CORRELATIONS BETWEEN THE STRUCTURES OF ERRORS AND LYAPUNOV AND SINGULAR VECTORS IN BAROTROPIC DYNAMICS

Mozheng WEI and Jorgen S. Frederiksen CRC for Southern Hemisphere Meteorology CSIRO Atmospheric Research, PMB 1, Aspendale Victoria 3195, Australia email: mozheng.wei@dar.csiro.au

Singular vectors (SVs) and Lyapunov vectors (LVs) are compared with structures of evolved randomly generated errors during the cases of block development in the S.H. in 1989. A tangent linear model with time-dependent basic states taken from observations is employed to describe the error growth. The statistics of 100 evolved errors are studied for six day period and compared with the growth and structures of fast growing LVs and SVs in enstrophy, kinetic energy and streamfunction norms. The amplification factors of most random errors are slightly less than those of LV 1 for the same time-interval; while the amplification factors of all the random errors are much smaller than those of SVs 1 in all three norms, as expected.
The probability distributions, the mean and standard deviations of pattern correlations between each of the 100 evolved error fields and the five fastest growing LVs and SVs have been calculated. The mean of the largest pattern correlation, taken over the five fastest growing LVs (or SVs), increases with increasing time interval. The mean pattern correlation between 100 evolved random errors and LV 1 is smaller than those of evolved SVs 1. In about 3-4 days, the structures of evolved SVs start to show the similarity to the evolved random errors and take up large scale dipole structures. The random errors and evolved SVs 1 converge to LV 1 after about 20 days.

MI11/P/02-B5 0945

STRANGE ATTRACTOR IN CLIMATIC PARAMETERS OVER INDIA AND THEIR COMPOUNDING

H.N. SRIVASTAVA (India Meteorological Department New Delhi-110003, India, e-mail: snb@imd.ernet.in)

Strange attractor characteristics have been determined for the climatic parameters like maxim and minimum temperature and atmospheric pressure for Indian stations representing different climatic regimes. It was found that the strange attractors lie between 5 and 6 over the Indian region. Similar computation for monsoon rainfall have shown larger variations between 4 and 7 for different meteorological sub-divisions of India and the country as a whole. It was found that the predictability of these parameters lies in the medium range namely 8 to 10 days. On the other hand, icecore results by other workers have reported climatic changes on much longer time scale.
A question arises whether the rainfall over the country, as a whole, for which long range forecast is issued using 16 parameters could be modelled when predictability of individual meteorological parameters lie in the medium range Using the concept of 'compound chaos', it has been found that the technique based on strange attractor could have limitation for climatic predictions since compounding two parameters gives a predictability of less than 8 days.

MI11/E/12-B5 1000

STOCHASTIC DYNAMICS OF EL NINO-SOUTHERN OSCILLATION

Bin WANG (Department of Meteorology, University of Hawaii, 2525 Correa Road, Honolulu, HI 96822, USA, email: bwang@soest.hawaii.edu) Albert Barcilon (Department of Meteorology and GFDI, the Florida State University, email: barcilon@joanna.gfdi.fsu.edu) and Zheng Fang (Department of Meteorology, University of Hawaii, email: zfang@soest.hawaii.edu)

A stochastically forced nonlinear dynamic model for El Nino-Southern Oscillation (ENSO) is advanced to explore the nature of the highly irregular ENSO cycle. The model physics includes nonlinear dynamics of the coupled ocean-atmosphere system, high-frequency stochastic forcing, and the annual forcing of a prescribed climatological basic state.
The model irregular ENSO-like oscillation arises from three different origins: stochastic resonance, coupled nonlinear instability, and stochastic transition. When the basic state is stable, the stochastic forcing excites irregular oscillations by stochastic resonance. When the system is unstable and the coupled dynamics sustains a nonlinear oscillation (stable limit cycle), the stochastic forcing perturbs the deterministic trajectory of the limit cycle in the phase-space, generating irregularities and modifying the oscillation period. When the system possesses multi-equilibrium states, the stochastic forcing may render the system oscillatory by randomly switching the system between a warm and a cold stable steady state.
The stochastic response depends not only on the nonlinear dynamic regimes of the ENSO system but also on the temporal structure (spectrum) and strength of the stochastic forcing. White and red noises are shown to be much more effective than band-limited white noises in stochastic resonance. The intraseasonal noise can alter the dominant period of intrinsic nonlinear oscillation, favoring biennial oscillation, especially when the intraseasonal forcing is modulated by monsoon (annual cycle). A sufficiently strong white noise forcing can destroy the nonlinear or resonant oscillation, leading to a Markovian process.
The model results suggest that ENSO may arise from multi-mechanisms. The different mechanisms may be at work in various phases of the ENSO evolution, depending on the basic state and the nonlinear dynamics of the system. The monsoon may affect ENSO through modulation of intraseasonal stochastic forcing, enhancing the biennial component of ENSO.

A NEW DYNAMICAL SYSTEMS THEORY OF INCOMPRESSIBLE FLOWS AND APPLICATIONS TO GENERAL OCEAN CIRCULATIONS

Shouhong WANG (Department of Mathematics, Indiana University, Bloomington, IN 47405, USA, E-mail: showang@indiana.edu)

I shall present in this talk a new dynamical systems theory of two-dimensional incompressible flows from the Lagrangian point of view, as well as its applications to large scale ocean circulations. The theory is developed recently jointly with T. Ma. On the theoretical side, I shall address a). the global structural classification of divergence-free vector fields, b). structural and block stability of divergence-free vector fields, c). structural bifurcation of the solutions of the 2D Navier-Stokes equations, and d). structural stability of solutions of the Navier-Stokes equations. The results and methods involved will be presented with simple schematic pictures. Then I shall apply the theoretical results and methods to the structure analysis of a wind-driven, double gyre, QG ocean model, as well as a two and half layer shallow water model. Several features related to climate low frequency variabilities shall be discussed. The work on double gyre circulations is joint with M. Ghil, K. Ide, E. Simonnet, J. Shen, T. Tachim Medjo and R. Temam.

VERIFYING NONLINEAR CLIMATE CONCEPTIONS FROM TIME SERIES: METHODOLOGICAL BRICKS

PETER CARL (Climate Dynamics Project, c/o Forschungsverbund Berlin, Hausvogteiplatz 5--7, D - 10117 Berlin, Germany, email: pcarl@spclim5.wias-berlin.de)

Given that low-dimensional behaviour of higher-dimensional systems should realize itself via synchronized motions, the search for rational frequency relationships in observational data may become a key issue in the goal of puzzling out what contribution to the explanation (and prediction) of real world phenomena can be gained from nonlinear systems conceptions of climate dynamics. Evolutionary spectra are mapped to this end on the Farey tree of rational numbers thus facilitating the study of complex, nonstationary modal structures with a view on frequency 'aggregations' and their (changing) coupling strength and structures, both internal and with respect to cyclic external forcing. The method is applied to different time--frequency representations, including windowed Fourier and Maximum Entropy spectra, the continuous wavelet transform and projection-based 'pursuits' using either empirical orthogonal functions in the time domain or highly redundant dictionaries of Gabor 'time--frequency atoms' and other functions. These "Projection" and "Matching" Pursuits are shown to be best suited for the present purpose using a number of real world time series including monsoon, trace gas, SO, NAO and Earth rotation data. The sensitive point of adequate representation of atmospheric variability in the models used for prediction is approached in a preliminary, demonstrative study using a conceptual, coarse--resolution, tropospheric GCM.

MI11/E/09-B5 1215

NON-MARKOVIAN DYNAMICS OF WEATHER REGIMES IN A T21L3 QUASI-GEOSTROPHIC MODEL

S. VANNITSEM, Royal Meteorological Institute of Belgium, Avenue Circulaire, 3, 1180 Brussels, Belgium.

The dynamics between successive weather regimes generated by a Quasi-Geostrophic model are investigated. A new clustering procedure of the anomaly weather fields based on the local Kolmogorov entropy is first performed, leading to three distinct clusters. It is shown that two of these correspond to large and small expansion rates, suggesting that these regimes display different predictability properties. The dynamics of the symbolic sequence as provided by the three clusters is subsequently investigated and shown to be non-Markovian. A simple model of this behaviour is developed and the implications for long term prediction are discussed.

MI11/W/03-B5 1230

STEADY RESPONSE OF BAROTROPIC ATMOSPHERE TO THE SMALL PERTURBATIONS OF EXTERNAL FORCING. THEORY AND NUMERICAL EXPERIMENTS

A.GRITSOUN and V.Dymnikov (both at Institute of Numerical Mathematics RAS, Gubkina 8, 117951, GSP-1, Moscow, Russia, e-mail: andrusha@inm.ras.ru)

In this study we consider the barotropic model of the low-frequency atmospheric variability. Using Monte-Carlo method, we construct the operator that describes the model response to small constant external perturbations. It is shown that this operator can be considered as linear with high accuracy. Moreover, it turns out, that maximum response of the system is close to its dominant low-frequency EOF. Next we investigate the possibility to describe the response of barotropic model by means of the linear dynamical-stochastic model. To this end we construct the linear dynamical-stochastical model witch low frequency variability is identical to that of original system. The linear operator of this model can be calculated using original model data and right hand side represents some random process. The singular vectors of the linear system matrix turn to be close to that of the original system response matrix. In addition we demonstrate that autocovariation matrix of right hand side of linear model can be selected as cI, where I is unity matrix and c is some number. The consequence of this fact is that the maximum responses of linear and original systems are close to the leading low-frequency EOF of the model circulation. In sum one can conclude that the use of the linear approach to predict the sensitivity of the barotropic atmosphere model leads to the satisfactory results.

INTERMITTENCY, DETERMINISTIC CHAOS, STOCHASTICITY

MI11/E/02-B5 1400

MULTIFRACTAL PROCESSES AND STOCHASTIC CHAOS IN THE WEATHER AND CLIMATE

S. LOVEJOY, (Physics dept, McGill University, 3600 University St., Montréal, Québec, H3A 2T8, Canada); D. Schertzer (LMM, case 162, Universite P. et M. Curie, 4 pl. Jussieu, Paris F-75252 Cedex 05, France)

Real world systems - especially weather and climate systems - have many chaotic features. These include apparently continuous change interrupted by sudden (often catastrophic) transitions, spatial structures spanning wide ranges of scale (mountains, clouds, "eddies"). Furthermore, the systematic study of nonlinear systems with few degrees of freedom - "deterministic chaos" - has lead to a profound change in the way we think about such nonlinear systems. We now expect their behaviour to be "chaotic". However, in spite of this important philosophical impact, deterministic chaos has actually lead to surprisingly few direct applications. We argue that the reason is that most interesting nonlinear systems involve large numbers of degrees of freedom; "stochastic chaos". When such systems obey the (non-classical) symmetry of scale invariance, then the outcome will be multifractal fields. Since these multifractal processes possess stable and attractive generators, "universal" features emerge with the attendant theoretical and analytical simplifications. We illustrate these ideas using a range of atmospheric examples, and show how they can be used to produce realistic space-time stochastic models. Finally, we compare and contrast the prediction limits for deterministic and stochastic forecasts.

MI11/E/04-B5 1430

NONLINEAR DYNAMICS, MULTIFRACTAL INTERMITTENCY AND THE RENORMALIZARION OF THE GENERATING EQUATIONS

D. SCHERTZER, M. Larchevêque (LMM, CNRS UMR 7607, Case 162, Université P.&M. Curie, Paris, France, 4 Pl. Jussieu, 75252 Paris Cedex 05, France) S. Lovejoy (Physics dept, McGill University, 3600 University St., Montréal, Québec, H3A 2T8, Canada)

Nonlinear dynamics of the climate system are strongly intermittent: the activity or efficiency of nonlinear couplings is highly inhomogeneous in time and space. Developments of multifractal notions and models have recently led to a deeper understanding of the phenomenology of intermittency. Indeed, wild probability distributions and corresponding coherent structures are a direct outcome of the multifractal processes, whereas they remain beyond the scope of the classical analytical/renormalization theories. Therefore, we are faced with a paradoxical situation: a deeper and deeper understanding of intermittency, but a looser contact with the structure of the generating equations. Contrary to a pessimistic recent viewpoint, we show that there is a way of bridging up this gap. We clarify that the failure of renormalization techniques is due to (rather implicit) quasi-gaussian assumptions concerning non only the fields, but also their adjoint fields that define the (non linear) infinitesimal response of the former to perturbations. With the help of multifractal Fractionaly Integrated Flux (FIF) models, we define a renormalized forcing which is strongly non gaussian, and therefore, with the help of the corresponding renormalization of the propagator, obtain intermittent models built directly on the structures of the generating equations.

MI11/W/08-B5 1500

INTERMITTENCY IN A MODEL OF NON-LINEAR PLANETARY WAVE INTERACTION

Roman BEKRYAEV (Arctic and Antarctic Research Institute, 38 Bering st., 199397,St.-Petersburg, Russia, e-mail: bekryaev@aari.nw.ru)

We consider the connection of bifurcations and statistical properties of the quasisolenoidal horizontally baroclinic model of the nonlinear interaction between planetary atmospheric waves in a zonal channel. Research of a low-order model has shown that in the conditions of inhomogeneous underlying surface the stationary state chaos-intermittency can be observed. Slow laminar stage of intermittency is connected with the blocking of zonal thermal west-east flow. We have shown that distribution of laminar interval length is bimodal. This property is typical to the first kind of intermittency connected with saddle-nodle bifurcation. A mechanism leading the intermittent fluctuations has been investigated analytically. It has been shown that in our case the intermittency is determined by intersection of Hopf bifurcation line with saddle-nodle boundary of Whitney set. The laminar phase of the intermittency is connected with gathering of the trajectories to "fantom" of the stationary stable point. The numerical experiments have shown that exponential scattering of trajectories can be observed only in the periods of chaotic dynamics. The error of prediction does not grow during the laminar stage of intermittency.
The work presented here was supported in part by the Russian Fund of Basic Research under Grant number: 96 05 - 64960.

MI11/W/04-B5 1515

CONTRASTING "LOCAL" AND GLOBAL LYAPUNOV EXPONENTS

Christine ZIEHLANN (University of Potsdam, Institute of Physics, Am Neuen Palais 19, PF 601553, D-14415 Potsdam, Germany. E-mail: chriss@agnld.uni-potsdam.de) and LEONARD A. SMITH (University of Oxford, Mathematical Institute, 26 St. Giles, Oxford OX1 3LB, UK. email: lenny@maths.ox.ac.uk)

In the thirty years since their introduction, both global Lyapunov exponents (LE) (Oseledec 1968), and their local counterparts (Lorenz 1965), have been widely employed to quantify the predictability. Distinct entities (with different properties) have been dubbed "local Lyapunov exponents", creating some confusion; two of these, finite time LE and finite sample LE are defined in Ziehmann et al. 1999. Relations between the finite time, the finite sample and the global Lyapunov exponents are noted. For predictions over finite periods of time, the finite time and the finite sample LE may provide completely different estimates of predictability for the same initial state. As long as the uncertainties remain small enough to be approximated by the tangent dynamics, the finite time LE appear more relevant; details may depend on the assimilation scheme employed. Contrasting the distributions of finite time LE and finite sample LE, provides a new tool for estimating the uncertainty remaining in a global LE computation. Results are presented for two chaotic maps, the Henon system and the Ikeda system; it is proven that true ``return of skill" exists in some chaotic systems. All Lyapunov exponents represent "effective" rates, and thus they are all fundamentally limited in terms of quantifying predictability inasmuch as, by definition, they require the selection of a timescale a priori. The advantages of an alternative approach, computing uncertainty growth timescales directly, are discussed.

INERTIAL MANIFOLD OF THE ATMOSPHERIC EQUATIONS

LI Jianping (State Key Laboratory of Numerical modelling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG), Institute of Atmospheric Physical, Chinese Academy of Sciences, Being 100080, China Chou Jifan Department of atmospheric sciences, Lanzhou University, Lanzhou 730000, China)

Abstract For a class of non-linear evolution equations, we study their global attractors and discuss the existence of their inertial manifolds using the truncated method. Then, on the basis of the properties of operators of the atmospheric equations, it is proved that the operator equation of the atmospheric motion with dissipation and external forcing belongs to this class of non-linear evolution equations. Therefore, it is got that there exists an inertial manifold of the atmospheric equations if the spectral gap condition for the dissipation operator is satisfied. These results furnish a basis for studying further dynamical properties of global attractor of the atmospheric equations and for designing better numerical scheme. Key words: Inertial manifold, Non-linear evolution equation, Global attractor, Operator Equation, Operator.

ELIMINATING COMPUTATIONAL UNCERTAINTY AND ITS METEOROLOGICAL USES

Qing ZHONG (Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029 CHINA. E-mail: zhongq@sgi50s.iap.ac.cn)

A computational intermittent turbulence like Uncertainty in a non-linear Lorenz's system is revealed in this work. The origin of this Uncertainty is analysed, and its unfavourable meteorological sequence in relation with predictability of numerical models for short range and long term integration is also discussed. Moreover, a successful approach to eliminating this kind of Uncertainty is discovered, formulated as well as tested. In addition, some applications of this approach is also discussed as a new way to reduce failures in actual numerical weather forecast and reduce Uncertainty in actual numerical climate forecast and simulation.

MI11/E/05-B5 1630

LIMITATION OF CLIMATE PREDICTION

Prof. Peter C. CHU

The limitation of climate prediciton is due to uncertain initial and boundary conditions. Much of the predictability studies (e.g., Lorenz, 1974) have been done on the sensitivity of model behaviour to tiny disturbances in the initial field. We may ask: What is the sensitivity of model behaviour to tiny disturbances boundary conditions, such as in the sea surface temperature (SST) anomaly. First, we use the Lorenz system (Lorenz, 1963) to show the existence of two kinds of predictability, in terms of initial error (first kind) and of the boundary error (second kind). Second, we use the latest version of the NCAR Community Climate Model (CCM3) to study the model response to tiny surface temperature disturbances. The model was integrated from 1 September 1977 observational data over the globe for 16 months with and without SST disturbances. A time-scale of 20-day is found such that the response increases rapidly within this time-scale and then oscillates at high values. Finally, some theoretical discussion will also be included.

NON-LINEAR STABILITY AND INSTABILITY IN ATMOSPHERIC DYNAMICS: THEORY AND APPLICATION

Mu MU, Wu Yonghui, Wang Jiafeng(all at LASG, Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029, China, e-mail: mumu@sun.ihep.ac.cn) Liu Yongming(Department of Mathematics, East China Normal University, Shanghai, 200062, China)

This paper is concerned with the non-linear stability and instability in atmospheric dynamics and its applications.
First, Arnold's non-linear stability theorems of barotropic motions obtained by energy - Casimir method are applied to diagnose the maintenance or breakdown of the zonal flows in the middle and high latitudes. The primary results show that the analyses correspond well to the evolution of the real atmospheric motions.
Second, the basic states, which are guaranteed to be nonlinearly stable or unstable by the non-linear stability criteria, are utilised to study the validity and limitation of tangent linear model (TLM) and the singular vectors (SVs). In the barotropic context, numerical results show that the validity period of the TLM and SVs depend essentially on the non-linear stability and instability of the motion. The energy of the fastest growing disturbance obtained by SV method, could less than significantly the energy of certain kind of disturbance gained by using non-linear model in case that the basic state is nonlinearly unstable.
Finally, the non-linear stability criterion of continuously stratified quasigeostrophic generalised Eady's model is established, which demonstrates the short-wave cut-off phenomenon and the impact of the Beta parameter.

THE RELATIONSHIP BETWEEN PRECIPITATION IN SOUTHERN BRAZIL AND SEA SURFACE TEMPERATURE IN SOUTHERN HEMISPHERE

Valentina M. KHAN (Russian State Center of Hydrometeorology, Moscow, Russia,
e-mail: odpp@glasnet.ru)

The relationship between rainfall anomalies in Southern Brasil and SST in Southern Hemisphere, with temporal lags varying from 0 to 12 months, is investigated using linear correlation analysis. The precipitation data represent monthly historical record from 13 meteostations objectively grouped in 5 classes. The data covered the period between 1911 and 1995. The historical SST data used in the work are the monthly averages that were compiled from different sources. Significant correlations were detected between precipitation in the study region and anomalies of SST in the belt of Antarctic Circumpolar Current. This teleconnection may be associated with ENSO-correlated perturbations in SST that translate around the Antarctic Circumpolar Current (the so-called "Antarctic Circumpolar Wave"). Significant relationship was also observed between regional precipitation in southern part of Brazil and SST anomalies in South Pacific Convergence zone, South Indian Convergence zone and the El Nino zone in the eastern equatorial Pacific. The possible mechanisms that control the connections between the anomalies of regional rainfall and SST in the detected specific areas of Southern Hemisphere are discussed.

ADAPTIVE ALGORITHM FOR LONG-TERM PROGNOSIS OF OBSERVED CHAOTIC DYNAMICS

Mr Dmitry N. MUKHIN (Institute of applied physics RAS)

The work is aimed to develop a new approach to long-term prognosis of the nonautonomous non-linear dynamic system behaviour. The essence of this approach, which is discussed in another IUGG99 report of the authors, is derivation of a special "prognostic" model from the observed chaotic time series. This article is devoted to significant enhancing the capabilities of the approach through special adaptive procedure elaborated. The procedure is "self-educated" and concludes an optimisation of prognostic model parameters via comparison of predicted system behaviour with a newly measured data. A specific arisen problem, which was overcome, is lack of information extracted from the new data. This lack results from system bifurcation from more complicative behaviour to simpler one. The algorithm is applied to time series obtained due to numerical experiment with dynamical models of atmospheric photochemical systems as well as a few classical models (e.g. Rossler model), in which trends of control parameters were entered. As a result, entire bifurcation sequences of these systems were predicted and both the bifurcation values of parameters , and a ranges of changes of the dynamic variables magnitudes were reproduced. Note that all mentioned predictions are quantatively very close to corresponding characteristics of the modelled systems.

MI11/E/03-B5 1745

PROGNOSTIC MODELS OF NON-LINEAR DYNAMIC SYSTEMS

Alexander M. FEIGIN, Eugene M. Loskutov, Yaroslav I. Molkov and Dmitry N. Mukhin (all at Institute of Applied Physics, Russian Academy of Sciences, 46 Ulyanov St., Nizhny Novgorod, 603600, Russia, email: feigin@appl.sci-nnov.ru)

A new approach to long-term prediction of bifurcations of nonautonomous non-linear dynamic system behaviour is suggested. The approach is based on the derivation of a special dynamic model through an analysis of observed chaotic oscillations of the system. This model not only reproduces a current system behaviour, but carries also information about dependencies of intrinsic characteristics of the system on parameters, which underwent slow trends during the observation period. The last point transforms the model into prognostic one, which is suitable for prediction of bifurcations of the system behaviour resulting from expected in the future variations of the parameters. The prognostic model is aimed to finding bifurcation values of the parameters as well as evaluating changes of magnitudes of the dynamic variables caused by the system bifurcations. The suggested approach has been elaborated and confirmed both by a few "classical" model dynamic systems (e.g. Rossler and Lorenz models), and a recently elaborated model of the mesospheric photochemical system forced by diurnal modulation of photolysis rates. All systems considered exhibit, depending on the parameter values, various types of non-linear dynamic behaviour (including chaotic oscillations) as well as different kinds of bifurcations. This gives possibility to analyse a broad spectrum of the representative situations which can be observed, and reveal both the advantages of the approach, and problems arisen, as well as propose ways for these problems overcoming. The derivation of the prognostic model from really observed time series is discussed.

PLANETARY SCALE ASPECTS OF MIDDLE ATMOSPHERE VARIABILITY

William J. RANDEL (NCAR, PO Box 3000, Boulder, Colorado, 80307-3000, USA, e-mail: randel@ucar.edu)

Long records of satellite observations and meteorological analyses provide global perspective to seasonal and interannual variability of the stratosphere. Planetary waves provide a strong coupling mechanism between the troposphere and stratosphere in winter; their effects extend to the near-global scale, with influence from the tropical tropopause to the polar vortex. The contrasts between Northern and Southern Hemisphere polar vortex structure further demonstrates the influence of planetary waves. Interannual variability of the stratosphere is dominated by the quasi-biennial oscillation (QBO) in the tropics and low latitudes; variability of the polar vortices are more closely related to forcing from the troposphere. Observed low-frequency changes (trends) in the stratosphere will be discussed, with focus on the recent springtime polar cooling observed in both hemispheres.

MI12/W/07-B4 1030

IS THERE A LONG-TERM TREND OF PLANETARY WAVES IN THE NORTHERN WINTER STRATOSPHERE?

Kirstin KRUEGER(1), Steven Pawson(2), Ulrike Langematz(1). (1 Institut fuer Meteorologie, FU Berlin, 12165, Berlin, Germany email: krueger@strat01.met.fu-berlin.de) (2 Universities Space Research Association, NASA GSFC, Greenbelt, MD 20771, USA)

A possible long-term change of the polar vortex spin up, duration and break-down in the northern winter stratosphere is studied over the period 1964-1998. The long-term DJF-climatology of the polar vortex reveals a zonally-asymmetric structure, which can be interpreted in terms of planetary waves. To analyse such changes of the polar vortex structure, a trend analysis of planetary waves (amplitudes, phases and corresponding fluxes) and the mean zonal mean wind during pre-, mid-, and late winter is calculated from the Free University Berlin (FUB) observational data. Possible dynamical feedbacks of observed stratospheric ozone decrease on planetary wave dynamics are discussed by comparing the results of the trend analysis with those from two multiyear simulations with the Berlin Climate-Middle-Atmosphere-model. In the model runs, either a climatological ozone field of the 1980s or an ozone field with observed ozone trends was used.

MI12/W/05-B4 1115

THE EFFECT OF INERTIAL INSTABILITY ON THE EVOLUTION OF A MODELLED STRATOSPHERIC WARMING

EUAIN F. DRYSDALE (Rutherford Appleton Laboratory, Chilton, Didcot, OX11 0QX, UK. email: e.drysdale@rl.ac.uk), Lesley J. Gray (Rutherford Appleton Laboratory, Chilton, Didcot, OX11 0QX, UK. E-mail: L.J.Gray@rl.ac.uk) and Suzanne M. Rosier (Department of Meteorology, University of Reading, Earley Gate, Whiteknights, P.O. Box 243, Reading, RG6 6BB.
E-mail: S.M.Rosier@reading.ac.uk)

The effect of inertial instability on the evolution of a northern hemisphere stratospheric sudden warming is investigated in a modelling study. In the tropical upper stratosphere and lower mesosphere, the model (and indeed the atmosphere) are often in an inertially unstable state. This inertial instability results in the formation of flat `pancake rolls' consisting of stacked layers of meridional wind with alternating directions. These rolls will act to stabilise the flow and it is hypothesised that they inhibit the advection of low latitude air into the extra-tropics and through this mechanism will prevent or delay stratospheric warmings. A vertical diffusion parameterisation is added to the model, and changes in the evolution of the modelled winter are seen. The main action of the applied vertical diffusion is to limit the formation of the small vertical scale rolls formed as a result of inertial instability. The effect of these rolls on a stratospheric warming is investigated by applying the vertical diffusion in a variety of model runs and observing the changes in both the evolution of this warming directly and the transport in the model. It is seen that restricting the model adjustment to inertial instability has the effect of advancing and strengthening the warming observed.

MI12/W/12-B4 1135

CAN THERE BE INTRASEASONAL AND INTERANNUAL VARIATIONS IN THE MIDDLE ATMOSPHERE IF THOSE VARIATIONS ARE NOT PRESENT AT THE LOWER BOUNDARY?

Mingyue Chen (Climate Prediction Center/National Centers for Environmental Prediction, Camp Springs, MD 20746); Carlos R. MECHOSO and J.D. Farrara (both at Department of Atmospheric Sciences, University of California, Los Angeles, CA 90095-1565, e-mail: mechoso@atmos.ucla.edu)

The answer to the question posed in the title of this talk is sought in the framework of a quasi-geostrophic, beta-plane, channel model of the middle atmosphere in the presence of conditions at the lower boundary that are either steady or whose zonal component is time-varying but without interannual variations. The model uses different spectral truncations in the horizontal and finite-differencing in the vertical. The circulation is driven by zonally-independent differential radiative heating, which is either time-independent or time-varying without interannual variations.
It is shown that intraseasonal variations can be obtained with steady conditions at the model's lower boundary and time-independent winter-type radiative forcing. In this case, the model's steady solutions are found and their dependence on truncation is analysed in detail when either one or both of the two longest zonal and meridional modes are retained. The number and stability properties of those solutions can depend strongly on model truncation. Model integrations in time illustrate that the variations appear as flow transitions between steady solutions.
It is also shown that significant interannual variability can be obtained for particular values of the model parameters in the case when both the zonal component of the conditions prescribed at the model's lower boundary and the radiative heating include a seasonal cycle. These variations resemble those observed during final warmings in the southern hemisphere.

MI12/W/13-B4 1155

INTERNAL VARIABILITY OF THE WINTER STRATOSPHERE THROUGH THE TROPOSPHERE-STRATOSPHERE DYNAMICAL LINK IN A SIMPLE GLOBAL CIRCULATION MODEL

Masakazu Taguchi, Takashi Yamaga and Shigeo YODEN (Department of Geophysics, Kyoto University, Kyoto, 606-8502, Japan, e-mail: yoden@kugi.kyoto-u.ac.jp)

We perform numerical experiments with an idealized troposphere- stratosphere global circulation model to investigate internal variability of the winter stratosphere which arises from the vertical dynamical link. While the model is simplified in some ways (dry atmosphere, no physical process except for Rayleigh friction at the surface, and perpetual external conditions), it explicitly describes dynamical processes related to the vertical link: excitation of planetary waves by the surface topography and their interaction with baroclinic eddies in the troposphere as well as their upward propagation and interaction with the mean zonal flow in the stratosphere. Amplitude of a sinusoidal surface topography is chosen as an experimental parameter to examine the relative importance of the forced planetary waves: 1000-day integrations are done for each of about 50 runs with different amplitude. The obtained winter stratospheric circulations can be classified into 5 regimes dependent on the topography amplitude: (1) nearly radiative-equilibrium state, (2) weak undulation of a strong polar vortex, (3) quasi-periodic occurrence of minor sudden warmings, (4) intermittent occurrence of major warmings, and (5) weak and warm polar vortex at all times. Time variations of the stratospheric circulation in some parameter ranges resemble those of the real atmosphere, and interhemispheric differences in the winter stratosphere can be understood as the regime difference. The southern hemisphere winter corresponds to the second or the third regime, while the northern hemisphere winter does to the fourth regime. Dynamical diagnosis is also done for some typical runs to clarify the excitation process of planetary waves and their interaction with the mean zonal flow and baroclinic waves in the troposphere and the lower stratosphere

MI12/W/15-B4 1215

THE WAVE-1 STRATOSPHERIC WARMING AND INTERNAL VARIABILITY

Andrew GREGORY, Alan O'Neill and John Thuburn (CGAM, Department of Meteorology, University of Reading, PO Box 243, Earley Gate, Reading, RG6 6BB)

Standard textbook theory links the stratospheric sudden warming to the development of planetary waves in the troposphere. This theory can be difficult to apply to many observed warmings notably warmings dominated by zonal-wavenumber 1 (a `wave-1 warming'). Such warmings are associated with the strengthening of a quasi-stationary anticyclone (the Aleutian high). Usually this happens as the quasi-stationary anticyclone merges with a second travelling anticyclone in the upper stratosphere. A series of seasonal integrations with a new stratosphere-mesosphere model has been performed with the idealisation of constant tropospheric wave forcing. It is found that with constant wave forcing of 300m, an amplitude comparable to that observed, the model stratosphere generates a series of travelling anticyclones which merge with a quasi-stationary anticyclone in a manner that can be closely compared to observations. It is argued that, although the resulting model warming is weaker than is often observed, the model shows that a wave-1 warming can be generated as a result of the stratosphere's internal variability and need not be linked with tropospheric wave development. Consequences for the success of simulations of observed wave-1 warmings with stratosphere-mesosphere models are also discussed.

EXCITATION MECHANISM OF QUASI STATIONARY ROSSBY WAVES IN THE SOUTHERN HEMISPHERE

Yasunobu MIYOSHI (Department of Earth and Planetary Sciences, Kyushu University, Hakozaki, Fukuoka, Japan, e-mail: miyoshi@rossby.geo.kyushu-u.ac.jp)

Quasi stationary Rossby waves with zonal wavenumber 1 (QS-wave 1) have large amplitude in winter-spring of the middle atmosphere. However, excitation mechanism of QS-wave 1 in the southern hemisphere has not been well understood. In this paper, excitation mechanism of QS-wave 1 in the southern hemisphere is studied. Effects of the zonal asymmetry of SST distributions in low and middle latitudes on excitation of QS-wave 1 are investigated by a series of GCM experiments. The GCM used in this study is T21L37 model, which is developed

at Kyushu University. Results indicate that the zonal asymmetry of the SST in low latitudes is essential for excitation of QS-wave 1. The interanuual variation of QS-wave1 in the stratosphere and its relation to the interannual variation of SST(ENSO) will be discussed.

MI12/W/01-B4 1420

STRATOSPHERIC VARIABILITY AND REPRODUCIBILITY IN SEASONAL ENSEMBLE INTEGRATIONS WITH A TROPOSPHERE - STRATOSPHERE GCM

W.A. LAHOZ and A. O'Neill (CGAM, University of Reading, Department ofMeteorology, Reading, RG6 6BB, UK. E-mail: wal@met.reading.ac.uk)

The Centre for Global Atmospheric Modelling (CGAM) has participated in the EU-funded PROVOST project to assess the capabilities of GCMs for seasonal forecasting. CGAM has used a troposphere-stratosphere version of the Unified Model developed at the UK Meteorological Office. It has 58 levels in the vertical and a horizontal resolution of 2.5deg latitude by 3.75deg longitude. It has the same tropospheric configuration and representation of physical processes as the current climate version of the Hadley Centre's version of the Unified Model (with so-called HADAM3 physics). A nine-member ensemble of four-month integrations has been run for the 18 northern winters from 1979 to 1997, each one started during the last nine days of November. Experiments were run in hind-cast mode with sea-surface temperatures prescribed with observational data. The simulated variability in the extratropical stratosphere during each winter, and the variability between winters will be discussed and analysed by comparison with ERA-15 data. The reproducibility of the seasonal cycle and of the intraseasonal variability among ensemble members will be assessed to determine the impact of ocean-surface boundary conditions on stratospheric variability.

MI12/W/04-B4 1440

INTERANNUAL VARIABILITY IN A MECHANISTIC MIDDLE ATMOSPHERE MODEL

Euain F. DRYSDALE (537 Rutherford Appleton Laboratory, Chilton, Didcot, OX11 0QX, UK. E-mail: e.drysdale@rl.ac.uk); Lesley J. Gray (Rutherford Appleton Laboratory, Chilton, Didcot,OX11 0QX, UK. E-mail: L.J.Gray@rl.ac.uk)

A series of long model runs are performed using the UKMO Stratosphere-Mesosphere Model and the interannual variability in the northern polar vortex is compared. This model used is a mechanistic model, with a vertical domain spanning 100 to 0.01 hPa. The troposphere is represented by supplying the model with a lower boundary condition of the geopotential height of the 100 hPa pressure surface. In these experiments, the model is run with a bottom boundary that is taken from a single years data and repeated in a loop to form a continuous data set. This eliminates any tropospheric interannual variability from the simulation while still providing the model with a realistic annual cycle in the bottom boundary. Two experiments are performed where different years data are used to supply the lower boundary and long runs are performed. The interannual variability observed in each of these two experiments is found to be quite different. One run produces a large amount of interannual variability (January temperature variations, for example, are comparable to those observed in the real atmosphere) whereas the other experiment produces very much less interannual variability. Initial inspection of the height fields yields no obvious reason why the model produces very different amounts of interannual variability, and a more detailed examination of the bottom boundaries is performed.

MI12/E/06-B4 1500

ON THE PRESENCE OF A WAVE-GUIDE FOR PLANETARY WAVES IN THE STRATOSPHERE DUE TO THE RADIATIVE AND PHOTOCHEMICAL PROCESSES

Igor KONOVALOV (Institute of Applied Physics of Russian Academy of Sciences, 46 Ulyanov Str., Nizhniy Novgorod, 603600, Russia. E-mail: konov@appl.sci-nnov.ru)

Qualitative effects appearing due to coupling of radiative and photochemical processes (RPP), and planetary-scale motions in the stratosphere are analysed using a quasi-geostrophic mechanistic model. The analysis has been fulfilled both for the stationary atmosphere case which roughly corresponds to the situation at April-May and September-October periods and for the summertime atmosphere case. The results for the former have been published earlier [Konovalov I. B.,Izv. Atm. Ocean. Phys., v. 33, 475-482, 1997] and this report is mainly focused on the latter. It is shown that RPP can significantly perturb a vertical profile of an index of refraction so that to provide its wave-guide-like structure and cause the existence of a distinctive mode of planetary waves whose energy is mostly concentrated at heights of 30-40 km. It is discussed that this mode with zonal wavenumber 1 and meridional wavenumber 6 or 7 may be accounted for the observed distinctive wave phenomenon in the summertime stratosphere [Muench H., J. Atmos. Sci., v.25, 1108-1115, 1968]. Both the vertical structure and period of our mode are close to those of the observed wave. However, the model provides rather short damping time (approximately 1.5 periods), what is an obstacle for the complete identification of the observed and simulated waves. It is shown, though, that the value of the damping time is very sensitive to the parameters of the model (it is not so for the period and vertical structure) and thus the more accurate modelling approach is necessary to obtain the reliable value of the damping time.

MI12/E/03-B4 1520

ON THE SENSITIVITY OF SUDDEN WARMINGS TO EQUATORIAL WINDS AND TEMPERATURES

lesley GRAY and Euain Drysdale (Rutherford Appleton Laboratory, Chilton, Didcot, Oxon., OX11 0QE, U.K. Tel: +44 1235 446745, Fax: +44 1235 445848, e-mail: lesley.gray@rl.ac.uk)

A 30 year simulation of a stratosphere mesosphere model is described in which the modelled winds are relaxed towards observations in the lower equatorial stratosphere so that a realistic quasi biennial oscillation (QBO) is reproduced. The influence of these lower stratospheric winds on the synoptic evolution of the Northern Hemisphere winter and timing of the stratospheric sudden warming is examined. Although there is some correlation between the QBO and the general evolution of the winter circulation in the expected sense i.e. warm, disturbed winters in the easterly QBO phase years and cold, undisturbed winters in the westerly QBO phase years, this is by no means universal. In fact, there are several examples that exhibit a strong anti-correlation, suggesting additional source(s) of variability that are more important in these years. These winters are examined in detail. In particular, we investigate whether there is in any sense a 'memory' of the previous winter carried over into the following year. The model experiments show that the synoptic evolution of the winter circulation and the nature of the stratospheric warmings exhibit significant sensitivity to the temperature distribution at the equatorial stratopause.

MI12/E/01-B4 1610

ON THE POSSIBLE CAUSES OF THE INTERANNUAL VARIABILITY OF THE PLANETARY WAVE ACTIVITY IN THE WINTER POLAR STRATOSPHERE

Boris SOUKHAREV, Olga Kozlova, Svetlana Renyova, Irina Gorodetskaya and Ekaterina Kutuzova (all at Department of Climatology, St.Petersburg State University, 10 linia, 33, 199178, St.Petersburg, Russia, e-mail: boris@seb.usr.pu.ru)

The varying activity of the planetary waves is responsible for the interannual variability of the polar stratosphere. As the planetary height-waves 1 and 2 explains most of the total spatial variance of the winter polar stratosphere, the interannual variability of the two waves at the four stratospheric levels (100, 50, 30 and 10 hPa) for the period 1957-1996 in months from November to March is studied. Amplitudes of height-waves 1 and 2 at 60 degree North are used as parameters of the wave activity because the two waves reach their peaks between 60 and 70 degrees North. Correlation coefficients between the amplitudes of height-wave 1 and equatorial stratospheric zonal winds are negative in November and December at all considered levels. But in January - March the signal of the equatorial QBO in the planetary waves amplitudes is very weak. It is evident that most of the interannual variability of the waves amplitudes in January - March depends on other factors. If the data are grouped according to the extremes (peaks and hollows) of 11-year solar cycle then strong opposite correlations between the amplitudes of height-wave 1 in February and March and equatorial zonal winds (positive correlations at solar minima and negative ones at solar maxima) are revealed. In the periods of transition between solar extremes the connections are not so evident. The differences E-W between the February mean amplitudes of height-wave 1 at 30 hPa during the easterly (E) a nd westerly (W) QBO phases are about E-W = 199 gpdm and E-W = -176 gpdm for the periods of solar maximum and minimum respectively. Thus, the solar/QBO interaction can be considered as important cause of the interannual variability of planetary wave activity.

MI12/W/02-B4 1630

PROPAGATION OF THE ARCTIC OSCILLATION FROM THE STRATOSPHERE TO THE TROPOSPHERE

MARK P. BALDWIN and Timothy J. Dunkerton (Northwest Research Associates, Bellevue, Washington, 98009-3027 USA. E-mail: mark@nwra.com)

Geopotential anomalies ranging from the earth's surface to the middle stratosphere in the northern hemisphere are dominated by a mode of variability known as the Arctic Oscillation (AO). The AO is represented herein by the leading mode (the first empirical orthogonal function) of variability of wintertime geopotential between 1000 and 10 hPa. In the middle stratosphere the signature of the AO is a nearly zonally symmetric pattern representing a strong or weak polar vortex. At 1000 hPa the AO is similar to the North Atlantic Oscillation, but with more zonal symmetry, especially at high latitudes. In zonal-mean zonal wind the AO is seen as a north-south dipole centered on 40–45°N; in zonal-mean temperature it is seen as a deep warm or cold polar anomaly from the upper troposphere to ~10 hPa. By examining separately time series of AO signatures at tropospheric and stratospheric levels, it is shown that AO anomalies typically appear first in the stratosphere and propagate downward. The midwinter correlation between the 90-day low-pass filtered 10-hPa anomaly and the 1000-hPa anomaly exceeds 0.65 when the surface anomaly time series is lagged by about three weeks. The tropospheric signature of the anomaly is characterized by substantial changes to the storm tracks and strength of the mid-tropospheric flow, especially over the North Atlantic and Europe. The implications of large stratospheric anomalies as precursors to changes in tropospheric weather patterns are discussed.

MI12/W/10-B4 1650

INTERANNUAL VARIABILITY OF THE GENERAL CIRCULATION DUE TO OZONE HOLE CHANGES: A GENERAL CIRCULATION MODEL EXPERIMENT

T. Hirooka, S. WATANABE, T. Nishiyoshi and S. Miyahara (all at Department of Earth and Planetary Sciences, Kyushu University, 6-10-1, Hakozaki, Fukuoka 812-8581, Japan,
email: hirook@geo.kyushu-u.ac.jp)

A general circulation model developed at Kyushu University has been used to examine effects of interannual variation of Arctic and Antarctic ozone holes on the general circulation of the middle atmosphere. In the model, ozone photochemistry is calculated by a parameterized Chapman cycle and is interactively coupled with radiation and dynamics. In order to simulate the ozone hole, the polar ozone destruction is expressed by a parameterized loss term added in a continuity equation for the ozone mixing ratio, which is initiated under suitable switch-on conditions. We have performed the experiment over successive five years with the interannual variation of ozone holes which is produced by internal nonlinear atmospheric dynamics as well as by slightly changing the threshold values of the switch-on conditions and in good agreement with observations. The general circulation exhibits interannual variability owing to feedback processes of the ozone holes. The degree and spatial structure of the variability are discussed with relation to those of the ozone holes, compared with corresponding observations.

MI12/W/08-B4 1710

STRATOSPHERIC OZONE VARIABILITY RESULTING FROM UNCERTAINTIES IN THE NOX PRODUCTION FROM LIGHTNING

Sergei P. SMYSHLYAEV (Russian State Hydrometeorological Institute, 98 Maloohtinsky, St.Petersburg 195196, Russia, e-mail: smyshl@meteo.rshmi.spb.ru)

A two-dimensional chemistry transport model with input parameters from a global circulation model is used to evaluate stratospheric ozone sensitivity to the strength of NOx lightning production. NOx production from lightning is one of the most important sources of reactive nitrogen in the atmosphere. Recent studies of NOx produced from lightning have concluded that the magnitude of this source is likely to be between 2 and 25 Tg N/year and cannot be better quantified at this time. Major variability in the effect of lightning on the background levels of atmospheric nitrogen oxides may lead to variability of ozone in the lower stratosphere and to uncertainties in the calculated effects of man-made impacts on the atmospheric ozone layer. To examine the role of NOx lightning production uncertainties in the atmospheric ozone variability, we have done a number of numerical experiments with the SUNY-SPB two-dimensional model. The amount of nitrogen oxides produced by lightning discharges was varied from 2 to 25 TgN/year. Results of model calculations show that ozone distribution in the lower atmosphere is very sensitive to the strength of NOx production from lightning. Assessment of man- made impacts on the ozone layer, such as chlorofluorocarbons and halons emissions and aircraft ejections are especially sensitive to the nitrogen lightning production.

GRAVITY WAVE VARIABILITY IN THE MIDDLE ATMOSPHERE

Robert A. VINCENT (Department of Physics and Mathematical Physics, University of Adelaide, Adelaide 5005, Australia, e-mail: rvincent@physics.adelaide.edu.au)

The seasonal and geographical variability of gravity wave activity in the middle atmosphere has been studied by a variety of techniques, including rockets, radiosondes, radar, lidar and satellites. The aims of these studies include the statistical description of the wave field and determining sources. Recent observations will be reviewed and some of the factors that influence their interpretation, such as the filtering effects of the background winds and observational selection, discussed.

LONG-TERM TRENDS IN LOWER STRATOSPHERIC CIRCULATION AND THEIR INFLUENCE ON COLUMN OZONE TRENDS AT NORTHERN MID-LATITUDES

Lon HOOD, S. Rossi, and M. Beulen (Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721, USA, e-mail: lon@lpl.arizona.edu)

It is well established that a major cause of global column ozone trends is heterogeneous chemical losses on lower stratospheric aerosols in the presence of increasing concentrations of anthropogenic chlorine and bromine. However, at northern mid-latitudes, several studies have obtained empirical evidence that a significant fraction (as much as 40 per cent) of the zonally averaged column ozone trend in winter and early spring is attributable to differences in ozone transport associated with long-term changes in lower stratospheric circulation. At certain longitudes, e.g., over western Europe, the contribution to ozone trends from this source is well over 50 per cent. We investigate here the origin of changes in lower stratospheric circulation in winter that have been responsible for this effective contribution to mid-latitude ozone trends. The primary signature of the circulation trend consists of a modification of the zonal wind field in the upper troposphere and lower stratosphere such that the winter vortex is strengthened near 60 N and weakened near 30 N. This results in a less cyclonic mid-latitude meridional wind shear that favors the occurrence of more anticyclonic breaking events. The acceleration of the vortex near 60 N is associated with polar cooling and has been predicted by some GCM's that include greenhouse gas forcing. However, a portion of the polar cooling is also attributable to chemical ozone depletion.

A CHANGE IN THE ABUNDANCE OF SUB-TROPICAL INCURSIONS INTO THE MID-LATITUDE LOWER STRATOSPHERE

Stephen J. REID (National Research Council, Washington D.C./NOAA Aeronomy Laboratory); Adrian F. Tuck and George N. Kiladis (NOAA Aeronomy Laboratory, Boulder, Colorado 80303, USA)

Incursions of tropical and subtropical air into the middle latitude lower stratosphere have been modelled by a number of researchers. The presence of a lower-stratospheric minimum in ozone, identified by an ozone content of * 200 ppbv, reduces the total column by 10-15% over several million square kilometres. According to the 30-year record of ozone data archived by the World Ozone Data Center in Canada, the number of minima entering the northern mid-latitude lower stratosphere has increased in recent years. The lowest ozone concentrations within the ozone minima are generally found in the isentropic range 370-380K, coincident with the altitude of the subtropical tropopause break. Clusters of back trajectories from each minimum detected at mid-latitude ozonesonde stations demonstrate that air containing an ozone minimum is subtropical in origin. An increase in the number of such events has implications for the mid-latitude ozone trend. In-situ measurements obtained by NASA's ER-2 aircraft in the subtropics and mid-latitudes show the presence of ozone minima. The suite of onboard instruments also reveals corresponding maxima in N2O, CH4 and CO, coupled with low H2O. The concentrations of N2O and H2O in particular suggest a strong tropical tropospheric component in these air masses. The global distribution of ozone minima, and minima/maxima in several other tracers, are provided by HALOE and SAGE II data. Evidence for dynamical changes which may be responsible for the increased numbers of mid-latitude ozone minima is provided by a statistical treatment of the NCEP re-analyses data set.

MEASURES OF SMALL SCALE VARIABILITY AND FRACTALITY IN TIME SERIES OF STRATOSPHERIC AIRCRAFT AND BALLOON DATA

Adrian TUCK (NOAA Aeronomy Laboratory, 325 Broadway, Boulder CO 80303-3328, USA, e-mail: tuck@al.noaa.gov); Susan Hovde (CIRES/NOAA Aeronomy Laboratory, 325 Broadway, Boulder CO 80303-3328, USA, e-mail: hovde@al.noaa.gov); Michael Proffitt (CIRES/NOAA Aeronomy Laboratory, 325 Broadway, Boulder CO 80303-3328, USA, e-mail: proffitt@al.noaa.gov)

Four measures of variability are applied to time series of meteorological and chemical quantities observed from the ER-2, WB57F and balloons. Modulation factor and relative dispersion give results that show maximum values in regions of sharp gradients, that is to say edges of filaments and laminae. The calipers measure, used in a way preserving phase information, shows minimum values at the centre of filament edges and maxima elsewhere; the fraction of 1 Hz time intervals having zero variability above instrument noise reveals a maximum scale of 3.2 km (16 s) for unmixed filament edges. The measure also reveals that over scales larger than about 60 km ozone has near maximum possible variability, and that about 65% of all 1 Hz bins are still inhomogeneous at 600 m. The Hurst exponent H is used to examine fractality, with the result that all quantities observed with adequate S/N ratio are indeed self-affine fractals; ozone and horizontal wind speed are random (H=0.5), wind direction has a small tendency to persistence (H>0.5), temperature is persistent (H>0.5) and vertical wind speed is antipersistent (H<0.5). It is argued that the measures together provide a sharper instrument than traditional power spectral analysis. The implications for stratospheric mixing and its affect upon calculations of chemical loss rates are discussed. Balloon data are examined up to 40 km, where the slow motion relative to the air and low pressure extend the examination for homogeneity as a function of scale.

TIME SERIES OF REACTIVE BROMINE, CHLORINE, AND NITROGEN SPECIES TOGETHER WITH OZONE OBSERVED AT ARRIVAL HEIGHTS (77.8S), ANTARCTICA

Karin KREHER, Gregory E. Bodeker, Stephen W. Wood, Brian J. Connor, and Paul V. Johnston (National Institute of Water and Atmospheric Research, Private Bag 50061, Omakau, 9182, New Zealand, email: k.kreher@niwa.cri.nz, g.bodeker@niwa.cri.nz, s.wood@niwa.cri.nz, b.connor@niwa.cri.nz, p.johnston@niwa.cri.nz) Philip M. Solomon (Dept. of Physics and Astronomy, State University of New York at Stony Brook Stony Brook, NY, email: psolomon@sbastk.ess.sunysb.edu)

Since 1993 ground-based measurements of OClO and NO2 have been made at Arrival Heights with a new diode array spectrometer. In 1995 measurements of BrO and ozone were added using the same instrument. Spectra in the UV/visible wavelength region are taken throughout the day and during the twilight period (solar zenith angle < 96) using zenith sky absorption spectroscopy.
Total column measurements of OClO, BrO and NO2 are presented to show diurnal, seasonal and interannual changes. These observations are discussed in the context of supplementary data sets such as total columns of ClO, HCl, HNO3 and NMC temperatures. Due to dynamically induced displacements of the vortex, observations at Arrival Heights are made in three regions: inside the polar vortex, in the vortex boundary region and outside the vortex. For a quantitative analysis, Ertel's potential vorticity and wind fields from the NCEP/NCAR reanalysis data set and the UKMO data set are used to define these three dynamically distinct regions and to investigate differences in stratospheric chemistry in these regions based on the observations discussed above.

MID-LATITUDE PLANETARY WAVE INFLUENCE ON THE SEVERITY OF ANTARCTIC OZONE DEPLETION

G.E. BODEKER, J.G. Keys and B.J. Connor (National Institute of Water and Atmospheric Research, Lauder, Private Bag 50061, Omakau, Central Otago, 9182, New Zealand)

Previous studies [Bodeker and Scourfield, 1995; Shindell et al., 1997] have shown that mid-latitude planetary waves play an important role in modulating the inter-annual variability in Antarctic ozone depletion. Planetary waves affect vortex temperatures above 25 to 30 km through heat transport, affect vortex area and isolation by eroding material from its edge, and affect sunlight conditions inside the vortex by elongating it and displacing its center from the pole. The purpose of this paper is to use global ozone and meteorological measurements to demonstrate more quantitatively these wave-vortex interactions and to better understand how they determine the severity of Antarctic ozone depletion.
Daily global total column ozone data from 1978 to 1997 were obtained from four different Total Ozone Mapping Spectrometer (TOMS) experiments and the Global Ozone Monitoring Experiment (GOME). These data were regridded by equivalent latitude calculated on the 450 K surface [Nash, 1996] and zonal means were calculated. Equivalent latitude mapping provides a vortex centered co-ordinate system which preserves steep meridional gradients across the vortex boundary when calculating zonal means. Likewise, daily 450 K NCEP/NCAR reanalysis temperatures for the same time period were regridded by equivalent latitude and zonal means were calculated. A measure of the strength of the polar vortex was derived by multiplying the first derivative of 450 K potential vorticity with the mean wind field along PV isolines as in Nash [1996]. The meridional maximum in this quantity defines the vortex edge and allows calculation of the vortex area. Mid-latitude planetary wave amplitudes for the first 6 wave modes are diagnosed by Fourier analyses of daily 20 hPa geopotential heights. Daily Antarctic depleted ozone mass values [Bodeker and Scourfield, 1995] are used to quantify the severity of Antarctic ozone depletion. The chain of events linking mid-latitude planetary wave variability to variability in the severity of Antarctic ozone depletion is investigated through lagged cross-correlation and linear least squares regression analyses of time series derived from the data sets discussed above. By examining the time lags revealed by these cross-correlations we plan to test the modelling based observation [Shindell et al., 1997] that midwinter wave activity may be the best predictor of the severity of the ozone hole the following spring.

MI12/E/04-B5 1155

INTERANNUAL VARIABILITY OF THE SOUTHERN WINTER POLAR VORTEX RELATED TO THE EQUATORIAL QBO

Yoko NAITO and Isamu Hirota (both at Department of Geophysics, Kyoto University, Kyoto 606-8502, Japan E-mail: naito@kugi.kyoto-u.ac.jp)

The correlation between the polar vortex in the northern winter and the equatorial quasi-biennial oscillation (QBO) has been studied long time since Holton and Tan (1980).
On the other hand, the evolution of the stratospheric circulation in the southern winter is different from that in the northern winter. Any major warming is not observed, and the polar-night jet shifts poleward and downward in late winter to early spring. The year-to-year variation of the timing of this shift-down makes the large interannual variability in connection with the planetary wave activity.
In order to investigate the variability, we made statistical analysis by using the NCEP/NCAR reanalysis data over 40 years (1958-1997). Unlike the northern winter, the polar-night jet in the southern winter has the largest correlation with the QBO in spring. It is found that, in November, the jet is stronger (weaker) in the westerly (easterly) category of the QBO. Further discussion is made in term of the planetary wave propagation and its interaction with the mean flow.

MI12/W/16-B5 1215

EFFECT OF THE QUASI-BIENNIAL OSCILLATION (QBO) ON TRACER TRASPORT - INTEGRATION WITH KASIMA (KARLSRUHE SIMULATION MODEL OF THE MIDDLE ATMOSPHERE)

Irmgard LANGBEIN and Wolfgang Kouker (Institut fuer Meteorologie und Klimaforschung Forschungszentrum Karlsruhe, Postfach 3640, D-76021 Karlsruhe, Germany)

The quasi-biennial oscillation (QBO) of the zonal wind in the equatorial tropical stratosphere significantly influences the transport of long-lived tracers and their distribution in the stratosphere. To see what role the QBO plays in the transport of tracers, a pertubation has been applied to the model wind field of the Karlsruhe Simulation Model of the Middle Atmosphere (KASIMA, a 3-dimensional primitive equation model), to simulate the effect of the QBO.
From the ECMWF dataset of the period from 1979 to 1994 the mean zonal wind was calculated and the time-height cross section showed a QBO in the equatorial region. From a harmonical analysis of this oscillation we determined the amplitudes and phases as a function of height and latitude. By applying a band pass filter, high and low frequent oscillations are suppressed. A zonal wind with an idealised QBO is reconstructed from this amplitudes and phases.
A zonal mean zonal force is applied to the model in the tropics in form of a Rayleigh friction type relaxation term with the idealized QBO-wind as equilibrium wind and a relocation time of 3 days. With this model version the QBO-induced mean meridional circulation, the correlated temperature signal and the influence on the transport of passive tracers are studied in detail and results are discussed.

THE LARGE-SCALE ZONALLY ASYMMETRIC OZONE DISTRIBUTION

Dieter H.W. PETERS (Institude fur Atmosphdrenphysik an der University of Kuhlungsborn, Meckleburg-Vorpommern, D-18225, Germany, E-mail: peters@iap-kborn.de)

The large-scale zonally asymmetric ozone distribution is mainly determined by advective transport of quasi-stationary waves in winter of northern and southern hemisphere. It is well known, that a decadal change of the quasi- stationary wave structure in the 80ies caused a change of the large-scale ozone distribution, especially in January over Europe, here we found a total ozone decrease of the same order as the zonal mean trend. In this paper we want to examine the role of quasi-stationary wave structure changes for changes of the zonally asymmetric ozone field in the 60ies and 70ies on the basis of re-analyses data. A linear transport model is used to perform transport calculations as a function of given geopotential and zonal mean ozone. A comparison and discussion of the model results for the North Atlantic European region with results received for the 80ies are presented.

HOW DOES THE GLOBAL-SCALE ATMOSPHERIC CIRCULATION PRODUCE CLOUDS?

William B. ROSSOW (NASA Goddard Institute for Space Studies, 2880 Broadway, New York, NY 10025, USA, e-mail: wrossow@giss.nasa.gov)

Although clouds are produced by "micro-scale" processes, these processes operate as a response to global-scale atmospheric motions to produce the complex geographic distribution of clouds on Earth. One way to attack this larger-scale problem is to combine global-scale satellite observations of cloud property variations with global-scale determinations of the atmospheric circulation. Such a global data analyses can be used to describe the mean characteristics of clouds and their variations, to identify systematic relations among observed cloud properties and atmospheric motions, or to estimate, directly, the derivative relations of the processes at work using statistical life-cycle- composites of cloud system evolution. Another approach is to find what characteristics of the global atmospheric circulation are revealed in observed global-scale cloud variations. All of these results can be used to verify the cloud representations in global climate models. For the first time last type of analysis is possible with the advent of global, satellite- based cloud (ISCCP), precipitation (microwave-based), and water vapor (merged infrared and microwave) datasets, together with global wind datasets (ECMWF and NCEP re-analyses), all of which resolve features at least down to the upper end of the mesoscale and cover more than a decade. We report on some preliminary attempts to identify quantitative relationships between atmospheric motions and cloud properties that are relevant to cloud processes. Three examples are given: (1) cloud variations at the smallest scales and what they reveal about the nature of small-scale turbulence in the atmospheric boundary layer, (2) cloud variations at "moderate" weather-scales and what they reveal about meteorological storm systems, and (3) cloud variations at the largest scales and what they indicate about interannual variations of climate.

MW02/W/04-B3 0910

THE CHARACTERISTICS OF CLOUD FIELDS AND ENERGY DISTRIBUTION ASSOCIATED WITH SYNOPTIC-SCALE CIRCULATION SYSTEM IN A GENERAL CIRCULATION MODEL

Cheng-Ta CHEN (Dept. of Earth Sciences, National Taiwan Normal University, Taipei, Taiwan, R. O. C., e-mail: chen@cloud.geos.ntnu.edu.tw) Erich Roeckner (Max Planck Institute for Meteorology, Hamburg, F. R. Germany)

Cloud fields and concurrent atmospheric dynamical structures associated with extratropical cyclone in a general circulation model are constructed using the ensemble mean of the cloud systems traced. The composite pictures of these simulated features are in good agreement with both the recent observational study using satellite cloud climatology and operational analyses and the classical conceptual model for the organization of cloud properties near cold and warm frontal zones. The vertical structure and wave characteristics of various dynamical and hydrological fields linked to the mid-latitude circulation system in the model are resemble to those observed feature characteristics of a baroclinic wave. The new approach to investigate the general properties of cloud system embedded in the focused midlatitude baroclinic activities enables the depiction of the interactions between cloud and circulation in the model. The impact of extratropical frontal system on the ambient atmosphere and its energy and water budget can be easily deduced from the dynamically consistent model data and their direct links to the physical processes in the model. The method provides an unique way to reveal the cloud systems in different climate regimes. Constrained by the empirical and theoretical findings, the composite pattern from the simulation can help in guiding the development of physical parameterization in the model.
