ELASTIC THICKNESS OF THE LITHOSPHERE AT THE AZORES PLATEAU. A SPECTRAL ANALYSIS APPROACH

Alexandra CARVALHO (Centro de Geofísica da Universidade de Lisboa, R. Escola Politécnica 58, 1250 Lisboa, Portugal, email: adias@fc.ul.pt); Joaquim Luis (Universidade do Algarve, UCEH, Campus de Gambelas, 8000 faro, Portugal, email: jluis@mozart.si.ualg.pt); J.M. Miranda (CGUL, R. Escola Politécnica 58, 1250 Lisboa, Portugal, email: jmiranda@fc.ul.pt)

The azores plateau is a zone of anomalously shallow topography with an approximately triangular form defined by the Mid-Atlantic Ridge (MAR) axis between 40 and 37º30´N in the West, the East Azores Fracture Zone (EAFZ) in the South and a line running WNW-ESE from the MAR to the Western limit of Gloria fault and is often interpreted as the morphological signature of the third arm of the Azores Triple Junction.
A study performed in 1996 account for a regional compensation scheme of the Azores Plateau and a lack of local compensation in topographic high and deep lows, reinforcing the conclusion that the Terceira Axis constitutes a zone of intense intraplate volcanism, but where there is no gravity evidence for the existence of a spreading axis.
Here we present a isostatic study based on a spectral approach, using a free air anomaly map and a bathymetric data shipboard gravity data. These data allowed to compute the admittance, which carries information on the rheology of the lithosphere, and to compare it to theoretical estimates of some isostatic models. Results were compared to available magnetic, gravity and seismic information.

GEO-DYNAMIC MEASUREMENTS OF COOPERATION BETWEEN CHINA AND SPAIN IN LANZAROTE ISLAND SPAIN

Jun JIANG (Institute of Seismology, China Seismological Bureau, Wuhan 430071, P. R. China, email: JiangJun@public.wh.hb.cn); R. Vieira (Institute of Astronomy and Geodesy CSIC-UCM, Madrid, Spain, email: vieira@iagmat1.mat.ucm.es); Weixin Cai and Shiling Tan (both at Institute of Seismology, China Seismological Bureau, Wuhan 430071, P. R. China); J. Arnoso and E. Velez (both at Institute of Astronomy and Geodesy CSIC-UCM, Madrid, Spain)

The geo-dynamic measurements of the cooperative project between China and Spain in Lanzarote Island of Spain were started in 1991, after the recommendation of United Nations to dedicate the last decade of the century to investigation and possible prevention of natural disasters. The objective is to obtain the tidal tilt and strain models as well as to study the non-tidal tilt and strain variations that can be produced by local tectonic movements. These variations can be studied by continuous observation of surface deformation with tilt and strain techniques (Vieira et. al., 1995). It was convenient to include between the objectives of our researches. It was not only the traditional results of tidal observations but also the investigation of those phenomena of geodetic origin that can disturb the tidal parameters or at least produce signals in the recordings of very sensitive instruments use in tidal research (Vieira, 1997). There have been three periods of the cooperation between China and Spain since 1991. We have installed seventeen geo-dynamic sensors in Lanzarote to take the cooperative researches in fields of tidal measurements, volcanic monitoring and possible prevention of natural disasters. In this paper, we will mainly introduce the results of the geo-dynamic measurements in Timanfaya from 1996 to 1998, that is the third period of the cooperation between China and Spain. There are nine geo-dynamic sensors included the tilt-meter (water tube and vertical pendulum), horizontal extensometer, air temperature thermometer, rock temperature thermometer and underground high temperature thermometer running in Timanfaya laboratory for tidal measurements and geo-dynamic researches. The sensitivities of the instruments in Timanfaya were changed into a lower than the instrumentation for tidal measurements on May of 1998 because the environmental influence is so stronger that is too difficult for the tidal measurement, and also they are completely settled for a volcanic activities monitoring and investigation. For the above purpose, here we make some new methods and use them to do the data analysis besides the tidal analysis. In this paper, the geo-dynamic instruments installed in Timafaya are introduced briefly. Three different filter and spectrum models are applied to the data processing. The spectrum features from the models are investigated and compared. The environmental influence for the geo-dynamic measurements is estimated. The features of ground deformation in Timanfaya is investigated and discussed.

Finally, we also put forward some proposals and applied ways to study the dynamic process of volcanic activities with tidal measurement and geo-dynamic researches.

TIDAL EFFECTS ON DETERMINING A POINT AT THE BOTTOM OF THE SEA BY COMBINING GPS AND SONAR OBSERVATIONS

Wenke SUN and Lars E. Sjoberg (both at Royal Institute of Technology, Department of Geodesy and Photogrammetry, S-10044 Stockhom, Sweden, e-mail: sunw@geomatics.kth.se)

This paper treats three kinds of Earth tides: crust tide, equipotential surface point (ocean depth) tide and geoid tide, which are closely related with an observation scheme to determine a point at the bottom of the sea by combining GPS and Sonar observations. The relations between the Earth tides and the tidal effects on GPS and ocean depth observations are discussed. The corresponding mathematical expressions are derived and numerical calculations are performed to demostrate the tidal effects on GPS and Sonar observations. The maximum vertical tidal effects are estimated to reach 102.9 cm for the geoid tide and 48.0 cm for the crust tide, while the maximum horizontal tidal effects are as much as 410.5 cm and 26.6 cm for geoid tide and crust tide, respectively. Theoretical results imply a very interesting conclusion, namely, in a local area, the static position of a point at the bottom of the sea can be obtained by the dynamic observations via a platform on the sea without any tidal correction. Actually, the tidal effects cancel each other in the mentioned observation scheme. It therefore indicates that the observation scheme is free of tidal effects. Furthermore, we learnt that the divergence caused by any error source on ocean surface is canceled and does not affect the final results. Therefore, to determine the position of a point at the bottom of the sea, we need not consider any tidal effects.

STUDY OF TRANSFER FUNCTIONS BETWEEN AIR PRESSURE AND OBSERVED EARTH TIDE AT CURITIBA TIDAL STATION, BRAZIL

Sílvia Helena S. SCHWAB (Graduate Program in Geodetic Sciences, Federal University of Parana, C.P.19001, Curitiba, Pr, Brazil, CEP - 81531-990, email: silviass@geoc.ufpr.br) Sílvio Rogério Correia de Freitas (Graduate Program in Geodetic Sciences, Federal University of Parana, C.P.19011, Curitiba, Pr, Brazil, CEP - 82531-990, email: sfreitas@cce.ufpr.br Wladimir Shukowsky (Astronomical and Geophysical Institute, São Paulo University, SP, Brazil, email: wladimir@iag.usp.br)

The influence of air pressure on gravity tide is theme of on-going research due to the increasing precision in observations. For this purpose it is important to study its influence in the different frequency bands of the tidal spectrum. Curitiba Tidal Station has been used as reference station since 80's for South American determinations of earth tide parameters but the local and regional air pressure influence patterns have not been studied until now. As a consequence, usually in data processing, standard values have been adopted to correct its influence on tidal gravity measurements. This work presents the study of the Curitiba station air pressure admittance in each tidal band, based on an observation series performed with the GEO 783 gravity meter. Comparisons of the obtained transfer functions of fortnightly blocks have been made as a way to generate a set of values which were compared with the usual pattern.

G5/E/08-A4 Poster **1556-09**

A DISCUSSION ABOUT GRAVITY PARAMETERS AT CURITIBA STATION

Silvio Rogerio Correia DE FREITAS (Graduate Program in Geodet Federal University of Parana, C.P 19011, Curitiba, Brazil 82531-990, Email: sfreitas@cce.ufpr.br); Silvia Helena Soares Schwab (Graduate Program in Geodetic Sci Federal University of Parana, C.P 19001, Curitiba, Brazil email: silviass@geoc.ufpr.br); Marta Silvia Maria Mantovani (Astronomical and Geophysical Ins Paulo University, SP, Brazil, Email: marta@iag.usp.br); Wladimir shukowsky (Astronomical and Geophysical Institute, Sao University, SP, Brazil Email: wladimir@iag.usp.br)

The tidal gravity factors at Curitaba Tidal Station, Brazil, determined in 1982/84. This determination was performed based month long series of observations with the Geo783 gravity calibrated at Brussels station. Besides this series of observations gravity meters were used around the same period to check main parameters.
The determined tidal parameters were considered as reference normalistion of other gravity meters used in the tidal observations in America. Considerations about the adequacy of the tidal factor Brussels Fundamental Station and observations with other gravity calibrated on other basis which operated in Curitiba Tidal Station indicate the need of discussion about the redefinition of tide in Curitiba.
A discussion is proposed in this presentation, taking into account the comparison of gravity tides residuals and ocean load at the station.

TIME-DEPENDENT PHENOMENA MONITORED BY ONE-HOUR GPS OBSERVATIONS

Janusz BOGUSZ, Mariusz Figurski and Micha Kruczyk (Institute of Geodesy and Geodetic Astronomy, Warsaw University of Technology, 00-661 Warszawa, POLAND, e-mail: jb@gik.pw.edu.pl)

From December 1998 Observatory in J¢zefosaw has started permanent GPS observations with one-hour sampling rate. WUT EUREF Local Analysis Centre plans to begin from 1st of January 1999 one-hour GPS data processing using BERESE v. 4.0 software and Hewlett Packard J200 machine. There would be tested simultaneously two methods of computing:
1. Processing of one-hour observations with the aim to explore local geodynamical changes based on part of EUREF network.
2. Analysis of possibility of generating ionosphere and troposphere parameters in quasi-real time.
We hope that acquired solutions would help us to create new possibilities of researching of local and fast changeable geodynamical processes. This paper will present preliminary results of such processing and analytical methods implemented to solute all involved problems.

UNION LECTURE 4

VARIABILITY OF WEATHER AND CLIMATE

Brian Hoskins, UK

The variability of weather and climate on time-scales from weeks to seasons will be discussed. The extent to which it is predictable is as yet largely unknown, though any such predictive power could have important consequences. It will be argued that the natural variability is now the key to progress on discussions of anthropogenic climate change. In one view it provides the noise against which the signal has to be determined. Alternatively, the most important regional anthropogenic climate change may be expected to occur through a biasing of the probablity distribution of the modes of natural variability. In this talk it will be stressed that the system whose variability is being considered is increasingly being extended from the physical atmosphere-ocean system to include more of the geosphere-biosphere system and that simultaneous consideration of the human dimension is also becoming increasingly important.

SEISMIC TOMOGRAPHY OF IGNEOUS SYSTEMS

Bernard CHOUET (U.S. Geological Survey, 345 Middlefield Road, Menlo Park, California 94025, USA, email: chouet@chouet.wr.usgs.gov)

High-resolution tomography based on iterative inversions of travel-time data from local earthquakes has been used to image the internal structures of a few volcanoes at scales ranging from 0.5 to 2 km.
In southern Hawaii, high-velocity bodies in the upper 9 km of the crust beneath the summits and rift zones of Mauna Loa and Kilauea Volcanoes are interpreted as solidified gabbro-ultramafic cumulates from which surface volcanism is derived. Embedded in the high-velocity body beneath the Kilauea Caldera region is a low P-wave velocity body roughly the size of the caldera and which extends through the upper 4 km of the crust. The velocity contrast between this body and the surrounding structure is about 10%. Associated with the low P-wave velocity structure is a zone with anomalously high ratios of P- to S-wave velocities, which is consistent with a hot volume which may contain a small fraction of melt.
The most prominent feature observed in the velocity structure of Redoubt Volcano, Alaska, is a relative low-velocity near-vertical, pipelike structure approximately 1 km in diameter that extends from 1 to 6 km beneath sea level. This feature aligns axially with the seismicity and is interpreted as a highly fractured and altered zone encompassing a magma conduit. No large low-velocity body suggestive of a magma chamber is resolved in the upper 7-8 km of the crust. Results at Mount Etna, Sicily, show a near-vertical low-velocity zone extending beneath the central crater to a depth of 10 km. This low-velocity region coincides with a band of steeply-dipping seismicity and is interpreted as a zone of crustal weakness through which magma migrates to the surface. A high-velocity body beneath the southeast flank of Etna is interpreted as a remnant mafic intrusion. This structural feature influences both volcanism and east flank slope stability and faulting.

FLOOD BASALTS, PLUMES, AND PLATE TECTONICS

Millard F. COFFIN (Institute for Geophysics, The University of Texas at Austin, 4412 Spicewood, Springs Road, Building 600, Austin, TX 78759-8500, USA, email: mikec@ig.utexas.edu); Olav Eldholm (Department of Geology, University of Oslo, PO Box 1047, Blindern, N-0316 Oslo, Norway, email: olav.eldholm@geologi.uio.no); James W. Head III (Department of Geological Sciences, Brown University, Box 1846, Providence, RI 02912, USA, email: James_Head_III@brown.edu)

Large igneous provinces (LIPs) result from voluminous mafic magmatism. On Earth, LIPs originate from the mantle via mass and energy transfer which acts both independently of, and in conjunction with, seafloor spreading processes manifested along the mid-oceanic ridge system. Not readily explained by plate tectonic theory, the massive magmatism is most commonly attributed to mantle plumes. Most LIPs form in extensional tectonic settings, suggesting a relationship with thinned lithosphere. The post-150 Ma LIP record reveals both many events and large melt volumes from 135-85 Ma, and a distinct decline since 50 Ma. These trends may reflect variations in mantle circulation and have links to global environmental change. In contrast to Earth, other terrestrial planets of the solar system show no significant evidence of plate tectonics: the dominant form of mass and energy transfer from planetary interiors is apparently plumes. On the Moon, ascending basaltic magma collected in reservoirs at the base of the thick anorthositic crust, and when the reservoirs became overpressurized, dikes propagated to the surface. Titanic Martian shield volcanoes formed on stable lithosphere over hot spots lasting a billion years or more. Impact cratering studies on Venus suggest rapid, planet-wide volcanic resurfacing at about 300 Ma, an event that resembles mantle overturn events proposed for Earth. Such an event has implications for episodic and catastrophic LIPs throughout the history of the planets.

EXPLOSIVE VOLCANISM: CAUSES AND CONSEQUENCES

R.S.J. SPARKS (Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK, Email: steve.sparks@bris.ac.uk)

Progress in understanding explosive volcanism has been prodigious in the last two decades as a consequence of detailed documentation of several major eruptions, the increasing sophistication of numerical models and the application of laboratory experiments. The eruptions of Mount St Helens (1980-86), Mount Pinatubo (1991) and the Soufriere Hills Volcano, Montserrat (1995-1998) have provided comprehensive case histories in which geochemical, geophysical, petrological and remote ensing techniques have been combined with geological studies to provide quantitative information and constraints from the magma chamber to the stratosphere on explosive processes. The rapid increase in computer power has enabled a number of research groups to develop numerical models of explosive flows which are increasingly realistic in terms of simulating natural complexity and conditions. Incorporation of non-equilibrium effects, strong rheological changes, compressible flow dynamics, better degassing models and fragmentation criteria are examples of features of the new generation of computer models. New insights including understanding changes and discontinuities in discharge rate, stability of eruptive discharges into the atmosphere and transitions between effusive and explosive eruptions. Major results include the recognition that strong non-linearities and feedback processes cause pulsations, sudden transitions in eruptive style and, in some cases, multiple states for exactly the same conditions, making explosive activity at a certain level inherently unpredictable. Laboratory experiments have also had an important role. Shock tube experiments, using both analogue and natural materials, show the complexities of two-phase flows, giving new insights into fragmentation mechanisms. Some features of explosive flows, for example strong spatial heterogeneity, are still beyond the reach of numerical calculations. Future developments are likely to involve application of geophysical and remote sensing techniques to make direct measurements of explosive flow properties.

U6/W/07-B2 Invited **1135**

MELTING, STORAGE AND MOVEMENT OF MAGMA

Jon DAVIDSON (Dept. of Earth and Space Sciences, UCLA, Los Angeles, CA 90095, USA, email: davidson@ess.ucla.edu)

Understanding processes of magma generation and differentiation remains an elusive yet critical goal in Earth Sciences. On the one hand, inferences about magma sources and mantle-crust fluxes or mantle reservoir characteristics and their evolution are largely based on incompatible trace element and isotope characteristics of mafic magmas. On the other hand, the nature of high-level differentiation processes, magma chamber or otherwise, and the timescales of operation are important controls on the volcanological behavior of magma systems, such as eruption magnitudes and frequencies. One approach in addressing such problems is "from the bottom up". Theoretical calculations of melt compositions are currently quite sophisticated. These calculations are able to incorporate empirical data collated from experiments – such as in the MELTS algorithm - and take into account elemental exchange effects during transport, which initially is assumed to be relatively slow (chromatographic porous flow). The alternative approach is more "top down", taking as its basis real data collected from magmatic rocks and their component minerals and glasses, and associated volatiles. Of the methodologies used to invert such data to constraining processes and sources U-series geochronology (to constrain differentiation timescales) and crystal isotope stratigraphy/ melt inclusion studies (to constrain differentiation pathways) have proved particularly fruitful. It is clear that differentiation may profoundly modify many of the geochemical characteristics of primary magmas thus creating a potential mismatch between the actual data characterizing a magma system, and the assumed source characteristics which form the basis of "bottom up" approaches. Nevertheless, an integration of perspectives is conceivable and should be pursued in our efforts to employ magmatic rocks as probes of crust and mantle processes through time.

OZONE DEPLETION: THE ROLES OF CHLOROFLUOROCARBONS AND VOLCANOES

Susan SOLOMON (Aeronomy Laboratory, 325 Broadway, Boulder, CO 80303 USA, email: solomon@al.noaa.gov)

Early theories of ozone depletion by chlorofluorocarbons were based upon understanding of gas-phase photochemistry. Ozone depletion was first observed in the Antarctic, and was quickly shown to be driven by heterogeneous chemistry involving chlorine compounds and polar stratospheric clouds. Significant ozone changes have also been observed in the Arctic and at mid-latitudes. Some aspects of ozone depletion are clearly related to gas-phase reactions, while others are coupled to heterogeneous reactions. Volcanoes play a major role in modulating the abundances of polar stratospheric clouds and of mid-latitude stratospheric aerosols. It will be shown that short-term (interannual) and longer-term (decadal) changes in volcanic aerosols very likely contributed along with trends in anthropogenic chlorine and bromine in triggering the ozone losses observed at mid-latitudes and in polar regions in the early l980s. However, this chemistry is linked to the chlorine abundance, so that volcanoes are not a mechanism for ozone loss independent of human emissions of chlorofluorocarbons. The timing and magnitude of future ozone losses are likely to be strongly dependent upon volcanic aerosol variations as well as on future chlorine and bromine loading, so that the recovery of the ozone layer in the 21st century will very likely be modulated by volcanic activity, as it has been in the 20th.

U6/W/10-B2 **1430**

GASES OF PLANET EARTH: MANTLE ORIGINS AND ATMOSPHERIC IMPLICATIONS

Bernard MARTY (Centre de Recherches Pétrographiques et Géochimiques et Ecole Nationale Supérieure de Géologie, BP 20, 54501 Vandoeuvre Cedex France, Email: bmarty@crpg.cnrs-nancy.fr)

Most of volatiles (water, carbon dioxide, nitrogen, halogens, rare gases) present at the Earth's surface were contributed early during accretionary processes. Since then, volcanism is supplying gases in proportions roughly proportional to its activity rate. Part of these volatiles are recycled back into the mantle, so that each species has its own geochemical cycle. Some are cycled between the mantle and the surface with time constants lower than the age of the Earth (e.g., C, S), so that it is possible to derive a mean residence time at the surface. For

others (e.g., nitrogen, rare gases), the flux from the mantle to the surface exceeds the return flux, allowing primitive isotope heterogeneities between the surface and the deep Earth to survive. Since the mantle is chemically heterogeneous, it is possible to characterise mantle sources of lavas and corresponding tectonic settings by analysing the isotope composition of some of these elements. Helium provides a sensitive provenance tracer since its isotopic composition in volcanic rocks and gases varies over an order of magnitude between arc-type, and plume-type volcanisms. Rare gases allow also to derive quantitative fluxes of major volatiles (e.g., carbon dioxide), and to model their geochemical history. Volatile isotope geochemistry has recently allowed to demonstrate that major LIP provinces are linked with the development of plumes originating below the convective mantle feeding mid-ocean ridge volcanism. Since the emission of CFB and related felsic volcanism occurs in a limited interval of time, it is likely that such gigantic volcanism has had noticeable climatic impact. The case of the Afar-Ethiopian plume province (CFB and ignimbrite emissions at 30 Ma) will be discussed in this context.

U6/W/12-B2 Invited **1500**

REMOTE SENSING: NEW WAYS TO LOOK AT VOLCANOES AND THEIR GASES

Peter FRANCIS (Earth Sciences, Open University, Milton Keynes, MK76AA, UK; email: P.W.Francis@open.ac.uk)

Increasing world population, urbanization and the technical complexity of society combine to increase the risks presented by volcanic eruptions, exemplified by the hazards to aircraft encountering ash clouds. Developments in remote sensing have provided new ways of both monitoring and to some extent mitigating such hazards, while minimizing risks to volcanologists. Satellite remote sensing provides a powerful volcanological tool because its synoptic coverage makes even the most remote volcanoes accessible; and because sensors working in different parts of the electromagnetic spectrum provide complementary information. Geostationary and polar orbiting platforms are used to measure the heights of ash columns; to assess ash burdens; and to track the dispersion of eruption clouds on an hemispheric scale. The Total Ozone Mapping Spectrometer (TOMS) provides a unique method of measuring sulphur dioxide injected into the atmosphere, while other instruments measure conversion of this gas to stratospheric aerosols which affect global radiation budgets. Infrared sensors are used to measure radiant thermal energy budgets of volcanoes and lavas, and form the basis of automated eruption detection and monitoring systems. Synthetic Aperture Radar satellites provide both high quality topographic data, and a method for detecting ground deformation at a scale of centimetres related to magma movements. Hitherto, observations have been made using sensors designed for purposes ranging from meteorology to agriculture. Future satellites will carry instruments specifically designed for volcanological applications.
New ground based optical remote sensing techniques provide a safer approach to conventional direct chemical sampling of volcanic gases. Open-path Fourier Transform Spectroscopy (FTIR) techniques have been successfuly used to study plume gases at several volcanoes, and have the potential for automated monitoring. Applications of LIDAR techniques promise further refinements to studies of gas composition, evolution of plume chemistry, and aerosol formation.

U6/W/09-B2 Invited **1530**

THE NEW EXPERIMENTAL VOLCANOLOGY

Donald B DINGWELL (Bayerisches Geoinstitut, Universitaet Bayreuth, D-95440 Bayreuth, Germany, Email: don.dingwell@uni-bayreuth.de)

Recent advances in laboratory-based investigations have now made possible a host of experiments on volcanic materials undergoing volcanic processes that may be collectively termed the "new experimental volcanology". The most distinct aspect of this branch of experimental geosciences; and that which makes it almost unique in the "solid" earth sciences, is that experiments are possible in real-time. Thus a key achievement of the past few years has been the enablement of precise experimental control and monitoring of real-time laboratory experiments on natural magmas at the conditions extant in volcanoes. The relevant experimental parameters of temperature, pressure and stress can be measured on extremely short timescales during processes of parameter variation such as decompression and in the context of the textural development of the magma such as crystallisation and vesiculation. The pre-experiment and post-experiment, magma and the experimental volcanic products, respectively, can be analysed using micro- and macro- physical and chemical methods. The resulting documentation of sample evolution yields a very complete comparative picture of the consequences of eruptive processes such as decompression, ascent, vesiculation, crystallisation, foaming and fragmentation on the volcanic materials investigated. The detailed comparison of the products of experimental volcanology with natural volcanic products is also a feature of experiments conducted on natural magmas that cannot be adequately achieved using analogous materials. The salient features of recent experimental work in this field, together with an outlook for future developments, will be presented.

GLOBAL MONITORING OF THE OCEAN

John WOODS (Huxley School of Environment, Imperial College, London SW7 2BP, email: j.woods@ic.ac.uk)

The Global Ocean Observing System (GOOS) was launched by the IOC at the Second World Climate Conference in 1992. That stimulated a proposal for a Global Climate Observing System, with the GOOS providing the ocean observations. Thus integration of global monitoring for climate has been on the agenda for a decade. However the customer base for GOOS is much broader than climate. It includes organisations in both the public and private sector that have responsibility for monitoring and predicting the ocean environment at particular locations. This multi-faceted business already totals billions of Euros per annum and is growing rapidly. The case for global monitoring is that these service providers will be able to improve their products if their operations are set in a global context. That will be achieved by providing each local operational area with information about the open ocean boundary conditions derived from analysis of a global model supported by a global network of observations. The first steps are being taken at a number of centres around the world to link operational global models to operational local high resolution models. Rapid progress has been made during the 1990s in developing ocean and ocean-atmosphere models, and as predicted the Teraflops computers needed to run them are now available. These are being supported by global observations from the World Ocean Observing System and from ongoing global observations of opportunity, notably satellites, drifters and XBTs. The field phase of the World Ocean Circulation Experiment (successfully completed in 1997) provided invaluable experience with novel observing systems, and others not available for WOCE are now being tested, notably acoustic remote sensing and long-range autonomous submersibles. The cost of these observing systems is falling rapidly. The next step is to undertake a number of pre-operational trials involving the integration of observing networks and models at global and local scales. Such trials are being promoted by EuroGOOS and other regional organisations. Their success will depend on the active involvement of the oceanographic research community, who will gain long term benefits from the provision of global observations on a consistent basis year after year.

U7/E/05-B1 Invited **0900**

MASS TRANSPORT IN GLOBAL GEOPHYSICAL FLUIDS

B. F. CHAO (Space Geodesy Branch, NASA's Goddard Space Flight Center, Greenbelt, Maryland 20771, USA; email: chao@denali.gsfc.nasa.gov)

Mass transports occurring in the atmosphere-hydrosphere-solid Earth-core system (the "global geophysical fluids") are important geophysical phenomena. They occur on all temporal and spatial scales. Examples include air mass and ocean circulations, tides, hydrological water redistribution, mantle processes such as post-glacial rebound, earthquakes and tectonic motions, and core geodynamo activities. With only a few exceptions on the Earth surface, the temporal history and spatial pattern of such mass transport are often not amenable to direct observations. Space geodesy techniques, however, have the capability of monitoring certain direct consequences of the mass transport, including Earth's rotation variations, gravitational field variations, and the geocenter motion. These techniques include the very-long-baseline interferometry, satellite laser ranging and Doppler tracking, and the Global Positioning System, all entail global observational networks. While considerable advances have been made in observing and understanding of the dynamics of Earth's rotation, only the lowest-degree gravitational variations have been observed and limited knowledge of geocenter motion obtained. New space missions, projects and initiatives promise to
further improve the measurements and hence our knowledge about the global mass transports. The latter contributes to our understanding and modeling capability of the geophysical processes that produce and regulate the mass transports, as well as the solid Earth's response to such changes in constraining the modeling of Earth's mechanical properties.

U7/E/08-B1 Invited **0925**

GLOBAL INTEGRATED GEODETIC AND GEODYNAMIC OBSERVING SYSTEM

Reiner RUMMEL (IAPG, Techn.Univ.Muenchen, Arcisstrasse 21, D-80333 Muenchen, Germany, email: rummel@step.iapg.verm.tu-muenchen.de)

In a very successful effort the international geodetic community succeeded to realize a terrestrial and celestial reference frame with greatest precision. Modern kinematic monitoring space techniques such as satellite altimetry (ocean and ice), interferometric SAR, or ground based GPS together with terrestrial techniques such as tide gauges or leveling provide a global picture of temporal changes of the Earth's land surface, its ice cover and of the oceans, provided these techniques are rigidly tied to one global terrestrial reference frame. Observation of the variations of Earth rotation adds information to the observing system of the integrated effect of any change in angular momentum of the Earth's system components. The third component, the Earth's gravity field, is currently least well determined, but the situation will change soon with the upcoming satellite missions CHAMP, GRACE and GOCE. Then the complete observing system, comprising geo-kinematics, Earth rotation and gravity, will increase significantly our understanding of surface ocean circulation (and consequently add insight to ocean mass transport), sea level rise, ice flux and mass budget, land surface motion and stresses, and off-sets between and biases of height systems.

U7/L/01-B1 Invited **0950**

INTERMAGNET - THE MODERN GLOBAL DIGITAL MAGNETIC OBSERVATORY NETWORK, IN A MULTI-DISCIPLINARY CONTEXT

Richard COLES (Geological Survey of Canada, Geomagnetic Laboratory, 7 Observatory Crescent, Ottawa K1A 0Y3, Canada, email: coles@geolab.nrcan.gc.ca

In the INTERMAGNET program, high-quality geomagnetic data from a world-wide network of observatories are sent in near-real-time via satellite and electronic connections, such as Internet, to collection and dissemination centres known as Geomagnetic Information Nodes (GIN). Currently, more than 70 observatories from over 30 institutes in 25 countries are participating in INTERMAGNET, with six GINs operating in North America, Europe and Asia. Each year, new participants are joining INTERMAGNET. The INTERMAGNET data are fundamental to much geophysical and space science research, particularly concerning our near-earth environment and deep-earth (core-mantle) studies. A survey of the world's observatories has shown that many are already co-located with stations belonging to other monitoring networks. Further, the survey showed an overwhelmingly positive response to the idea of accepting additional co-located monitoring systems and to the concepts of increased synergy in operations and data management.

U7/E/07-B1 Invited **1045**

SELECTED GROUND-BASED OBSERVATIONS OF THE UPPER ATMOSPHERE AND IONOSPHERE

Jurgen ROETTGER (Max-Planck-Institut fur Aeronomie Katlenburg-Lindau, Germany); Shoichiro Fukao (Radio Atmospheric Science Center Kyoto University, Uji, Kyoto, Japan)

We will present selected ground-based observations of the upper atmosphere and the ionosphere which are performed in polar, middle and equatorial latitudes. We will concentrate this summary on observations by radar and supporting instrumentation. Of particular importance are studies of the coupling of the lower atmosphere with the upper atmosphere, which is primarily occurring in equatorial latitudes by convective processes and upwelling. Effects of the solar wind on the magnetosphere are linked down into the ionosphere, which is the dominating coupling mechanism in polar regions. Latitudinal coupling between high and low latitudes is of eminent importance and it needs to be considered how these low and high latitude phenomena develop and interact in the middle and upper atmosphere. On the global scale the dynamical coupling in vertical direction is dominantly by gravity waves generated in the troposphere, which propagate upwards and deposit their energy and momentum in the middle and upper atmosphere. A brief summary of the coupling phenomena in the polar and equatorial ionosphere and upper atmosphere will be given and examples of observations will be discussed, which are obtained by radar systems. This is partially done in a globally coordinated manner. We will also highlight certain international programs, campaigns and projects, which had been performed or are underway for these studies of the global response and development of atmospheric processes.

REVIVING HYDROLOGICAL NETWORKS

John C. RODDA (IAHS, Institute of Hydrology, Wallingford, Oxon OX IO 8BB, UK, email: 106201.1774@compuserve.com)

With a rapidly rising global demand for water, the increasing havoc wrought by floods and the growing degradation of the aquatic environment by pollution, it might be assumed that the capture and management of water data of all types would be a top priority. But this is not the case. National hydrological networks and those providing most of the other types of water data are generally degrading over much of the world. Many nations are now less able to assess their water resources than 30 years ago, largely because of reducing government support for these activities. And this is happening when the threat of climate change should be placing a new premium on hydrological data. Then from the scientific point of view, there is the problem that modelling capabilities have outrun the capacity to capture data, while remotely sensed data is not yet the expected panacea for the ills of ground-based data acquisition systems.
There are, however, a number of initiatives underway which are designed to redress this situation, both nationally and internationally. International data centres have been established, while certain international programmes cater for scientific cooperation in large scale field experiments. Others give support hydrological networks in developing countries. Fresh ideas are being developed which are likely to provide additional help. Will integration with global monitoring networks add a further stimulus?

U7/E/01-B1 Invited **1135**

AT THE CROSS-ROADS OF TIME, SPACE, ACCURACY AND URGENCY: MONITORING OF LARGE AREA LAND EVAPORATION

Massimo MENETI(1), Z.B. Su, G. Roerink, H. Pelgrum, B.v.d. Hurk(2) and B.J. Choudhury(3) The Winand Staring Centre (SC-DLO), P.O.B.125, 6700 AC Wageningen, The Netherlands; (1) Universite Louis Pasteur e-mail: menenti@sepia.u-strasbg.fr (2)Royal Netherlands Meteorological Service (3) Laboratory for Hydrospheric Processes.

The loss of water from water and land to the atmosphere is the focus of research and applications in a diverse context. Precise answers to theoretical and practical issues are scarce, notwithstanding significant efforts over a long period of time. The paper attempts to explain this situation in terms of the diverse spatial and temporal scales involved, of the accuracy of observations and of the demanding requirements of science and application. The feasibility of accurate observations of potential, maximum and actual evaporation is discussed first. Observational concepts to measure actual evaporation are briefly reviewed to explain the interest of space- and airborne measurements to understand and model the evaporation of heterogeneous land surfaces. This is illustrated with examples of application of the Surface Energy Balance Index (SEBI) at local and large spatial scales. Radiative and PBL forcing can be considered constant when dealing with small areas. Under these conditions use of remote measurements to estimate actual evaporation through the heat balance of the land surface is feasible. Spatial and temporal variability of radiative and PBL forcing must be taken into account in the large-area case. In the example shown this was done using data sets produced through four dimensional data assimilation. Finally, modeling of land evaporation is revisited in view of the ESA Land Surface Processes and Interactions Mission.

U7/L/06-B1 Invited **1200**

A NEW INTEGRATED APPROACH TO THE WORLD WEATHER WATCH GLOBAL OBSERVING SYSTEM

Robert LANDIS (email: landis@www.wmo.ch)

The World Weather Watch (WWW) was established over 35 years ago with the Global Observing System (GOS) as one of its major components. It has evolved as the major worldwide infrastructure supporting meteorological requirements for observations and processed data for most all nations and territories of the world. The initial objective of the WWW/GOS was to provide those observations needed in support of Numerical Weather Prediction for time scales out to about 48 hours. Since that time it has grown in scope to parallel the developments of NWP in both the shorter time scales as well as time scales of medium range (i.e. 10 days) and beyond. To meet the requirements of both finer spatial resolution and longer time scales (seasonal to interannual) a new integrated approach to the GOS has been initiated. This approach involves integration from several aspects: (1) the co-ordinated observing of the atmosphere, hydrosphere, lithosphere, and cryosphere; (2) the combination of In Situ and remote sensed observations, particularly from space based platforms; (3) the use of observing tools provided for a multitude of purposes including research, long-term monitoring, and operations; and (4) the co-ordinated effort of individual scientists, institutions, agencies, and national governments. Initial efforts are already underway that include a new composite upper air observing system and co-operative observing schemes for voluntary ships and data buoys. Major key elements needed to assure success for such a large integrated approach include the ability to utilise new complex data assimilation techniques and a mechanism for dialogue among those participating in the Integrated Global Observing Strategy.

GLOBAL MONITORING OF RADIATIVE EFFECTS OF AEROSOLS

Teruyuki NAKAJIMA: (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan TEL: +81-3-5453-3959; FAX: +81-3-5453-3964; e-mail: teruyuki@ccsr.u-tokyo.ac.jp)

The methodology for global monitoring of radiative effects of aerosols will be discussed in this paper. Satellite remote sensing of aerosol optical parameters is useful for finding the aerosol amount and species on global scale. Optical thickness and single scattering albedo can be estimated by the aid of such satellite retrievals and a global circulation modeling. Ground-based measurements of solar irradiance and sky radiance are another important component for providing a useful information for aerosol radiative effects. Validation of satellite-retrieved values of aerosol optical thickness and single scattering albedo is indispensable to maintain the quality of the global monitoring. Ideas and real data processing with NOAA/AVHRR and ADEOS/OCTS will be presented.

U7/W/17-B1 Invited **1425**

TOWARD OPERATIONAL OCEANOGRAPHY AND CLIMATE PREDICTION

Neville SMITH (Bureau of Meteorology Research Centre, Melbourne Vic. 3001, Australia, email: N.Smith@BoM.GOV.AU)

Oceanography is gradually evolving from an era characterized by research, experimentation and discovery, into one where routine applications and valued services are an accepted component. Through analogy with meteorology, we think of this as the transition from scientific research to operational oceanography. In reality it is simply a natural evolution whereby application and exploitation follow research and development. The development of predictive skill is usually the paradigm adopted for operational activities - the notion that foreknowledge of the ocean state, or of climate conditions, can be used to benefit industry, commerce and other sectors of our society. However in oceanography, and particularly in climate, it is not only the ability to forecast that is valued, but also the ability to integrate, extrapolate and interpolate information for nowcasts and hindcasts. As a young field, oceanography relied on the careful analysis and interpretation of data gathered specifically for research. For the future, data will be gathered for many different uses, both research and applied, and analysis and interpretation will more often than not rely on processed fields from models and data assimilation. In this paper we will concentrate on the processing and predictive elements of the global ocean and climate systems. The term "intelligence gathering" is often used in the non-scientific world to describe the process of collecting data and knowledge on a subject. It is also an apt term in the present context since it is impossible to build skilful analysis, assimilation and model systems without adequate knowledge of the ocean and climate. This "intelligence" comes not only in the form of data but also in the form of parameterizations used for ocean state estimation and for unresolved model scales. This implies that the development of assimilation and prediction systems will forever depend upon data and improved understanding (science). For oceanography and climate, the TOGA and WOCE initiatives have delivered the advances necessary to make this step and it is the responsibility of the present community to ensure proper advantage is taken of their legacy.

GLOBAL OCEAN OBSERVATIONS FOR CLIMATE STUDY

Dean ROEMMICH (Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA, 92093-0230, USA, email: droemmich@ucsd.edu)

The need for global climate-relevant observations in the ocean has been recognized for many years. Observations are required to reveal the evolving state of the climate system, for improved understanding of processes controlling climate variability, and for data assimilation and forecast model initialization. The WOCE hydrographic survey, the TOGA/WOCE thermal network and the TAO array provide modern examples of observations with great value. Until now, however, the lack of appropriate technologies has placed systematic global observing systems beyond reach. The needs for data greatly exceeded the practical capabilities. Revolutionary advances in technology during the past 5 years have finally brought the required observing systems within reach. Rapid progress in development of in situ instrumentation has been spurred on in part by parallel advances in satellite measurements of the sea surface. Altimetric sea level, surface temperature and scatterometer winds are of higher quality and greater community value than could be imagined a few years ago. While in situ networks cannot match the resolving power of satellite systems, they provide essential information for interpretation and calibration of surface measurements. There is now a near-consensus in the oceanographic community on the components of a global observing system.
Major enabling technological advances include:

Development of cost effective mooring technologies for the TAO array.
Development of the autonomous profiling float. A global array of temperature and salinity profilers is now practical and has been proposed (the Argo network).
Improvements in meteorological sensors and their incorporation into systems with potential for broad deployment. The capability exists to make measurements of air-sea fluxes of momentum, heat and freshwater with the accuracy needed for climate research.
These developments have greatly elevated the achievable value of an ocean observing system for climate. Additional elements of an integrated observing system include time- series measurements at special locations, measurements in boundary currents and selective deep-ocean hydrography. The remaining challenges are for implementation of the global systems by international consortia, for efficient design of the additional measurements, and for flexibility to accomodate new technologies and sampling strategies.

GLOBAL GEOPHYSICAL NETWORKS AND THE CORE-MANTLE COUPLING

Yozo HAMANO, (Dept. Earth & Planetary Physics, Univ. of Tokyo, Bunkyo-ku, Tokyo, 113-0033, JAPAN); Hisashi Utada, (Earthquake Research Institute, Univ. of Tokyo, Bunkyo-ku, Tokyo, 113-0033, JAPAN)

Ocean Hemisphere Project (OHP) Network consists of seismic, geomagnetic and geodetic networks covering the wide area of the Pacific Ocean. One of the purposes of the joint observations by the geophysical networks is to investigate the nature of the core-mantle coupling through the core-mantle boundary. Causes of the lower mantle heterogeneity and the surface motion of the outer fluid core are the main targets for the purpose. Global networks are inherent for investigating the dynamics of the earth's deep interior, but most of the observatories are distributed on land, and the observatories in and around the Pacific ocean are scarce. In order to cover the Pacific Ocean, sea floor observatories are necessary as well as the observatories on islands. For long-period (more than several years) sea floor measurements, power source and data recovery are main difficulties. We have been developed the long-term geomagnetic observation apparatus and made a preliminary observation at sea floor in 1998. The long-term deployment is planned within this year (1999). The apparatus measures three components of the geomagnetic field by the fluxgate sensors, the total force of the geomagnetic field by the Overhauser proton magnetometer, two components of the horizontal electric field, and two components of the tilt of the apparatus, and is equipped with long-life Li-battery power sources, a recording system, and a ultra-sonic communication system for data transfer. In order to elucidate the cause of the heterogeneity (temperature or chemical) of the lower mantle (D" layer and hot plumes), we need to obtain the information on the electrical conductivity of the heterogeneity in addition to the seismic observation. Since the Electro-magnetic sounding from the surface cannot clarify the lower mantle structure, we need to identify the Electro-magnetic signals from the core surface. Decay of the signals through the lower mantle can be used to obtain the conductivity structure of the lower mantle. However, atpresent, identified geomagnetic field variations of core origin arelimited to belonger than several tens of years, because of 1) the comparable order of the external and the internal geomagnetic signal at the period range of 1-10 years, and 2) the nhomogeneous distribution of the geomagnetic observatories on the earth's surface.

THE NEW GENERATION GLOBAL SEISMIC NETWORK: CONTRIBTIONS TO THE STUDY OF DEEP EARTH STRUCTURE

Barbara ROMANOWICZ (Seismological Laboratory, University of California, Berkeley, CA, 94720, USA, email: barbara@seismo.berkeley.edu)

Through complementary efforts of about a dozen countries, coordinated within the Federation of Digital Seismic Networks (FDSN), there now exists a global network of over 200 state-of-the-art, high dynamic range, broadband seismic stations, developed over the last 15 years. These stations contribute to an ever growing global database suitable for a large number of seismological studies on topics ranging from deep earth structure (from the upper mantle down to the inner core) to detailed studies of the rupture process of large earthquakes, and including many regional fine scale studies as well. The individual data archives are generally accessible on-line over the internet and are currently being linked into a "seamless" database. Recently, efforts have also focused on the establishement of permanent ocean bottom observatories to complement the land-based network and fill gaps in the global distribution of stations. These efforts are being coordinated on the international scale within the International Ocean Network (ION).
The high quality global broadband seismic dataset has in particular led to improved resolution of deep mantle structure, which we illustrate through examples of work in our laboratory on global waveform elastic and anelastic mantle tomography as well as forward modelling of complex structure at the base of the earth's mantle.

MITIGATING THE HAZARD OF VOLCANIC CLOUDS USING SATELLITE REMOTE SENSING

W I ROSE (Geological Engineering and Sciences, Michigan Technological University, Houghton, MI 49931, e-mail: raman@mtu.edu) A J Krueger (NASAGoddard Space Flight Center, Greenbelt, MD 20771)

Satellite remote sensing is providing a unique and increasingly comprehensive portrait of explosive volcanism, by its ability to map and quantify volcano/atmosphere interactions. Data collected by meteorological satellite detectors (TOMS, AVHRR, GOES) designed for other purposes provide an archive record of earth`s volcanism which is being interpreted by scientists. Because these detectors are able to map the position of volcanic clouds and because of the well demonstrated near-realtime use of satellite data for weather forcasting, the goal of using satellite data to mitigate hazards to aircraft from volcanic clouds is being seriously explored. Timing is a key issue. Jet pilots need to get information about the 3 D position of volcanic clouds near them that is as current as possible. One stated goal is to get information communicated within 5 minutes, a period during which a jet may travel ~70-80 km. Satellite volcanic cloud detectors must be uniquely sensitive to volcanic clouds, and need to be able to detect volcanic clouds anywhere with high temporal and adequate spatial resolution. The global responsibility for this hazard must be regionally shared so that the people close to the hazard know immediately. Successful mitigation will require that: 1. Satellite detectors must be positioned more favorably and the way their data are used to map and measure volcanic clouds must be improved. 2. An unprecedented cooperative effort between scientists, agencies and countries must be developed and IUGG could play a valuable role. 3. Challenging scientific/technical communications to regional centers must be completed. A new initiative by NASA, called VOLCAM, is planned to attempt the above. New detectors specifically designed for volcanic clouds will be placed on geostationary satellites. Data will be collected every 15 minutes and analyzed and communicated within 5 minutes. A 2 year demonstration period is planned for 2002-2004.

TOWARDS GLOBAL, GEODETIC, REAL TIME MONITORING OF VOLCANOES

Timothy H. DIXON (RSMAS, University of Miami,4600 Rickenbacker Cswy., Miami, FL33149-1098, USA, email: tdixon@rsmas.miami.edu); C. Meertens, (UNAVCO, A. Newman, Northwestern University,S. Stein, Northwestern University and UNAVCO)

Geodetic measurements of ground deformation are an important tool for monitoring volcanoes, predicting eruptions, and investigating magma dynamics at depth. Two recent technological advances make it possible to develop a cost-effective global volcano monitoring system that includes geodesy. First, new phase-tracking single frequency Global Positioning System (GPS) receivers can provide the required high-precision, high-rate data at dramatically lower cost than previously possible. These systems can be deployed in large numbers, making possible continuous, high spatial and temporal resolution "imaging" of magmatic sources. Second, new VSAT satellite communications make it possible to return data from remote areas in essentially real time, without reliance on ground-based communication, at low cost, using small, rugged, low power systems. This communications infrastructure can be used for any data type, in any area. We believe it will revolutionize autonomous monitoring of remote regions, which until now has suffered from lack of a cost-effective space-based approach. We have performed limited tests of key parts of both systems. This paper will present the result of those tests, as well as cost comparisons with other real-time and near-real-time data delivery systems.

MEASUREMENTS FOR EARTH SYSTEM SCIENCE

Francis BRETHERTON, (University of Wisconsin-Madison, Space Science and Engineering Center, 1225 West Dayton St, Madison ,WI 53706 U.S.A); E-mail: fbretherton@ssec.wisc.edu Phone: (1) (608) 262-7497 Fax: (1) (608) 262-5974)

Driven by concerns over human influences on the global environment, renewed attention is being given to the functioning of Earth as an complete system. A new discipline is emerging, devoted to understanding the interactions between the component parts which have been the foci of customary areas of specialization. Quantitative modeling can assist a synthesis, but structuring, organizing, and sustaining appropriate long-term measurements is a continuing challenge. There will be no single global observing system, but interoperating networks sharing information dedicated to common standards of quality measurements for critical variables. Great progess has been made, but it is essential to demonstrate sufficient utility to the public and their governments to assure continued support. New modes of collaboration are needed among scientists and end users of this information. New measures of scientific achievement must reward those contributing to this common understanding. Still broader horizons are needed to allocate scarce resources in an effective manner.

THE INTERNATIONAL SPACE GEODETIC AND GRAVIMETRIC NETWORK (ISGN)

Hermann DREWES (Deutsches Geodaet. Forschungsinstitut, Marstallplatz 8, D-80539 Muenchen, Germany, email: drewes@dgfi.badw-muenchen.de); Gerhard Beutler (Astronomisches Institut, Universitaet Bern, Sidlerstr. 5, CH-3012 Bern, Switzerland, email: beutler@aiub.unibe.ch); John Bosworth (NASA, Goddard Space Flight Center, Code 920.1, Greenbelt MD 20771, USA, email: jmb@ltpmail.gsfc.nasa.gov); Claude Boucher (Institut Geographique National, 6-8 Avenue Blaise Pascal, Cite Descartes, F-778455 Champs-sur-Marne, France, email: boucher@ensg.ign.fr); Tom Herring (Mass. Institute of Technology, Dept. of Earth, Atmospheric and Planetary Sciences, Cambridge MA 02139, USA, email: tah@mtglas.mit.edu); Ivan Mueller (Ohio State University, 4361 Shire Creek St., Hilliard OH 43026, USA, email: mueller@mps.ohio-state.edu)

The ISGN is an integrated global monitoring network of space geodetic observatories. It is jointly installed by the IAG Commission VIII on Coordination of Space Techniques for Geodesy and Geodynamics (CSTG) and the International Earth Rotation Service (IERS). The observatories being included in the network have to fulfill certain criteria which were set up by a CSTG/IERS Working Group in order to guarantee an effective operation and optimum scientific benefit. The scientific objectives of the ISGN are discussed and the criteria for the inclusion of stations into the network are summarized. A list of included stations is presented and the role of observatories or groups of observatories, respectively, with respect to the scientific objectives is characterized. The future scientific impact of the ISGN and its status in the international services is discussed.

DATA ASSIMILATION IN THE MERDIAN NETWORK

Jian-Shan GUO(Center for Space Science and Applied Research, Chinese Academy of Sciences, P.O.Box 8701, Beijing 100080,P.R.China, Email: guojs@center.cssar.ac.cn); Hong Zheng, She-ping Shang, Nana Liu(idem)

Meridian Network is a regional network for collection, processing, and dissemination of data for Meridian Chain-a project that has been approved by Chinese government. The Meridian Chain is a ground-based observatory chain equipped with multi-instruments(radio, optical and geomagnetic).The Meridian Network consists of data base; high performance computer system and a communication platform covering five main nods along about 120*E meridian from Mohe(122*E, 53*N) to Zhongshan(76*E,69*S) and being able to connect with worldwide data centers. We discuss the key topics - data assimilation in view of physical process, model studies and deign of network topology of the Meridian Network. The considerations here would be validate for integrated global monitoring network . the data assimilation is a data processing procedure fully taking advantages of different type of observations. The main points would be: State estimation is a procedure making use of optimally constrained weighted least-squares method to estimate the values of a physical(electrodynamic and/or dynamic) parameter with error values to form a pattern (state) over the interested region or global by fitting to a set of direct and indirect observations took within so short period that the physical process could be considered as steady-state. The state shows the physical characteristics of the region for the instant of time, and can also be converted from other fitted parameter state in the light of physical law. The error pattern on the region provides the basis for network topology design

Physical process could be illustrated by a series of states for individual instant of time. The carefully chosen state could be considered as initial or boundary conditions or coefficient model for driving physical model or solving a set of physical equations to obtain the evaluation of the process numerically or analytically. The set of physical equations could also be solved by moment method with time point match function - a series of fitted states at different instant of time, to obtain a point fitted process.

THE SCIENTIFIC AND TECHNOLOGICAL OBJECTIVES OF THE INTEGRATED GEOPHYSICAL MONITORING NETWORK IN RUSSIA

Oleg Starovoit (Geophysical Survey, Russian Academy of Sciences, 189 Lenin str., Obninsk, Kaluga region, 249020 RUSSIA, e-mail: ostar@gsras.ru); Suria Tatevian (Institute of Astronomy RAN, 48 Pyatnitskaya str.,Moscow 109017, RUSSIA, e-mail: statev@inasan.rssi.ru); Alexander ZAITZEV (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Troitsk, Moscow Region, 142092, RUSSIA, e-mail: zaitzev@izmiran.rssi.ru)

Rapid advances in global geophysics based on the recent technological achievements in computers, telecommunications and space observations.In this paper we consider the idea of integrated geophysical monitoring network which include seismic, magnetic and geodetic instruments. Such an idea has a new chance for realization in the coming decade due to achievements referred to above. This idea is based on the scientific and technological objectives. First, taking into account that transition between mantle and core is the key factor for understanding of the internal dynamics of the Earth, we believe that all available observations regarding the internal structure of the Earth (seismic, magnetic, gravity, and rotational) should be gathered in order to derive a coherent model, able to fit all types of data. Geomagnetic and gravitational fields variations have sources in the crust and correlate with seismic activity. External disturbances take place due to solar activity which trails also observed in geophysical fields. Second, technological objectives are evident if we take into account that the volume of seismic-magnetic-geodetic digital data is in proportion as 100-10-1. So it is the way to save the funding if we'll use the same basic links of the INTERNET for data transfer to the analyses centers. A real situation with the existing Russian geophysical stations is considered and a project of upgrading of the integrated network for the geophysical monitoring is discussed.

U7/E/09-B1 Poster 0830-04

GLOBAL MONITORING OF CLIMATE VARIABILITY VIA THE SCHUMANN RESONANCE

Colin PRICE (Department of Geophysics and Planetary Sciences, Tel Aviv University, Ramat Aviv 69978, Israel, email: cprice@flash.tau.ac.il); Earle Williams (Parsons Laboratory, Massachesetts Institute of Technology, Cambridge, MA 02139, USA, email: earlew@juliet.ll.mit.edu)

The earth's surface and the ionosphere at an altitude of 60-100km result in the earth-ionospheric waveguide that allows for the propagation of electromagnetic waves over great distances. Waves in the extremely low frequency (ELF: 1-100 Hz) range can propagate with little attenuation in the atmosphere and therefore travel a few times around the earth before decaying. In the atmosphere the main natural source of these waves is from lightning discharges. Since the ELF waves from each lightning discharge travel around the globe a few times before decaying, we can theoretically sit at a single location and monitor changes in global lightning activity. Furthermore, due to the physical structure of the earth-ionosphere waveguide, certain resonance frequencies occur at 8, 14, 20, 26 ...Hertz known as the Schumann resonance. By monitoring the amplitude of these resonant modes continuously, we are able to monitor changes in lightning activity around the planet on hourly, daily, monthly, annual and interannual timescales. Such monitoring stations now exist at a few locations around the globe, and are providing a cheap, reliable way of monitoring the global climate system. Lightning activity is directly related to microphysical processes that occur in deep convective clouds. The strength of updrafts, the amount of convective rainfall, the production of nitrogen oxides, and the location of flash floods are all associated with the lightning activity in these storms. Since the majority of the earth's lightning activity occurs in the tropics, we propose that ground-based measurements of the Schumann resonance are a way of monitoring changes in the tropical hydrological cycle. In addition, the authors have previously shown strong connections between the globally integrated ELF lightning signals and global climate parameters such as surface temperature and upper tropospheric water vapour. It may therefore be extremely useful to include in future integrated global monitoring networks parameters related to atmospheric electricity.

TYPIFICATION OF NATURAL AND CULTURAL BIOGEOCOENOSES LOCATIONS FOR HYDROLOGIC AND INTEGRATED MONITORING NETWORKS DESIGN (ARAL AND CASPIAN BASINS CASE STUDY)

Vijay P.Singh, Dr.Sci., Prof. (Louisiana State University, Civil and Environmental Engineering Department, 3502 CEBA Building, Baton Rouge, LA 70803-6405 USA, email: cesing@unix1.sncc.lsu.edu); Nina M. NOVIKOVA, Dr.Geogr.Sci. (Water Problems Institute, email: novikova@novikova.msk.ru); Yeugeny M. Gusev, Dr.Biol.Sci. (Water Problems Institute, email: sowa@ipcom.ru); Valentina A.Khaydarova, Ph.D (Water Problems Institute, email: akalashnikov@usaid.gov); Natalia V.PENKOVA , Ph.D (State Hydrological Institute, Water email: george@tetris.dux.ru)

Within the spatial domain of scientific design and exploitation of integrated (ground and spase-based) monitoring networks the different level geoecosystems structure investigations are under consideration. The emphasis to the problem of compatibility of hydrologic and ecologic geosystems parameters in space-geometric and "matter" ("substance") aspects is given.
The results of comparison analyses of some geographycal (the comparative-descriptive) and relatively rigorous formal methods of biogeocoenoses locations typification in mountain, piedmont and lowland parts of the regions examined are presented: - identification of hydrologic conditions with the help of plants-indicators using ground and space data; - detailing the cartographic images and technique for mapping the homogeneous geophysic and geobotanic "fields" with due regard for geostructural features of the regions and for peculiarities of topologically connected channel networks; - dependence of the geochemical landscape types on exposition and steepness of watersheds slopes; - methods of "mono-systems" (vertical) articulation of the landscapes at inadequate water consumption by irrigated crops assessment.

AN ENVIRONMENTAL MONITORING NETWORK AND DATABASE FOR MOZAMBIQUE

U.ASWATHANARAYANA (c/o Ministry for the Coordination of Environmental Affairs, C.P. 1947, Maputo, Mozambique ; Email: anarayan@zebra.uem.mz)

Presently, biological pollution due to human wastes constitutes the main environmental problem for Mozambique. Pollution due to industries, and the use of fertilizers and pesticides is currently limited to particular pockets, but this situation is changing rapidly. An environmental monitoring network and database have been designed to address the emerging situation in Mozambique. The monitoring process involves the following : (i) Identification of the various sources of pollution of drinking water, soils, sediments, air and biota, (ii) Modelling the pathways of pollutants to man and risk analysis of the pollutants, (iii) Ways and means of monitoring the pollutants (in technical and regulatory terms, cooperation with industries and communities and with neighbouring countries) and (iv) Cost-benefit analysis of the various pollution mitigation measures.The chemical analyses will be performed in the central laboratory in Maputo (being equipped with ICP-AES, GC-MS-MS, GC-ECD, etc.) in cooperation with five field units equipped with portable instruments for the analysis of waters, soils and biota. To facilitate decision-making and implementation, databases are being organised, (i) sector-wise (such as, chemical and metallurgical industries, food and beverage processing, textiles, transport, tourism, habitation and sanitation, waste disposal, etc.) for the country as a whole, (ii) ecosystem-wise (e.g. Coastal Resources Management), and (iii) area-wise (town-wise and province-wise).The data will be disseminated through the Mercure satellite station located in Maputo.

AUTOMATIC GREENHOUSE GASES MONITORING, DATA DISSEMINATION SYSTEM AND ANALYSIS SUPPORT TOOL FOR GLOBAL ENVIRONMENTAL RESEARCH

Y.Fujinuma, M.Hashimoto, M.KATSUMOTO (National Institute for Environmental Studies Center for Global Environmental Research 16-2 Onogawa, Tsukuba-shi, Ibaraki-ken 305-0053, Japan FAX/+81-298-508-2645 (contact person Masayuki Katsumoto e-mail: katsumoto.masayuki@nies.go.jp)

CGER-NIES has carried out several Greenhouse gases monitoring studies in East-Asia: by two ground-based stations at remote sites of Japanese-Archipelago, by chartered airplane over Siberian wetland and forest, and by ship-of-opportunity over Pacific Ocean. To analyze these data, the evaluation of the air mass attained at the sampling points is indispensable.
In this presentation, the automatic monitoring system at remote sites, "Analysis Support System for " , developed at CGER/NIES, will be introduced. In the latter, the ECMWF data, Japanese meteorological data, etc., have been used. Also the trajectory analysis of air mass attained at Hateruma and Cape Ochi-ishi monitoring stations, located at south-west and north-east extreme of Japanese archipelago, will be discussed. Keywords: Global Environmental Monitoring, Air Mass Evaluation,Trajectory, Greenhouse gases.

ON MECHANISMS OF THE EARTH CLIMATE AND ECOSYSTEM VARIATIONS

Vadim V. NAVROTSKY (Pacific Oceanological Institute, 43 Baltiyskaya Str.,Vladivostok, 690041 Russia, email: navr@online.vladivostok.ru)

The notions of Climate Change and Climate Variability are discussed. It is shown that generally used parameters for detecting and analysing Global Climate variations are inadequate to description of real climate regime shifts. A more precise definition of the notion 'Climate Change' is given, and a scheme of climatic informational system is proposed, based on the specific spatio-temporal net of observations, averaging and analysis. It is generally recognized that climate regime shifts are connected to ecosystem changes. There are many published results showing rather high correlations between global climate characteristics and productivity of the specific widely separated populations, although in many cases the local conditions for the populations are very different. Our approach to the explanation of such high correlations is based on the experiments and theory of coherent oscillations in biological systems, excited by extremely weak electromagnetic signals. Electric vibrations in the 100 to1000 billion Hz region, associated with metastable states with very high dipole moments in biological membranes, lead to the specific oscillatory biochemical reactions and to macroscopic oscillations in the 10 to 100 Hz region, which directly influence functioning, productivity and state of organisms, as well as their collective behaviour. Electromagnetic fluctuations on the Earth are influenced by many external processes, such as solar activity, cosmic rays, tilt of the Earth rotation axis, precession of the equinoxes, changes in eccentricity of the orbit, motions inside the Earth etc. Evidently, these processes influence also climatic changes, and careful analysis of their cyclicity and periods of biological fluctuations gives an explanation to many climate-ecosystem correspondances even without taking into account many fold casua linteractions between climate conditions and living matter on the Earth.

MULTI-CRITERIA OPTIMIZATION APPROACH FOR OPTIMAL LOCATION AND EQUIPMENT OF REGIONAL METEOROLOGICAL NETWORK SITES

Oleg POKROVSKY, Vladimir Kondratyuk (Main Geophysical Observatory, Karbyshev str.7, St.Petersburg, 194021, Russia, e-mail: pokrov@main.mgo.rssi.ru)

Ground-based observational network efficiency is described by criteria set, which could be distributed into three groups : informational, economical and instrumental ones. First group is linked with such characteristics as a meteorological field accuracy representation, its spatial resolution, list of measured parameters et al. Economical criteria includes: total expenditures, e.g. measurement costs and expected gain of potential meteorological information users. Measurement precessions, systematic and stochastic error components, list of observed parameters, instrument costs are among instrumental criteria. Multi-criteria optimization model of observational networks has been proposed and considered as a mathematical problem of Boolean programming. Three types of optimization problem are discussed: 1)maximization of information content (Shannon information measure is used); 2) minimization of observational sites under some guaranteed value of inferred information content.; 3) minimization of total expenditures. Some application examples are considered. This approach is developed with respect to any set interrelated meteorological parameters. So corresponding results are fair for any complex observing sites. Results of numerical optimization for several Russian regional networks (North-West region, Kamchatka peninsula and Far East region) allow to formulate some recommendation for optimal observing site set (its composition and configuration), by its ordering, accordingly to information content contributions. The obtained conclusions also show how to find out the compromise between informational and economic criteria, having near values for some of considered sites. This approach allow us to determine the regional observational network providing the lowest optimal interpolation error level with respect to any other choices. Its other advantage is capability to consult optimal instrument selection for each meteorological site equipment. This method could be used for other ground-based networks : hydrological, oceanological and sea-coastal ones. Next step is to generalize the proposed approach for global networks.

REPEAT MERIDIONAL SURVEY OF THE WESTERN PACIFIC SURFACE CURRENT BY AN ADCP ON A COMMERCIAL SHIP

Arata KANEKO, Zhu Yuan, Noriaki Gohda, Masazumi Arai and Hideo Nakajima (Faculty of Engineering, Hiroshima University, Higashi-Hiroshima 739-8527, Japan, email: akaneko@ipc.hiroshima-u.ac.jp); Hong Zheng (Japan Science and Technology Corporation/Hiroshima University, Higashi-Hiroshima 739-8527, Japan, email: hzheng@ocean.hiroshima-u.ac.jp); Takashige Sugimoto (Ocean Research Institute, University of Tokyo, 1-15-1 Minamidai, Nakano-ku, Tokyo 164-8639, Japan, email: sugimoto@ori.u-tokyo.ac.jp)

The western Pacific is one of the most important regions considering global climate research. Poleward transport of warm water by the Kuroshio may be part of the coupling mechanism between tropical and subtropical ocean at the decadal scale. An ADCP program, which has started since January 1997, aims at measuring ocean surface currents in the western Pacific on a almost monthly basis, intending to run over 10 years. A huge mineral transport ship, the "First Jupiter" (83,658 t in weight and 289 m in length), equipped with a shipboard RDI-BB 150 kHz ADCP, operates mainly between Japan and Australia. During regular cruises, the ship crossing of the Kuroshio south of Japan leads by about five days the crossing of the North Equatorial Current off Philippines, in the source region of the Kuroshio. Time-series of both currents contribute to monitor the western part of the Pacific Subtropical Gyre. The meridional distribution of the annual mean zonal transport for upper 220 m is determined from the 1997 data. The Rossby waves of first baroclinic mode are also caught with the westward propagation at 6N and 25 N by analysing the anomaly from the annual mean data

AN INTEGRATED SYSTEM FOR OBSERVING, MODELING AND PREDICTING OCEAN TIDES

C. Le PROVOST (email: Christian.Le-Provost@cnes.fr); F. Lefevre (email: Fabien.Lefevre@cnes.fr); F. Lyard (email: Florent.Lyard@cnes.fr); F. Ponchaut (email: ponchaut@cnes.fr); and P. Techine (email: Philippe.Techine@cnes.fr); (all at LEGOS/GRGS, UMR5566 CNES-CNRS-UPS, 14 Avenue E. Belin, 31400 Toulouse, France)

Tides are the major contributor to the high frequency variability of the sea level. They have been observed by traditional tide gauge techniques since more than a century, but along the coasts and on islands. During the sixties, deep sea tide gauge technology developed, allowing to measure tides offshore. But only a few hundreds of sites have been visited. Since the advent of high precision satellite altimetry, it is now possible to observe tides over almost the whole ocean, with however unusual time sampling, and particular space sampling. The mid-nineties have seen a major step in our ability to precisely describe ocean tides, through hydrodynamic modelling, satellite data analysis, and data assimilation in these models. The aim of this talk is to present an integrated approached based on a finite element hydrodynamic model, analysis of sea level data from in situ networks and satellite altimetry, and a methodology for assimilation of these data. This approach has been successfully applied to the determination of the deep ocean tides by assimilating satellite data. We have more recently applied the same approach but focusing on the assimilation of in situ data in order to improve our tidal solution in shallow waters and along the coasts. This system has been used also to evaluate the quality of the in situ data sets accumulated since the beggining of the century, and estimate their representativeness of the local or more global characteristics of the tides. The model/assimilation technique can help also to study the impact of a given observation on the local and global quality of the product issued from this system

SONEL: TOWARDS A NATIONAL INTEGRATED COASTAL SEA-LEVEL MONITORING SYSTEM

Serge Allain (1): 13 rue du Chatellier, BP 426, 29275 Brest, France), Claude Boucher (2): IGN/LAREG, 6-8 Avenue Blaise Pascal, 77455 Marne-la-Vallee, France), Loic Daniel (3): IGN/ENSG, 6-8 Avenue Blaise Pascal, 77455 Marne-la-Vallee, France), Bernard Simon (1) et Guy WOPPELMANN (1)

SONEL stands for "Système d'Observation du Niveau des Eaux Littorales". The project is developed by both French agencies: IGN (Institut Géographique National) and SHOM (Service Hydrographique et Océanographique de la Marine). The motivation is to ensure the maximum efficiency in existing services related to sea and land surface level measurements and to get a greater benefit from those through synergy and cooperation. The primary goal of SONEL is to provide a service to support, through geodetic and tide gauge data products, research activities on long term sea level variations related to climate change. SONEL aims to be the natural national interface with international organizations and projects: GLOSS, Med-GLOSS, EOSS... The concept of SONEL is based upon the idea of getting more from several mono-thematic permanent observing networks (either geodetic or sea-level oriented), this will come from integrating them in an efficient data collection and dissemination scheme and combining their measurements in order to provide specific products. This synergy is indeed the only way to get a clear and unambiguous sea-level signal among other things.
After a quick description of SONEL and its main components our presentation will focus on the data management aspects. We will present the precise scheme of the data management system, its objectives and specifications. Some technological data processing and computer systems aspects will be developed. In conclusion, we will present the status of the project, its first realizations and the upcoming actions.

THE GLOBAL SEA LEVEL OBSERVING SYSTEM (GLOSS)

Philip L.WOODWORTH (Permanent Service for Mean Sea Level, Proudman Oceanographic Laboratory, Bidston Observatory, Birkenhead L43 7RA, UK, email: plw@pol.ac.uk)

The Global Sea Level Observing System (GLOSS) is an Intergovernmental Oceanographic Commission (IOC) coordinated programme for the establishment of a global network of tide gauges, and associated geodetic devices, for application to climate, oceanographic and coastal sea level research. GLOSS can be considered a component of the Global Ocean Observing System (GOOS), and particularly as a major contributor to its Climate and Coastal Modules. During 1996-97, GLOSS objectives were extensively re-assessed by the GLOSS Group of Experts, resulting in a new Implementation Plan for the programme approved by the IOC Assembly in July 1997. The Plan defines a GLOSS Core Network (GCN) of around 280 gauges distributed worldwide, designed to provide an approximately evenly-distributed sampling of global coastal sea level variations; a GLOSS Long Term Trends (LTT) set of gauge sites (some, but not all, of which are in the GCN) for monitoring long term trends and accelerations in global sea level, these will be priority sites for GPS and DORIS receiver installations to monitor vertical land movements; a GLOSS altimeter calibration (ALT) set, mostly islands, to provide an ongoing facility for mission intercalibrations; and a GLOSS ocean circulation (OC) set, including in particular gauge pairs at straits and in polar area, complementing altimetric coverage of the open deep ocean. The Implementation Plan has also outlined updated mechanisms for global tide gauge data flow. These are intended to make sea level data more accessible to the community. GLOSS activities now include a large number of regional projects and products, and a range of international training courses and materials. Manuals are available on 'How to Operate a Tide Gauge', and a manual on 'How to Operate GPS at Gauge Sites' is planned for 1999. The present manuals are also available in CD-ROM form. GLOSS has newsletters on the web and in conventional paper form.

TOWARDS MULTIPARAMETER NETWORKS FOR THE NEXT CENTURY

Genevieve ROULT, Jean-Paul Montagner, Jean-Francois Karczewski and Eleonore Stutzmann (Departement de Sismologie, Institut de Physique du Globe, 4 place Jussieu, 75252 PARIS-Cedex 05, France)

The design of the future networks cannot be separated from the scientific issues which scientists are faced to, nor from the new technology tools that are to be developed for the next century. The trilogy, science, scientist and instrument must be well balanced in order to make implementation of the network achievable. Since most of the scientific issues are multiscalar for spatial scales as well as for temporal scales, we present the general design of the network which should enable to address these scientific issues. They must be able to explore different scales of heterogeneities from global scale to local scale. We review the different technological developments which are presently explored, and which prefigure what will be the future geophysical networks. The technical developments carried out by various French scientific programs (GEOSCOPE, OPTIMISM, SOFM) will be presented as an illustration. The concept of multiparameter station is defined and it is demonstrated the great scientific interest in installing different kinds of sensors at the same place in a seismic station. Every seismic station will have to be transformed into a multiparameter geophysical station. It is also necessary to cover the oceanic desert by a dense network of geophysical observatories which can fulfill the scientific requirements of the whole geoscientist community.
The recent progresses made by Japanese, French and US groups show that the technical challenge of installing permanent geophysical ocean bottom observatories (coined GOBOs) is not out of reach. Therefore, the new generation network will have to be composed of multiparameter continental or oceanic stations including at least broadband seismometers, microbarometers, microthermometers, and eventually other sensors (electromagnetic sensors, strainmeters, GPS, ...). The design of the complete chain of acquisition, from the sensor to the distribution of data, will imply to integrate all the technical progresses made in micromechanics, electronics, computers, space science, and telecommunication systems. Finally, the new generation of geophysical networks must be able to provide scientific data at all scales, from the global scale to the local scale.

OCEAN HEMISPHERE NETWORK PROJECT DATA CENTER

Shingo WATADA and Yoshio Fukao (both at Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi Bunkyo-ku, Tokyo 113-0032, Japan, email: watada@eri.u-tokyo.ac.jp); Seiji Tsuboi (Department of Geosciences, National Defense Academy,Yokosuka 238-8686, Japan, email: tsuboi@cc.nda.ac.jp)

The Ocean Hemisphere network Project (OHP) is to establish a network that comprises of a wide range of geophysical sensors on islands and the ocean floor in the western Pacific and its peripheral continents. For example, broad bandseismic, GPS, geo-electromagnetic, and superconducting gravimeter networks have been operating on land. Ocean bottom seismometers and hydrophones are attached to retired ocean bottom cables, borehole drilling for broadband seismometry on the ocean floor is expected soon, and voltage measurements between the two ends of retired ocean bottom cables already started. All these data are, or will be, available through the OHP Data Center (http://ohpdmc.eri.u-tokyo). The data center facilitates the data exchange between other data centers and data distribution to every researcher in a standardized format. The former POSEIDON seismic network is being upgraded with new data loggers and STS-1 seismometers. OHP seismic waveform data, including accelerograms and hydrophone data from the TPC-1 ocean bottom cable, and broadband data from the CMG-3T network of the Earthquake Research Institute in central Japan area, are distributed in the SEED format. As a data exchange, seismic event waveform data archived by IRIS are also available from the data center. The data center also collects software packages developed by the members of OHP. A package to compute synthetic seismograms using the Direct Solution Method is downloadable from the home page.

THE GLOBAL SEISMOGRAPHIC NETWORK

Jonathan BERGER, IGPP, SIO, (University of California San Diego, 9500); Gilman Dr. La Jolla CA 920393-0225, email: jberger@ucsd.edu); Rhett Butler, (IRIS, 1200 New York Ave, NW, Washington DC, 20005, Email: rhett@iris.edu) Charles R. (Hutt, U.S. Geological Survey Seismological Laboratory, Building 10002), Kirtland AFB-East, Albuquerque, NM 87115, email: hutt@asl.cr.usgs.gov

We describe the genesis and development of the Global Seismographic Network, a collection of about 125 geophysical observatories with common management, funding, instrumentation standards, and data distribution. Organized and managed by the Incorporated Research Institutions for Seismology (IRIS), stations of the network are operated and maintained by the USGS and by the University of California San Diego. Stable long-term funding is provided by the U.S. National Science Foundation and by the U. S. Geological Survey. Each station of the network is organized with the following key elements: 1. A formal agreement with a local host organization which covers the establishment and long-term operation; 2. Observatory facilities required to support instrumentation; 3. Local operational personnel; 4. Data collection, archiving, and distribution mechanisms; 5. Internet connectivity at most stations. The current GSN represents over 15 years of development and an investment of over 80M USD. We describe some of the practical problems encountered in the execution of this enterprise and a few of the lessons learned. While the principal purpose of these observatories is seismological, they can easily be equipped with a variety of other geophysical instrumentation. With sites on all continents and many oceanic islands, the GSN offers valuable opportunities for other global geophysical monitoring programs to utilize these facilities and their associated logistic support.

CONTRIBUTION FOR THE MONITORING OF THE SW PORTUGUESE MARGIN: CRUSTAL THINNING ALONG IAM5

Alexandra AFILHADO (at CGUL, R.Escola Politécnica 58, 1250 Lx, Portugal, email: ammga@fc.ul.pt; also at ISEL, R. Conselheiro Emídio Navarro, Lx, Portugal); Dina Vales (IM, R. C Aeroporto, Lx, Portugal, email: dina.vales@meteo.pt); Alfred Hirn (IPGP, P. Jussieu, Paris, France, email: hirn@ipgp.jussieu.fr); A.Gonzalez (DCCT, CICESE, Ensenada, B.C. México, mindundi@cicese.cicese.mx); Luis Matias and L. Mendes-Victor (both at CGUL and DFFCUL, email: lmvictor@fc.ul.pt)

In order to complement the understanding of the Geodynamic processes that generate rifted margins, many deep crustal seismic surveys have been performed in the last few years. OBSs as well as land seismic stations (LSS) are usually included in the surveying, providing very helpful information on the deep crust and upper mantle velocity structure. The Tagus Abyssal Plain (TAP), SW offshore of Portugal, cannot be closed in most Pangea reconstructions. The nature of the crust as well as the amount of thinning is still debated, mainly due to a poorly constrained crustal structure related to a lack of data. Both OBSs and LSS wide-angle seismic information were collected during Iberian Atlantic Margins (IAM) fieldwork along the line IAM5 crossing the TAP up to the continental margin. The modeling of the data sets were performed by two steps: (1) separately modeling of LSS data and OBS data; (2) modeling simultaneously both data sets, using the former P-wave crustal velocity models as initial models. This procedure allows us to better constrain the convergence of both models and it also quantitatively evaluates the reliability of non reversed wide-angle data modeling to study the thinning at continental margins. New seismic data on the TAP is being collected under the scope of Big Source of Earthquakes and Tsunamis (BIGSETS) project. The deployment of OBSs is also programmed and will be an important contribution for the network design in order to assure an adequate monitoring of this region.

SOME ASPECTS OF USING OBJECT-ORIENTED TECHTNIQUE FOR DISTRIBUTED SEISMIC DATA PROCESSING

Osadchuk, A (Institute of Geophysics NASU, Palladin 252680, Ukraine, Tel: 380 44 414 90 90, Email: osadchuk@adam.kiev.ua)

Modern seismic is faced with a problem of simplifying methods of searching and acquiring seismic records from different data sources. The fact is that the data is stored in different formats on separate servers which use different access procedures. Using of object-oriented modular tolls can help to solve this task, by means of attracting independent developers for writing access methods to each information block. Under centralized control should be only the basic set of classes that define the main information structures and their interrelations. As an example of such set of classes one can take FISSURES classes, proposed by IRIS. Further development of seismic data processing instruments will include adding and modification of classes responsible for the work with specified information format. Author demonstrate realization of object-oriented technique on the example of Java-based platform independent client's program that visualize multi-ray seismic records and can be upgrade (without rebuilding) to support any seismic data format.
The next question under discussion is distribution data processing tasks between servers and clients programs and choosing of appropriate software solutions for each of them.

U7/W/18-B1 Poster **0830-19**

DATA COLLECTION FROM THE GLOBAL SEISMOGRAPHIC NETWORK

Robert WOODWARD (United States Geological Survey, Albuquerque Seismological Laboratory, Bldg. 10002, Kirtland AFB-E, Albuquerque, NM 87115-5000, USA, e-mail: woodward@asl.cr.usgs.gov); J. Peter Davis (Institute of Geophysics and Planetary Physics, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA, 92093-0225, USA, e-mail: pdavis@ucsd.edu); Tim Ahern (Incorporated Research Institutions for Seismology, Data Management Center, 1408 NE 45th Street, Seattle, WA, 98105, USA, e-mail: tim@iris.washington.edu)

The Global Seismographic Network (GSN) comprises roughly 125 seismographic stations distributed around the Earth. Data are used for a variety of purposes, including studies of Earth structure, seismic hazard, and monitoring of the comprehensive test ban treaty. Each station site is comprised of a suite of sensors, including three-component very-broad-band-response seismometers, high frequency seismometers, and in some instances strong-motion seismometers and meteorological instrumentation. Typical stations generate 10 megabytes of data per day, with some sites generating 30 to 40 Mb of data per day. Data are retrieved by two Data Collection Centers using a variety of methods, including mailing of tapes, Internet links, telephone dial-up, satellite links, and Inmarsat telephone connections. Data from a number of the stations are available in near-real-time. At the Data Collection Centers the data are subjected to quality control review, data problems are identified and flagged and/or repaired, and the data are reformatted to a standardized distribution format. All data are then forwarded to key data centers around the world, including the Incorporated Research Institutions for Seismology (IRIS) Data Management Center (DMC) in Seattle, Washington, USA. From the IRIS DMC all GSN data are available to the entire geophysical community. Key issues in the collection and distribution of the GSN data are the standardized format, open data access policies, and highest possible quality standards. The increasing emphasis on retrieval of data in near-real-time, combined with the availability of all digital data ever collected by the GSN and its (digital) predecessor networks, allows studies at multiple time- and spatial-scales

CABLE-CONNECTED OCEAN BOTTOM OBSERVATION NETWORKS IN JAPAN

Katsuyoshi KAWAGUCHI, Hajimu Kinoshita, Kenji Hirata and Ryouichi Iwase (Japan Marine Science and Technology Center 2-15, Natsushima-cho, Yokosuka 237-0061, Japan)

Real-time scientific measurements at deep seafloor are getting very important to make clear scientific phenomena in earth. Ocean bottom observatories utilizing submarine cables have been very attractive for the geo-scientific studies and natural hazards (such as earthquakes and tsunamis). The developments of observatories are accelerated by the demand for the arrangement of seismic observation network around the Japan islands and retirement of coaxial submarine cables for overseas telecommunications. JAMSTEC has designed submarine cable connected seismic observatory and helped deployment and data transmission to Japan Meteorological Agency (JMA) database, which is accessible to other institutions and universities. The point of the end of 1998, two of seven sets of deep seafloor observatories deployed around the Japan islands are designed by JAMSTEC and a new observatory is under construction. The telecommunication submarine cable systems on world seafloor are innovated optical fiber cable system and coaxial cable system is to be closed its service. Some of the demission submarine cable system was donated from international telegram and telephone company in Japan (KDD) to universities coalition for scientific reutilization. Nine research institutes in Japan are joining and planning to carry out a project to construct complex scientific observatory using demission submarine cable for studying deep sea environmental changes around the Philippine Sea plate. This is a foremost complex observatory which will install to demission telecommunication cable and the project is named VENUS (Versatile Eco-monitoring Network by Undersea-cable System) project.
These types of cable connected ocean bottom observatories will be a powerful tool for precise natural hazards observation and geo scientific studies.

A BRIEF HISTORY OF SEISMOLOGY AND TEST BAN VERIFICATION

P.D. MARSHALL & A. DOUGLAS (AWE Blaeknest, Brimpton, Reading RG7 4RS, UK. email: alan@blacknest.gov.uk)

In the beginning the only method that seismologists could suggest for distinguishing between earthquakes and underground explosions was first motion. For explosions the first motion of P should everywhere be away from the source; for earthquakes there should be somewhere where motion is towards the source. In practice the method is difficult to apply principally because first motion could not be used confidently at low signal-to-noise ratios. Complexity of P seismograms then looked to be capable of identifying at least 90% of earthquakes from observations at teleseismic distances. The short-period P signals from explosions (as observed at arrays) were always it seemed simple - a single wavelet followed by a low amplitude coda - whereas the signals from shallow earthquakes often had amplitudes 30s after onset, as large as or larger than direct P. With time this apparent clear separation became blurred. The most robust criterion for distinguishing between earthquakes and explosions is the so-called mb/Ms, criterion: for a given Ms/mb, is Much larger for explosions than for earthquakes, but again as with all criteria there are difficulties in its application. Now after 40 years of research the basis of most identification criteria is understood and these criteria can be combined to answer the question: are the observations from a given seismic disturbance compatible with an earthquake source? If not then the disturbance could precipitate a demand for an on-site inspection to look for evidence of a possible nuclear test.
The paper describes some of the main advances in test ban seismology since 1958 and how these advances influenced the negotiations for a treaty banning all nuclear tests and eventually led to the signing of the Comprehensive Test Ban Treaty in September 1996.

U8/W/11-B3 Invited **0925**

THE INTERNATIONAL DATA CENTRE OF THE PREPARATORY COMMISSION FOR THE COMPREHENSIVE NUCLEAR-TEST-BAN TREATY ORGANIZATION PROVISIONAL TECHNICAL SECRETARIAT

Rashad M. KEBEASY (CTBTO, Provisional Technical Secretariat, Vienna, International Centre, P.O. Box 1250, Vienna, A-1400 Austria, email: rkebeasy@ctbto.org)

According to the Comprehensive Nuclear-Test-Ban Treaty (CTBT), the International Data Centre (IDC), of the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) Preparatory Commission has the function to receive, collect, automatically process, interactively analyze, report on, and archive seismic, hydroacoustic, infrasound and radionuclide data from the 337 stations and laboratories of the International Monitoring System (IMS). Its function is also to carry out, at no cost to States Parties, special studies, technical assistance and technical analysis of IMS or other data if requested by the organization or State Party. Moreover, the IDC has to progressively enhance its technical capabilities and provide standard IDC products with no prejudice to final judgements.
The plan for progressive commissioning of the IDC in Vienna, Austria continues according to the schedule established by the Preparatory Commission. A number of major milestones have been achieved since the start of the IDC establishment in 1997. Following to this plan more than 60 highly qualified staff members have already been hired. Most computer hardware and commercial software required for installation, testing and validation of software releases from the prototype International Data Center (pIDC) in Arlington, Virginia have been procured. A high speed telecommunication link between the IDC in Vienna and the pIDC in Arlington has been established to support transition and installation of the various releases as well as transmitting data for real-time testing of the software. A US $70 million contract was signed last September for turnkey services including the design, manufacture, delivery, installation, operation and maintenance of a complex Global Communication Infrastructure (GCI) to ensure the swift and secure transport of data between the IDC and over 500 IMS facilities and National Data Centres of the Treaty Signatory States.
Already the IDC is demonstrating its potential as testing continues using the second release of applications software delivered from the pIDC. This system provides the capability to process and analyze realtime data from a network of about 100 "volunteer"stations, with the ability to expand and improve as the IMS network grows and experience is gathered.

U8/E/08-B3 Invited **0940**

THE INFRASOUND SEGMENT OF CTBTO'S INTERNATIONAL MONITORING SYSTEM

Douglas CHRISTIE (Provisional Technical Secretariat, Comprehensive Nuclear-Test-Ban Treaty Organization, Vienna International Centre, P.O. Box 1250, A-1400 Vienna, Austria, email: Dchristie@ctbto.org)

The infrasound component of the International Monitoring System (IMS) for Comprehensive Nuclear-Test-Ban Treaty verification will consist of 60 array stations distributed as uniformly as possible over the surface of the globe. This network of high sensitivity stations will be capable of detecting and locating all nuclear explosions in the atmosphere with yields of 1 kt or more. In many parts of the world, the detection threshold will be significantly less than 1 kt.
The infrasound monitoring system will be far larger and more sensitive than any other

previously operated infrasound network. High-resolution data from this network will provide an unprecedented opportunity for the study of a wide range of geophysical phenomena in the atmosphere. In addition to infrasound from nuclear explosions, the network will detect acoustic and non-acoustic waves generated by large chemical explosions, volcanic eruptions, severe storm activity, tornadoes, the aurora, air flow over mountains, supersonic aircraft, meteors, earthquakes, and a variety of sources associated with the space industry. Data from the network will be especially important for studies of the frequency of occurrence and size distribution of meteors and studies of the dynamical behaviour of the upper atmosphere. All significant volcanic explosions will be detected by the IMS infrasound network. The data will therefore be of interest to the aviation community since prompt notice of volcanic activity can be used to reduce the hazards associated with volcanic ash clouds.

U8/W/08-B3 Invited 1005

GLOBAL RADIONUCLIDE SURVEILLANCE THE SENSITIVE NOSE OF THE CTBTO VERIFICATION SYSTEM

Lars-Erik De GEER (Provisional Technical Secretariat, Vienna International Centre, P.O.Box 1250, Vienna, A1400, Austria, Email: ledg@ctbto.org)

The Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) verification system employs four different techniques, three of which are basically listening to and analysing the continuous sound in the three terrestrial environments, the underground, the oceans and the atmosphere. The fourth technique, the collection and analysis of airborne radionuclides, is mainly focused on the atmosphere, but it can also catch information from the other two environments if the circumstances are right. And, that is very important, for a cheater to try to avoid being heard by the "sound" system he/she has inevitably to create those circumstances and increase the risk of putting radioactive odours into the atmosphere which can be smelled by the CTBTO radionuclide system.The Treaty defines a total of 80 stations worldwide for the collection of atmospheric aerosols, half of which will also be collecting samples of noble gases, especially focusing on xenon isotopes. All aerosol samples will be collected during 24 hours, allowed to let co-collected and disturbing radon daughters to decay for up to 24 hours and then they will be counted for another 24 hours. The xenon samples need no decay period and the technique employed might well even work on shorter cycles (like 6 hours) although the reporting time is only requested to be 24 hours by the Treaty.
The results in the form of energy spectra will be sent daily to the IDC in Vienna where they will immediately be subject to an automatic analysis and then interactively checked by an analyst. To minimise the human interaction time great efforts are put into developing effective software capable of finding all existing nuclides with a minimum of false detections of nuclides which are not present.
The current status of the network and the analysing software employed by the CTBTO/IDC in Vienna will be described.

COSMOS 1809 SATELLITE MEASUREMENTS OF VLF EMISSIONS IN NEAR EARTH SPACE ASSOCIATED WITH UNDERGROUND NUCLEAR TESTS

Vlalimir KOSTIN and Yury Romanovsky (both at Fedorov Institute of Applied Geophysics, Rostokinskaya 9, Moscow, 129128, Russia, email: hciag@sunny.aha.ru); Yakov Sobolev (Institute of Terrestrial Magnetism,Ionosphere and Radiowave Propagation, Troitsk, Moscow Region, 142092, Russia, email: ymich@izmiran.rssi.ru)

During 1987-1991 years COSMOS 1809 satellite (the orbit parameters: H= 950km, inclination-82?) carried out in near Earth space measurements of VLF emissions (f=70Hz-20kHz) associated with underground nuclear tests (UNT) of USA, France and former Soviet Union. Ten UNT events were observed at different distances from test ranges. Electromagnetic impulse of UNT has been revealed only one time when the satellite crossed L-tube projected immediately at a test range. Anomalies of whistler propagation were registered during 5-10 hours within the region of 2000 km from UNT point. This effect is proposed to be caused by the ionosphere disturbances due to acoustic waves after an explosion. Relaxation processes after UNT with power of 100 kt were appeared in near Earth space over UNT ranges as an increase of VLF noises in 2-3 times during 2-3 days. To clarify and indicate VLF signatures of UNT the database of VLF appearances of different man-made effects on near Earth space was prepared and analyzed. It is concluded that VLF emissions associated with UNT can be additional mean to monitor environmental effects caused by nuclear tests.

U8/E/03-B3 Invited 1110

T-WAVE STATIONS FOR THE CTBT: A GLOBAL PERSPECTIVE

Emile A. OKAL, (Department of Geological Sciences, Northwestern University, Evanston, IL 60208, USA)

As part of its monitoring efforts, the CTBT mandates the deployment of a network of "T wave stations", i.e., seismic stations located in the immediate vicinity of a shoreline and detecting the seismic waves resulting from the conversion of acoustic "T" waves. We review the mechanisms by which the seismic/acoustic and acoustic/seismic conversions take place, and give a perspective on the principal milestones in the use of seismically recorded T waves in the geophysical exploration of the Pacific Ocean over the past 40 years.
The application of simple models of reflection and refraction at the water/rock interface, as well as more involved modeling based on finite element applications, and the comparison with actual records, indicate that the optimal conditions for an efficient conversion require steep slopes as found on coral reefs, or at the heads of fresh basalt flows, similar to the Hawaiian "palis". The conversion can result in a shadow zone for converted-P, in which case the arrival can take the form of an S wave, or of a surface wave guided in the surficial layers.
In the environment of the Pacific Ocean, T waves have led to the discovery of several underwater volcanoes (Macdonald -- from acoustic records; and Hollister -- from seismic records), and to the recognition of various forms of their activity depending on the particular spectral characteristics of the phase. In addition, because of their capability to transmit energy at very high [seismic] frequencies over distances limited only by the size of the oceanic basin, T waves have been used to investigate such diverse problems as the tomographic mapping of the source of large earthquakes (Antarctic event of 25 March 1998), or the mechanical structure of subducting slabs (from such deep earthquakes as the 1994 Bolivia and 1990 Sakhalin events).
Finally, regarding the detection of explosive sources in the ocean, we will discuss seismic records of T waves from such sources as local seismic refraction experiments in Polynesia, a crustal refraction study in Mexican waters, marine seismics off the coast of California, and the presumed firing of ICB test missiles from submarines (all recorded in the Central Pacific.

THE SEISMOLOGICAL SEGMENT OF THE CTBT MONITORING SYSTEM

Robert NORTH (Center for Monitoring Research, 1300 North 17th Street, Suite 1450, Arlington, Virginia 22209, USA, email: north@cmr.gov)

The majority of the recording stations of the International Monitoring System are seismic. Digital data from 171 sites, of which 37 are arrays with apertures of up to 60km, will be received at the International Data Centre (IDC). Here they will be automatically processed and the results reviewed by experienced analysts. The techniques and procedures for rocessing and analysis are the culmination of many decades of research and algorithm development, and the corresponding software in many cases represents the first routine and automatic application of many such developments in an operational global seismic monitoring system. Examples include maximum likelihood estimation of magnitudes, a variety of event characterization measurements, and the association of hydroacoustic and infrasonic observations with seismic events.
A prototype IDC has been operating continuously at the Center for Monitoring Research since 1995, and the software that has been progressively developed and exhaustively tested there forms the basis of the CTBT IDC system. With continuous data from only 35 stations, the prototype IDC has achieved lower overall global detection thresholds than existing centres and provided an extensive data base of new parameters that is being used as the basis for further improvements. The seismic processing and analysis system will be briefly described and a summary provided of some of the more significant results to date.

U8/E/09-B3 Invited 1155

CONSTRUCTION AND CALIBRATION OF A COMBINED P AND S MODEL OF THE CRUST AND UPPER MANTLE BENEATH CENTRAL AND SOUTHERN ASIA

M Barmin, E R ENGDAHL, A Levshin, P Molnar, M Ritzwoller, A Villasenor (ph. 1 303 535 4853; e-mail: engdahl@lemond.colorado.edu, University of Colorado at Boulder, Boulder, CO 80309-0390 USA); W Mooney (U. S. Geological Survey, Menlo Park, CA 94025 USA); W Spakman, J Trampert (Utrecht University, Utrecht, The Netherlands); C Thurber (University of Wisconsin, Madison, Madison, WI 53706 USA)

Our aim is to combine the complementary features of global and regional scale body and surface wave tomography to produce a new model of P and S wave structure of the crust and upper mantle beneath Central and Southern Asia. The purpose of the model will be to improve location capabilities in the region of study under realistic regional monitoring conditions. The goal is to provide a uniform lateral resolution of 100 - 200 km across the entire region of study. To accomplish this goal we utilize the following recently published data: for S velocities in the crust and upper mantle we use long-period surface wave phase velocities and regional and continental scale group velocity measurements at intermediate periods; for P velocities in the mantle we use teleseismic and regional P-wave measurements; finally we use a priori information about the crust to regularize the inversions. To ensure its accuracy and usefulness, we validate and calibrate the model with empirical travel times, including those from Ground Truth data bases. We present information about how 3D structures in the crust and upper mantle affect travel times and ray paths and how these effects are manifested in biasing event locations under a variety of regional monitoring scenarios, in particular where data coverage is governed by the proximity of International Monitoring System (IMS) stations.

U8/E/06-B3 1215

RECOGNIZING CHEMICAL EXPLOSION SITES AND LOCATING EARTHQUAKES TIED TO AUTOMATED ENVELOPE ANALYSIS OF LOCAL NETWORK RECORDS

Eystein S. HUSEBYE (IFJ, UoBergen, Allegaten 41,N-5007, Norway, email: eystein.husebye@ifjf.uib.no) Yura V. Fedorenko (IFJ and Inst. North Industrial Ecology Problems RAS, Fersman Str. 14, Apatity, 184200 Murmansk Reg., Russia)

In monitoring local seismicity we are faced with 2 major problems namely that of properly identifying numerous chemical explosions and also locating accurately earthquakes. Preferably this should be done in an automated manner which is not feasible if tied to high-frequency network recordings. An alternative to conventional analysis is to replace the original complex waveforms with corresponding smooth envelope traces which are convenient for automated analysis. Chemical explosions are characterized by stationary envelope waveforms in time and space for individual mines. stationary. demonstrate how we utilized these features in combination with an artificial neural net (ANN) scheme for teaching the computer to recognize new explosion recordings from a specific site. In case of a single 3-comp. station recording we used the 9 different complex covariance elements in a multitude of frequency bands as diagnostic features. We are attempting to adapt the same procedure to non-stationary earthquake recordings. The new strategy here aims at utilizing waveform information from former earthquake recordings serving as a basis for construction of an automatic event locator. The basic idea is to 'backproject' individual station records to a fixed distance (100km) and compare waveforms using the ANN scheme. The distances providing the best fits are then used for epicenter locations. This approach is in principle similar to synthetic seismogram analysis but modelling is empirical and not physical - energy propagation in stratified media is complex. Both the explosion and earthquake location concepts have been extensively tested on Norwegian network recordings of very many local events with excellent results.

OUTSTANDING ISSUES IN CTBT MONITORING. HOW CAN GEOPHYSICISTS CONTRIBUTE TO THE TREATY VERIFICATION SYSTEM?

K. L. MCLAUGHLIN (Center for Monitoring Research, SAIC, Suite 1450, 1300 N. 17th. St. Arlington, VA, 22209, 703-247-1826, email: scatter@cmr.gov)

Calibration of each network (seismic, hydroacoustic, infrasound, and radionuclide) remains a major task before their full monitoring potentials can be realized. This talk will highlight how geophysics can make significant contributions to this international effort. Regional travel-time calibration is required to provide location uncertainties for small continental events better than 1000 square km. This ambitious goal requires maximum use of high quality seismic arrays and regionalized travel time tables. Most small events will be detected by only three primary plus one or two regional auxiliary stations. The Prototype International Data Center (PIDC) currently uses regionalized corrections to IASPEI Pn, Pg, Sn, and Lg tables for North America and Fennoscandia. Corrections are specified for source-specific locations on a lat-lon grid. Major effort remains to coordinate construction of such corrections for the entire Earth. Corrections must be independently validated against well recorded or ground truth events. In

addition, empirical azimuth and slowness corrections are estimated for each station and array since all stations and arrays show some significant azimuth and slowness anomalies. Calibration of seismic surface waves remains another furtive area. Detection and identification of long-period Rayleigh (LR) waves is based on a worldwide group velocity grid. Further refinement of the grid is required to lower LR thresholds. Infrasound is the least mature of the monitoring technologies. It is well known that infrasound propagation is strongly affected by 3D atmospheric winds and temperature profiles. Less well understood is whether useful propagation can be predicted from atmospheric models and how often the models must be updated. The hydroacoustic network will include 4 high frequency island seismic stations. to register acoustic energy converted to seismic energy. Researchers have yet to provide a predictive model for this conversion process.

STATUS OF THE IMPLEMENTATION OF THE INTERNATIONAL MONITORING SYSTEM FOR THE CTBT

Peter BASHAM, Sergio Barrientos, Alberto Veloso, Martin Lawrence and Joachim Schulze (International Monitoring System Division, CTBTO Provisional Technical Secretariat, Vienna, email: pbasham@ctbto.org)

The implementation of the International Monitoring System (IMS) began with the establishment of the CTBTO Provisional Technical Secretariat (PTS) in Vienna in March 1997, although a critical mass of staff were not in place until late 1997. This presentation will describe the status of the stations of the IMS: 321 seismic, hydroacoustic, infrasound, and radionuclide stations identified in the Treaty that need to be established around the globe. The annual budgets for the IMS Division of the PTS for 1997, 1998 and 1999 are $US9.8, 25.9 and 35.6 million, respectively, representing a total capital investment in stations of $US57.5 million. This is approximately 40% of the total capital investment required to complete the IMS networks.
Seismic is the most mature technology of the IMS, with about 85 primary and auxiliary stations currently sending data to the International Data Centre (IDC) in Vienna. By the end of 1999, these networks should be about 70% complete. Three hydroacoustic stations are currently sending data to the IDC, although they will require significant upgrades to meet specifications; this network will be about 70% complete at the end of 1999. Only one infrasound station existed at a Treaty location at the beginning of IMS developments; this network will be about 30% complete at the end of 1999. Although there are many pre-existing radionuclide stations monitoring atmospheric radioactivity, very few meet the IMS specifications; this network will also be about 30% complete at the end of 1999. This presentation will give the status of these networks as of July 1999, and a plan for completing the networks prior to entry-into-force of the Treaty.

U8/W/04-B3 1450

OPTIMIZED THRESHOLD MONITORING

Tormod KVÆRNA, Frode Ringdal, Johannes Schweitzer, and Lyla Taylor (all at NORSAR, P.O. Box 51, N-2007 Kjeller, Norway, email: tormod@norsar.no)

In order to enhance the automatic monitoring capability for the Novaya Zemlya (NZ) nuclear test site, we have derived a set of optimized processing parameters for the arrays SPITS, ARCES, FINES, and NORES. From analysis of the tuning events we have derived values for beamforming steering delays, filter bands, STA lengths, phase travel-times and amplitude-magnitude relationships for each array. By using these parameters for Threshold Monitoring (TM) of the NZ testing area, we obtain a monitoring capability varying between mb 2.0 and 2.5 during normal noise conditions.
The advantage of using a network, rather than a single station or array, for monitoring purposes becomes particularly evident during intervals with high global seismic activity (aftershock sequences), high seismic noise levels (wind, water waves, ice cracks) or station outages. For example, for the time period November-December 1997, all time intervals with network magnitude thresholds exceeding mb 2.5 were manually analyzed, and we found that all these threshold peaks could be explained by teleseismic, regional, or local signals from events outside the NZ testing area. We could therefore conclude at the 90% confidence level that no seismic event of magnitude exceeding 2.5 occurred at the Novaya Zemlya test site during this two-month time interval.

U8/W/06-B3 1505

MONITORING THE COMPLIANCE WITH THE CTBT FROM THE PERSPECTIVE OF THE GERMAN NATIONAL DATA CENTER (NDC)

Manfred HENGER (Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany, Email: henger@sdac.hannover.bgr.de)

National data centers (NDCs) are important elements of the international monitoring system (IMS), however, their functions are nowhere defined in the CTB treaty text. In general, NDCs are responsible for the operation and maintenance of participating national IMS stations, act as communication hubs, technical point of contact for the Vienna International Data Center (IDC), and have to provide expertise to national authorities. Since the CTBT was opened for signature, and even before, there were several cases where the German NDC was confronted with the problem of event identification. On the basis of IMS data and IDC products available at that stage this was a rather challenging task. The various problems encountered will be presented for selected questionable events. It can be shown that data from seismic networks operated for other purposes than CTBT monitoring considerably improved seismic event location and facilitated identification. However, there are a number of reasons that may prevent or make it impossible for an NDC to use data from other national networks, such as a lack of communication facilities, limited availability of events due to recording of seismic signals in triggered mode, lack of knowledge about seismic stations operated by a country, impossibility of timely data access, format problems, a lack of calibration data, and others. These difficulties could be solved with existing technical means without significant cost. Moreover, it is recommended that irrespective of the dedication of seismic stations and networks, the operation, as well as procedures of data retrieval and data archiving, should be standardized as much as possible for the sake of solving both scientific and politically motivated seismological issues.

U8/E/11-B3 1520

FOCAL MECHANISMS OF LOW-MAGNITUDE EARTHQUAKES FROM HIGH-FREQUENCY P AND S OBSERVATIONS: AN EXAMPLE USING SOURCES IN THE BARENTS SEA REGION

David BOWERS and Alan Douglas (AWE Blacknest, Brimpton, Reading RG7 4RS, UK. Email: bowers@blacknest.gov.uk)

At long range earthquakes have successfully been identified by demonstrating that the observed seismograms are consistent with the radiation pattern expected from a double couple. For seismograms from small disturbances recorded at regional distances the effect of the path is so dominant that the radiation pattern can rarely, if ever, be inferred. We present evidence that paths across the Barents Sea, from northwest Russia and the Kara Sea, to Spitsbergen (SPITS) show weak P and S attenuation, allowing clear P and S to be observed at frequencies above 15 Hz at distances of at least 1200 km from small (3.3 mb) disturbances. As a result of the efficient propagation of P and S in the Barents/Kara sea region, clear three-component P and S seismograms were recorded at SPITS, KEV (Kevo, Finland) and AMD (Amderma, Kola, Russia) from the 16 August 1997 3.3 mb seismic disturbance in the Kara Sea. The S waves recorded at these three-component stations, and the P waves recorded by the Scandinavian arrays HFS (Hagfors, Sweden) and NORES (Norway), are consistent with a double couple.

GLOBAL ENVIRONMENTAL MONITORING AND THE CTBTO INTERNATIONAL MONITORING SYSTEM

DR. John A. ORCUTT, (Cecil & Ida Green Institute of Geophysics and Planetary Physics (0225), Scripps Institution of Oceanography, La Jolla, CA 92093, email: Jorcutt@igpp.ucsd.edu)

The International Monitoring System for the Comprehensive Test Ban Treaty presents many opportunities for enhanced monitoring of the environment on a global basis. In many cases, the increases in capability are incremental (e.g. seismology) while in other areas (e.g. Infrasound), the enhancement of capability is fundamental. I will discuss each of the four elements of the IMS: Seismology, Hydroacoustics, Infrasound, and Radionucliides. In each case, the augmentation of present capabilities will be noted and the requirements for the instrumentation will be compared with current standards. Potential environmental monitoring tasks for each of these capabilities, including capabilities resulting from synergies between technologies, will be explored. In many cases, limitations on the full utilization of the installed instrumentation will be seen to arise from political rather than technical issues.

U8/W/07-B3 1625

MULTIMODAL DISTRIBUTION OF SEISMIC PHASE ARRIVAL TIMES FOR AUTOMATIC LOCATION OF REGIONAL SOURCES

Vladimir PINSKY. (Seismology Division, Geophysical Institute of Israel, P.O. Box 2286, Holon 58122, Israel, tel: 972-3-5576050; e-mail: vlad@iprg.energy.gov.il).

Adoption of the CTBT regime leads to increased sensitivity of regional seismic networks and an expansion of the event flow. Automation of location thus becomes a crucial issue. Recently, several research groups concentrated on the possibility of using envelopes of the pre-filtered network seismograms for automatic location of event epicenters and provided simple and robust solutions. Our approach, tested with Israel Seismic Network (ISN) recordings, is based on inversion of characteristic time points: Tp and Ts - local maximums of the envelopes, related to P and S phases. For local ISN events the corresponding travel times were measured to be close to: Tp(R)=2.5+R/6.4 sec., Ts(R)=3.5+R/3.6 sec., where R is distance in kilometers. The bottleneck of the whole approach is automatic recognition of the phases from seismograms or envelopes which is provided by a logic based on choosing the specific threshold levels and time windows [1]. However, misidentification of the phases frequently occurs. We overcome this problem by introducing the statistics tp(R) and ts(R), both having 2-modal (multi-Gaussian) distributions concentrated at Tp(R) and Ts(R). Vector statistic dT of differences of the measurements for all pairs of the network stations we represent as scalar statistic dt, described by the multi-Gaussian density function. Epicenter location is provided by maximization of the corresponding likelihood function through a grid search. As a result of the preliminary study of a set of more than 120 local earthquakes and quarry blasts , ML~1.5-2.5, we obtained an accuracy of approximately < 6 km for epicenter estimation for both types of events. The procedure was also successfully tested on a set of calibration quarry blasts with precisely known coordinates and ignition time. The algorithm can be considered as a first step, providing constrained time windows for P and S on-sets on the seismograms. Further improvement of results is achieved by estimating P and S wave arrival times within the time windows specified above, using the well-known maximum likelihood algorithm [2] with following application of the standard location procedure

U8/W/02-B3 Poster 1640-01

COUPLING OF SEISMIC WAVES TO T-WAVES VIA SEAFLOOR SCATTERING

Catherine de GROOT-HEDLIN (IGPP, SIO, University of California at San Diego, 92093-0225, CA, USA, email: cdh@eos.ucsd.edu) John Orcutt(IGPP, SIO, University of California at San Diego, 92093-0225, email: jorcutt@igpp.ucsd.edu)

One of the challenges of monitoring the ocean basins for nuclear explosions at sea is in discriminating between hydroacoustic signals from nuclear tests and those excited by earthquakes occuring below the seafloor. T-phase excited by earthquakes can be classified into 2 types: abyssal T-phases which are generated near earthquake epicenters at depths well below the SOFAR channel, and "slope-generated" T-phases which are excited at shallow depths at continental margins or ocean islands at some distance from the epicenter. In this study, we demonstrate that both types of arrivals are consistent with scattering from a rough seafloor. We show that abyssal T-phases result from scattering into high order, bottom-interacting acoustic modes, while the "slope-generated" T-phases are modelled as low order acoustic modes generated at shallow depths which cease interaction with the bottom as they propagate seaward to the deeper ocean. The synthesized T-phase coda exhibit characteristics also observed in hydroacoustic recordings of T-waves: the abyssal T-phase coda is nearly symmetric and typically peaks at frequencies of 10-20Hz, whereas the slope-generated T-phase coda usually peaks at 4-8Hz and has a shape which is strongly influenced by near-source bathymetry. Furthermore, the modelling correctly predicts that abyssal T-waves are attenuated more severely by bathymetric interactions along the propagation path than the "slope-generated" T-phases. We compare hydroacoustic recordings of T-waves from earthquakes in the Pacific basin with results from synthetic modelling of T-phases, and contrast these with recordings of the 1995-1996 French nuclear tests in the islands of the Tuamoto archipelago.

ANALYTIC AND NUMERICAL STUDIES OF NATURAL SOURCES OF ATMOSPHERIC INFRASOUND: MICROBAROMS AND MOUNTAIN INFRASOUND

David C. FRITTS, Steve Arendt, and Gregory S. Poulos, (Colorado Research Associates, 3380 Mitchell Lane, Boulder, CO 80301 USA)

We have used analytic and numerical techniques to assess the mechanisms responsible for infrasound radiation from ocean storms and mountain topography. Microbaroms arise from interactions among ocean surface waves having frequencies of a few seconds (wavelengths of ~ 100 m) and approximately equal and opposite wavenumbers. Contributions to microbarom radiation come from monopole, dipole, and quadrapole terms in the resonance equations. Mountain infrasound arises from flow intermittency over and around mountain obstacles on scales of ~ 10 km and comprises exclusively dipole and quadrapole radiation. Also discussed will be the manner in which infrasound radiation frequencies are selected.

COLLECTION OF GROUND TRUTH INFORMATION FOR THE CALIBRATION OF THE CTBT INTERNATIONAL MONITORING SYSTEM

Istvan BONDAR and Petr Firbas (both at CTBTO, IDC, Vienna Int'l Centre, P.O.Box 1200, A-1400 Vienna, Austria, emails: Istvan.Bondar@idc.ctbto.org, Petr.Firbas@ctbto.org)

Although there is a general agreement that location calibration is necessary to improve locations provided by international agencies, no such attempt has so far been made on a global scale. The On-Site Inspection provision of the Comprehensive Nuclear-Test-Ban Treaty (CTBT) limits the inspection area to 1000 sq km. In order to achieve a corresponding location accuracy with the relatively sparse and largely teleseismic CTBT International Monitoring System network a detailed location calibration is required.
The prototype International Data Centre (pIDC) has started and the CTBTO IDC is taking over a program of seismic location calibration program that includes the collection, categorisation and validation of "ground truth" events from a variety of sources as well as the development and operational testing of both empirical and model based corrections. The collection of ground truth events requires broad international co-operation between scientific as well as governmental institutions. The events belonging to different ground truth categories (GT0, GT2, GT5, GT10 and GT25) are used to derive and validate corrections in both time and slowness domain. The scientific community may benefit from preparation of the ground truth database. Technical information on the selection procedures and categorisation of calibration and ground truth events will be given.

MONITORING ACTIVITY OF THE IDC

CHERNOBAY, I (CTBTO, Provisional Tecchnical Secretariat, Vienna International Centr, Vienna, Austria, Email: ichernobay@ctbto)

The commissioning plan for the International Data Center (IDC) of the Preparatory Commission for the Comprehensive Nuclear-Test-Ban Treaty Organization Provisional Technical Secretariat consists of seven phases. The IDC is currently at its fourth stage. To perform its functions, the IDC receives monitoring capabilities from its prototype (pIDC) in Arlington, Virginia (USA). The transition of these functions will take place in a series of four technically progressive software releases. Release 1 of the IDC application software was under operation in Vienna since May 15 till December 1998 and provided to the IDC initial limited operational capability. Realtime data from about 60 stations of the International Monitoring System were flowing through the pIDC to the IDC via a high capacity T1 link. Automatic data acquisition and automatic processing continued 24 hours per day and 7 days per week to assess the capability and robustness of the software. Standard Event Lists (SELs) were automatically produced daily. The IDC's analysis staff reviewed and corrected one data day per week of seismic, hydroacoustic and infrasound data, and almost all of the radionuclide spectra. At this stage, automatic processing of the waveform data was based on the data from primary stations and used only one network processing pipeline -- 2 hours behind realtime. No data from auxiliary stations were involved in producing the Standard Event Lists. With this limited capability, the IDC succeeded in locating the 100 tons calibration chemical explosion in Kazakhstan (August 22).
Starting in the middle of December 1998, the IDC is under preparation for the installation and operation of Release 2 Application Software. With this Release, the IDC will be running automatic data processing based on three consecutive network processing pipelines (2, 6 and 12 hours behind real time). The first one will use data from primary stations only while the second and third pipelines will also incorporate data from auxiliary stations. In May 1999, the IDC is expected to distribute Reviewed Event Bulletins, ramping up from one day per week in May to seven days per week in a few months.

SEISMIC ANALYSIS AT THE UK NDC

David BOOTH, Russ Evans, and Aoife O'Mongain (British Geological Survey, West Mains Road, Edinburgh EH9 3LA, UK, email: d.booth@bgs.ac.uk)

The UK has chosen to set up a National Data Centre for the purpose of monitoring the Comprehensive Test Ban Treaty (CTBT), using data recorded by the International Monitoring System, and transmitted by the International Data Centre, of the CTBT Organisation. The British Geological Survey accepted responsibility for the establishment and operation of the UK NDC in January 1998. Since then, the BGS has been developing systems to receive the IDC data and present it in a form suitable for its scientists to analyse and interpret. Initially, the UK NDC is concentrating on the analysis and interpretation of seismic data. The seismic analysis system makes use of the flexibility of the Geotool software developed by Coyne and Henson, which has proved to be very versatile and has allowed the development of a system which is being customised for the analysis requirements of the UK NDC. Assessments of various seismic events are presented, to illustrate the capability of the system.

U8/W/10-B3 Poster **1655-06**

SLOWNESS CORRECTIONS- ONE WAY TO IMPROVE THE IDC PRODUCTS

Johannes SCHWEITZER (NORSAR, P.O.Box 51, N-2007 Kjeller, Norway)

The first step to identify and locate a seismic event is the association of observed onsets belonging to the same event. During this process the challenge is to define only real events but to associate as much as possible of all detected phase.
One advantage of the data processing at the IDC is the extensive measurement of all relevant parameters of the detected phases. Well defined slowness (i.e. ray parameter, or apparent velocity and backazimuth) measurements are very useful for associating seismic onsets. For events only defined by a small number of observations, slowness measurements are also helpful for locating these events. Therefore such data are used during all steps at the IDC to produce the final bulletins. The observed slowness parameters measured with small aperture arrays, which are mostly used in the IMS as primary stations, show a relatively large scatter. However, one can derive mean slowness deviations, which show a relatively stable and array specific pattern, a result of differences between Earth models and the local and regional structure around these arrays. In this contribution, different approaches will be presented to estimate an easily implementable set of slowness corrections.

U8/E/07-B3 Poster **1658-07**

COMPLEXITY OF TELESEISMIC P WAVES FROM THE CASPIAN SEA EARTHQUAKE OF 29 OCTOBER 1995

C. B. SNOWDEN (Dept of Geology and Geophysics, Grant Institute, West Mains Rd., Edinburgh, EH9 3JW, UK, email: conor.snowden@glg.ed.ac.uk); A. Douglas and D. Bowers (AWE Blacknest, Brimpton, Reading, RG7 4RS, UK)

Both the source radiation pattern and earth structure contribute to the complexity of observed teleseismic short-period (SP) seismograms.Modelling shows that the amplitude of a S-to-P conversion, at a boundary below the source, can be larger than the geometric phases P, pP and sP. SP array seismograms from the Caspian Sea earthquake (mb=5.8) of 29 October 1995 (06:27 UT) appear to show a large phase (bP) after P, which if pP, suggests a source depth of about 30 km (REB pIDC). A simple SP S-wave recording in the UK indicates a simple near-receiver structure and low attenuating path, suggesting that the observed complexity is related to the source region (radiation pattern and/or structure).
We show that the interpretation of bP as pP is inconsistent with a double couple at a depth of 30 km. On broadband seismograms bP is weak and P, Pp and sP are clear, suggesting a source depth of 68 km. Further, we demonstrate that the SP phase bP can be modelled as a S-to-P conversion at a boundary approximately 100 km below the source. Reliable depth estimates are important in the monitoring of the CTBT and this shows the usefulness of teleseismic records even if regional data is not available.

P-WAVE AMPLITUDES OBSERVED FROM EXPLOSIONS AND EARTHQUAKES AND THE DISTRIBUTION OF REGIONS OF HIGH ATTENUATION IN THE EARTH

A. DOUGLAS, D. Bowers and J.B. Young (AWE Blacknest, Brimpton, Reading RG7 4RS, UK. Email: alan@blacknest.gov.uk)

The body-wave magnitude (mb) of a seismic disturbance is estimated from the individual station magnitudes; the station magnitudes being estimated from SP P seismograms. Station magnitudes are usually widely scattered. Such scatter is due to both source and path effects. Body-wave magnitude plays an important role in test ban verification and thus has been the subject of detailed study principally to estimate and allow for path effects and so improve estimates of source size. The path effects however, reveal something of the distribution of attenuating regions in the earth. The association of high attenuation with orogenic regions is well-established. However, the attenuating zones must have a patchy distribution because for example, some stations in orogenic regions that lie on paths that are highly attenuating for P, record PcP that shows little evidence of attenuation. The paper draws together amplitude observations from explosions at most of the sites where underground tests have been carried out, to determine the distribution of the attenuating regions.

LOW-FREQUENCY SPECTRAL CLASSIFICATION FOR CONTROLLED QUARRY BLASTS RECORDED BY ISRAEL SEISMIC NETWORK AND SINGLE BB STATION EIL

Yefim GITTERMAN (Seismology Division, The Geophysical Institute of Israel, P.O.B. 2286, 58122 Holon, Israel, email: yefim@iprg.energy.gov.il)

Based on numerous observations of quarry blasts, is was found that spectral modulation analysis at low (0.5<f<10 Hz) frequencies is more effective for event classification than at high frequencies (10-50 Hz) and it is better to reveal and analyze the modulation using usual smoothed spectral curves for several stations at different azimuths. The observed source features - the first spectral null f1 (at low frequencies) and the main maximum fm (at high frequencies) - are explained by the physical phenomenon of interference of seismic waves from inter-shots with millisecond delays and not by source (space or time) finiteness. For a regular blast pattern the feature are connected with delays, t, and number of delays, n, by the simple linear interference theory: f1=1/(nt), fm=1/t. Any random variation of a delay time or charge per delay, or any other non-regularity of a last pattern, will destroy the spectral modulation features, most significantly at high frequencies. For controlled regular quarry blasts (t=40 msec, n=5) in the Negev with Ground Truth Information of class GTI0, an outstanding first spectral null was observed at short-period network stations and the EIL BB station, corresponding well to the theoretical value of f1. The main maximum spectral modulation feature (fm=25 Hz) could not be found, even at the BB records, owing to the steep descend of spectra after 10 Hz associated with the regional crustal structure of widespread unconsolidated sediments absorbing intensively high frequencies. All three components of the BB EIL showed the same spectral modulation pattern and the spectra average corresponds well with the network stations average. Application of the new-developed discriminants - energy ratio (1-3 Hz)/(6-8 Hz) and spectral semblance (1-12 Hz) (measuring spectral curves coherency) - to network stations and single BB (3C) recordings showed surprisingly similar results related to the explosion population.

RECENT NUCLEAR TESTS RECORDED BY THE ISRAEL NETWORK AND BB STATIONS

Yefim GITTERMAN, Vladimir Pinsky, Rami Hofstetter (Seismology Division, Geophysical Institute of Israel, P.O. Box 2286, Holon 58122, Israel, e-mail: yefim@iprg.energy.gov.il)

We analyzed observations of Israel Seismic Network (ISN) and Broad Band (BB) stations of the recent nuclear tests conducted by India and Pakistan. Only the test on 28.05.98 (NEIC mb~4.8, r~26 deg.) triggered the short-period ISN stations. Two tests (11.05.98, mb=5.2, r~32deg. and 28.05.98) triggered the EIL BB station (80 Hz data), and signals of the weakest test (30.05.98, mb=4.6, r~25 deg.) were revealed in the continuous BB 20 Hz data after heavy band-pass filtering in different ranges.Detectability of the BB stations, EIL, MRN and JER, was investigated for the three known detectors of STA/LTA, Murdock-Hutt (MH) and Adaptive Optimal Detector (AOD) algorithms, using 20 Hz continuous records. The EIL station, installed in a 100 m long tunnel, is the quietest (spectral density of noise ~ 3 nm^2/Hz at 1 Hz), where the Indian test was reliably detected by all the three detectors. The first Pakistan test was

detected by AOD and MH at all the stations within 0.5-5 Hz band, but STA/LTA failed for the JER station. The smallest Pakistan test was masked by coda of a local event and was hardly detected by STA/LTA, but was reliably extracted by AOD and MH for all the stations. Spectra of a P-waves portion (~17 sec) at vertical components of the ISN stations for the test on 28.05.98 showed a pronounced coherent spectral null at 1.7 Hz, which could be interpreted in terms of interference of P and pP phases. The relatively high null frequency corresponds to the reported shallow source depth of a few hundreds meters.Two new-developed multi-channel spectral discriminants (energy ratio and semblance) were applied to the P-wave spectra for a set of events including the three tests and several close Pakistani earthquakes. The two discriminants were calculated for a sub-set of the short-period ISN stations, and for the three components of the BB EIL station. The both estimates (multi- and single station) correspond well to the results obtained before for Kazakh and Chinese events - nuclear tests demonstrate lower values of energy ratio (0.6-1Hz)/(1-3Hz) and spectral semblance (0.6-2Hz) than earthquakes.

U8/E/05-B3 Poster **1710-11**

YIELD ESTIMATION OF PAKISTAN NUCLEAR EXPLOSION OF MAY 28, 1998 BY ILPA SEISMOGRAMS

Abdolrahim JAVAHERIAN and Ahmad Sadidkhoi (both at Institute of Geophysics, Tehran University, P. O. Box 14155-6466, Tehran, I. R. Iran, email: javaheri@chamran.ut.ac.ir)

Seismic measurements are recognized as a valuable source for use in monitoring underground nuclear tests. Their uses include detection, yield estimation and discrimination of nuclear explosions. In order to investigate seismic yield one has to obtain relationships between seismic parameters and yield of underground nuclear explosions.
In the present research, we estimated the yield of Pakistan nuclear explosion of May 28, 1998 by two methods. In the first approach, the magnitude of surface waves (in the frequency domain) using the maximum amplitude spectrum of the vertical component of Rayleigh waves recorded at ILPA (Iranian Long Period Array) have been considered. In the second approach, the amplitude of P wave (with a period of 1 s) recorded at ILPA have been employed. The yield of this explosion have been estimated for 4 possible media which may surround the test site. These media were granite, salt rock, tuff and alluvium.

MONITORING OF THE INDIAN AND PAKISTANI NUCLEAR TESTS

Tormod KVÆRNA, Frode Ringdal, Johannes Schweitzer, and Lyla Taylor (all at NORSAR, P.O. Box 51, N-2007 Kjeller, Norway, email: tormod@norsar.no)

Monitoring of possible testing areas is one of the main applications of the Threshold Monitoring (TM) method. Recently, both India and Pakistan conducted underground nuclear tests, and, in particular, the Pakistani explosions provided a very interesting scenario for testing of the method. Firstly, the two events on May 28, 1998 (Explosion 1) and May 30, 1998 (Explosion 2) were located about one degree apart, and it is interesting to investigate the performance of the TM method for Explosion 2 when monitoring the target area for Explosion 1. Secondly, the origin time of Explosion 2 was about 38 minutes after the origin time of an mb 5.5 earthquake in Afghanistan, and the explosion signals were mixed with the coda and aftershocks from this earthquake. The earthquake was located 9-10 degrees away from the explosion sites. Our results demonstrate that the TM method can be effective at teleseismic distances. Using data from European and Australian arrays, the Pakistani test area can be monitored down to a magnitude of 3.0 during background noise conditions. The benefit of using a network for monitoring becomes particularly apparent during the earthquake sequence located as close as 10 degrees from the target region, where the TM method suppressed the aftershock signals by up to 0.5 mb units.

SEISMOLOGICAL CONSTRAINTS IN DETECTION OF UNDERGROUND NUCLEAR EXPLOSIONS

H.N. SRIVASTAVA (India Meteorological Department New Delhi- 110003, India,
e-mail: snb@imd.emet.in)

The Pokhran underground nuclear explosion of 17th May, 1974(M5.0) in Rajasthan, India, produced a seismogram exactly similar to near earthquake at about 600 km away through SP Benioff seismograph showing typical Pn, P*, Pg and Sn, S* and S phases at Delhi observatory. However, the S phases became less discernible at larger epicentral distances from the source as expected. The yield of the explosion estimated from Wood Anderson Seismometers agreed with the estimates of US Geological Survey. Since then, several stations have been upgraded through digital seismographs including broadband type. A question arises whether in case of multiple nuclear explosions at short intervals as reported in India and Pakistan during May, 1998, the seismological methods would be able to provide a realistic estimate of the yield even if location problem is resolved by using only P wave arrival time for the fist explosion. Techniques of analysis for such exigencies have been proposed for discussion.

HAZARD AND RISK ASSESSMENT, RISK MITIGATION AND MANAGEMENT

JSP23/C/U5/P/01-A5 Invited **0830**

ATMOSPHERIC HAZARDS ASSOCIATED WITH THE EL NINO/SOUTHERN OSCILLATION PHENOMENA: A SYNTHESIS

Madhav L KHANDEKAR (Consultant, Baird & Associates, Ottawa, Ontario, CANADA, L3R 7Z5)

The ENSO phenomenon – spreading of warm water from the equatorial central Pacific to the equatorial South American coast and associated global weather anomalies -- is now identified as the strongest signal in the global climate system after the annual cycle. The term El Nino refers to the spreading of anomalously warm water off the coast of Ecuador and Peru and associated weather anomalies over the west coasts of the Americas. The Southern Oscillation is the atmospheric counterpart of El Nino and refers to the slowly varying atmospheric pressure differential over the eastern and western regions of the tropical Pacific. The two phenomena together are now popularly known by the acronym ENSO (El Nino/Southern Oscillation).
The appearance of warm water off the coast of South America and associated changes in the regional weather patterns were known to Peruvian fishermen for over 400 years. The landmark papers of Jacob Bjerknes in the Nineteen Sixties provided a physical link between ENSO and weather anomalies over the entire equatorial Indo-Pacific basin. Several studies inspired by Bjerknes' landmark papers and reported in the last twenty-five years have documented a link between ENSO and global weather anomalies.
This paper provides an overview of global weather anomalies and associated atmospheric hazards in the context of the ENSO phenomena. The paper further presents several examples of atmospheric hazards associated with extreme weather events and their relationship to the various phases of ENSO. The importance of monitoring various phases of the ENSO phenomena through suitable atmospheric and oceanic indices will be discussed in the context of long-range weather forecasting.

ENSO AND 'ENSO-LIKE' IMPACTS ON INTERANNUAL TO SECULAR TIME SCALES

Robert J. ALLAN (CSIRO Atmospheric Research, Aspendale, Victoria 3195, Australia, email: rob.allan@dar.csiro.au); Ian N. Smith (CSIRO Atmospheric Research, Aspendale, Victoria 3195, Australia, email: ins@dar.csiro.au).

Efforts to improve our understanding of the various types of natural variability inherent in the global climate system have included a growing focus on the El Niño Southern Oscillation (ENSO) phenomenon and lower frequency 'ENSO-like' decadal to secular scale fluctuations. Signal detection analyses applied to global historical sea surface temperature and mean sea level pressure anomalies, reveal significant climatic signals operating on quasi-biennial, inter-annual, decadal multi-decadal and secular time scales. The ENSO signal is seen to consist of quasi-biennial (QB) and lower frequency (LF) components that interact to produce important modulations of the phenomenon. 'Protracted' El Niño and La Niña episodes are found to be a consequence of the 'phasing' of quasi-decadal and inter-decadal 'ENSO-like' signals with the QB and LF ENSO components. Further climatic modulations are provided by 'ENSO-like' phenomena operating on multi-decadal time scales. The secular trend, reflecting the observed global warming signal, reveals neutral to slightly 'La Niña-like' conditions in the Pacific sector. The impact of the above climatic signals can be seen in the patterns of correlation with global precipitation and mean surface land temperatures. Significant contributions to rainfall and land temperature variability are evident, not just in known 'ENSO-sensitive' regions. In addition, El Niño and La Niña episodes on inter-annual time scales can be both synchronous and asynchronous with 'El Niño-like' and 'La Niña-like' signals on various decadal to multi-decadal time scales, resulting in the range of fluctuations seen in many rainfall and temperature impacts over time.

JSP23/L/01/A5 **0930**

HAZARD AND RISK MITIGATION BY IMPROVING THE CULTURE OF SOCIETY AND OF THE DECISION MAKERS

FABRIZIO FERRUCCI and Giovanni P. Gregori

Hazard and risk management requires a precise preliminary assessment of their respective formal definition, sources and causes. The natural environment, likewise demography, territory use, and energy consumption, are not steady in time. They rather experience a continuous transformation or evolution. Every so-called natural catastrophe is a strict need by natural reality. Neither it makes sense to search for a forerunner (that in a strict sense can be given, at most, only with some relevant error bar, that makes a forecast of little practical help). Moreover, a prevision is often useless in terms of concrete reduction of causalities and/or damages. The entire problem rather emphasises per se the great need for improving the consciousness of the specific characteristics of every type of natural catastrophe, and of the ways by which its consequences can be prevented or minimised. A forgotten aspect of human history is concerned with the epoch when mankind got the consciousness of space orientation, and much later also of absolute time. Similarly to this, at present there is a great need for educating both society and decision makers about the correct cultural approach to Nature, to environmental knowledge, and to territory management. All this appears the unique concrete viable approach for solving the threaten by the progressively stronger impact of mankind on environment, a factor that is closely and unavoidably related to the same progress of civilisation. Several case histories will be specifically discussed.

JSP23/W/31-A5 **0950**

FLOOD EVENTS IN THE RHINE RIVER BASIN: GENESIS, INFLUENCES AND MITIGATION

Markus DISSE (German Federal Institute of Hydrology, P.O. Box 309, D-56003 Koblenz, Germany, Email: disse@bafg.de); Heinz Engel (German Federal Institute of Hydrology, P.O. Box 309, D-56003 Koblenz, Germany)

The catchment of the river Rhine can be distinguished in 4 main subcatchments: the alpine region with the river Aare as the main tributary and downstream the lower mountain regions of the tributaries Neckar, Main and Moselle. These four basins clearly generate different hydrographs. Due to the geographical circumstances, the average discharge maximum shifts from summer towards winter downstream the Rhine. However, spatial and temporal precipitation patterns have a strong influence on the individual flood. The particular genesis of recent and historical floods will be discussed. Besides the climatological causes a brief overview of the manmade alterations to the river system itself (Rhine and tributaries) and to the linked catchments are given and their effect will be indicated. However, up to now the influence of land surface and river training measures on flood conditions in the Rhine basin has not exactly been quantified. Therefore, the Dutch-German project LAHoR has been established within the framework of the EU-project IRMA (INTERREG II C Rhine Maas Activities). The results of this project may give efficient advice for the "Action Plan on Flood Defence" of the International Commission for the Protection of the Rhine (ICPR), which is briefly introduced. In this plan a multidisciplinary approach to mitigate floods is suggested that can yield to synergic effects between flood prevention, water management, regional planning, agriculture, forestry and ecological demands.

JSP23/E/37-A5 **1010**

THE SUVA EARTHQUAKE RISK MANAGEMENT SCENARIO PILOT PROJECT (SERMP) - MITIGATION OF EARTHQUAKE AND TSUNAMI RISKS FOR THE CITY OF SUVA, FIJI

Jack RYNN (Centre for Earthquake Research in Australia, PO Box 276, Indooroopilly, Brisbane, Queensland 4068, Australia, email: sally.brown@uq.net.au); Poasa Raveo (Department of Regional Development and Multi-Ethnic Affairs, Government of the Republic of Fiji, PO Box 2219, Government Buildings, Suva, Fiji); Atu Kaloumaira (South Pacific Disaster Reduction Management Office, c/o UNDP, Private Mail Bag, Suva, Fiji, email: atu@sopac.com.org)

The 1953 Suva earthquake (ML 5.6) and associated tsunami is a stark reminder of the vulnerability of the City of Suva to such natural hazards. Through the UN IDNDR program, per the 1994 "Yokohama Statement", the Government of the Republic of Fiji took the challenge to counter mitigation strategies. SERMP was a co-operative effort of the Government, UNDP-UNDHA and international consultants. A specific methodology was developed to address definitive project components of hazard, vulnerability and risk assessments, mitigation measures, response planning, public awareness, policy support and dissemination of findings. Wide-ranging outcomes for both earthquake and tsunami, of risk assessments, loss estimations, disaster planning, risk management and tsunami warning, with 90 recommendations, were documented as an ""information resource:" These were implemented as "practical applications" in building codes, GIS, land use planning, disaster plans, training, emergency management and community education. A Sub-Regional Seminar and exercise "SUVEQ 97""were conducted. SERMP also demonstrated mitigation measures to decision makers in all Pacific Island Countries.

JSP23/W/19-A5 **1050**

THE AUSTRALIAN ENVIRONMENTAL RISK MANAGEMENT FRAMEWORK

Tom BEER (CSIRO Atmospheric Research, Aspendale, 3195, Australia, email: Tom.Beer@dar.csiro.au)

Environmental risk management deals with impacts on the environment, as well as with impacts on organisations that disturb the environment. Management options are based on a measure of the risk, which is obtained through an analysis of both the likelihood and the consequences of the impact. Many of the concepts, and much of the terminology, of environmental risk assessment have arisen from its use by the US EPA as an objective tool that provides information on which to base environmental decisions. A key step in the United States was to maintain a clear separation between risk treatment and risk assessment. Risk treatment is an activity undertaken by decision-makers and managers, whereas risk assessment is an activity undertaken by technicians. Many workers have argued that one cannot maintain such a clear distinction and a conference of the Australian Academy of Science developed an Environmental Risk Management framework. Australia has been reluctant to embrace the US-inspired clear distinction between risk treatment and risk assessment. Australia has, instead, combined risk assessment (envisaged as a combination of risk analysis and risk evaluation) and risk treatment within a generic risk management framework that has been incorporated into the Australian/New Zealand Standard on Risk Management, AS/NZS 4360. This presentation synthesises the Australian Risk Management and Environmental Risk Management frameworks.

CAUSE-EFFECT MODELS OF LARGE LANDSLIDES

Ewald P. BRUECKL (Vienna University of Technology, Gusshausstrasse 27-29, A-1040 Vienna, Austria, email: ebrueckl@ luna.tuwien.ac.at)

Within the scope of IDNDR cause-effect models of large landslides are being developed to estimate potential danger. This work is based on structural exploration of the landslides mainly by seismic methods. Information about the status of deformation is got by comparison of the actual topography with a reconstruction of the original topography, GPS and SAR interferometry. Geological and geomorphological evidence, as well as relevant information from other geoscientific disciplines, is included. The Finite Element method is used to model the initial phase of a mass movement. Later on this modelling will be extended to the quasi-stationary creep phase and the transition from creeping to rapid sliding.
Three large landslides within the crystalline rocks of the Eastern Alps have been investigated since 1997. The largest one is the Koefels landslide with a total volume of 3.9 km3 and a potential energy release of 5_1016 Joule. Refraction and reflection multi-component seismic techniques were applied successfully to resolve structure and elastic parameters of the landslide masses. For the modelling of the initial phase of the landslides by the Finite Element method a strain softening behaviour of the rock mass has been assumed. The development of softened or fractured zones according to the structures obtained by the seismic measurement was simulated.

PSEUDOSCIENCE U.N. DOCUMENT: GEOMAGNETIC FORECASTING OF EARTHQUAKES AND METEOROLOGICAL DISASTERS

Wallace H. CAMPBELL (World Data Center A for Solar-Terrestrial Physics, NGDC / NOAA, 325 Broadway, Boulder, CO 80303-3328, USA, e-mail: whc@ngdc.noaa.gov)

The United Nations recently published a "Manual on the Forecasting of Natural Disasters: Geomagnetic Methods" (1998) by Chinese and U.N. authors that stretches the imagination with prediction of earthquakes and Meteorological disasters. A careful reading of this document reveals an illusionary approach to the subject with no valid supporting evidence of prediction capability. The "mathematical" section simply copied well-known formulae that provided no scientific details of any physics connecting changes in geomagnetic recordings and subsequent localized disastrous earthquakes or meteorological events. The presented data indicated that 82.3 % of the recorded earthquakes did not correspond well to predictions. The authors ignored the recommendations and testing suggestions of a 1996 international London meeting, Assessment of Schemes for Earthquake Prediction. The manual provides clear and reliable evidence of the improper use of public funds for building hopes of disaster relief with projects totally lacking in scientific merit.

JSP23/W/26-A5 1150

25 SECONDS FOR BUCHAREST

Friedemann WENZEL, Mihnea C. Oncescu, Michael Baur and Frank Fiedrich (University of Karlsruhe, 76128 Karlsruhe, Germany, email: fwenzel@gpiwap1.physik.uni-karlsruhe.de); Constantin Ionescu (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: viorel@infp.ifa.ro)

The Romanian capital Bucharest faces a significant earthquake hazard with a 50% chance for an event in excess of 7.6 moment magnitude every 50 years. Within the last 60 years Romania experienced 4 strong Vrancea earthquakes: Nov. 10, 1940 (Mw = 7.7, 160 km deep); March 4, 1977 (Mw = 7.5, 100 km deep); Aug. 30, 1986 (Mw = 7.2, 140 km deep); May 30, 1990 (Mw = 6.9, 80 km deep). The 1977 event had catastrophic character with 35 high-rise buildings collapsed and 1500 causalities, the majority of them in Bucharest. A group of civil engineers and seismologists from the National Institute of Earth Physics (NIEP) in Romania and Karlsruhe University in Germany propose an Early Warning System (EWS) for the capital city of Bucharest. The group studied the seismological boundary conditions of an EWS for the Romanian capital of Bucharest. The earthquakes threatening the capital are intermediate deep events with magnitudes close to Mw = 8.0 at an almost fixed epicentral distance of about 150 km. The travel-time difference between the destructive S-wave arriving in Bucharest and the epicentral P-wave is always greater than 25 s, which represents the maximum possible warning time. Moreover source mechanisms are extremely stable for larger and smaller events so that a projection of the level of ground motion to be expected in Bucharest can be based on the amplitude of the epicentral P-wave rather than on cumbersome determination of magnitude and depth. This feature allows the design of a simple, robust and fast EWS. With 25 s, a system with the largest warning time after the Seismic Alarm System for Mexico City could be established. Even this small time window can provide opportunities to automatically trigger measures such as, shutdown computers; re-route electrical power; shutdown airport operations; shutdown manufacturing and high-energy facilities; stop trains; shutdown gas distribution; alert hospital operating rooms; open fire station doors; start emergency generators; stop elevators in a safe position; issue audio alarms; maintain safe-state in nuclear facilities. The value of an EWS can be judged on the basis of an application specific costs-benefit analysis, but simple considerations suggest that it will be cost-efficient.

JSP23/E/31-A5 1210

GLOBAL VOLCANIC SIMULATOR: ERUPTION FORECASTING AND URBAN PLANNING OFDENSELY POPULATED AREAS

Flavio DOBRAN (Global Volcanic and Environmental Systems Simulation, 32-50, 34 Street, Long Island City, New York 11106, Email: dobran@idt.net)

A Global Volcanic Simulator consists of physico-mathematical models of the volcano that are effectively implemented for solution on distributed or parallel computers. Such a simulator can be used to forecast future eruptions and for studying their effects on people and infrastructures for the purpose of mitigating eruption consequences. Current simulator for Vesuvius models magma reservoir volume, temperature, and pressure changes, variable rates of magma supply into the chamber, and varying elastic, plastic, and heat transfer characteristics of magma reservoir surroundings. Different types of magma ascent models allow for time-varying and non-isothermal simulations, including magma flow regime changes and melting of conduit walls. These models have been used to forecast that a plinian or subplinian eruption of Vesuvius will occur within the next 100 years and that the pyroclastic flows from column collapses can destroy the surrounding territory in several minutes. The simulator is also being employed to study the effects of different eruption scenarios on the territory and how this territory can be protected by engineering intervention measures. Computer simulations of possible eruptions of Vesuvius are also being utilised to sensitise the population of the area.
A useful simulator requires reliable geological and geophysical data of the volcano's internal structure, whereas the verification and validation of complex physical models on computers presents both computational and physical modeling challenges that are described in: Dobran, F., Theory of Structured Multiphase Mixtures, Springer Verlag, New York, 1991; Dobran F., Global Volcanic Simulation of Vesuvius, Giardini, Pisa, 1993; Dobran, F., Etna: Magma and Lava Flow Modeling and Volcanic System Definition Aimed at Hazard Assessment, Topografia Massaroa Offset, 1995.

JSP23/E/20-A5 1400

EXTRATROPICAL EVOLUTION OF TROPICAL CYCLONES AS AN UNEXPLORED HAZARD IN MIDDLE AND HIGHER LATITUDES

Jenni L. EVANS (Department of Meteorology The Pennsylvania State University University Park PA 16802, USA.)

A recent climatology of extreme rainfall incidence in the northeast United States (including New England) reveals that the passage of a tropical cyclone is the cause of major rainfall events every 2-3 years over most of this region. Locations such as Boston and Cape Cod are particularly susceptible, with individual events resulting in twice their monthly rainfall due to a single tropical cyclone passage every 5-6 years. At the time that these tropical cyclones are delivering such copious rainfalls, they are typically undergoing complex structural changes that are poorly understood.

The lifecycle of the tropical cyclone through to a hybrid or truly extratropical cyclone and the associated rainfall evolution will be elucidated here and a theoretical underpinning provided.

JSP23/C/U5/E/14-A5 1420

NATURAL DISASTERS: A POSTGRADUATE PROGRAM AT UNIVERSITY OF KARLSRUHE

Jens MEHLHORN, Frank Fiedrich and Fritz Gehbauer (Institute for Construction Equipment and Construction Management, University of Karlsruhe, Am Fasanengarten, 76126 Karlsruhe, Germany, email: mehlhorn@imbdec1.bau-verm.uni-karlsruhe.de)

According to the United Nations the annual financial loss as a result of natural disasters increased from 50 billion to 360 billion US-dollar during the last 35 years. This fact presents a tremendous challenge to politics, society, and the scientific community. Disaster related research has to be increased. On the basis of fundamental research new knowledge will be created and used to develop practical tools for hazard and risk assessment. More effective measures for reducing this risk can be taken and the performance of emergency response can be improved. These steps towards a better understanding of disaster causes and effects and improved disaster management have been demanded since the UN-decade IDNDR (International Decade for Natural Disaster Reduction) started in 1991. The Postgraduate Program Natural Disasters has to be seen in this context. A total of 15 institutes of different fields work together in this project involving five departments of the university.
The research projects include topics like Modelling of Hazard and Risk, Development of Disaster Scenarios, Mitigation Aspects and Economic Consequences of Natural Disasters. During the first period the activities concentrate on floods, earthquakes, strong rainfalls and land-slides. Natural sciences like physics, hydrology, meteorology and geosciences give a contribution to the basic understanding of the disaster process. Mathematics and computer sciences are used for complex models, for modelling fuzzy and imprecise information and for forecasts. With the help of economics the risk can be quantified and evaluated. In addition the institutes dealing with engineering aspects develop measures and tools for risk mitigation.

JSP23/C/U5/W/13-A5 1440

WORLD MAP OF NATURAL HAZARDS – A DEPICTION OF THE GLOBAL DISTRIBUTION OF SIGNIFICANT HAZARDS AND THEIR INTENSITY

G. Berz, S. Ehrlicher, T. Loster, E. Rauch, A. Siebert, J. Schimetschek, J. SCHMIEDER, A. Smolka and A. Wirtz (Munich Re, Geoscience Research Group, D-80791 Munich, Germany, Tel. 0049-89-3891-5291, Fax: 0049-89-3891-5696, E-mail: info@munichre.com)

For over 25 years now Munich Re's Geoscience Research Group has been looking at natural hazards throughout the world. Twenty years ago it summarised the overall results of its work in the first edition of the World Map of Natural Hazards. The map represents a unique source of information for numerous insurance companies, engineering offices, planning authorities, geoscientists, schools and interested lay people world-wide. For the recently released third edition all the basic data was for the first time captured and analysed using Munich Re's geographical information system (GIS). The resulting maps were created using digital cartography. Four auxiliary maps have supplemented the new edition. The earthquake and windstorm zones contained in the previous editions have been updated, refined and augmented. There are also details of other significant natural hazards like severe rainfall, storm surges, hail and lightning. A particularly interesting innovation is the auxiliary map on climate change. It deals on the one hand with the effects of El Niño, which generated so much interest and concern internationally in 1997/98 and was responsible for numerous natural catastrophes. Even more important are the effects that are to be expected from the emerging phenomenon of global warming, which will be accompanied by more frequent and more dramatic natural catastrophes in many parts of the world and will lead to a distinct long-term deterioration in the risk situation. The accompanying publication provides a detailed catalogue of historic natural catastrophes that have occurred in countries all over the world, grouped by continent and listed chronologically with additional information on the number of deaths and the economic losses.

JSP23/C/U5/W/11-A5 1500

ASSESSMENT OF HYDROLOGICAL HAZARDS OF VOLCANIC ALLUVIAL FANS

Kazuo OKUNISHI (Disaster Prevention Research Institute, Kyoto University); Gokanosho Uji, (611-0011 Japan, Email: okunishi@slope.dpri.kyoto-u.ac.jp); Hiroshi Suwa (Disaster Prevention Research Institute, Kyoto University, Gokanosho Uji, 611-0011 Japan, Email: suwa@slope.dpri.kyoto-u.ac.jp)

Alluvial fans on the foot of volcanoes have high hazard potential because of frequent inundation of debris flows and floods accompanying marked topographic changes. However, the social needs for the development of such lands are ever increasing, because of their high demand for recreational and touring sites. Assessment of hazard potential and regulation of land use are thus urgent problems. We propose fundamental principles for the assessment of hazard potential on the basis of a case study carried out at the Kikkakezawa Fan on the southern foot of Mt. Yatsugatake, central Japan. Existing villages are located below a major spring zone in the alluvial fan, which is fed by the groundwater in the volcanic body. Construction of a new road stimulated land developments along it and further upstream. It has been found that the debris-flow deposits had covered the fan in three geologically distinct ages. The ages of the deposits of new-age and middle-age debris flows are estimated on the basis of aerial photographs and a field investigation to assess their recurrence interval. The three kinds of debris flows are characterized by relative height from the current stream bed and by the area of deposition. Since the hazard assessment is needed for any part of the fan for any time span of the planned land use, it is advisable to define and assess the hazard potential of a fan from which the risk is calculated taking account of the location in the fan, and the time-span and the mode of the planned land use.

JSP23/E/54-A5 1520

THE ADVANTAGES OF HOLONIC DESIGN FOR WARNING AND ALARM SYSTEMS

Gary GIBSON (Seismology Research Centre, 2 Park Drive, Bundoora, Victoria 3083, Australia, email: gary@seis.com.au)

Warning and alarm systems are near real-time monitoring systems. They may be adversely affected by the events they are seeking to detect, such as a communication failure caused by an earthquake. Holonic systems were developed in manufacturing engineering, and require that each system element involves both task performing and decision making. A holon is an intelligent system element, either human or computer based, that is normally in communication with other holons. A holon is AUTONOMOUS (it can perform tasks alone if communications fail) and COOPERATIVE (overall results are enhanced when holons help each other, and it monitors the health of neighbouring holons, providing an immediate alarm if a failure is detected, and may attempt to compensate for any loss of function).
Holonic systems are designed so that no elements or communication links are critical. It must

be accepted that any particular component will fail, and the system must be designed to cope with this. The Internet is a system designed to continue in operation after individual components have failed. An holonic system is one, which self-organises and evolves to dynamically optimise survivability, adaptability, flexibility, efficiency and effectiveness.
Earthquake and tsunami warning and alarm systems are ideally suited to holonic design. They use "Event Oriented Seismology", requiring minimal data flow. Each seismograph may be event triggered, may record continuously and only transmit selected waveform segments on request, and/or may transmit minimal continuous data to facilitate event detection. They respond to requests or issue messages to other holons in the system. Communication can vary from the Internet, to slow digital radio links, or even dial-up telephone. A system is holonic if each element sends and receives information to and from other elements, but continues to function autonomously when communications fail. Any system failure should be immediately reported by one or more system elements. Holonic systems may be very economical because they only perform the tasks that are required. Compared with continuously tele-metered data from non-holonic digitisers, there is a dramatic reduction in total data flow, and usually in operating cost, with enhanced reliability and flexibility.

URBAN LOCAL EARTHQUAKE DISASTER RISK INDEX

Yang TING (Geophysics Institute, China Seismological Bureau. Now at Shanghai SeismologicalBureau, No.87, LanxiRd. Shanghai,China, 200062, Email: tyang@263.net); Zhu Yuanqing (ShanghaiSeismological Bureau,No.87,Lanxi Rd.Shanghai,China,200062)

In many modern cities, especially megacities with low seismicity, there exist a lot of hidden disadvantages, except for the frequency of historical earthquake and ground shaking level, that may amplify the influence of earthquakes and cause a catastrophe to them. The Urban Local Earthquake Disaster Risk Index (ULEDRI), which is firstly presented by authors, will highlight those disadvantages with an easily understandable form for city decision-makers, planners, organizations and individuals. ULEDRI is a variation of EDRI, which is a new approach that can directly compare the relative overall earthquake disaster of megacities worldwide, and describe the relative contributions of various factors to that overall risk. Unlike EDRI, whose study unit is the greater metropolitan area, ULEDRI uses the local area of an urban, e.g. administrative district, postal area, as its unit of study. Whats more, depended on the demand of users, ULEDRIs study unit can be a larger one (e.g. every administrative district of city), or a smaller one (e.g. several blocks). As a result of this difference between EDRI and ULEDRI, the objectives, uses and developing approach of ULEDRI will differ distinctly from those of EDRI. ULEDRI involves a large amount of knowledge about earthquake disaster of a wide range of disciplines, and the factors that contribute to overall ULEDRI of a city include those of geophysics, geology, engineering, residents, socio-economics, culture and so on. ULEDRI has the following potential uses. First, this kind of index can serve as a simple tool to directly compare the relative overall earthquake disaster risk of different local area of a city, so the decision-makers and administrators can find where the most dangerous local area is when an earthquake affects the city. Second, through disaggregated ULEDRI, the users can find the reason why a local region has a high overall ULEDRI, and which factor is the most important one that causes this. For city planner and disaster manager, the information will be significant in urban function planning and disaster mitigation. Third, any organization and individual will be able to refer to the index in allocating resources and increasing awareness of disaster. As a sample, ULEDRI of Shanghai, which is based on several districts, has been constructed, and its feasibility and potential application have also assessed.

THE GSHAP WORLD MAP OF SEISMIC HAZARD

D. GIARDINI (ETH, 8093 Zurich, Switzerland, email: giardini@seismo.ifg.ethz.ch); G. Grunthal (GFZ, Potsdam, Germany); H. Gupta (NGRI, Hyderabad, India); D. Mayer-Rosa and S. Sellami (ETH, Zurich,Switzerland); K. Shedlock (USGS, Boulder, USA); P. Zhang (SSB, Beijing, China); T. Annaka (Tokyo Electric Power Sevices, Japan); M. G.-Ashtiany (IIEES, Tehran, Iran); K. Atakan (Bergen University, Norway); S. Balassanian (NSSP, Yerevan, Armenia); P. Basham (CTBTO, Vienna, Austria); C. Dimate (Ingeominas, Bogota, Colombia);; M. Erdik (Kandilli Obs., Istanbul, Turkey); M. Garcia (CSIC, Barcelona, Spain); Giesecke (CERESIS, Lima, Peru); K. McCue (AGSO, Canberra, Australia); R. McGuire (Risk Engineering, Boulder, USA); R. Musson (BGS, Edimburgh, UK); S. Riad (Assiut University, Cairo,Egypt); D. Slejko (OGS, Trieste, Italy); V. Ulomov (JIPE, Moscow, Russia)

The Working Groups of the GSHAP regions: Central-North America, Central-Northern Europe, Eastern Asia, Northern Eurasia, Ibero- Maghreb, Adria, the working Groups of the projects: PILOTO, CAUCAS, RELEMR, SESAME, PAIGH-IDRC, EU-QSEZ-CIRPAN.
The Global Seismic Hazard Assessment Program (GSHAP) was launched in 1992 by ILP and ICSU and endorsed as a demonstration program by the UN/IDNDR. The GSHAP promoted a regionally co-ordinated, homogeneous approach to seismic hazard evaluation. Regional activities were concluded in 1992-98; the results have now been compiled in a uniform set of databases and in a world map of seismic hazard expressed in PGA. Support for the GSHAP implementation was provided by ING, Roma, by national and regional institutions, by IASPEI, UNESCO, ICSU, ILP, IDNDR, EU, NATO, INTAS and IGCP. All GSHAP materials (regional report, maps, datasets) can be retrieved on the GSHAP web site at http://seismo.ethz.ch/GSHAP/. The GSHAP world map of seismic hazard will be presented for the first time at the IUGG assembly and will be available for distribution at the assembly.

JSP23/E/33-A5 1640

RISK ASSESSMENT AND MANAGEMENT IN RUSSIA

Shakhramanjyan M.A.(1), Nigmetov G.M.(1), Larionov V.I (1), FROLOVA N.I.(2), Suchzhev S.P.(3), Ugarov A.N.(3) Agency on Monitoring and Forecast of Emergency Situations, Ministry of Emergency Situation of Russian Federation (2)Seismological Center of IGE, Russian Academy of Sciences (3) Extreme Situations Research Center

At present in Russia the new technologies and procedures of natural and technological disasters monitoring and forecast of their consequences are elaborated and implemented. they are the following: procedure for individual seismic risk and losses assessment and identification of effective response scenarios; technology of operative zonation of the territories according to the rate of forest fires and flooding hazards; procedure of complex risk assessment and mapping with taking into account different natural and technological hazards; technology od estimation of buildings and structures' stability and earthquake resistance with the help of mobile diagnostic complexes; technology of operative monitoring of the territories with the use of remote sensing. All the technologies and procedures are realised on the basis of modern geographical information systems (GIS). The main blocks of the special GIS is described. The examples of individual seismic risk computations for different earthquake prone areas and cities of the Russian Federation, as well as for other countries are given. The influence of secondary engineering geological processes (landslides and liquefaction) is considered. The procedure of acceptable seismic risk level estimation is proposed. The examples of complex risk estimations are also given for the areas where different natural hazards (earthquakes, volcanic hazard, tsunami, flooding, hurricanes and storms, avalanches, forest fires) are possible. The preventive measures plans and measures for reduction the risks from separate hazards are proposed. The maps of operative zonation of the territories according to the rate of forest fires and flooding hazards are presented for some regions of Russia and other countries. The application of the obtained results to disaster management practice may increase significantly the efficiency of measures aimed at risk reduction for population in urban areas.

JSP23/E/39-A5 1700

EARTHQUAKE RISK ASSESSMENTS AND PRACTICAL APPLICATIONS FOR EARTHQUAKE MITIGATION STRATEGIES IN AUSTRALIA

Jack RYNN (Centre for Earthquake Research in Australia, PO Box 276, Indooroopilly, Brisbane, Queensland 4068, Australia, email: sally.brown@uq.net.au)

In response to the United Nations IDNDR program, the Australian IDNDR Co-ordination Committee of Emergency Management Australia facilitated the earthquake zonation mapping of urban areas in Australia as one of its initial projects. The catalyst for this was the devastating 28 December 1989 Newcastle earthquake. A specific methodology was developed which has been expanded to address the national requirements for earthquake mitigation strategies. This involves a multidisciplinary approach integrating, both quantitatively and qualitatively, earth science, engineering, socio-economic, humanitarian, disaster planning, emergency management and community aspects. The results are compiled as an "information resource" in terms of hazard and vulnerability assessments and the integrated risk assessments, earthquake scenarios, potential ground motions and possible damage situations relative to the built and natural environments and the community. the outcomes are translated into practical applications to address awareness and preparedness for earthquake codes,

JSP23/W/11-A5 1720

HYDRODYNAMIC SIMULATION EXTREME STORM SURGES IN AZOV AND CASPIAN SEAS

Olga TIKHONOVA, Sergei Popov, Guennady Safronov, Oleg Zilberstein (State Oceanographic Institute, Kropotkinski per. 6, 119838, Moscow, Russia, email: oleg@soins.msk.ru)

Problems of storm surges description and prediction are very important because surges often lead to loss of human life and bring substantial damages to national economies. Thus for prevention their fatal consequences it is necessary to forecast storm surges according to available operative meteorological information and to calculate the storm surges characteristics. Besides of that, each extreme storm surge case is very important for determination of long return period characteristics of sea level and currents for hydrodynamic support hydro-technical engineering and marine shelf oil and gas exploration. Design and installation of stationary shelf oil platforms require information about vertical structure of currents. These characteristics are obtained by the 3D hydrodynamic model simulation. In this paper a non-linear 2D and 3D hydrodynamic models were applied for calculation of some extreme storm surges in Azov and Caspian Seas (including the catastrophic cases). The regime of sea level variations was investigated.
GIS mapping, education and training, loss reduction, disaster planning and emergency management. Such projects have been undertaken in the urban areas of Sydney, Southeast Queensland, Newcastle and Melbourne. Particular effort is directed towards real-time simulated earthquake exercises in co-operation with emergency services authorities. Collaboration with several international organisations and other risk projects in Australia is continuing. Although Australia is a moderate seismicity active interplate regime, the record of albeit "rare" earthquake disasters pointedly attests to the need for mitigation strategies.

JSP23/E/40-A5 1740

TOWARDS REAL-TIME MONITORING OF LAVA EFFUSION RATES DURING VOLCANIC ERUPTIONS

Andrew HARRIS and Luke Flynn (HIGP/SOEST, University of Hawaii, 2525 Correa Road, Honolulu, HI 96822, USA, email: harris@kahana.pgd.hawaii.edu)

Determining volumetric effusion rates for lava flows is an important but challenging task. Effusion rates are a major consideration in considering the potential threat posed by a lava flow. For channel-fed flows, higher effusion rates produce flows that are longer, more rapidly moving, voluminous, and aerially extensive than those with low effusion rates. High effusion rate flows thus have greater potential to inflict damage on distant communities with less advance warning. To calculate effusion rates we use satellite-derived (TM and AVHRR) thermal data in a heat balance. High spatial resolution TM data are collected infrequently, but allow high precision. Using TM data for active flows at Kilauea, Hawaii, we obtain effusion rates of 1.76±0.57 and 0.78±0.27 cubic meters per second on 23 July and 11 October 1991, respectively. These rates compare with field measurements of 1.36±0.14 and 0.89±0.09. Using lower spatial resolution weather satellite (AVHRR) data collected at higher spatial resolution (>1 image per day), we obtain similar but more poorly constrained effusion rates. However, comparison with ground-based and TM data for eruptions at Kilauea, Krafla and Etna show that the AVHRR-derived time series reliably show waxing and waning phases of effusive eruptions with high temporal precision.
All of our systems are automated, and with direction reception of TM and AVHRR at the University of Hawaii we anticipate providing a web-based real-time lava flow monitoring tool. This will display current effusion rate time series, up-dated within minutes of satellite overpass at-least once every 6 hours for AVHRR, once every 8 days for TM. This system will be similar to our GOES-based real-time hot spot monitoring site at http://volcano1.pgd.hawaii.edu.

SEISMIC RISK MAPS AND SCENARIOS: TOOLS FOR THE PROTECTION AGAINST EARTHQUAKES

JSP23/W/17-A6 0830

THE LONG AND WIDING ROAD FROM EARTHQUAKES TO DAMAGE

A. Ansal (Istanbul Technical University, Faculty of Civil Engineering, Maslak, Istanbul 80620, Turkey, tel: (90)-212-285 3702, fax: (90)-212-2856006, e-mail: ansal@itu.edu.tr); D. SLEJKO (Osservatorio Geofisico Sperimentale, P.O.Box 2011, 34016 Trieste, Italy, tel: (39)-40-2140248, fax: (39)-40-327307, e-mail: dslejko@ogs.trieste.it)

The impact of destructive earthquakes has two faces: one in the short term and the other in the long term. The first is given by the number of victims, damaged structures and direct economic losses. The second is given by the negative influence on the social structure in the

following years. Although the direct economic loses can be absorbed by the country, especially with international support, in most cases the social structure suffers permanent damages. The recent earthquakes of Northridge and Kobe have shown the long term problems caused respectively to the insurance companies and private habitants. This is one of the reasons why in seismically active countries (e. g.: Italy), a general private insurance against natural calamities is now being implemented. The knowledge on seismic risk is, therefore, fundamental for loss reduction. Seismic hazard maps at national level are the basic tool for defining the national seismic zonation which is relevant for planning adequately new settlements and constructing properly new buildings. The choice of the hazard parameter to consider for zonation is critical when the description of the whole contents of the seismic excitation is desired. However, these maps are only valid at large scales and local effects are not taken into consideration. Seismic risk maps at national scale are strategic for planning the policy for retrofitting old buildings in the presence of limited investments: their definition in a quantitative manner remains mainly a research topic for the difficulty of quantifying properly the ingredients. Risk scenarios at regional to local scale are very popular in recent years as they have the potential to limit earthquake victims and structural damage when a dangerous event is presumed to take place. In fact, based on the information and analysis concerning earthquake resistance capacity of existing buildings and structures, strengthening and retrofitting programmes can be optimised. The good knowledge …

JSP23/E/34-A6 0850

DETERMINISTIC VS. PROBABILISTIC EARTHQUAKE HAZARDS AND RISKS

Robin K. MCGUIRE (Risk Engineering, Inc., 4155 Darley Ave, Suite A, Boulder, Colorado, 80403, USA, email: mcguire@riskeng.com)

Deterministic vs. probabilistic approaches to assessing earthquake hazards and risks have differences, advantages, and disadvantages that often preclude the use of one over the other. Factors that influence the choice include the decision to be made (i.e. the purpose of the hazard or risk assessment), the seismic environment (whether the location is in a high, moderate, or low seismic risk region), and the scope of the assessment (a single-site risk, a multi-site risk, or risk to a region).
Decisions coming from earthquake assessments include selection of design or retrofit criteria and levels, financial planning for earthquake losses, and planning for emergency response and long-term recovery. The more quantitative the decision to be made, the more appropriate is probabilistic hazard and risk assessment.
For high seismic regions (e.g. California or Japan) where the largest earthquakes occur every 100-300 years), a deterministic scenario for the largest event will allow details to be examined such as ground motion effects caused by rupture propagation. In low seismic regions, extreme deterministic scenarios will have probabilities of occurrence that are too low to be useful for most decision purposes.
Specific site analyses generally require a probabilistic approach. Multiple-site analyses (e.g. for a portfolio of exposed or insured properties, or a lifeline) often require a probabilistic analysis because of multiple variables and complexities of the system, and a deterministic check can be misleading. Regional assessments often benefit most from deterministic models.

JSP23/C/ST3/E/21-A6 0910

METHODOLOGICAL CONSIDERATIONS OF PROBABILISTIC SEISMIC HAZARD MAPPING

R.M.W. MUSSON (British Geological Survey, West Mains Road, Edinburgh, EH9 3LA, UK, Email: R.Musson@bgs.ac.uk)

The study of seismic hazard is perhaps the most practically oriented aspect of earthquake seismology. As such, it should not be treated in an idealised or academic manner, but with regard to the needs of the consumers of the final product. This has important consequences when it comes to the topic of probabilistic seismic hazard maps. Who are these for? Historically, early studies of probabilistic seismic hazard tended to be done for engineers for specific design requirements. Consequently, there has been a tendency to treat seismic hazard maps as a sort of pan-national study for engineers, who can identify the design requirements for any site by picking them from the map. A dissenting point of view argues that seismic hazard maps are by their very nature too generalised to be used in this way; that such maps provide a first indication of relative hazard and should not be a substitute for site studies. There are, therefore, a number of interesting and important methodological questions to be asked: what are the practical differences in undertaking a seismic hazard map from calculating hazard for a site? Should probabilistic seismic hazard maps have the same degree of conservatism as site studies? How can seismologists meet the needs of different audiences? An engineer may think in terms of ground acceleration, but this parameter probably means little to people in other professions who still need access to seismic hazard data, but in a form they can understand. These are questions that need to be addressed directly; one should not leave them to be answered by default.

JSP23/E/03-A6 0930

EARTHQUAKE SCENARIOS FOR SWITZERLAND

FAEH, D., Bay, F., Giardini, D., Kind, F., Mayer-Rosa, D., Sellami, S. (Swiss Seismological Service, ETH Zurich); Lang, K., Bachmann, H., Wenk.,T. (Institute of Structural Engineering, ETH Zurich); Noack, T., Huggenberger, P. (Institute of Geology, University of Basel)

The goal of our project is to develop a method for the estimation of expected damage from earthquakes. The presentation is giving an overview of the state of the project, which includes, the modelling and mapping of ground motion on a regional scale for the area of Switzerland, and on a local scale for the Basel area, the classification of the vulnerability of buildings to earthquake ground motion for some target areas, and the realization of scenarios. We will present the deterministic seismic hazard in form of scenario ground motion maps. This can be done on a regional scale or on a local (microzonation) scale. On the regional scale the scenario ground motion maps should include significant earthquakes in a regional sense. Maps will then display ground motion with different probabilities of occurrence in different locations. On a local scale, ground motion scenario maps are most appropriately computed for single possible earthquakes, and these maps can be combined with a vulnerability assessment of existing structures. In this combination the scenario maps include the level and duration of shaking. Furthermore they make it possible to identify localities where ground is likely to fail through liquefaction or landslides, and they enable us to pinpoint structures that are likely to be severely damaged and to find weak links in life-line structures. Such studies can be done with different levels of detail. The project will contribute to the necessary seismic upgrading of existing buildings, as well as to reliable earthquake resistant design of new structures, to the education of the general public, the emergency planning and it will serve as a reminder that there is a large difference between what is expected from probabilistic maps and what is a possible event.

JSP23/E/08-A6 0950

REGIONAL AND LOCAL SEISMIC HAZARD ASSESSMENT

A. MARCELLINI, R. Daminelli, G. Franceschina e M.Pagani (Istituto di Ricerca sul Rischio Sismico, CNR, via Bassini 15, 20133 Milano, Italy, e-mail: marcel@irrs.mi.cnr.it)

Site effects can produce, at a local scale, abrupt changes of the ground motion as also instability phenomena such as landslides and soil liquefaction; microzonation studies are the scientific response for the evaluation and mitigation of this kind of phenomena. Seismic microzonation generally produces on a municipal scale Landuse planning criteria and defines seismic actions for engineering purposes. Seismic codes instead, are issued on the basis of Seismic Hazard studies, that is, seismic actions and seismic zonation are a direct consequence of a probabilistic seismic hazard, generally assessed considering a 474 yr R.P. In other words seismic actions assessment is biased by the inefficiency of seismic hazard evaluation procedure to account properly of parameters controlling the ground motion, mainly due to the limited number of factors used in the attenuation laws. It should be pointed out that till now this limits appears unavoidable due to the scarcity of strong motion accordings. Microzonation investigation can overcome these limitations, but only if the reference input motion is properly assessed by adopting the same level and the same criteria of protection used to issue seismic codes at national level. The case study here presented refers to a zonation and microzonation investigation performed in the Forlì provincia (Emilia-Romagna) for the purposes of seismic prescriptions to be issued both at regional and local level and we will main focus on the importance of multiple approach for the definition of the reference input motion.

JSP23/C/U5/W/06-A6 1010

NEAR-FIELD GROUND MOTIONS

N. AMBRASEYS (Imperial College, London)

The assessment of earthquake hazard of interest to the engineer must be based on the analysis of reliable observational data than on statistics of many records and seismological parameters of questionable quality. Theoretical methods for the prediction of ground motions have become highly developed, whilst knowledge of the observational material is usually lacking. Differences between attenuation laws arise from the size and distribution of the sets of data used in their derivation and from the use of different magnitude scales, which introduce significant bias in the results. In addition, the correction of records and the modelling of attenuation laws and fitting method used to regress the data are sources of systematic errors. Taking some of these differences into consideration we find no significant variation of attenuation laws among different regions for shallow earthquakes, and a remarkable agreement between attenuation laws derived for Europe, western North America and New Zealand. They are all within the standard deviation of the determinations, which are not better than by a factor of 1.7 for accelerations. The importance of the vertical acceleration needs further investigation. However, the observation that the ratio of peak vertical zero-period or spectral value, to that of the horizontal, can be larger than 1.0 does not necessarily imply large vertical accelerations or spectral ordinates, most certainly when these maxima occur simultaneously. Also the assessment of peak and spectral ground displacements, which is of some engineering importance, needs further investigation. Near-field ground motions from medium and large magnitude earthquakes associated with surface faulting or, from sites on low-strength deposits, contain a significant component of permanent displacement, not accounted or in standard base-line correction procedures. An answer to these question is needed in order to rank these effects among other variables, and clarify the need to include or exclude them from building codes.

JSP23/W/18-A6 1050

ASSESSMENT OF STRONG EARTHQUAKE GROUND MOTIONS FOR NEAR-FAULT CONDITIONS

Mustafa ERDIK, Eser Durukal (Bogazici University, Kandilli Obs. And Earthq. Res. Inst. 81220 Cengelkoy, Istanbul, Turkey, email: erdik@boun.edu.tr, durukal@boun.edu.tr)

Near-fault ground motions are strongly influenced by the earthquake faulting mechanism. Especially, the motions with periods above 1s may follow certain radiation patterns, predicted by equivalent double-couple source models, and exhibit distinct long period pulses with amplitudes depending on the orientation of the site with respect to the rupture direction. Widely use predictive earthquake engineering tools, such as empirical attenuation relationships and spectral shapes fail in the assessment of such near fault motions. Deterministic theoretical predictions of the ground motion can be achieved by convolution of the Green's Functions and the slip function. Such deterministic predictions cannot be extended into the frequency regions above 1Hz, since, high frequency ground motions are controlled by the heterogeneities in the fault rupture, which cannot be accounted for in a deterministic manner. This requires either the use of stochastic source models or the stochastic treatment of the high frequency components in the ground motions.
Based on these developments a state-of-the art hybrid procedure is developed for the assessment of the time history of the DBE (or SEE) ground motion for important engineering structures near major faults. The essential elements of the procedure can be listed as follows: (1) Assessment of the source parameters of the DBE motion associated with the corresponding return period for specific conditions of site and seismicity; (2) Deterministic assessment of the low frequency (DC-1Hz) ground motion, at the outcrop of a reference soil layer, due to rupture of seismic faults using numerical simulation; (3) Use of a Boore (1983) type stochastic simulation method to complement the deterministic low frequency ground motion with high frequency (1Hz- 50Hz) components; (4) Combination of the two parts of ground motion to yield a site-specific simulation for a frequency range of DC-50 Hz.; and (5) Site response analysis, if required, to include the local wave propagation effects in the soil media above the reference soil layer.
An example that illustrates the application of this procedure is provided.

JSP23/E/01-A6 1110

MODIFICATIONS TO SEISMIC HAZARD DUE TO SITE-CITY INTERACTION

Pierre-Yves BARD, Philippe Gueguen (Laboratoire Central des Ponts- et-Chaussies and Observatoire de Grenoble, BP 53 - 38041 Grenoble Cedex - France,
email: Pierre-Yves.Bard@lgit.obs.ujf- grenoble.fr); Jean-Frangois Semblat (LCPC, 58 Bd Lefebvre, 75732 Paris Cedex 15 - France); Martin Cardenas and Francisco Chavez- Garcia (Coordinacion de Ingenieria Sismologica, Instituto de Ingenieria, UNAM, Ciudad Universitaria, Apdo. Postal 70-472, Coyoacan, 04510 Mixico, D.F)

Soil-structure interaction has long been known to significantly affect the seismic behavior of large buildings on soft soils. A few observations, and several computations as well, recently indicated the possibility for significant feed-back effects from buildings into the soil: the waves radiated back into the soil from the soil-struture interface are trapped in the surface layers when the impedance contrast at depth is large enough, so that the building is acting as a

secondary source of surface waves. This phenomena has been shown to be maximum in case of coincidence between the building and ground natural frequencies: the worst case corresponds to the matching of fundamental frequencies, and induces ground motion modifications of at least 30 % in time- domain amplitudes within distances up to 5 to 10 times the building base dimensions. The question then arises of the possibility of large-scale site-city interaction due to the quasi- random superposition of such phenomena for a large number of buildings in a given city, or in a given quarter, which, in turn, raises two issues: Is the "free-field record" concept relevant in such areas? And will the construction or destruction of some buildings modify locally the hazard? The aim of the presentation is not to answer these questions, but simply to briefly review the reasons why these issues have to be addressed, and to present some preliminary, first order computations exhibiting significant effects not only for "exceptional" configurations such as Mexico City, but also for much more common situations with "ordinary" sediments and "ordinary" buildings.

JSP23/W/20-A6 1130

THE CYCLIC BEHAVIOUR OF SOILS AND EFFECTS OF GEOTECHNICAL FACTORS IN MICROZONATION

Atilla ANSAL (Istanbul Technical Uni, Civil Engng., Maslak, Istanbul, Turkey, email:ansal@itu.edu.tr)

The behaviour of soils subjected to cyclic loading is briefly reviewed. The results obtained from cyclic triaxial, simple shear and torsional hollow cylinder tests conducted on undisturbed, normally consolidated clay samples subjected to different shear stress amplitudes and different loading patterns are summarised. Results of the tests conducted under uniform cyclic stresses to evaluate "cyclic yield stress" and "threshold cyclic shear stress" are presented. The effects of cyclic loading on static shear strength and induced settlements due to pore water pressure dissipation are discussed. Cyclic tests performed to evaluate the liquefaction susceptibility of laboratory prepared and undisturbed sands and silty clayey sands are briefly reviewed in the light of the findings reported in the literature.
Geotechnical site conditions is one of the main factors controlling earthquake forces affecting structures. Therefore, in analysing the observed damage in previous earthquakes and for microzonation studies, this factor and its coupled effect with earthquake source characteristics need to be evaluated. The earthquake source characteristics induced by a tectonic source mechanism are on macro level and are not sufficient to explain the variations in structural damage observed within short distances. On the contrary, the geotechnical site conditions that can be very different due to changes in the thickness and properties of soil layers, depth of bedrock and water table, can have more dominant influence on damage distribution. In addition the effect of coupling between site and source characteristics may modify earthquake ground motion characteristics significantly. There are large numbers of instrumental field observations obtained during recent earthquakes reflecting the coupled effects of geotechnical site and earthquake source characteristics. During earthquakes soil layers are subjected to multi-directional cyclic stresses with different amplitudes and frequencies that lead to cyclic deformations and to changes in stress-strain and strength properties of soil layers. Extensive laboratory, model and field studies were conducted concerning response of soils subjected to cyclic stresses. Significant improvements were achieved in the field of insitu tests to obtain more reliable soil properties. Numerous analytical and empirical relationships were developed to model the behaviour of soil deposits subjected to earthquake excitations. From an engineering perspective, it is possible to investigate the properties of geo-technical site conditions in detail and analyse the response of soil layers with sufficient accuracy.

JSP23/E/05-A6 1150

LOCAL SITE EFFECTS AND DYNAMIC SOIL BEHAVIOUR

Erdal SAFAK (U.S. Geological Survey, Box 25046, MS 966, Denver, CO 80225, USA,
email: safak@usgs.gov)

Amplitudes of seismic waves increase significantly as they pass through soft soil layers near the earth's surface. This phenomenon, commonly known as site amplification, is a major factor influencing the amount of damage on structures. It is crucial that site amplification is accounted for when designing structures on soft soil sites. The characteristics of site amplification, at a given site, can be estimated by analytical models, as well as field tests. Analytical models require as inputs the geometry of all soil layers from surface to bedrock, their dynamic properties (e.g., density, wave velocity, damping), and the incident bedrock motions. Field tests involve recording and analyzing the dynamic response of sites to artificial excitations, ambient forces, and actual earthquakes. The most reliable estimates of site amplification are obtained by analyzing the recorded motions of the site during earthquakes.
This paper presents a review of the models and methods that are used to characterise site amplification, and introduces some new ones with better theoretical foundations. The models and methods discussed include spectral and cross-spectral ratios, response spectral ratios, constant amplification factors, parametric models, physical models, time-varying filters, methods for downhole records, single-station methods, and generalised inversion techniques. The paper also examines the validity of one-dimensional models, in comparison to 2D and 3D models, and shows the effects of surface waves and surface-to-bedrock topography on site amplification estimates. The paper concludes that probabilistically cross-spectral ratios give more reliable estimates of site amplification than spectral ratios. Spectral ratios should not be used to determine site amplification from downhole-surface recording pairs because of the feedback in the downhole sensor. Response spectral ratios are appropriate for low frequencies, but overestimate the amplification at high frequencies. One-dimensional site amplification models are not appropriate for sites in deep sedimentary basins that are susceptible to generating surface waves. The surface topography…

THREE DIMENSIONAL PLATE KINEMATICS IN ROMANIA

Georg Dinter (Department of Geodesy, University of Karlsruhe, D-76128 Karlsruhe, Germany,
email: dinter@gik.uni-karlsruhe.de); Guenter SCHMITT (Department of Geodesy, University of Karlsruhe, D-76128 Karlsruhe, Germany, email: schmitt@gik.uni-karlsruhe.de)

Since 1996 the Collaborative Research Center (CRC)461 ``Strong Earthquakes: A Challenge for Geosciences and Civil Engineering'' is funded by the Deutsche Forschungsgemeinschaft (German Research Foundation) as a German Contribution to the UN initiative ``International Decade of Desaster Reduction'' (IDNDR). A central project of this CRC is the subproject B1 ``Three dimensional Platekinematics in Romania'' which is installed to detect borders of the geotectonic plates in Romania, to quantify their three dimensional movement rates and to determine in detail the deformation of each geotectonic unit in the Vrancea Region as a contribution to the research of the tectonic cause of the intermediate depth earthquakes in this region. These aims shall be accomplished by repeated GPS-measurements in a network which has been installed in 1997 and measured until now in 1997 and 1998. This network is consisting of 26 stations, covering an area of 250 x 380 km with the Vrancea area as the centre. The frame is given by six stations of the CEGRN (Central European Geodynamic Regional Network) of the CEI-Initiative CERGOP, for which co-ordinates and velocities in a global tectonic scenario are available. The paper gives information about the tectonic background, the geodetic network, the GPS-measurements and the achieved accuracy's and first results of deformation analyses.

EVALUATION OF VULNERABILITY OF CIVIL ENGINEERING STRUCTURES

Mauro DOLCE (Department of Structures, Soil Mechanics, Applied Geology, University of Basilicata, Potenza, Italy)

The impact of earthquakes on man-built systems (buildings, groups of buildings, lifelines, cities, etc.) is usually expressed in terms of losses. Loss assessment is a highly complicated task, involving, besides structural engineering and seismology, many disciplines such as geotechnical, transport, hydraulic and electrical engineering, geology, urban planning, social and economic sciences, etc. However most of the losses results from the consequences of direct damage to civil engineering constructions, particularly buildings. The evaluation of their seismic vulnerability is then a fundamental step in the process of determining the impact of earthquakes on man-built systems. This is usually assessed in terms of seismic risk in a period of time (e.g. one year, hundred years), i.e. in terms of probability or of expectation of losses during that period due to all the possible arriving earthquakes. This representation is very general but presents many drawbacks such as the difficulty of interpreting the results in practical terms and the difficulty of expressing and quantifying losses for territorial systems. In fact they are highly dynamical systems, whose future developments are difficult to forecast, particularly after the occurrence of an earthquake. A long term loss prediction is therefore not much significant, if it is referred to the current situation or even to the current trend.
Recently the interest of researchers and operators has been focused on risk scenarios, where the impact of a given earthquake is investigated and quantified. This approach permits to better understand the behavior of the built environment under study and to take the countermeasures aimed at reducing its impact. Scenarios can be prepared considering different aspects of the earthquake consequences. Different levels of accuracy can be assumed in the preparation of a scenario, starting from the assessment of shaking intensity and characteristics, through damage prediction up to loss assessment. Obviously the accuracy levels in the different steps must be consistent.
The assessment of damage to constructions deserves a special attention. In this respect, two ...

FROM VULNERABILITY OF OBJECTS TO VULNERABILITY OF SYSTEMS

Carlo GAVARINI (Universita' La Sapienza, Roma, Italy)

First of all the paper outlines the current conceptions relevant to vulnerability of constructions, describing the various approaches and the different research levels, then, in the second part, a more global vision is developed in which the constructions belonging to an aggregate, or a centre, or a city, or a territorial area, are considered as a part of a vulnerable system, with all the complexity that it brings about, in terms of different variables that must be taken in consideration, properties and values that are in danger, disciplinary, cultural and historical aspects that must not be ignored.
Assessment of vulnerability is strictly connected with another basic problem, risk mitigation, that will be briefly considered in the third part, analysing the interrelations between vulnerability and environment aggressions. Also here we must point out how today it is a common exigency, also as regards technical codes, to abandon the sectional vision of objects considered separately and to promote instead the above mentioned 'picture in picture' vision applied to systems, better said to complex systems, specially when the areas in question are rich with particular 'objects' with a 'cultural value', such as historical buildings and monuments.
Lastly, in the fourth part, we return to deal with single objects, giving a short account of problems specific to monuments and in particular to churches subjected to seismic actions; referring to studies regarding the Cathedral of Noto, partially collapsed in 1996 and now in course of reconstruction.
The need for experiments, either real or virtual, is recognized as a key for understanding and classifying the…

LOSS ESTIMATION: A POWERFUL TOOL FOR RISK ASSESSMENT AND MANAGEMENT

Fouad BENDIMERAD (Risk Management Solutions, Inc., 149 Commonwealth Drive, Menlo Park, CA 94025, USA; email: fouadb@riskinc.com)

Earlier loss estimation studies were limited to investigating particular scenarios and were carried out by highly specialized experts. Today, loss estimation techniques are translated into efficient software applications that are accessible by a large constituency of end-users. These techniques offer a high level of analysis sophistication and enable users to perform various "if-then" scenarios to study the sensitivity of the results, to develop a better understanding of the outcomes and to gain insight on the consequences of the findings and decisions.
Loss estimation techniques have benefited from the advances in information technology. Modularity, encapsulation and a new generation of computer codes such as C++, provide a logical and flexible structure for organizing the analytical procedures involved in loss estimation. These techniques organize the multitude of analytical calculations into modules that are logically inter-related by hierarchical rules. This flexible architecture permits ease in development, testing, validation, maintenance and upgrade. The study region is divided into geographical units (Geo-Units) such as postal codes or census tracks. The data, calculations and results are then associated with the centroid of the Geo-Unit. The aggregated results from the Geo-Units yield the results for the study region. Geographical Information Systems (GIS) and Relational Database Management Systems (RDMS) are used to organize data in data warehouses, to manipulate data during analysis, and to associate results to geographical regions from which they can be queried, aggregated and/or mapped. GIS and RDMS also allow for easy display of input and output (in standard reports and maps) providing a critical functionality for communication of outcomes to end-users. Loss estimation has become a critical tool to the insurance industry and is quickly being adopted by a wide range of users including emergency managers and planners. The key to this expansion is the integration of new information technologies that gave these techniques greater analytical capabilities, flexible architecture, and user-friendliness.

GLOBAL SEISMIC HAZARD AND RISK ASSESSMENT

YONG CHEN, Qi-fu Chen, Ling Chen, Juan Li and Jie Liu (No. 63, Fuxing Avenue, China Seismological Bureau, Beijing 100036, P. R. China)

A global seismic hazard assessment was conducted using the probabilistic approach in conjunction with a modified means of evaluating the seismicity parameters. This method is applicable to both oceanic and continental regions, and for any specific duration of time. It can be used for those regions without detailed geological information or where the relation between existing faults and earthquake occurrence is not clear.
Most seismic risk studies use a probabilistic approach in which predicted damages in various categories of structure and facilities in the region in concern are estimated and added together to obtain a total loss for particular intensity ranges. We have used an alternative means of estimating earthquake losses based on several macroeconomic indices such as the gross domestic product (GDP) and population. A global seismic loss map is then compiled.
The expected losses(in USD) of selected countries and regions for the next 50 years are as follows:

World 949 (USD), Asia 563 (USD), European 184 (USD), N.America 115 (USD), S.America 60 (USD), Oceania 12 (USD), Japan 390 (USD), USA 66 (USD), China 17 (USD)

JSP23/W/16-A6 1520

SEISMIC HAZARD MAPPING FOR ADMINISTRATIVE PURPOSES

L. Peruzza (C.N.R. Gruppo Nazionale Difesa Terremoti, c/o OGS, Trieste, Italy); A. Rebez and D. SLEJKO (Osservatorio Geofisico Sperimentale, Trieste, Italy, tel: (39)-40-2140248, fax: (39)-40-327307, e-mail: dslejko@ogs.trieste.it)

Local site conditions strongly influence the seismic hazard assessment, even if done using standard probabilistic techniques, with average soil classification. GIS applications, nowadays, enhance these variations, without entering into a detailed microzonation study, that is not possible at wide, regional scale. On the other side, the administrative border of municipalities remains the basic units to face the problems of legislative measurements devoted to risk evaluation and reduction. The aim of this paper is to present maps of different hazard parameter devoted to better represent the free field shakebility in NE Italy. The dominant soil in each municipality has been classified, taking into account the location of buildings and structures: then soil dependent hazard estimates have been performed and mapped, according to the some of the criteria leading the new proposal of seismic classification in Italy.

JSP23/W/29-A6 1600

EARTHQUAKE HAZARD ASSESSMENTS FOR THE GULF OF CORINTH (CENTRAL GREECE) AND KRESNA REGION (SW BULGARIA)

Vladimír SCHENK, Zdeka Schenková and Pavel Kottnauer (all at Institute of Rock Structure and Mechanics, Academy of Sciences, CZ-182 09 Praha 8, The Czech Republic, email: schenk@ irsm.cas.cz)

The earthquake hazard calculations were realised for two seismically high-active European zones, for the area round the Gulf of Corinth (Central Greece) and for the Kresna region (SW Bulgaria). To make reliable earthquake hazard calculations all available data were collected. For the Gulf of Corinth data of the National Observatory of Athens compiled by Drakatos, Kalogeras and Papadopoulos and as well the published earthquake catalogues, geological and geophysical materials (Ambraseys & Jackson 1990, Ganas & White 1996, Hatzfeld et al. 1990, Makropoulos 1985, Papazachos 1988, Papazachos & Kiratzi 1993, 1996, Papazachos et al. 1991, 1996, Shebalin et al. 1974) were applied. Simultaneously, for the Kresna region similar available data of the Geophysical Institute, Bulgarian Academy of Sciences, were sent to us by Ranguelov and Shanov. All these data allowed seismogenic zones with respect to earthquake occurrence and main tectonic structures to be delineated, dependent events from independent ones to be identified, an earthquake regime per requested observation period and/or a size of the area to be normalised, a maximum possible earthquake to be assessed and an acceptable attenuation law to be applied. Every quantity was statistically tested in order to be possible to introduce the logical tree of the input parameters to the hazard calculations. A reliability of the earthquake hazard calculations in common practice will be discussed. The presented calculations were realised under the EC INCO-Copernicus ASPELEA Project No ERBIC 15CT97 0200.

EARTHQUAKE DISASTER MITIGATION AND EMERGENCY RESPONSESYSTEM (EDMERS) OF SHANGHAI BASED ON GIS

YANG TING (Geophysics Institute, China Seismological Bureau. Now at Shanghai Seismological Bureau, No.87, Lanxi Rd. Shanghai,China,200062, Email: tyang@263.net) Zhu Yuanqing and Song Jungao (Both at ShanghaiSeismological Bureau,No.87, Lanxi Rd.Shanghai,China,200062)

As the largest city of China, Shanghai is also under the earthquake threat. In order to understand how severe disaster Shanghai will be suffered and what should be done by government when a possible earthquake affects the city, the Earthquake Disaster Mitigation and Emergency Response System (EDMERS) has been developed based on Geographic Information System (GIS). The EDMERS mainly includes two subsystems and several databases. The first subsystem, rapid earthquake damages estimation subsystem, will provide the rapid estimation of all kinds of earthquake damages according to the real earthquake parameters, (the origin time, epicenter location and source depth) which determined by Shanghai Telemetry Seismic Network in minutes while a destructive earthquake occurs. The second subsystem is the emergency response, in which the following emergency responses should be completed in time after a shock: determining the rescue scheme, evacuating victims, coping with dangerous materials, making decisions against fire following earthquake. The databases of EDMERS include building information, lifelines, soil conditions, aerial photographs, historical earthquake catalogues and so on. The following features of EDMERS should be highlighted: first, making use of GIS can enable the system to process the spatial data in a reasonable way, for example, The overlay and buffer functions of GIS can deal with the comprehensive effect of damage of buildings and lifelines. The network analysis of ARC/INFO can be directly used in emergence response such as victim evacuation and pathfinding. Second, emergence response can carry out on the base of real damage conditions by integrating damage estimation subsystem and emergence response subsystem. Third, using remote sensing, namely aerial photograph as an auxiliary tool, make EDMERS visual, vivid and informative.

JSP23/E/15-A6 1640

FIELD SURVEY OF TSUNAMI DISASTER IN PAPUA NEW GUINEA ON 17 JULY 1998

Yoshiaki KAWATA (Research Center for Disaster Reduction Systems, DPRI, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, email: kawata@drs.dpri.kyoto-u.ac.jp)

On the evening of Friday 17 July at about 7:30 p.m. a breaking wave from a massive tsunami swept across the sand bar that forms the outer margin of Sissano Lagoon, west Sepik, PNG. Initial reports claimed that the wave was between 7 and10m and that up to 3,000 persons were killed or missing. This seemed to be an unusually damaging tsunami given the size of the earthquake. Members of the International Tsunami Survey Team decided that a field survey was necessary as soon as possible to try and determine the true value of the maximum run-up and to accurately map the run-up distribution along the coast. The first surveys to the Sissano region confirmed the 7 - 10m wave reports and even found place where the waves were larger - up to 15 m. The severe damage and extreme wave heights were confined to a relatively short (30 km) stretch of coast between Aitape and Sissano Village. The survey was conducted by a multi-national team with representatives from Japan, the United States, Australia, and New Zealand. The team was broken up into two groups, the Japanese and everyone else. By the numerical estimation, it is impossible to get such gigantic tsunamis with the earthquake magnitude of 7.0. We found many marks of liquefaction at the sand bar and many residents reported that they had three earthquakes and middle one was the most severe. Therefore, we concluded that the earthquakes were not slow earthquake. Numerical simulation models of submarine landslide show good agreement with tsunami heights and their longshore distribution.

PRECISE TOPOGRAPHIC AND GEOPHYSICAL SURVEYS OFF SISSANO LAGOON, NORTHERN PAPUA NEW GUINEA

TAKESHI MATSUMOTO(1), David Tappin(2) and R/V KAIREI KR98-13 Cruise Scientific Party 1) Japan Marine Science and Technology Center (JAMSTEC), 2-15, (BNatsushima- cho, Yokosuka 237-0061, Japan (2) British Geological Survey, Keyworth, Nottingham, UK

The northern coast of Papua New Guinea suffered from a M7.1 earthquake and aftershock events which occurred on July 17, 1998. A large-scale tsunami also occurred just after the earthquakes. KR98-13 Cruise by the Research Vessel KAIREI was carried out in January 1999 in order to locate the possible seismic faults and/or underwater landslides as the source of tsunami. Precise topographic and other geophysical mapping off Sissano Lagoon, in the area of 200km (E-W) and 120km (N-S), was completed after the 9 days' survey.
The study area is characterised by enormous amount of fan sediment supply from Sissano Lagoon, deep-sea canyons on the shelf, arc-shaped slump and offshore strike-slip faults. Straight small-scale submarine canyons and valleys are eroding the shelf slope. The meandering canyon is located on the old shelf to the north of Aitape. Topographic features caused by landslides are recognised at numerous sites of the study area. Most of them are old, and the most recent is located 25km north-east off the Sissano Lagoon. The most prominent of the many tectonic faults located in the study area is E-W trending escarpment, the length of which is about 40 kilometres, recognised 25 kilometres north of Sissano Lagoon.
The result of simplified numerical modelling of tsunami propagation by use of the new bathymetric data shows that the distribution of maximum wave height is in good agreement with the observation. This suggests that the bottom topographic feature is an important factor to amplify the wave and to generate the focused tsunami runup, and that both earthquake faulting and underwater landslide should be taken into account as possible origins of the tsunami.

SUPER DENSE REAL-TIME MONITORING OF EARTHQUAKES: SUPREME

Fumio YAMAZAKI (Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106-8558, Japan, email: yamazaki@iis.u-tokyo.ac.jp); Yoshihisa Shimizu, Wataru Nakayama and Ken-ichi Koganemaru (all at the Center for Supply Control and Disaster Management, Tokyo Gas Co., Ltd., 1-5-20 Kaigan, Minato-ku, Tokyo 105-8527, Japan, email: yshimizu@tokyo-gas.co.jp)

To cope with earthquake-related secondary disasters, city gas companies in Japan have promoted several countermeasures in the last two decades: increasing seismic resistance of facilities and pipelines, segmentation of gas networks into blocks, earthquake monitoring by seismometers, installation of intelligent gas meters with a seismic sensor etc. As one of such earthquake countermeasures, Tokyo Gas Company introduced an earthquake monitoring and rapid damage assessment system, SIGNAL, with 331 SI-sensors, which measure the peak ground acceleration (PGA) and spectrum intensity (SI) at district regulator stations. The strong motion indices and the results of damage estimation are used for the decision-making whether or not to shut off gas supply.
Recently Tokyo Gas further developed new SI-sensor, having several new functions with the much cheaper price. The new SI-sensor can store acceleration time histories in its IC memory and send monitored strong motion indices to the Supply Control Center through public telecommunication lines. The new sensors will be installed at all the 3,600 district regulator stations with in the next 8 years. The new SI-sensor network is named SUPREME (Super-Dense Real-time Monitoring of Earthquakes), which may be the most dense seismic monitoring network in the world. The data from the network will significantly contribute to the strong ground motion research as well as promote seismic safety of the greater Tokyo Metropolis.

POTENTIAL OF DISRUPTION OF HUMAN ACTIVITIES ON EARTH AND IN SPACE AS A CONSEQUENCE OF THE INTERACTION BETWEEN THE SOLAR CORONA AND EARTH'S MAGNETIC FIELD

Gordon ROSTOKER (Department of Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2J1, email: rostoker@space.ualberta.ca)

Over the past few decades, mankind has become increasingly dependent on various technologies which have helped greatly to improve the standard of living around the world. Two examples of such technologies that have had an enormous impact on human activities are global communications and the provision of readily available electric energy through the development of large transmission grids. Unfortunately, with the advent of new technologies comes human dependence on them. The use of satellites for communications and position finding purposes serves as a useful example of this dependence. It is now recognised that both geostationary communications satellites and the position-finding GPS satellites are vulnerable to the energetic electron environment in which they orbit. In this paper I shall outline the nature of this vulnerability and what the consequence of the loss of these satellites might be. As well, it is worth noting that large fluctuations in the geomagnetic field at auroral latitudes can induce electric currents in large power transmission grids sometimes causing them to be disabled for significant periods of time. I shall describe the nature of this problem and how space researchers are attempting to develop techniques to predict the potential for power outages. These practical manifestations will be presented in the context of the physical processes through which the solar corona interacts with the earth's magnetic field.

DESTRUCTIVE ATMOSPHERICALLY-GENERATED LONG WAVES: SEPARATION BETWEEN SOURCE AND TOPOGRAPHY

S. MONSERRAT (1), A.B. Rabinovich (2) and B. Casas (1). (1) Instituto Mediterráneo de Estudios Avanzados, IMEDEA, (CSIC-UIB), Palma de Mallorca, SPAIN, emiail: dfssmt4@ps.uib.es, (2) Tsunami Center, P.P. Shirshov Institute of Oceanology, Moscow, RUSSIA

Destructive long waves caused by atmospheric disturbances (meteotsunamis) present a significant threat for the Mediterranean coast, in particular, for the Iberian Peninsula and the Balearic Islands. Ciutadella Harbour, Menorca Island, is the place where extreme oscillations, locally known as 'rissaga waves', occur most frequently. The understanding of their origin and generation mechanism is a key scientific and applied problem. A method was first elaborated to suppress the influence of the initial source in order to isolate the general topographic function. The next step was to separate the resonant influence of the outer shelf from the local coastal features (bays or inlets). This second step allows reconstructing the corresponding admittance functions for any bay or inlet, which may be afterward used to predict amplification of meteotsunami but also of tsunami waves in a given location. The data of LAST-97 hydrophysical experiment (June-September, 1997) gave us a good opportunity to test this. A set of bottom pressure recorders were deployed on the shelf of Menorca Island, in two neighboring inlets of this island (Ciutadella and Platja Gran), and in Palma Bay (Mallorca Island); a number of precise microbarographs were working simultaneously. The first step of our analysis allowed reconstructing the open-sea source spectra for several abnormal seiche events recorded in the region of Ciutadella which, after compared with the observed atmospheric spectra, were used to estimate the so-called 'transfer function' between the atmosphere and the sea surface. This function is clearly related to the topography of the source area, but when computed for Ciutadella region, the transfer function was quite similar for different rissaga events suggesting consistency of the basic parameters (phase speed and direction of propagation) of the atmospheric waves generating large seiches. This fact can be used to predict the sea-level spectrum at a given location with the knowledge of the atmospheric pressure spectrum only. The second step of…

JSP23/L/05-B1 0950

ASSESSMENT OF GEOMAGNETIC HAZARD TO POWER SYSTEMS

D. H. BOTELER (Geomagnetic Laboratory, Geological Survey of Canada,Observatory Crescent, Ottawa, Ontario K1A 0Y3, Canada)

During severe geomagnetic disturbances electric currents induced in high voltage power transmission systems can cause transformer saturation resulting in transformer heating, generation of harmonics and increased reactive power demand. These effects can damage transformers, cause misoperation of protective relays and, in the worst case, cause power blackouts. An extensive study has been made to assess the geomagnetic hazard to power systems in Canada. Data from the Canadian Magnetic Observatory Network and conductivity models for different parts of Canada were used to calculate the electric fields produced during different levels of geomagnetic activity. This was combined with statistics on the occurrence of geomagnetic disturbances to determine the electric fields the power systems could expect to experience, on average, once a year and once every ten years. These electric field values were then used as input to power system models which calculated the corresponding levels of geomagnetically induced currents (GIC) in each power system.

THE SATELLITE CONCEPTION FOR MONITORING OF IONOSPHERE EXCITATION BY SEISMIC OR TECTONIC PROCESSES.

Vladimir DOKUKIN, Victor Oraevsky, Yury Ruzhin and Vladimir Alekseev (IZMIRAN,Troitsk-town, Moscow Region, 142092, RUSSIA; E-mail: ruzhin@izmiran.rssi.ru)

The deep tectonic faults are known to be zones of concentration of stresses, canalisation of fluids, aerosols and gases, change of magnetisation and electro- conductivity of rocks, appearance of high electrical potentials and so on. Also the tectonic faults are associated with the geodynamical structures which form the zones of elevated seismicity (quakes or volcanic eruptions) or zones of dangerous natural hazards. The results of joint processing of the data of low-frequency emission, corpuscular flows as well as temperature and density of plasma permitted us to reveal the previously unknown effect of the generation of low frequency noises in space over the deep faults of the earth crust. The developing now in Russia method of ionosphere tomography also is very perspective for that .The system of the small satellites can be especially important for revealing and research of global and regional net of geological faults in an effort to plan searches of mineral resources and to forecast destructive earthquakes (volcanic eruptions). The first microsatellite COMPASS, weighting about 80 kg, is planned to launch to the circular orbit with height 400 km and inclination 790 for development of the methods of monitoring and forecasting of natural disasters on the base of co-ordinated monitoring at the Earth and from space the pre-earthquake phenomena. COMPASS is composed of several sensors associated to a data processing unit and a large memory in order to record the information all around the Earth independently from telemetry station. The details of the measurements, instruments and general conception of the microsatellite system based on the COMPASS mission are presented in the report.

JSP23/W/09-B1 1050

AIR QUALITY AS A GEOPHYSICAL HAZARD

Tom BEER (CSIRO Atmospheric Research, Aspendale, 3195, Australia, email: Tom.Beer@dar.csiro.au)

Geophysical hazards are usually considered to be earthquakes, volcanic eruptions, landslides, floods, droughts, tsunamis, storm surges, wildfire, tropical cyclones and extreme weather events. Air pollution is not normally considered to be a geophysical hazard. This view has arisen because the causes of air pollution – industrial and motor vehicle emissions – are not geophysical in nature. However, as air pollution regulations succeed in reducing the amount of pollutant emissions, air pollutant episodes become sporadic in nature, and their occurrence depends on a particular combination of meteorological factors. Analyses of air pollution episodes and hospital admissions indicate that there is a significant increase in morbidity and mortality as a result of air pollution episodes. Time-series studies undertaken in Sydney have shown that particulate matter, ozone and nitrogen dioxide are the pollutants that are primarily responsible for adverse health effects. Air quality forecasting systems can play an important role in mitigating the adverse effects of air pollution. The forecasts will affect the behaviour of susceptible individuals, and thus reduce adverse health effects. The outputs from forecasting systems can also be used to provide improved estimates of the total exposure to air pollutants of the inhabitants who are at risk. Such improved estimates can then be used in conjunction with longitudinal studies of health effects to obtain better understanding of the complex interaction between air quality and health. This presentation will illustrate the manner in which air pollution depends on meteorology, review some of the data concerning the resulting health effects, and discuss the future research needed for a better understanding of the interaction between air quality and human health.

JSP23/W/13-B1 1110

MULTIFRACTAL ANALYSIS OF TROPICAL ATMOSPHERIC STRUCTURES AND TYPHOONES GENERATION.

I. TCHIGUIRINSKAIA (E.E.&S. Dept., Clemson University, 342 Computer Court, Anderson, SC29625, USA, E-mail: iouliat@clemson.edu); D. Schertzer (L.M.M., Université Pierre et Marie Curie, 4 Place Jussieu F-75252 Paris Cedex 05, France); S. Lovejoy (Physics Dept., McGill University, 3600 University st., Montréal, Qué., H3A 2T8, Canada)

During the last past ten years numerous investigations have been lead on the tropical atmospheric structures: boundary layer coherent structures, tropical storms and typhoons. Emphasis has been often placed on the structural conditions of generation of typhoons. Contrary to other approaches, we investigate this question on a large range of scales and intensities, trying to understand the crucial relationships between extremes events (such as typhoons) and more average ones, how the latter can build up to the appearance of the former. We chose thus a universal multi-fractal approach, since in this case the mean as well as the extreme events are ruled by three fundamental multi-fractal exponents determining the infinite hierarchy of singularities of the field and their corresponding co-dimensions. We analysed data sets obtained during two aircraft expeditions over South China Sea in 1988 and 1989 (Karmazin and Mikhailova, 1991). Measurements were usually done everyday from July to October on 8 or 11 levels from 50 meters up to 5 km heights, every 125 ms along 40 km in the horizontal for each level across the largest clouds bands. In the latter case, some flights were carried at a distance of Ed typhoon center as close as 7 km. Although variations of the estimates of the multi-fractal exponents are present, they do not seem to be significant, since these values remain close to those obtained in mid-latitude boundary layers or wind tunnel experiments (Schmitt et al. 1992). In conclusion, we discuss the rather low critical order of divergence of statistical moments qD=7 which rules the self organised criticality of extreme wind shears, temperature gradients and generation of related structures, in particular typhoons.

JSP23/W/32-B1 1130

LARGE-SCALE EVOLUTIONARY PROCESSES IN HAZARD SYSTEMS OF EARTHQUAKES, A PHENOMENOLOGICAL MODEL BASED UPON SELF-ORGANIZED CRITICALITY [SOC]

Natalia SMIRNOVA, Vladimir Troyan (both at Institute of Physics, University of St.Petersburg, St.Petersburg 198904, Russia, e-mail: nsmir@snoopy.phys.spbu.ru); Masashi Hayakawa (The University of Electro-Communications, Chofu, Tokyo 182, Japan,
e-mail: hayakawa@whistler.ee.uec.ac.jp); Thomas Peterson (TFPLAB, Cleveland, Ohio 44124-5441, U.S.A., e-mail: TFPLAB@aol.com); Yury Kopytenko (St.Petersburg Filial of IZMIRAN, St. Petersburg 191023, Russia, e-mail: galina@admin.izmi.ras.spb.ru)

The concept of self-organised criticality (SOC) is now widely used for the interpretation of the behaviour of natural hazard systems. This concept was recently introduced by the present authors as a way to search for earthquake precursory signatures. Here, we continue to consider earthquake region processes on the basis of the SOC concept. We suggest a phenomenological model for large-scale evolutionary processes that occur between violent earthquake episodes. Four principal stages of evolution are proposed and analyzed. They are: random chaos, subcritical, critical, and super-critical. External stimuli such as geomagnetic storms, sharp temporal and spatial variations in atmospheric pressure, and ULF impulses are considered as driving forces for a "cellular automata" process in active seismic regions. We discuss the possibility of using fractal characteristics of signals to study the critical dynamics of a hazard system. The important fingerprints of SOC - temporal and spatial fractal structures are analyzed using seismic and ULF electromagnetic data timed to violent earthquakes near Guam (August 8, 1993, M = 8.0) and Kobe (January, 16, 1995, M = 7.2). The research was supported by NASDA (Japan) and Russian Foundation for Basic Research (Grants No. 98-05-65554 and 99-05-NNN).

Boris W. LEVIN (*Shirshov Oceanology Institute of RAS and Russian Foundation for Basic Research, 32a Leninsky prosp., Moscow, 117334 Russia; email: levin@rfbr.ru)Yeugeny Chirkov (**Union Institute of the Earth Physics of RAS, 10 Bolshaja Gruzinskaja, Moscow, 123810 Russia; email: chirkov@uipe-ras.scgis.ru)

An importance of the Earth's rotation influence to earthquakes occurrence was noted by I.Kant (1756), I.R.Mayer (1893), G.H.Darwin (1908) and was often discussed by geophysicists at present time. Supposing the unpredictability of natural hazards is connected partially with our poor understanding of the planetary processes role, we investigated a geographical distribution of the earthquakes. Using the catalog NEIC, we had created the histograms of the earthquake numbers and its energy as a function of a latitude F from 90 deg. N to 90 deg. S at period of 1900-1993. We had found that the latitude distribution of the event numbers N(F) is similar to the curve describing a dependence R^2(F) or I(F) where R is a distance from the axis of rotation and I is an inertia momentum of mass unit. Also we discovered the local maximum of the seismicity on so-called "critical latitude" 35 deg. N which was first mentioned by geographer A.Veronne (1912) and was calculated by F.Krasovsky and V.Magnitsky (1941) as a specific parallel for the Earth figure theory. The preliminary analysis of the seismicity-time dependence (more than 100000 events with M>4.0) for different latitude layers showed that the seismicity varies with main period of near 6 years practically at all latitude layers of the Earth.

VOLCANIC RISK ASSESMENT AND ZONATION OF THE MAIN ERUPTIVE HAZARDS IN TENERIFE (CANARY ISLANDS)

Vicente ARAÑA and Alicia Felpeto (Dept. Volcanologia, Museo Nacional de Ciencias Naturales, Jose Gutierrez Abascal 2, 28006 Madrid, Spain); Mar Astiz (Dept. Matematica Aplicada, E.T.S. Arquitectura, U.P.M., Avda. Juan de Herrara, 4, 28040 Madrid, Spain, email: civgv@pinar1.csic.es); Francisca Gomez (Centro di Studio per la Geologia Structturale e Dinamica dell´Apennino, CNR, Pisa Italy); Alicia Garcia and Ramon Ortiz (Dept.Volcanologia, Museo Nacional de Ciencias Naturales, Jose Gutierrez Abascal 2, 28006 Madrid, Spain, email: mcngg92@pinar1.csic.es and mcnor72@pinar1.csic.es)

Taking into account that the island of Tenerife is a complex case, that one unique volcano and a unique eruptive style cannot be considered, the methodology developed in this paper to define a volcanic hazard-risk zonation in the island consists of: (1) Definition of the different hazards. (2) Numerical gradation of the probability of occurrence of each phenomenon by area. (3) Selection of the areas that show the higher probability of being emission centres. (4) Numerical simulation of the effects of an eruption of the corresponding eruptive style in those areas. The steps (1), (2) and (3) are based on the extensive knowledge of the eruptive activity of Tenerife Island and structural parameters. The results obtained from these three steps and the hazard map are implemented in a GIS and also used for the organisation of the surveillance network in terms of efficiency.

STRESS CHANGES AT THE SOUTH ICELAND SEISMIC ZONE - A MODEL FROM 1706 UP TO THE PRESENT FOR BETTER HAZARD ESTIMATION

Frank ROTH (Section "Earthquakes & Volcanism", Division "Solid Earth Physics and Disaster Research", GeoForschungsZentrum, Telegrafenberg, D-14473 Potsdam, Fed. Rep. of Germany, email: roth@gfz-potsdam.de)

The South Iceland Seismic Zone is situated between two sections of the mid-Atlantic ridge, i.e. the Reykjanes Ridge SW of Iceland and the Eastern Volcanic Zone on the island. It is a transform zone, though no typical one, as it is not connecting both rifts at right angles. Following this hypothesis, earthquakes should occur on EW-trending left-lateral shear faults, equivalent to conjugate, NS-oriented right-lateral, rupture planes. In fact earthquakes take place on NS-oriented faults, which are indicated by intensity and aftershock distributions, as well as by surface fault traces.
The stress field permanently generated in the fault zone by opening of the adjacent ridges with slightly more than 2 cm per year is computed and superimposed with the stress field changes induced by a series of 11 earthquakes (M >= 6) between 1706 and 1912. For these, different rupture depths are assumed, depending on the distance to the rifts. Finally, the post-seismic stress field of 1912 is extrapolated to the present, to see where highest stresses might have accumulated. In addition, the influence of loads at the Eastern Volcanic Zone on the stress field in the seismic area is studied.
The modelling shows that the stress is released by the series of events in the whole area, even though the ruptures planes are located on parallel NS-striking zones. The pre-seismic stress level for most events is high and pretty stable with the exception of situations when several strong shocks occur over a time span of several days, i.e. display typical main shock-aftershock patterns.

INITIAL STRUCTURES AND PACKING TRANSFORMATIONS OF LOESS DEPOSITS: IMPLICATIONS FOR THE ANALYSIS OF CATASTROPHIC MASS MOVEMENTS.

Eleanor PARKER and Tom Dijkstra (Coventry University)

Gradual settlement from aeolian suspension means that loess particles generally form very open initial packing. There is less than 50% solids in a unit volume of soil - unless there is too much water or additional stress which will cause particles to settle in a much denser state. As long as the deposit remains relatively dry, cementation and other bond types will maintain the open structure; the loess is metastable. The potential of metastable loess to collapse is impressive. Rapid transformations from undisturbed packing with dry densities of about 1.3 Mg/m3 (void ratio e ~ 1), to more closely packed 'deformed' fabrics with dry densities of about 1.65 Mg/m3 (e = 0.65) after collapse. At failure, signifcant pore volume reductions (often more than 10%) result in considerable rapid increases in pore pressures (principally related to water pressures, but in loess air pressures are also important). Such pore pressures are necessary ingredients to produce very mobile mass movements, usually in the form of flowslides. In situations where pore pressure dissipation is impaired, a lowering of the shearing resistance may last long enough to allow long run-outs and high sliding velocities. The study material is Chinese loess from Gansu province, but there are important parallels with similar collapsible deposits such as the brickearths of South East England.

EARTHQUAKES PREDICTABILITY: A CASE STUDY

Valery KOREPANOV, Yevhen Klymovych and Pavlo Maltsev (Lviv Centre of Institute of Space Research, 5-A Naukova str., 290601, Lviv, Ukraine, e-mail: vakor@isr.lviv.ua); Masashi Hayakawa (Dept. of Electronic Engineering, University of Electro-Communications, 1-5-1 Chofugaoka, Chofu, Tokyo 182-8585, Japan, e-mail: hayakawa@whistler.ee.uec.ac.jp); Katsumi Hattori (International Frontier Program on Earthquake Research, Institute of Physical and Chemical Research (RIKEN), c/o Earthquake Prediction Research Center, Tokai University, 3-20-1, Orido, Shimizu 424, Japan, e-mail: hattori@iord.u-tokai.ac.jp); Victor Tregubenko (Kyiv Branch of Ukrainian Geology Research Institute, 78 Avtozavodska str., 252144 Kyiv, Ukraine, e-mail: direct@kgou.ru.kiev.ua)

It is accepted that large earthquakes (EQ) are accompanied by different electromagnetic phenomena. They are also found to precede the EQ and the most debatable question is whether they can be used as EQ precursors. Two of such positive examples for EQ with M; 4,5 are investigated: near Matsushiro (Japan) 01.07.1998 and near Crimea peninsula (Ukraine) 16.10.1998. In both cases three components of magnetic fluctuations only were studied: for Matsushiro in frequency band from 0,01 to 30 Hz and for Crimea the DC magnetic field was sampled once per 10 seconds. For Matsushiro EQ some preceding events were extracted: short spikes with some features deviating from noisy background and also about 50% overall growth of daily averaged amplitude of ELF emission. For Crimea EQ the variations of mean longitudinal conductivity of the crust were calculated. The resulting curves excellently suit the Scholtz dilatant-diffusional model: for 15 days averaged variations of the conductivity defection from the mean value before earthquake was about 6% what was fairly beyond mean error ~ 1,2%. Still higher was the deflection for daily averaged variations: more than 25%. The peculiarities of the study and processing methodology are discussed.

JSP23/C/U5/L/01-B1 1500

MACRO SCALE MODELLING OF CATASTROPHIC NATURAL HAZARDS

Adrian STEWART, and Dr Claire McQueen, (EQE International Ltd, 500 Longbarn Boulevard, Warrington, WA2 0XF, UK. Tel:- +44 1925 838372, fax +44 121987 654, Email: astewart@eqe.co.uk, cmcqueen@eqe.co.uk.)

Economic losses from Natural disasters over the last few decades have been enormous, as demonstrated by Hurricane Andrew in the US. The impact on the Global economy can reverberate for years after a single event. Assessing the risk to regions and countries is essential in the context of enabling International Organisations, Governments a International Industry and Commerce to plan, mitigate and manage losses.
In terms of risk from damaging earthquake or windstorm events, the risk is a function of the hazard intensity combined with the vulnerability of the properties within any given unit or area. The deterministic results of such studies may also be combined With expected frequencies to obtain probabilistic estimates of risks. In order that the losses expected within an area from an event be estimated accurately, the vulnerability functions and hazard models should be representative of the scale of the are that they are located in. Scale is an important issue. The Hazard Model needs to reflect the reduced risks expected over larger areas. However, the detail needs to remain in order that the spatial resolution of the hazard across an area is accurately represented. The question is whether vulnerability and hazard models can be created for a specific scale, or whether it is possible to calculate losses on a detailed grid and aggregate consistently at any macro scale.

JSP23/W/39-B1 1520

SPACE PRECURSORS OF EARTHQUAKE REGISTERED BY SATTELLITE AT GEOMAGNETICALLY CONJUGATED AREAS

Yuri RUZHIN, Vera Larkina and Anna Depueva (IZMIRAN, Troitsk-town, Moscow Region, 142092, RUSSIA; email:ruzhin@izmiran.rssi.ru)

There is some progress in investigations of space plasma precursors of earthquake (EQ) - the magnetic conjugation of VLF pre-seismic emission on satellite orbits was found in both hemispheres. It means that some signature of precursor could be found inside the geomagnetic flux tube (shell) which connected with both conjugated ionosphere regions where the VLF precursors on satellite orbits were registered. Satellites INTERCOSMOS-18 and ALOUETTE data were analyzed from this point of view. Conjugated EQ-precursors are found in very low frequency (VLF) emission and ionosphere F2-layer plasma parameters. It should be pointed out that F2-precursors appears some days before the earthquake, manifest themselves as an plasma anomaly like Appleton anomaly if epicenter of future earthquake is situated near magnetic equator. It is shown that the electric field less than one mV/m have to be generated in the ionosphere. Then we'll can be able to observe the above ionosphere phenomena as an equatorial earthquake forerunners. We are able to show that VLF precursors which appears some hours before the earthquake are localized close to magnetic shell corresponding to future earthquake epicenter and have a belt-like structure (longitude aligned on more than some tens thousands kilometers) in bot hemispheres. In the presented work relationship of VLF fields intensity and spectra with energetic electrons flux density are investigated over epicentral zone of the prone earthquake. On the base of our estimations and phenomenological development of the event in the ionosphere (plasmasphere) over the seismic region and over magnetically conjugated region the possibilities of the seismoionospheric anomalies (space precursors of EQ) generation are discussed.

JSP23/C/U5/W/10-B1 1600

THE CENTRAL POSITION OF GEOPHYSICS FOR THE EVALUATION OF THE NEAR-FUTURE AND ESPECIALLY THE DISTANT FUTURE

Nils-Axel MÖRNER, (Paleogeophysics & Geodynamics, S-10691 Stockholm, Sweden, email: morner@pog.su.se)

Geophysics and its paleogeophysical expresions over past periods will always play a central role for all types of predictions and estimations of the future. This applies for the near-future and its evaluation based on our understanding of the natural variability in environmental parameters on a decadal-to-century time scale, and its interaction with induced anthropogenic factors. On the 104-105 year time scale, the selestrial mechanical calculation of the so-called Milankovitch variables form a strong basis in climate prediction. Distant predications and evaluations are, in general, neither simple nor straight-forward. Still, there is a desperate need for safity predictions over 104-106 year time scale when it concerns the long-term stability and safity of high-level nuclear waste repositories. This has added a completely new dimension to geophysics. For a "safe" final bedrock deposition of high-level nuclear waste, we need guarantees for the immense time period of "hundreds of thousands of years". No one can, of course, give meaningful guarantees over such long time periods. The Fennoscandian crystalline bedrock is, by no means, as stable and reliable as sometimes claimed. Only some 10,000 years back in time, the seismic activity was (as a function of the extreme rates uf glacial isostatic uplift amounting as much as some 10 cm per year) tremendously high; in amplitude

as well as in frequency. In such an environment – to be repeated at the next future ice age – we can, of course, give no guarantees for a waste disposal in the bedrock; on the contrary, most facts suggest that it would be seriously damaged. In the absence of a true long-term safity, we can only propose that the waste produced: (1) is kept at a minimum, (2) is stored under constant control, and (3) is kept accessible for reparations as well as possible future innovations of how to render the waste harmless.

JSP23/E/14-B1 1620

LONG-TERM HAZARD FROM RIVER-BED AGGRADATION FOLLOWING VOLCANIC ERUPTIONS

Thomas C. PIERSON (U.S. Geological Survey, Cascades Volcano Observatory, 5400 MacArthur Blvd., Vancouver, WA 98661, USA, email: tpierson@usgs.gov)

Explosive volcanic eruptions can provide immense volumes of readily erodible volcaniclastic sediment to drainage basins on or near source volcanoes. Posteruption rainfall, or other types of rapid runoff, mobilizes sediment from hillslopes or from source deposits in upper valleys, episodically moving it downstream during periods of high discharge (probably as long, slow-moving sediment waves). Depending on the volume of sediment added to a fluvial system, this sediment mobilization can result in dramatic and hazardous vertical aggradation of river beds. Data from recent historical eruptions at Mount Pinatubo (Philippines), Mount St. Helens (USA), and other volcanoes demonstrate that river-bed aggradation can occur rapidly (at varying rates as high as 0.4 m/day) in channels up to hundreds of meters wide over extensive downstream reaches in the first year or two following an eruption. Although periods of aggradation may be interrupted by irregular periods of degradation (channel downcutting), river-bed elevations may show net rises of as much as 20 to 30 m within only a matter of months within 50 km of source, and net aggradation of at least 8 m has been documented as far as 280 km from source. Under these conditions, floods and lahars need not have extraordinarily high discharges to be able to reach and inundate previously safe homes, roads, and farmland.
Aggradation may continue for decades before sediment supply from the disturbed areas decreases enough to allow rivers to incise back down to previous bed levels. Tree-ring data from terraces along the Sandy River, 80 km downstream from Mount Hood (USA) indicate that significant reincision (about 8 m or nearly 50 percent) occurred within about 40 years of the ~200 yBP eruption of Mount Hood, and the river nearly regained its original bed level within about 60 years. Efforts to mitigate river-bed aggradation hazards, such as has been done at Mount St. Helens, should be planned with knowledge of this potentially long-term impact on fluvial systems.

A SEA LEVEL-WAVE JOINT DISTRIBUTION FOR SEVERE STORM SURGE HAZARD ASSESSMENT USING OFFSHORE PLATFORM DATA

Le KENTANG (Institute of Oceanology, Chinese Academy of Sciences, Qingdao 266071, PRC, email: ktle@ms.qdio.ac.cn)

Generally speaking, the direct economic losses from a severe storm surge disaster consist mainly of that from sea water flooded over land and that from damage caused by high sea. However, the traditional method for storm surge hazard assessment in China is to construct one or two single-parameter distributions by using historical sea level and/or wave data at some coastal stations and/or ocean stations. In this case, apparently, both sea level data and wave data at these stations must be long enough to estimate the return periods needed for mitigation. However, the existing data of sea levels and waves at most of these stations can't meet the needs of the estimation. In this paper we presents a method to construct the sea level-wave joint distribution for severe storm surge hazard assessment by using a couple of years data on such a stations. Using a one-year platform data in the Bohai Sea, an example is given to illustrate the capabilities of this methodology.

STATISTICAL METHODS FOR SLUSHFLOW SITUATIONS RECOGNITION, MONITORING AND FORECASTING

Pavel CHERNOUSS and Olga Tyapkina (Center of AvalancheSafety,"Apatit" JSC, 33a, 50 years of October St.,Kirovsk, Murmanskregion184230, Russia, e-mail: P.Chernous@apatit.murmansk.su); Erik Hestnes and Steinar Bakkehoi (both at NorwegianGeotechnicalInstitute, P.O. Box 3930 Ullewal Hageby, N-0806, Norway, e-mail: eh@ngi.no)

Slushflows - flowing mixtures of water and snow - are a hazardous phenomena in mountainous regions all over the world. They are most frequent in higher latitudes, i.e. in Norway, Iceland, USA(Alaska),Canada and Russia (northern and eastern parts). Slushflows exert high destructive forces and they are almost unpredictable due to inadequate studies. The work is an attempt to classify meteorological situations at different heights above sea level on "slushflow" and"non-slushflow" with linear discriminant analysis and Bayes'formula. Standard meteorological observations were used as primary parameters to describe the situations. Classification was made on daily base. Data for the mountain regions of Norway and the Khibini Mountains in Russia were taken to derive the classification rules and to carry out a verification of the methods. Different sets of parameters were tried to find out most informative ones. Two parameters have been chosen -daily water income (designed parameter) and snow cover thickness. Classification accuracy, obtained with independent data, was better than 75% for both types of the situations. For more detail slushflow danger monitoring one day moving average values are used. There are two ways to transform the diagnostic methods into forecast ones- by using of forecasted parameters as predictors or by extrapolation of situation probabilities. The methods are an effective tool for slushflow forecaster and realized as software package for the real-time work at the Center of Avalanche Safety of "Apatit" JSC.

JSP23/W/23-B1 1720

PRESEISMIC ELECTROMAGNETIC SIGNALS GENERATED IN ATMOSPHERE

Yuri RUZHIN (IZMIRAN, Moscow, 142092,RUSSIA; E-mail: ruzhin@izmiran.rssi.ru); Costas Nomicos (Technological Educational Institute of Athens, GREECE); Filippos Vallianatos (Technological Educational Institute Chania branch, Crete, GREECE)

Electromagnetic (EM) precursors of Earthquakes (EQ's) are modern possibility to monitor pre-earthquake situation and to improve the EQ forecast. Its nature up to now is under the question. The EM signals registrated (before the EQ) onboard of satellites is the object of intensively investigations during last decade. Here we overview of EM seismo precursors and present situation with its explanation but the high frequency (HF) precursor (43MHz and 51MHz) is main point of our presentation. It is showed that precursor type HF signals are appeared before the EQ for one-three days and the some new peculiarity is found. This is under horizon epicenter position for main part of events under question. It means that emitted volume must be located at some altitude in atmosphere or ionosphere. The another unusual result is that such pre-seismic signals are responsible for seaquakes (not, as usually, for the earthquakes!). In result, we made conclusion about existing of some thunderstorm type activity above the sea level before the seismic event. It means that above sea level (up to 3-8 kilometers) the space charge cloud would be generated at one-three days before the active seismicity (under sea floor). Based on above mentioned we can supposed that probably this is new pre-seismic signature which will be used in future EQ forecast. Some additional experimental facts and mechanisms are discussed to explain this HF precursor (EM signals) generation above the epicenter of future seismic activity.

MONITORING THE CURRENT SUMMIT ERUPTION OF MOUNT ETNA USING INFRARED SATELLITE DATA FROM THE ERS ATSR-2

Rob WRIGHT, David Rothery, Stephen Blake (Department of Earth Sciences, The Open University, Milton Keynes MK7 6AA, UK, email: r.wright@open.ac.uk); Martin Wooster (Department of Geography, King's College London, Strand, London, WC2R 2LS, UK)

After the unusually quiet period that followed the end of the 1991 to 1993 eruptions, magmatic activity resumed within Etna's summit crater complex in July 1995. All four summit craters have been characterised by strombolian activity while between July 1997 and July 1998 the South East crater was also the site of sustained lava effusion. Intense paroxysmal explosions have also occured intermittently from the North East crater and La Voragine.
In March 1998, at the request of the Italian Civil Protection Authority, the European Space Agency commissioned the "Empedocles" project. This aim's to assess the role that satellite remote sensing can play in monitoring the volcano, and understanding the nature and future evolution of the current activity. Using data acquired by the ERS-2 along Track Scanning Radiometer (ATSR) we show how the amount of short-wave infrared radiance emitted from the summit crater complex has fluctuated since July 1996. The data reveal patterns that correlate well (on a weekly time scale - ATSR acquires data ~ every 3 days) with Etna's general level of activity as documented in field reports. Examining the amount of radiation emitted at different wavelengths allows us to distinguish activity associated with high temperature vents from that associated with lava flows. By applying rank order statistics to the ATSR data-set we have inferred changes in the level of activity on Etna that may reflect changes in the eruptive state of the volcano.

JSP23/C/U5/W/07-B2 0950

THE SPACE VOLCANO OBSERVATORY (SVO) PROJECT

Pierre BRIOLE (Institut de Physique du Globe, 4 Place Jussieu, F-75005 Paris, email: briole@ipgp.jussieu.fr) and the SVO science team

1500 volcanoes on the earth are potentially active. One third of them have been active during this century and about 70 are presently erupting. At the beginning of the third millennium, 10% of the world population will be living in areas directly threatened by volcanoes. Presently, in spite of the efforts of many countries, only a few volcanoes are monitored by modern observatories. Even in the best equipped of them, real-time data acquisition on the active parts of the edifices during crisis is an extremely difficult and risky task. The only way to provide global, continuous, real–time and all–weather information on volcanoes is to combine observations from space and from the ground. Spaceborne observations (with satellites, helicopters, drones, balloons,…) are mandatory and complement the ground ones that can be implemented on a limited set of volcanoes. A project called SVO (Space Volcano Observatory) has been proposed to the European Space Agency to remotely monitor the deformations and thermal changes of the highest active areas of the volcanoes (lava lakes, lava domes, lava flows, eruptive vents…). These zones are unstable and often deform significantly prior to paroxysmal events (sudden collapses, flank pyroclastic flows, …). They are also remote and dangerous and cannot be easily equipped with ground equipment. We propose to map at high resolution (1.5m pixel size) the topography and the thermal changes (for pixels above ~ 450°C) of active volcanic areas with a return time of one to three days and an image size of 6 x 6km. Those variations will put constraints on the physical and dynamic processes of the system. Other applications like landslide monitoring, will be possible. The requirement of fast data processing and interpretation imply the set up of several ground-based stations for data collection. The 12-15 major volcanological observatories of the world could host those receiving stations.

JSP23/E/42-B2 1010

VOLCANIC RISK AND EMERGENCY PLANS OF THE NEAPOLITAN VOLCANOES

Lucia CIVETTA (Co-ordinator of the thecnical committee for preparation of the emergency plans Osservatorio Vesuviano, via Manzoni, 249, 80123 Naples, Italy e-mail: civetta@osve.unina.it)

The volcanoes of the Neapolitan area, Vesuvius, Campi Flegrei and Ischia, have generated more than 100 explosive eruptions in the past 10 ka. However, they can lie dormant for many centuries and the great risk posed by volcanic activity in the region was, therefore, not always apparent. Vesuvius has exhibited various types of activity in the past 25 ka. Plinian and subplinian explosive eruptions occurred every few millennia or few centuries, respectively. Strombolian activity, lava effusions and phreatomagmatic eruptions usually follow the plinian and subplinian eruptions until conduit closes. Since the last eruption of 1944, Vesuvius has not shown signs of unrest. Only moderate seismicity and fumarolic emission testify the current state of activity of the volcano. The Vesuvius eruptive history however suggests that the longer is the quiescent period, the more violent is the renewal of the activity. The last eruption of the Campi Flegrei caldera occurred in 1538 AD, at the north-western edge of the. La Starza resurgent block. Since that time, after hundreds of years of subsidence, two bradyseismic events occurred in 1969-70 and 1982-84, which totalled a net vertical uplift of 350 cm of the central caldera block, at the harbour of Pozzuoli. The last eruption of Ischia occurred in 1302 AD, at the edge of the resurgent Mt. Epomeo block. Since that time intense fumarolic activity, hot springs and seismicity characterise the island current state. Intense urbanisation and inadequate planning of the Neapolitan territory have significantly contributed to the increment of the volcanic risk since the fifties. In response to the increasing volcanic risk, in 1993 the

Minister for Civil Defence appointed a commission to prepare the emergency plan of the Vesuvian area that was completed at the end of 1995. In 1996 the Minister of Civil Defence appointed a new Commission to update the emergency plan of Vesuvius and prepare the scenario of the expected eruption at the Campi Flegrei Caldera and define the guidelines for the Campi Flegrei emergency plan.

JSP23/E/26-B2 1050

VOLCANIC HAZARD MAPS OF TENERIFE ISLAND (CANARY ISLANDS)

Alicia FELPETO , Vicente Araña (Dep. Volcanology, Museo Nal.Ciencias Naturales, CSIC, J. Gutiérrez Abascal, 2, 28006 Madrid, Spain, email: mcnaf66@pinar1.csic.es); Mar Astiz (Dep. Matametica Aplicada, ETSA, Universidad Politécnica, Avda. Juan de Herrera 4, 28040 Madrid, Spain); Francisca Gómez (Centro di Studio per la Geologia Structturale e Dinamica dell'Apennino, CNR, via Santa Maria, Pisa, Italy); Alicia García , Ramón Ortiz (Dep. Volcanology, Museo Nal. Ciencias Naturales, CSIC, J. Gutiérrez Abascal 2, 28006 Madrid, Spain)

The first steps for the generation of volcanic hazard maps of Tenerife consists of the definition of the most significant hazards and the selection of the most suitable areas for containing emission centres, taking into account all the data of the eruptive history of the island. Then, for the evaluation of the effects of an eruption, a numerical model for each hazard has been chosen. The application of the different models allows the computation of the probability of each point of the island being affected by each type of eruption, and so, building up the volcanic hazard maps. The methodology proposed, integrated on a GIS framework, allows the automation of the generation of hazard maps for more specific studies of smaller areas of the island or specific risk scenarios. It also represents the starting point for developing risk maps.

MAPPING AND MONITORING OF VOLCANOES USING SPACE-BORNE SAR

Woolil M. MOON, Lanying Feng and (Geophysics, The University of Manitoba, Winnipeg,Canada R3T 2N2 (email: lfeng@gis.geop.umanitoba.ca, wmoon@cc.umanitoba.ca); DUK-JIN>KIM , K.H. Choi, C.W. Lee and Woolil M. MOON (Earth System Science, Seoul National University (email: wmoon@eos1.snu.ac.kr, djkim@eos1.snu.ac.kr); J. L. Lizeca (SERGEOMIN, La Paz, Bolivia ("Jose Liuseca" email: abtema@coord.rds.org.bo

In this study, we have investigated several active volcanic areas (Baiktu-san (China-Korea border), Cerro Caquella (Bolivia), and Halla-san (South Korea)) using RADARSAT and JERS-1 SAR data for their geological characteristics and for their application criteria in view of natural hazard monitoring. Baiktusan is located at the junction of northeastern edge of Huabai tectonic block of the Eurasian continent and mid-Cenozoic off-shore Pacific volcanic zone, and have gone through several stages of crustal evolution. According to historical records, Baiktusan had a major eruption in 1002 AD, and several minor eruptions in 16th and 18th century. However, the strategic location of Baiktusan at the political boundary between P. R. China and North Korea, has resulted in a situation with rather poorly surveyed geology maps and inconsistent geological interpretation of recent volcanic activities. The Halla-san volcano has not been active during the histrocial time, but it is the main feature of the Jeju Island (a volcanic island), which has recently been rapidly developed for increasing human settlement. In the Cerro Caquella region, which is a remote barren Andean range, a detailed DEM could be extracted to investigate morphological changes associated with active volcanic activities, in addition to correlation of the DEM with respect to several other geological and geophysical data collected over the study area. Several sets of JERS-1 SAR and RADARSAT data are acquired for this study with the objectives of investigating the surface geology of Baiktu-san and Halla-san volcanoes and the surrounding area to delineate consistent geological and volcanic characteristics. Both traditional geological remote sensing approach and the space-borne InSAR (SAR interferometry) approach were used (i) for structural geological interpretation of the study area using the pre-processed SAR data, and (ii) for correlation of the interferogram fringe pattern…

THE MONTSERRAT VOLCANO ALERT AND WARNING SYSTEM

Lloyd L. LYNCH (Seismic Research Unit, University of the West Indies, St. Augustine, Trinidad W.I., email: sru@wow.net)

From the onset of the Soufriere Hills volcano eruption on July 18, 1995, to the waning stages of the eruption almost three years later most areas of the more developed half of the island of Montserrat faced the threat of devastation. The relatively small size of the island, its complex political and governance structure, and the demographic setting in relationship to the threatening volcano were factors which all combined to make the management of the crisis one of the most challenging of the twentieth century. Compounding matters, was the fact that the eruption followed a style for which there was no well-documented precedent. As in most volcanic crises, an alert and warning system was instituted primarily to facilitate risk and emergency management. The system employed was an adoption of the generic alert and warning system popularised by the UN Volcanic Emergency Handbook. In this article the Montserrat volcano alert and warning system is modelled as network of closely interrelated functional entities comprising of a management subsystem, a detection subsystem and a response subsystem. This provides a comprehensive abstraction of the functions and interaction between the administrative authorities, scientists and the public during the eruption. With aid of this model a detailed analysis of the strengths and shortcomings of the system is performed and presented. Attempt is also made to document the major changes within the subsystems during the crisis. There were several. Among the most remarkable were the many changes in the management personnel such as chief minister, governor and chief scientists. Throughout the crisis key institutions such as the Montserrat Volcano Observatory and the Emergency Operation Center also endured constant evolution. Operational and decision-making policies and procedures within these institutions encountered numerous revisions. Generally, these changes were intended to facilitate the tacit objective of local authorities to maximise life safety while retaining a sustainable level of functionality on the island. In the absence of…

A DEVELOPING VOLCANIC CRISIS IN DOMINICA, LESSER ANTILLES

John B. SHEPHERD, Lloyd L. Lynch, Mark Stasiuk, Joan L. Latchman (Seismic Research Unit, UWI, St. Augustine, Trinidad, e-mail: johnbshepherd@hotmail.com); Joseph M. Devine (Brown University, Providence, R.I. USA)

The island of Dominica is in the centre of the volcanically active Lesser Antilles island arc. The island is approximately 35 km long by 12 km wide and is composed entirely of Pleistocene to recent volcanoes. Earthquake swarms have been reported from Dominica since it was first settled by Europeans. These originate in all parts of the island but are most common in the southwestern part of the island where there are at least three volcanic vents which have erupted in the last few thousand years.
The most recent swarm began in September 1998 and is continuing. By January 10 1999 over 1,000 shallow volcanic earthquakes had been recorded by a nine-station digitally recording short period seismograph network. Over 300 earthquakes had been felt in the southwestern part of Dominica causing significant damage. Epicentres were initially located close to Morne Plat Pays volcano but during the swarm have spread to the most of the southwestern region. Focal depth are in the range 1-5 km and are becoming shallower as the swarm progresses. GPS measurements have detected widespread inflation of the epicentral region. An extensive programme of geological mapping is in progress and a response plan has been developed by the civil authorities.

THE SEISMIC ALERT SYSTEM IN MEXICO CITY AND THE SCHOOL PREVENTION PROGRAM

ESPINOSA ARANDA J M, A Jimenez, G Ibarrola, F Alcantar, A Aguilar, M Inostroza, S Maldonado Director, (Centro de Instrumentacion y Registro Sismico, A.C. Anaxagoras #814, C.P. 03020, Mexico, D.F. E-mail: cires@cires.org.mx Home page: http://www.cires.org.mx;); R Higareda (Director, Direccion de Emergencia Escolar Subsecretaria de Servicios Educativos del Distrito Federal Secretaria de Educacion Publica Callejon de Torresco #12, C.P. 04010, Mexico, D.F. E-mail: rhigareda@yahoo.com)

The Seismic Alert System (SAS) is a public service developed with the sponsorship of the City Government Authorities, with the aim to mitigate seismic disasters. Since August, 1991, after 88 months of continuous operation, the SAS has being capable to detect 714 seismic events in the Guerrero Coast; 12 of them so strong to trigger general alerts in Mexico City, 34 restricted, and one false general alert. The warning ranges strong or restricted correspond to seismic magnitude forecasted great than 6, or great than 5. During the "Copala" M7.3 earthquake, in September 14, 1995 the SAS was activated and issued a general warning signal in Mexico City, 72 seconds prior to the ``S'' ground motion first arrivals. This earthquake warning reached an estimated population of more than 4 million citizens. The response of children in schools was massive because of the application of an earthquake hazard reduction program. The Copala earthquake helped us to identify the societal response strengths and weaknesses to the earthquake early warning signal. The long-term plan of hazard mitigation of the National Ministry of Public Education, Secretaria de Educacion Publica (SEP), has created awareness to earthquakes in the children that have assisted in these years to various school levels. Even though they did not suffered the disastrous consequences of the 1985 earthquake, they are more aware than the average people that lived through that disastrous event, who still are not trained.

SEASONAL WARNING FOR CLIMATIC HAZARDS: PROSPECTS AND RESPONSES

T.DOWNING (Environmental Change Unit, 1A Mansfield Road, Oxford, OX1 3TB,
Email: tom.downing@ecu.ox.ac.uk)

With climate change, there is increasing concern that climatic hazards will become more frequent and more severe. One of the most promising developments is seasonal climate forecasts. Already forecasts are operational in many parts of the tropics and sub-tropics, and particularly for droughts and floods associated with ENSO events. Prospects for further development of seasonal forecasting for a range of climatic hazards are reviewed, illustrated with case studies in Africa and Europe. A critical evaluation of the utility of seasonal forecasts centres on vulnerability, communication channels, and effective responses. In contrast to short-term prediction, seasonal forecasts raise new issues of preparedness and the use of information.

JSP23/E/10-B2 1420

CHANCES FOR A LONG TIME FORECAST OF SEVERE STORM EVENTS IN WESTERN EUROPE WITH RESEPCT TO THE NORTH ATLANTIC OSCILLATION

Mattius KLAWA, Uwe Ulbrich and Johannes Wefers (Institut fuer Geopyhsik und Meteorologie, Kerpener Str. 13, 50923 Koeln, Germany, e-mail: mklawa@meteo.uni-koeln.de, phone: 49 (0)221/470-3689)

The North Atlantic Oscillation is the dominant variability pattern in sea level pressure over the North Atlantic. Spectral analyses of the variations of this pattern show peaks on seasonal, yearly or decadal time scales. Also research proved influence of the NAO on the North Atlantic Stormtracks and on the European climate e.g. rainfall rates, winter temperatures in western Europe. In this presentation extreme storm events in western Europe are evaluated with respect to the NAO. Probabilities for extreme storm events on time scales of 5-10 years dependent on the NAO are estimated. In combination with daily weather regimes (since 1881) the long time series of the NAO pattern (since 1865) is used for a more detailed analyses on European weather events. In a first step damaging storms named by reinsurance companies and meteorological extreme events are compared. Weather regimes associated with these events are used for a description for the atmospheric circulation over Europe and to find out common features of periods around storm events. In a final step the probabilities for storm events are evaluated and interpreted.

JSP23/E/29-B2 1440

FRACTURE CRITICALITY: A NEW CRITERIA FOR MONITORING THE ONSET OF EARTHQUAKES AND FRACTURING

Stuart CRAMPIN (Department of Geology & Geophysics, University of Edinburgh, Edinburgh EH9 3JW, UK; email: scrampin@ed.ac.uk)

Seismic shear-wave splitting, diagnostic of distributions of stress-aligned fluid-saturated grain-boundary cracks and low aspect-ratio pores is seen with very similar characteristics in almost all igneous, metamorphic, and sedimentary rocks with a few well-understood exceptions. There is a minimum shear-wave velocity anisotropy of about 1.5% and a maximum of about 4.5% in intact un-fractured rock below about 1km in the crust. Theory and both field and laboratory observations suggest that this maximum value is close to the level of fracture criticality, associated with the percolation threshold, where rocks are so heavily fractured that shear-strength is lost, through-going fractures propagate, pore-fluids disperse, and earthquakes and fracturing occur. The evolution of such fluid-saturated rock can be modelled with anisotropic poro-elasticity (APE), where the driving mechanism is fluid migration by flow or diffusion along pressure gradient between neighbouring grain-boundary cracks and pores at different orientations to the stress field. APE shows that shear-wave splitting is controlled by the same parameters as control pre-fracturing deformation so that shear-wave splitting can be used to monitor directly the approach of fracture criticality before earthquakes or other failures

by fracturing. The high seismicity of SW Iceland and the extensive SIL seismic network now allow changes in shear-wave splitting before earthquakes to be observed routinely with hindsight. A real-time "stress-forecast" in a narrow magnitude/time window was made with forecasts 17, 15, and 3 days before a M=5 earthquake on 13 November 1998. The key feature is monitoring the increase of stress in the relatively-undisturbed rockmass away from the complications of the earthquake source, and estimating the time at which induced cracking reaches the level of fracture criticality. By monitoring the build-up of stress, such stress-forecasts can give (potentially reliable) estimates of time and magnitude of future earthquakes but cannot give estimates of location. However, forecasts may well stimulate local studies, as was the case in Iceland, where investigations by the Icelandic Meteorological Office correctly identified the rupturing fault.

JSP23/W/01-B2 1500

THE COASTAL OCEAN MONITORING AND PREDICTION SYSTEM FOR WEST FLORIDA

MARK E. LUTHER, David Burwell, Meredith Haines, Nan Schmidt, Mark Vincent, Robert Weisberg, and Huijun Yang (University of South Florida Department of Marine Science, 140 Seventh Avenue South, St. Petersburg, FL 33701; Tel: 727/553-1528; Fax: 727/553-1189; E-mail: luther@marine.usf.edu)

Florida is the United States' fourth most populous state, with 80% of the population living in a coastal county. Several recent storms have brought large, unpredicted flooding to Florida's west coast. The coastal sea level response to tropical and extra-tropical storms results from wind forcing over the entire continental shelf. Much of the local response may actually be due to storm winds quite distant from the local area of concern; a case in point being tropical storm Josephine, a modest storm that nevertheless caused extensive flooding in the Tampa Bay area. The University of South Florida is implementing a real-time Coastal Ocean Monitoring and Prediction System (COMPS) for West Florida that will provide additonal data needed to give more accurate predictions of ocean storms and coastal flooding by storm surge. This system consists of an array of instrumentation both along the coast and offshore combined with numerical circulation models and builds upon existing in-situ measurements and modelling programs funded by various state and federal agencies. This observing system fulfils all of the requirements of the Coastal Module of the Global Ocean Observing System (CMGOOS). Data and model products are disseminated in real-time to federal, state, and local emergency management officials via the internet (URL http://comps.marine.usf.edu).

JSP23/W/03-B2 1520

EARTHQUAKE PREDICTION AND EARTHQUAKE PREPAREDNESS: CURRENT POSSIBILITIES FOR THE PACIFIC RIM

Vladimir KOSSOBOKOV, Vladimir Keilis-Borok, (International Institute for Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, 79-2 Warshavskoye Shosse, Moscow 113556, Russia, E-mail: volodya@mitp.ru); John Healy (USGS, Menlo Park, CA 94025, USA, E-mail: jhhealy@aol.com); Donald Turcotte (Department of Geological Sciences Cornell University, Ithaca, NY 14853-1504, USA, E-mail: Turcotte@Geology.Cornell.edu)

The recent results of real-time testing in the Pacific Rim, 1992-1998, have established the high statistical significance of intermediate-term predictions of the largest earthquakes by algorithms M8 and MSc. Among predicted are all earthquakes of magnitude 8 or greater. Predictions are completely reproducible and use precursory activation of seismic static at different space and time ranges to reduce consecutively time and space where disastrous earthquake has to be expected. Although the predictions are of limited accuracy they do create a possibility to prevent part of the damage. This encourages a multi-scale approach to mitigate earthquake disaster. In general, earthquake predictions range from a zero-approximation of seismic zoning through long- and intermediate- to short-term ones. Accordingly, the preparedness measures range from building code, to simulation alarms and reinforcement of high-risk facilities, to the imminent "red alert" (e.g. evacuation of population and introduction of martial law). Different time from decades to seconds is required to undertake different measures; having different cost, they can be realistically maintained during different time periods and in the territories of different size. The key to damage reduction in the area of concern is escalation or de-escalation of preparedness measures depending on the current state of alert. That is the standard practice for mitigation of other major disasters, wars included. The interface between prediction and preparedness is delivered by the recent development of optimal strategies based on a trade-off between total volume of alert and rate of failures-to-predict. We demonstrate case histories of intermediate-term predictions that would have led to preventing a considerable part of losses by low-key safety measures.

JSP23/E/06-B2 1600

SANARIS PROJECT: A SATELLITE NETWORK FOR NATURAL RISKS MONITORING

Marta TARRAGA (Dept. Volcanologia, Museo Nacional de Ciencias Naturales, Jose Gutierrez Abascal 2, 28006 Madrid, Spain, email: mcnt184@mncn.csic.es); Alicia Garcia, Ramon Ortiz, Rafael Abella and Javier Peña (Dept. Volcanologia, Museo Nacional de Ciencias Naturales, Jose Gutierrez Abascal 2, 28006 Madrid, Spain, email: mcnp182@mncn.csic.es)

A new satellite communication system specifically designed for low-rate data applications has been developed and prototyped. A validation project is proposed to install a pilot network to be operated during 6 months. One of the target markets related to volcanoes has been selected, so a group of users is integrated in the project. A specific application for this market will be developed regarding data acquisition, processing, storage and dissemination to distant users. The feasibility of using the new satellite system to provide a new Eutelsat service for low-rate data applications will be evaluated from the pilot network performance. According to the Department of Volcanology (M.N.C.N.-C.S.I.C.) experience on the development of systems for volcano monitoring, its role in the project will be: -Co-ordinate the definition of users requirements for the pilot application. Installation of the digital seismic stations. –Maintenance of Teide and/or Timanfaya stations (Canary Islands).

JSP23/C/U5/E/06-B2 1620

EFFECTIVE EARTHQUAKE MONITORING PROCESS FOR EMERGENCY RESPONSE ON RESCUES (EMPEROR)

Yutaka NAKAMURA (System and Data Research Co. Ltd., SDR Bldg., 3-25-3 Fujimidai, Kunitachi-shi, Tokyo, 186-0003, JAPAN, E-mail: yutaka@sdr.co.jp)

It has been widely recognised that systematical and continuous monitoring of earthquakes is necessary for the early warning. In this presentation an effective earthquake monitoring process is proposed. DI, Damage Intensity of seismic motion, is defined as an inner product of acceleration vector and velocity vector at each time step dt. The multiplication of DI with mass received seismic motion, indicate the power of the motion act to the object. DI-value, defined as maximum of DI, is generally appeared after S-wave arrival. When P wave arrives, DI increases drastically, and after S wave arrival DI reaches to its maximum value, DI-value, soon. P wave Index, PI-value, is defined as maximum DI of P wave part. This value is suggested to be used for P wave alarm. DI-value is related with seismic intensity. DI-value has a very important practical advantage, since it can be calculated in real-time soon after the P wave arrives. Additionally, DI-value has a clear physical meaning and it is strongly related with the earthquake damage. This can be concluded as, with the continuous observation of DI, earthquake alarm can be issued efficiently and damage can be estimated precisely. According to combination of S wave and P wave alarms, early and/or reliable alarm is realised. P wave alarms can be issued when PI-value over the pre-set level, and S wave alarm can be issued when ordinary monitored values or DI-value exceed pre-set level. Combining PI, DI values together with K values is promising for the future early warning systems, since it has been clarified with both methods that it is possible to estimate the vulnerabilities of all ground and structures concerned and it is possible to issue the alarm before the real damage occurs.

HIGH RESOLUTION AEROMAGNETIC SURVEY FOR CONCEALED FAULTS IN THE FUKUI PLAIN, CENTRAL JAPAN

Shigeo OKUMA, Masahiko Makino and Tadashi Nakatsuka (Geological Survey of Japan, 1-1-3 Higashi, Tsukuba, Ibaraki, 305-8567 Japan, email: okuma@gsj.go.jp)

Geological Survey of Japan (GSJ) has conducted a helicopter-borne high-resolution aeromagnetic survey in the Fukui Plain, Central Japan, to better understand concealed faults associated with the 1948 Fukui Earthquake (June 28, 1948, M=7.3) which brought disastrous damages to this area. The survey was flown along east-west flight lines at an altitude of 150 m above terrain and spaced 300 m apart with a Cesium Vapour magnetometer with a sensitivity of 0.01 nT at a sampling interval of 0.1 second and a differential GPS system. The compiled total intensity map of IGRF residuals shows interesting magnetic features as follows: 1) A broad magnetic high area occupies the western half of the plain with a sharp NNW-SSE trending boundary to the east, which corresponds well to the assumed location of the concealed Fukui Earthquake fault. 2) Three distinctive dipole magnetic anomalies lie in the magnetic high area, two of which lie at the northern edge of the area, implying the existence of intrusions associated with the Awara Hot Spring. 3) Magnetic lows are dominant along the coast line of the Sea of Japan and in its offshore areas, suggesting the existence of reversely magnetised volcanic rocks which lie offshore and maybe outcrop along the coast line.

JSP23/E/27-B2 1700

LAND SUBSIDENCE OF JAKARTA (INDONESIA) AND ITS GEODETIC-BASED MONITORING SYSTEM

Hasanuddin Z. ABIDIN , I. Meilano, M. A. Kusuma , J. Kahar (Department of Geodetic Engineering, Institute of Technology Bandung, Jl. Ganesha 10, Bandung, Indonesia, email: hzabidin@indo.net.id and hzabidin@gd.itb.ac.id); Rochman Djaja (National Coordinating Agency for Survey and Mapping, Cibinong, Bogor, Indonesia); Samsul Hadi (Jakarta Provincial Agency of Surveying and Mapping, Jakarta, Indonesia)

Jakarta is the capital city of Indonesia with population of about 12 million peoples, inhabiting the area of about 25-km by 25-km. It has been reported for quite sometimes that several places in Jakarta are subsiding at different rates from place to place. Up to the present times, however, there has been no definitive, detail, and comprehensive information about the characteristics and pattern of land subsidence in Jakarta areas. Usually the land subsidence in several places of Jakarta is estimated using their geological parameters or inferred from the ground water level observations. In order to give a better picture about these land subsidence phenomena in Jakarta, the geodetic-based land subsidence monitoring system has been implemented. The system is based on GPS and levelling measurements.
In this paper the land subsidence study in the city of Jakarta using repeated GPS and levelling surveys will be described and discussed. The land subsidence characteristics of Jakarta and its surrounding area are investigated using the data from three repeated GPS surveys conducted in 1994, 1997, and 1998 and four repeated levelling surveys performed in 1982, 1991, 1993, and 1997. The main goal of this land subsidence study is to understand the characteristics of land subsidence in Jakarta area and their generating forces and factors. Therefore, in this paper, the geological, geophysical, and hydrological aspects of Jakarta area would also be investigated and correlated with the geometrical changes information obtained from geodetic based systems. The paper would be sum up with some closing remarks.

JSP23/W/38-B2 1720

INTERNATIONAL TECTONIC REAL TIME RADON OBSERVATION AND TRANSMISSION - RELIMINARY RESULTS OF GEODYNAMIC MONITORING

G.SOBOLEV (United Institute of Physics of the Earth, RAS, Moscow, Russia,
email: sobolev@uipe-ras.scgis.ru); S.Balassanian (National Survey for Seismic Protection, Yerevan, Armenia, email: presidnt@nssp.yerphi.am); A.Belayev (Vernadsky Institute of geochemistry and analytical chemistry, RAS, Moscow, email: abelyaev@chat.ru); S.Bushati (Center of Geophysical and Geochemical Exploration, Tirana, Albania, email: bushati@cgge.tirana.al); E.Lagios (Department of Geophysics and Geothermy, National & Kapodistrian University of Athens, Athens, Greece, email: elagios@atlas.uoa.gr); R.A.Nicholson (British Geological Survey, Keyworth, Nottinghamshire, NG125GG, United Kingdom, email: RAN@wpo.nerc.ac.uk); A.Ponomarev (United Institute of Physics of the Earth, Moscow, email: avp@uipe-ras.scgis.ru); A.Pronin (Geological-technological Scientific Inductional Enterprise "Geotechvims", Naro-Fominsk, Russia); G.Sideris, F.Zervos (GeoMentor, European Economic Interest Grouping, Athens, Greece, email: geomen@otenet.gr).

Seismic activity is a potential threat to populations and commerce throughout the world. Geophysical-geological research institutes and commercial companies in Greece, France and the UK are collaborating with similar organisations from Russia, Armenia and Albania, under the EU-funded Inco-Copernicus (Framework IV) programme, to develop new techniques for the automatic acquisition of gas geochemical data from remote sites using gas-sensing probes and telemetry. The data are being integrated with seismic information acquired in parallel, and used to determine whether or not the technique is a suitable method for monitoring ground disturbance associated with tectonic events.A number of data loggers (transducers/detectors) have already been installed since 1998 at specific locations (base stations) selected by the Project scientists in Caucasus (Southern Russia and Armenia), Greece, Albania and Scotland (UK). The seismic and gas-hydrogeochemical maps as the results of geophysical prospecting were used to select eligible sites for radon monitoring. Each base station includes two data loggers with the latest version of the Barasol MC radon probe incorporating sensors for barometric pressure and temperature combined with local rainfall measurements. These parameters are being transferred to attached cordless modems and are transmitted via INMARSAT global satellite communication system to Greece (Project co-ordinator) where all data are collected for joint processing. Signal processing software has been developed on the base of standard and original approaches. The spectral composition and structure parameters of obtained time series are determined by applying descriptive statistics, causal analysis and methods of the dynamic theory systems. The first stage realisation of Project indicates that telemetry systems are operating satisfactorily and the data are collecting, but that longer-term monitoring is necessary to link seismic measurements to radon exhalations and consider mentioned data acquisition-broadcasting system as real warning system.

JSP23/C/U3/W/21-B2 **1740**

DEVELOPMENT OF SEISMIC RAPID REPORTING AND EARLY WARNING SYSTEM IN TAIWAN

Yih-Min WU, Jen-Kuang Chung, Tzay-Chyn Shin (Central Weather Bureau, 64 Kung Yuan Road, Taipei, Taiwan, email: ludan@ss2.cwb.gov.tw); Yi- Ben Tsai (Institute of Geophysics, National Central University, Chung-li, Taiwan); William H.K. Lee (862 Richardson Court, Palo Alto, CA 94303, USA)

In 1994, two prototype seismic early warning systems have been implemented in Taiwan: (1) a rapid reporting system using a tele-metered network of digital accelerographs spread over the entire island, and (2) an alert system exploring the use of modern technology for the highly seismic area of Hualien. After four-years operation, the rapid reporting system was successfully operated in the seismic monitoring system of the Central Weather Bureau (CWB) for felt earthquake observation (Taiwan Rapid Earthquake Information Release System, TREIRS). It has achieved in the determined of precise earthquake location and magnitude computation about in one minute after the earthquake origin times. On the other hand, the Hualien alert system was phased out in 1998 due to large uncertainty of source parameters determination caused by small station coverage and only using P signal in determining the magnitude. Although it performed a very well reporting time (less than 10s after the earthquake origin time). Recently, the Hualien alert system stations were equipped with the digital accelerograph and combined to the TREIRS system. By adding the Hualien alert system stations to the TREIRS system, we have obtained a good precision for source parameter determination and a well reporting time for Hualien area earthquake monitoring. During the experiment in the past several years, we benefited from these two prototype seismic early warning systems and optimised the TREIRS system. We are encouraged forwards in the development of seismic early warning system based on the successful experience

HAZARD AND RISK ASSESSMENT, RISK MITIGATION AND MANAGEMENT

JSP23/W/30-A5 Poster **0830-01**

MISLEADING SIGNALS IN HAZARD CATALOGS

Allen M. HITTELMAN (NOAA's National Geophysical Data Center (NGDC), World Data Center-A (WDC-A for Solid Earth Geophysics, 325 Broadway, Boulder, CO 80303, U. S. A.,
email: ahittelman@ngdc.noaa.gov); Lowell S. Whiteside and James F. Lander (Co-operative Institute of Research in Environmental Sciences, NOAA, 325 Broadway, Boulder, CO 80303, U. S. A.,
email: lws@ngdc.noaa.gov)

The primary purpose of natural hazard data catalogs is in the mitigation of future disasters. It is hoped that future natural disasters can be anticipated and populations warned if long term catalogs, which record the regional periodicity of events, are available. While such long-term variations in hazard are possible, we show that many current catalogs of natural hazard data may not be satisfactory to determine whether they actually occur.
Most hazard catalogs cover periods of less than 200 years and are reasonably complete and accurate for only the past 20-50 years. Such catalogs are not sufficient to investigate long term hazard variations. Earthquake, tsunami and volcanic catalogs, acquired and integrated at NGDC, illustrate artificial long-term variations created by cultural and scientific reporting changes, which can introduce unanticipated cyclical variations in the catalogs. These inconsistencies are often related to changes in the way magnitudes are calculated, evolving network equipment, network discontinuities of operation and personnel.

JSP23/W/35-A5 Poster **0830-02**

DISASTERS CAUSED BY CATASTROPHIC STORMS AND THEIR PREVENTION IN SMALL CATCHMENTS IN THE QIN MOUNTAINS

Guozhang FENG (College of Water Resources and Architectural Engineering, Northwestern Agricultural University, Yangling, Shaanxi, 712100, China, e-mail: gfeng@public.xa.sn.cn)

Catastrophic storms often cause flash floods and corresponding geophysical hazards in the Qin Mountains in Shaanxi Province, China. The disasters are difficult to be prevented due to their rare occurrence, extremely high severity, non-predictability and too short warning time. The 980709 storm, occurred in a small area in the southeast of the Qin Mountains on 9 July 1998, is the maximum storm event in the records in the region and has an investigated maximum point storm rainfall of approximately 2122 mm during 6 hours and 40 minuets at one of two storm centers, and 1511 mm during 11 hours and 30 minutes at another center. The areas involved inside the isohyets of 1500 mm, 1000 mm, 500 mm and 50 mm's storm rain, are 31.4 km2, 45.5 km2, 86.8 km2 and 847.1 km2, respectively. The storm formed enormous flash floods, landslides, mud-rock flows and aggradation of the riverbeds. As a combined consequence of the storm related disasters, 82 people and over 2000 thousands livestock were lost, over one hundred families were homeless, and most of the farmlands with growing crops were destroyed in the disaster involved two small catchments, especially in their densely populated valleys. Similar disasters with relatively lower severity frequently occur in the Qin Mountains even during the periods of general storms.
Reconstruction and protection of the areas both under and facing the damages are considerably important. Based on the natural and sco-economic features in the damaged and relevant areas, some integrated reconstruction and protection strategies for mitigation of the disasters and sustainable development of the region as an optimal eco-sco-economic system are proposed. The strategies consist of appropriate flood control standards, optimal land uses, reasonable economic structures, and safe residences and environments, in which some detail measures of engineering and non-engineering are involved. The strategies may be suitable to the similar catchments in the Qin Mountains.

JSP23/W/08-A5 Poster **0830-03**

VOLCANIC HAZARD ASSESSMENT FOR A PROPOSED HIGH-LEVEL RADIOACTIVE WASTE REPOSITORY AT YUCCA MOUNTAIN, NEVADA, USA

Charles CONNOR and Brittan Hill (CNWRA, Southwest Research Inst., 6220 Culebra Rd, San Antonio, Tx, 78238, USA, e-mail: cconnor@swri.org); Andrew Woods and Steve Sparks (Centre for Geophysical and Environmental Flows, University of Bristol, Bristol, UK,
e-mail: a.w.woods@bristol.ac.uk)

The proposed high-level radioactive waste repository at Yucca Mountain, Nevada, USA, is located within a geologically active basaltic volcanic field. Probabilistic volcanic hazard models for future eruptions through the proposed repository depend heavily on spatial controls on basaltic volcanism, including: Pliocene-Quaternary vent clustering, development of volcanic vent alignments, and localisation of vents along normal faults. When these spatial controls on past volcanism are considered, the probability of volcanic eruptions through the repository is estimated to be 10^(-7) to 10^(-8) annually, or 1:1000 during the 10,000 yr performance period for the repository. This estimate is greater than some previous estimates that do not consider structural controls on basaltic volcanism explicitly, primarily because of the location of the proposed repository within a broad density low produced by a half-graben. Modification of spatial hazard models to include this structure, which appears to have controlled past volcanism, provides a mechanism to link patterns in basaltic volcanic activity and crustal extension in a quantitative hazard assessment for the first time. This technique may be widely applicable to assessment of volcanic hazards resulting from small-volume basaltic volcanic fields.

A SEISMIC HYDRAULIC BEARING

Federico BARTOLOZZI (Civil Engineering an Independent Researcher, via dei carracci 4, 21100 varese, Italy, email: ciuciuzza:iol.it)

The proposed bearing consists of two parts. The fixed part, connected to the building is a steel sliding surface in the shape of a spherical bowl with a safety side spandrel. The movable part, connected to the foundation-soil complex, consists of a movable steel ball (rolling friction) in direct contact with the overhanging spherical bowl; alternatively, the ball may be fixed and coated on the top with Teflon (sliding friction). The lower part of the ball is linked to a movable cylindrical piston housed in the central chamber of a hydraulic device, also having two lateral symmetrical chambers with movable pistons, subjected to the elastic reactions of pre-stressed springs. Two holes connect the lateral chambers with the central one. During an earthquake, the horizontal displacement of the foundation-soil complex slightly affects the rest state of the building and the corresponding seismic energy in the building is negligible. The vertical displacement of the foundation-soil complex does not notably alter the rest state of the building, where there is no danger of resonance occurring due to the damping action of the liquid contained in the hydraulic device. The main advantages of the seismic insulation system, characterised by this type of bearing, are: 1. self-catering of the building after an earthquake; 2. possibility of application to modern and old buildings with any planimetric shape; 3. negligible pendulous effet in the building; 4. economical competitiveness with the existing aseismic systems both with partial and total absorption of seismic energy; 5. negligible psycho-physical effects for the inhabitants.

JSP23/P/04-A5 Poster **0830-05**

SELF-CENTERING ASEISMIC SYSTEM WITH ELASTIC BEARINGS AND HYDRAULIC DAMPERS

Federico BARTOLOZZI (Civil Engineer and Independent Researcher, via dei Carracci 4, Varese, Italy, email: ciuciuzza@iol.it)

The theoretical and experimental analyses emphasise the following characteristics of the proposed system: 1. the self-centring of the building after an earthquake; 2. the undulatory seismic energy in the building is constant and about 1% of the weight, by using bearing with sliding friction (pure Teflon). It is negligible, by using bearings with rolling friction (steel balls). In addition, it is independent on the seismic frequency and the soil displacement; 3. the vertical seismic energy in the building is minor and it increases both with the increase of the ratio between the frequencies (phase opposition) and with its decrease (phase); 4. the building remains almost motionless (negligible displacement) with respect to the horizontal translation of the foundation-soil complex for all values of the direction angle of the motion, of the soil displacement and acceleration; 5. in the interval of emergency vertical seismic frequencies, including the resonance frequency, the automatic starting of the dampers occurs. They progressively decrease the dynamic strain of the springs, which are integral parts of the bearings; 6. because of the sub-undulatory shock, the total load on the bearings increases for upward soil displacements and it decreases in the contrary case, both in phase and in phase opposition conditions; 7. the experimental tests, executed with reference to th undualtory shock, confirm the theoretical results.

A PROPOSAL FOR COASTAL SAFEGUARDS

MARABINI

Abstract not available at the time of going to press

JSP23/W/37-A5 Poster **0830-07**

ABOUT THE ENSO IMPACTS IN NORTH-EASTERN ARGENTINE

Norberto O. GARCIA and Maria del Valle Venencio (Facultad de Ingenieria y Cs. Hidricas - Univ. Nac. del Litoral, CC 495 - (3000), Santa Fe, Argentina. E-mail: nogarcia@ fich.unl.edu.ar)

Frequently the North-eastern Argentine Republic is affected by floods on the riversides of the Paraná river, originated in the precipitation on the High Basin, and/or floods caused by the local rainfalls. With the same recurrence characteristic, drought situations take place that also affects the region, going from an extreme to the other in a short time generating emergencies totally different, but equally serious.
The present work makes an analysis of the extreme situations of the Paraná River associating them with the development of the sea surface temperatures on the Pacific Equatorial Ocean (EL NIÑO, LA NIÑA and neutral years). In this sense was found, as it was hoped, that most of the EL NIÑO events were associated with extraordinary floods of the Paraná river; although there were some floods that they were associated with the neutral phase (1959). The phase LA NIÑA (cold events) not always was associated with notable low waters of the river.
The behaviour of the precipitations over the region was non-homogeneous, and not always coincident with what it was hoped from a statistical point of view (Ej. 1983). The situation of EL NIÑO 1997/98 was permanently scanned and climatologically predicted through several models. So much in the river such as in the region the forecasts were completed acceptably. While, the socio-economic impact of the extreme events was very graphically shown in the means of communication.

ESTIMATION OF SEISMIC INTENSITY ATTENUATION LAWS FOR BANAT REGION

AURELIAN PANTEA and Iren-Adelina Moldovan Ivan (National Institute for Earth Physics, P.O. Box MG-2, Bucharest-Magurele, Romania, e-mail: pantea@infp.ifa.ro and iren@infp.ifa.ro)

An attenuation relationship for macroseismic intensities for Banat (Romania) crustal earthquakes has been developed. We have used a data base including macroseismic maps from 21 earthquakes occurred during the period 1900 to present with MGR>4.0. The general form of the attenuation relation used is: log (I)=f1(M)+f2(r,E)+f3(r,M,E)+f4(F)+e (where: I is the

macroseismic intensity, M is the earthquake magnitude, r is the hypocentral distance, E is the tectonic environment, f4(F) is a function of fault type and "e" is a random variable representing the uncertainty in log(I). Comparison with other attenuation relationships have been made.

TROPICAL CYCLONE RISK ASSESSMENT

M.V.RODKIN (Geophysical Center, Russ. Ac. Sci., 117296 Moscow, Molodezhnaya 3, email: rodkin@wdcb.rssi.ru); G.S.Golitsyn (Inst. of Physics of Atmosphere, Russ. Ac. Sci., Moscow); V.F.Pisarenko (Intern. Inst. of Earthquake Prediction Theory and Math. Geophysics, Russ. Ac. Sci., Moscow); M.I.Yaroshevich (NPO Taifun, Rosgidromet, Obninsk, Russia)

A method of statistical estimation of tropical cyclone hazard is suggested. Probabilities of exceeding of certain levels of wind velocity (quantiles of distribution function) at a given area for given time intervals T are evaluated. The evaluation is based on the following velocity/distance relation: V(R)=Vmax*(Rmax/R)**2, where Rmax is the radius of central part of tropical cyclone where maximum of wind velocity Vmax at given moment is observed. Accuracy of this relation is estimated by an error with standard deviation 7 knots. Suggested method is applied to typhoons in the Western Pacific, 1950-1988. The used catalog contains 1013 events. The 50%-quantiles (medians) and 90%- and 95%-quantiles of maximum possible wind velocity for time intervals T=1, 2, 5, 10 and 20 years at 4 areas were evaluated: Tokyo, Hong-Kong, Taiwan Isl., and Vladivostok. Problem of possible temporal change in the typhoons regime is discussed in connection with the solar activity and El-Nino regime. The suggested typhons risk assessment method can be useful for insurance industry and administration in areas subjected to tropical cyclones.

LARGE SCALE DESTRUCTIONS OF BUILDINGS, THEIR CONNECTION WITH GROUNDS SPECTRAL PECULIARITIES DURING THE SPITAK EARTHQUAKE OF 12.07.1988 IN LENINAKAN (NOW GIUMRY), ARMENIA

Hrachya ABRAHAMYAN (Institute of Geophysics & Engineering Seismology, NAS RA, Leningradian 5, Gyumri, 377515 Armenia, email: iges@shirak.am)

Severely consequences of Spitak catastrophic earthquake force us to carry out the investigations revealing the causes of much more in quantity destructions. The most interesting aspect of testing the possibility of microvibrations using for prediction the grounds frequency characteristics is the comparision of buildings destructions measure by the grounds frequency elective property giving through the microvibrations. During the earthquake of December 7, 1988 with M=7.0 the full destruction of frame-panel 9-storey buildings (from 138 buildings in Leninakan were undamaged only 6) and frame-stone 5-storey buildings (from 335 buildings were undamaged 87) was observed.
Registrations of buildings natural oscillations before the earthquake and grounds dominant periods by microvibrations after the earthquake showed that statistically the largest amount of destructions were obtained on the parts of town where the grounds natural dominant periods T were approximately of 0.5-0.6 sec for five-storey frame-stone buildings. On the grounds with T=0.2-0.38 for nine-storey buildings and T=0.2-0.3 for five-storey buildings damages were been of least amounts. Natural periods of nine-storey buildings are of 0.5-0.6 and of five-storey buildings are of 0.25-0.4. The high damages may be explained by strong influence of oscillations due to resonance phenomenon when the ground natural dominant periods tally with the buildings natural periods.
In seismic microzonation of region the possible spectrum of disastrous earthquake must be assessed. By this assessment only the grounds frequency peculiarities may be compared with buildings frequency characteristics. Such a complex approach only enables us to solve correctly the task of connection of possible damages by grounds frequency characteristics. Neglect of this factor will bring to tragic consequences such that were been in Leninakan.

MINERAL PATHOGENIC DEPOSITS INTO A HUMAN ORGANISM AS A SIGN OF NATURAL HAZARDS

Nadezhda PAL`CHIK (United Institute of Geology, Geophysics and Mineralogy of Siberian Branch of RAS, Koptjug prosp. 3, Novosibirsk 630090, Russia; email: nadezhda@uiggm.nsc.ru)

It is known that minerals exist not only into the Earth's crust but also into all human organisms. The physiogenic minerals contained into tooths and bones (as an apatite) are discovered also into pathogenic formations which can be found into different organs and tissues of a human body. We show, using the X-ray diffraction and the infra-red spectroscopy methods, that the apatite is present into urinary calculi, gallstones, dental stones, salivary calculi and also calcified cardiac valves as only phase of a mineral formation. Observations show that the full pathogenic mineralization of all living tissues of an organism occurs in some cases. Such peculiar natural hazard and its geographical distribution require a special attention and further investigation.

ASSESSMENT OF LANDSLIDE HAZARDS USING GEOPHYSICAL TOMOGRAPHIES

Simeon KOSTYANEV, Petar Srefanov and Peshka Stoeva (University of Mining & Geology, Sofia-1100, Bulgaria, e-mail: skost@staff.mgu.bg)

Landslides and unstable slopes are among the major natural and man-made hazards affecting mankind and yet their causes, their consequences for human life and property, and possible strategies for mitigating their effect are not very well understood. We will note, that only in Bulgaria there are over thousand active landslides on populated and health resort areas. The material and social losses have not been calculated yet. But in preliminary data they are enormous. Numerous and dangerous are the landslides and unstable slopes in open-cast coal-mines too.
In this paper we offer methods for combined application of high-resolution electrical tomography and seismic ray tomography for characteristic of landslide hazards and unstable ones. The major aim here is to predict where and when landsliding will occur, establishing their variability in space and time, and appraising their impact on the natural and socio-economical environment.
The above methods are applied for the studying of concrete landslide in Bulgarian Black sea coast and on some unstable slopes in an open-cast coal-mine of Maritza-Iztok area. This combined application of electrical and seismic tomography for assessment of landslide hazard is very useful.

SEISMICITY AND SEISMIC HAZARD STUDIES IN EGYPT AND SURROUNDING COUNTRIES

Samir RISAD (Geology Department, Assiut University, Egypt), Mahmoud Ghaleb (Geophysics Department, Cairo University, Egypt)

The tectonic setting of the Eastern Mediterranean Region is complicated because of the interacting effect of the principal plates: Africa, Eurasia and Arabia. The highest level of activity occurs at the northern margin of the Arabian plate, where it collides with Turkey and Iran. Strong earthquakes also occur along the western edge of the plate, along the Sea rift and the axis of the Red Sea Gulf of Aden. Egypt has a historical record of earthquake activity extending over the past 4,800 years. The most devastating earthquake in the recent history of Egypt, Dahshour earthquake, occurred some kilometers south of Cairo on the 12th of October 1992 damaged over 1,000 schools and other buildings, ed and injured over 7,000 people. In addition, other significant earthquakes occurred during this century interrupting the socio-economic development process of Egypt. Vulnerability to earthquakes increases steadily as urbanisation and development occupy more areas that are prone to the effects of significant earthquakes. The uncontrolled growth of cities in such areas are often associated with the construction of seismically unsafe buildings and infrastructures, mostly due to the insufficient knowledge of existing seismic hazard. Moderate and even small earthquakes may turn catastrophic in highly populated areas with poor building construction practice. In addition to the direct socio-economic impact of an earthquake, the long-term effects (the disruption of the economic chain, human resettlement, the reconstruction to modern standards) may last decades and absorb a considerable part of the national budget. In the absence of strong motion records a possible alternate method for seismic risk evaluation is the study of the attenuation of intensity with distance. For this purpose isoseismal maps for 17 historical and instrumental earthquakes that occurred in different parts of Egypt were analysed. Relations for intensity attenuation in different direction for different regions were obtained and have been used to calculate maximum intensity values all over Egypt. In addition, peak ground acceleration maps were produced for exposure time 10, 25, 50, 100 and 250 years, making use of an updated earthquake catalogue for Egypt. More than 20 seismogenic zones in and around Egypt were involved in the calculations. Hazard studies in Egypt have been carried within the framework of the regional IGCP Project 382, entitled "Seismotectonics and Seismic Hazard Assessment in the Mediterranean Basin (SESAME)", and in co-ordination with the activities of RELEMR Project. The results on Egypt were integrated with other available data for the surrounding countries.

JSP23/E/55-A5 Poster **0830-16**

DIRECT AND INDIRECT LOSSES DUE TO EARTHQUAKES

KOFF G.L (1), Lobatskaya R.M. (2), Frolova N.I. (3). (1) Institute of Lithosphere, Russian Academy of Sciences, Moscow, Russia, (2) Irkutsk University, Irkutsk, Russia, (3) Seismological Center of IGE, Russian Academy of Sciences, Moscow, Russia

The stability of urban area development is strongly depended on the hazardous natural processes. In order to secure the stable development of the territory the expected losses due to future events should be estimated. Direct and indirect economic losses are distinguished. We understood direct economic losses due to natural processes as losses in economy within the current reproductive cycle which are expressed in terms of annual indexes of social economic development. All other losses are referred to indirect ones. They do not influence directly on the achieved results in the economy in the current year. The indirect losses is an estimation of negative consequences resulted from secondary effects. In contradiction to direct losses, indirect ones may arise and manifest within the long time interval. The indirect losses may not have a definite place in space and are usually characterised by cascade effects. Four main groups of factors, which influence upon direct and indirect economic losses due to earthquakes and other natural processes are distinguished; they are the following: origination, susceptibility, cycles and state. Different factors and their influence on losses due to earthquakes are analyzed. For different urban areas it is possible to construct in advance the index system which will allow to estimate the value of mentioned factors. Than it is possible to identify zones according to the weights of different factors which may be used in order to improve prevention, mitigation and response from future events. The system analysis of existing connections of urban areas with other regions will allow to estimate the rate of possible instability of the territory in the case of emergency and to obtain more reliable estimations of acceptable level of economic and ecological risks.

RECENT ANOMALOUS GEODYNAMICS OF PLATFORM FAULTS AS THE NEW ECOLOGICAL RISK FACTOR

CHURIKOV V.A., Kuzmin Yu.O. (both at United Institute of Physics of the Earth, Recent Geodynamic Lab., B. Gruzinskaya Str. 10, Moscow, Russia, email: vt.churik@relcom.ru)

New data on the existence of recent superintensive deformations (SD) of the ground surface are obtained for fault zones in aseismic regions (Russian platform, Pripyatskaya depression (Belorussia), Turanskaya platform (Turkmenistan) and etc.).
These deformations have amplitude approximately 20 - 50 ppm, extension 0.1-1.0 km, velocity of vertical and horizontal displacements up to 5 - 7 cm per year. They have a pulsating character (the duration of the impulses of the activity of 0.5 - 1.5 year). These anomalous deformations call into existence the ecological risk of two types. 1. Direct - by the plums of anomalous fluids during the periods of activating fault zones; 2. Indirect - by the casualties of ecologically dangerous objects (wells on oil field and gas deposits, pipelines, underground depots of gases and toxic wastes, atomic power stations and etc.). The mechanism of SD-processes is suggested based on the parametrical excitation (the induction) of anomalous deformations in fault zones. In this case, the induction is evoked by small disturbances with nature and technogenic origins.

DISASTER MITIGATION PROGRAMMES FOR EARTHQUAKES, CYCLONES, DROUGHTS AND LANDSLIDES

H.N. SRIVASTAVA (India Meteorological Department, New Delhi-110003, India, email: snb.imd.ernet.in)

Peninsular India earthquake of September 1993 (Latur, Magnitude 6.3) which caused the death of about 10,000 persons and major damage to stone built mud houses led to the development of a World Bank aided project for relief and rehabilitation work besides reconstruction of cheaper but safe dwellings in the area. Under this project, broad band digital seismographs (GSN) were installed in India to improve earthquake risk assessment.
Issue of warnings about the land fall of tropical cyclones through INSAT based disaster warning system have helped in saving the lives of people living in coastal areas of peninsular India. Improvement of the rainfall measurements through another World Bank Project for the peninsular India will enable us to study agricultural droughts with greater reliability.
Recent landslides and floods in Garhwal and Kumaon regions during May, 1998 in Himalaya which have taken a heavy toll of life and property during August, 1998 have focussed the need for a coordinated approach for landslide zonation integrating seismological, meteorological, remote sensing and other observations.

TOWER OF PISA: STABILITY RESTORATION PROPOSAL TO SAFEGUARD AGAINST SEISMIC RISK

Federico BARTOLOZZI (Civil Engineer and Independent Researcher, via dei Carracci 4, 21100 Varese, Italy, email: ciuciuzza@iol.it)

The proposed technique includes the solution of two problems. The former immediately provides to the removal of the instability due to the rotation in the north-south direction. The second problem consists in preserving the stability against the occurrence of two different phenomena: 1. the restarting of the instability, caused by a possible uneven subsidence of the foundation soil; 2. the instability consequent to an earthquake. Both phenomena could be avoided with the following complex operations: 1. planning and laying of a sub-foundation with geometrical and structural characteristics which ensure the stability of the foundation soil; 2. operation for preserving or decreasing the present inclination and, even, operation for conferring the perfect verticality, as well as, if wanted, the counter-inclination; 3. interruption of the solidarity between the building and the sub-foundation-soil complex, by using multidirectional movable bearings with low sliding or rolling friction, with or without dissipators of sub-undulatory seismic energy and laying laterally or rigid connections with alternative function of elastic linkages. This technique has two important advantages: 1. possibility to remove a future rotation of the Tower, due to an eventual subsidence of the soil; 2. easy maintenance of the sub-foundation structural elements, of the movable bearings and the side connections. The technique permits the removal only of the present instability, disregarding the seismic risk. In this case it is evidently less complicated and expensive. In addition, all operations for preserving or decreasing the present inclination and, even, for conferring the verticality and the counter-inclination are possible.

SEISMIC RISK MAPS AND SCENARIOS: TOOLS FOR PROTECTION AGAINST EARTHQUAKES

JSP23/C/U5/E/09-A6 Poster **0830-01**

THE PREDICTABILITY OF EARTHQUAKE: TWO RECENT CASES IN YUNNAN, CHINA

Lin RONGHUI (Seismological Bureau of Yunnan Province, Kunming 650041, CHINA); Tel: 86-871-3312339 Fax: 86-871-3315049 E-mail: ydj@public.km.yn.cn

China is one of few countries, which have the stipulation for issuing earthquake prediction and put it in practice. In the past three decades, the Chinese scientists did predict a few events of a certain type and with obvious characteristics. Though on a largely empirical basis such experience is a wealth, as the standpoint of practice should be first and fundamental in the theory of knowledge. The Menglian M7.3 earthquake occurred in the Sino-Burmese border (21¡ã59¡äN; 99¡ã04¡äE) at 05:46¡ä41.2¡åon July 12, 1995. Predictions of the intermediate-term(>1 year), short-term(3 months) and immediate-term (1 day before the mainshock) were made by analyzing in detail the observed seismic and precursory anomalies. The outcome of the prediction effort was only really significant when the immediate-term prediction was made at site just one day ahead of time. The Lijiang M7.0 earthquake occurred in 27¡ã18¡äN; 100¡ã13¡äE at 19:14¡ä18.1¡åon Feb. 3 1996. The observed precursory signals laid bases for making the intermediate- and short-term predictions. Yet, at the time of impending stage, a failure was made to locate the event, due to the superposition of post-precursors caused by Wuding earthquake (M=6.5) which occurred in central Yunnan in later October 1995.

JSP23/C/U5/E/07-A6 Poster **0830-02**

CHARACTERISTIC PRECURSORS OF THE 1996 LIJIANG, YUNNAN, EARTHQUAKE (M=7.0)

Lin RONGHUI (Seismological Bureau of Yunnan Province, Kunming 650041, CHINA); Tel: 86-871-3312339 Fax: 86-871-3315049 E-mail: ydj@public.km.yn.cn

The Lijiang M7.0 earthquake occurred in Yunnan (27¡ã18¡äN;100¡ã13¡äE) at 19:14¡ä18.1¡åon Feb. 3, 1996. Before the event, precursory anomalies in the regional seismicity pattern were characterized as the absence of moderate-strong and small events around the source area. Since 1925, an average interval between M¡_6.0 events was 6.4 years in the Lijiang area, northwest Yunnan, with the longest lasting 15 years. The latest Yanyuang M6.7 and Ninglang M6.4 events in the area occurred in 1976, surpassing the longest interval. Along the northern segment of the Zhongdian-Dali seismic belt M¡_5.0 events were absent form 1983 to 1993, forming a gap of 150 km long. From 1990 to 1995, small events of M¡_3.5 were also absent in the source area (¡÷¡Ü60km). Activity of small events began to increase in the Yhongsheng earthquake window (¡÷=77km) in Dec.1995 and Jan.1996. Around the Eryuan area (¡÷=122km), a foreshock swarm with the maximam magnitude 3.6 occurred on Dec.10, 1995. In addition, in the short and impending stage from Dec.1995 to Jan, 1996, 6 items of abnormal precursors were observed at 7 stations, namely the water level at Jianshui; water temperature at Liuku, Gangyuan, and Lincang; tilt at shiping; water quality (ion of HCO3-1) at Longling; and short leveling and short base line at Yongsheng. Besides, anomalous variations were also obtained from a synthetic analysis of precursory network data in the Lijiang area (which is consisted of 17 deep wells, 20 Radon points, 6 mercury points and 28 hot springs), and from the mobile gravity measurements in the networks of Western Yunnan Test Site before the event. Together with the seismic anomalies, all laid bases for making the intermediate (1-3 years)-, medium-short (1 year)- and short-term (months) predictions. Yet, at the time of impending stage, a failure was made to locate the event, due to the superposition of post-precursors caused by Wuding earthquake (M=6.5) which took place in later Oct. 1995.

RECENT CRUSTAL MOVEMENTS AND SEISMIC ACTIVITY STUDIES IN THE ASWAN REGION, EGYPT

Abdel Monem S. MOHAMED (National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt, email: mooonm98@yahoo.com)

Aswan region is one of the most important regions in Egypt and because it encompasses the vital engineering structure of the High Dam, it has been selected as a pilot project for the present study. Such a chose has been motivated by the fact that both geodetic and seismic data needed for the current investigation have been collected and become available from the Aswan region. So, the main objectives of the current research is to unify the results of the crustal movements and seismic studies which have been made in the Aswan region. This has been done for reaching the best understanding about the geodynamics of the area through investigating the relation between the crustal movements, seismic activity and earthquake occurrence and also for detecting the precursory events associated with earthquake occurrence. For the purpose of monitoring earthquake activity continuously around the Aswan Lake, a radio-telemetry network of 13 seismic stations was established. For monitoring the recent crustal movements several local geodetic networks were established around active faults in the area. Regional geodetic network covering the whole area of the northern part of Aswan Lake was established.
These studies use the seismicity recorded by the Aswan network from December 1981 to December 1997 and analyses different aspects of the data. Geodetic data were collected from local and regional geodetic networks. These studies were initiated to obtain an improved understanding of the seismotectonies in the Aswan region because this information is of importance in assessing the seismic risk.

SEISMICITY OF IRANIAN PLATEAU AND ITS BORDERING REGIONS

Arezou DOROSTIAN (Department of Geophysics, Azad University, North Tehran Branch); M. R. Gheitanchi (Institute of Geophysics, Tehran University, email: mrghchee@chamran.ut.ac.ir)

During the 20th century, from Jan.1, 1900 to Dec.30, 1998,nearly 5100 earthquakes of magnitude 4 And above occurred in the region of 20-40 N and 40-75 E. The area lies Along the Alpine-Himalayan belt and surrounded by active seismic faults. This study shows a general aspect of seismicity of different parts of Iranian plateau and bordering regions. Historical and Instrumental data have been collected from several different sources. In order to minimize the uncertainty in magnitude estimation we present a uniform magnitude scale for the calculation of earthquakes. Seismicity maps for periods of time before 1965 and after that in five-year intervals were constructed. Seismic activity in some areas has changed with time. Within major seismic zones, large earthquakes fill gaps in the seismicity pattern. A grid interval of 0.5-degree in Lat. and Lon. covered the whole area. The seismic energy and strain release in each quadrangle were computed for each interval up to 29 years from 1970 to 1999. Maps of tectonic flux and two and three dimensional energy maps were constructed to define the distribution of seismic zones in the area and to give a dynamic measure of their variation. The a and b values for 99 years period are same for some seismotectonics provinces of area and the regions of homogeneous seismicity were constructed. The frequency distribution of earthquakes of different magnitude is discussed. Recurrence curves support a high level of activity for the Zagros zone and they indicate a lower rate of activity for northern Iran faults zone than for other areas in the region. Recurrence curves for central Iran area Indicate that the rate of activity in a given region may remain practically constant over periods at least as long as a century, whether or not large earthquakes occur in the region during those periods. Comparisons between seismic hazard, energy maps, faults location and earthquake epicenters distinguish areas which will be damaged or have a heavy casualty.

EXPERIENCES GAINED IN THE RESPONSE TO THE EARTHQUAKE EARLY WARNING SIGNAL IN THE UNIVERSIDAD AUTONOMA METROPOLITANA, CAMPUS IZTAPALAPA IN MEXICO CITY

Delfino LASCARES. Universidad Autonoma Metropolitana, Iztapalapa Av. Michoacan y Purisima, Col. Vicentina, Delegacion Iztapalapa, C.P. 09340, A.P. 55-535, Mexico D.F. Tels. 724-46-98, FAX 724-46-88, email: held@xanum.uam.mx.

Since June 1997 a radio receiver of the Seismic Alert System of Mexico¸ City (SAS) was installed in the Universidad Autonoma Metropolitana, Campus Iztapalapa and an integral program for hazard mitigation has been applied in the campus. The population reached by the early warning signal is about 17,000 students and academic personnel, with an average near-by population of 45,000 people. To date 7 early warning signals have been received. During these early warning that occurred in working hours, evacuation has been carried out in an average time of 30 to 60 seconds. Surveys show that, since the SAS warning operation the attitude of the near by population toward earthquake prevention has changed. To date 90 percent of the population respond to the early warning signal. The Seismic Alert System (SAS) was developed by the Centro de Instrumentacion y Registro Sismico (CIRES). The alerts have provided as much as 30 to 60 seconds average in advance warning, before the ground motion sake reach Mexico City.

PRECURSORY SEISMIC SIGNALS DURING THE 1998 GUAGUA PICHINCHA CRISIS

HUGO A., Mario C. Ruiz, Minard L. Hall, Monica Segovia, Alexandra Alvarado, Acinoe Calahorrano, Darwin Villagomez, Diego Viracucha, Patricia Mothes, Andres G. Ruiz, Daniel Andrade; (Instituto Geofisico, Escuela Politecnica Nacional, P.O. Box 17-01-2759, Quito, Ecuador;
e-mail: geofisico@accessinter.net)

The Geophysical Institute in Quito, Ecuador, began the instrumental monitoring of Guagua Pichincha volcano in 1981. Until 1988, activity was characterized by a small number of earthquakes and sporadic phreatic explosions, which generated an explosion crater approximately 200 meters in diameter in the bottom of the caldera. In 1988, a swarm of VT earthquakes occurred 9 km southeast of the caldera at a depth of 8-12 km. Moderate phreatic explosions were detected in 1990, 1993, 1995, and 1997 during periods of rain. Between December 1997 and April 1998, three VT earthquake swarms were registered underneath the caldera, and in June 1998, an important swarm of VT earthquakes began 15 km northeast of the caldera. This swarm lasted until October, and at its height more than 100 earthquakes per day with a magnitude between 2.5 and 4.0 were noted. Furthermore, since June 1998, there

have been hybrid earthquakes at depths less than 9 km.
A subduction earthquake with a magnitude of 7.1 occurred on the Ecuadorian coast 220 km from the volcano on 4 August. On 7 August, almost continual explosive activity began at Guagua Pichincha. This activity was characterized in the initial weeks by explosions followed by various days/hours of tremors. Between 7 October and 22 November, the tremors were shorter, with frequencies between 1.8 and 2.0 Hz. Between 22 November and 19 December, the number of explosions diminished with cycles of tremors between 28 and 32 hours. A new cycle of activity began on 19 December with spasmotic tremors and strong explosions followed by short episodes of tremors (<10 minutes) with frequencies of 1.6 Hz.
In addition, earthquakes characterized by narrow spectrum (between 2 and 5 Hz) have been registered since 10 September. These earthquakes have originated at shallow depths under the caldera and have accompanied periods of intense phreatic activity. Guagua Pichincha's continuing activity is attributed to various pulses of intrusion of small magmatic bodies, a process, which could ultimately result in a volcanic eruption.

THE HYDROPHYSICAL METHOD OF TSUNAMI ESTIMATION

Yury KOROLYOV and Alexander Poplavsky (Institute of Marine Geology and Geophysics, Sakhalin Scientific Centre, Nauki st., Yuzhno-Sakhalinsk 693002, RUSSIA,
email: tsunami@sakhmail.sakhalin.ru)

The estimation of tsunami danger is based on seismological data at present. It doesn't take into account inhomogeneity of tsunami source, directivity of tsunami, diffracting effects, which may both amplify and attenuate tsunami waves, and duration of tsunami. Therefore it gives some erroneous forecasts. Information of some level gauges placed on sea may confirm or refute tsunami danger. The hydrophysical method of tsunami estimation using information of some remote level gauges is based on well-known reciprocity principle. This method needs in minimal seismological data (time of beginning and co-ordinates of earthquake), data on sea level in three points and numerical "mareograms" in these points and in point to be warned. These "mareograms" must be obtained by tsunami simulation from some model tsunami sources placed on earthquake epicentre. This method takes into account inhomogeneity of tsunami source, directivity of wave radiation, different difracting and resonance effects. As a result the time of tsunami attack, form, heights and number of tsunami wave and duration of tsunami alarm are determined. This hydrophysical method will improve the reliability of tsunami warning and allow a creating of networks of local tsunami warning systems. This work was supported by grant 97-05-96625 from Russian Foundation for Basic Researches.

HISTORICAL DOCUMENTATION OF THE SEISMICITY OF LESVOS ISLAND (E. AEGEAN, GREECE) IN THE SECOND HALF OF THE 19TH CENTURY: COMPARISON WITH THE INSTRUMENTAL PERIOD DATA

Vicki KOUSKOUNA (Department of Geophysics & Geothermy, University of Athens, 157 84 Athens, Greece, email: vkouskou@atlas.uoa.gr); Kostas Taxeidis (Psichari 20, Mytilini 81 100, Greece); Kostas Macropoulos (Department of Geophysics & Geothermy, University of Athens, 157 84 Athens, Greece, email: kmacrop@atlas.uoa.gr)

A total number of 32 earthquakes from Lesvos island for the period 1851-1899 are listed in the existing published catalogues, five of which were destructive and were felt in the Eastern Aegean and Minor Asia. A detailed investigation carried out on the island revealed new, local sources of information (manuscripts, newspapers, etc.) reporting the earthquakes of Lesvos. These sources, together with the existing ones, present a more complete seismic picture of the island, and almost double the total number of its earthquakes, i.e. 34 new single earthquakes (or series of earthquakes) were located, one of which (in 1882) was damaging. The seismicity of the island in the 20th century, as derived from instrumental data, for a time window of 50 years, was compared to the above mentioned period, in an effort to: a) re-evaluate the parameters of the known, major destructive earthquakes by adding the new sources of information, and b) answer to certain questions of tectonic character, i.e. the existence of foreshock/aftershock activity and its characteristics. In this sense, the catalogue of earthquakes of the area is extended backwards up to 1850, and the completeness of its seismicity is tested. This enables the creation of an artificially complete data set, which will therefore contribute to more realistic local seismic hazard assessment and microzonation studies.

MODULE AND GRADIENT HIGH-SENSITIVITY MEASUREMENTS OF GEOMAGNETIC FIELD VARIATIONS AT THE SEISMIC RESEARCHES

Oleg KUSONSKI (Observatory Arti, Institute of Geophysics, Urals Branch of Russian Academy of Sciences, Geophysics Str., 2a, Arti, Sverdlovsk region, 623350, Russia); Vladimir Sapunov and Olga Dekusar (Ural State Technical University, Quantum Magnetometry Lab, Mira St., 19, Ekarerinburg, 620002, Russia)

The researches are carried out at the observatory Arti (WDC's mnemonic is ARS, coordinates are 56˚25.8¢ N, 58˚33.7¢ E) that is located on the Preduralsky pericratonice trough of the East-European platform. This area is seismically active. Observable here earthquakes have both natural and industrial origin. The last is connected with production of minerals and oil. The magnetic field of this region is characterized by presence of anomaly up to 1200 nT. The module and gradient variations are measured by the proton Overhauser's magnetometer POS-1 with resolution 0.001 nT (sensitivity up to 0.02 nT and 0.01 nT/meter at single measurement). At the same time a registration of super-long-period seismic oscillation (SSO) are made by the ARU IRIS station. A gradiometer allows to control the real measurement sensitivity for absolute value of magnetic fields and to locate geological and technogeneous effects caused by a near zone. The submitted methods and equipment allow to study geoblocks movements creating intensive deformations of mountain breeds, geoblocks response to tectonic factors, SSO excitation mechanism, trigger factors of earthquakes. The data can essentially soften dramatic and economic consequences of earthquakes at the mining enterprises of Ural.

OBSERVED AND PREDICTED INDUCED SEISMIC IMPACTS IN PREADRIATIC COASTAL AREA OF ALBANIA

Siasi KOCIU (Seismological Institute, Tirana, ALBANIA, email: kociu(sizmo.tirana.al)

Albania, situated on Western Balkans, with a coastal line of 470 km long, represents an attractive area for the future development of tourism. Adriatic seacoast of Albania with many , as one of the most populated areas of the country (where more than 70% of the population is concentrated, with many inhabited centers as those of Durres and Vlora towns in seacoast and Shkodra, Fieri and Tirana (capital), not far away (20-40 km), from the seacoast), represents one of the most hazardous seismic zones of the country, where many seismic impacts were observed during the past earthquakes and may be developed during expected future earthquakes.
Preadriatic area as a flat area filled mainly by recent very poor Quaternary sediments of thickness down to 100-150 m, with shallow underground water level, represents an area where a lot of soil in stabilities were observed during past earthquakes and can be observed in the future. Based on seismic hazard assessment procedures at local level for two of the biggest coastal cities of Albania (Durres and Vlora) it is shown that during the expected strong earthquakes induced seismic impacts as liquefaction of sands , new and induced landslides and appearance of fault rupturing on free surface can be observed not only along Adriatic seacoast, but especially within urban areas of these two cities.

THE RISK OF LARGE VOLCANIC ERUPTIONS AND THE IMPACT OF THIS RISK ON FUTURE OZONE DEPLETION

Howard ROSCOE (British Antarctic Survey/NERC, Madingley Rd, Cambridge CB3 0ET, UK,
email: h.roscoe@bas.ac.uk)

Ozone depletion at mid-latitudes due to reactive halogens from man-made halocarbons is enhanced by the increase in stratospheric sulphate aerosol, which follows large volcanic eruptions. Mid-latitude ozone depletion due to halocarbons almost doubled for the two to three years following the eruption of Mt Pinatubo in 1991. Although the Montreal Protocol is expected to reduce amounts ofhalocarbons in the atmosphere during the next century, the predicted reductions are such that stratospheric ozone will be at risk from such depletion enhancement for the next 50 years. Vulcanological mechanisms, models, and measurements in ice cores, suggest that large volcanic eruptions are random and that their global rate is constant over periods of a few centuries. From the rate of large eruptions observed in ice-cores, the probability of one or more eruption, the size of Pinatubo or larger, is 58% in 50 years. This probability is large enough that it should be taken into account in predictions of future ozone loss. Several of the eruptions in the ice-core record were many times larger than Pinatubo, so that a more comprehensive analysis, which also included the probability of eruptions as a function of size, would be beneficial.

STATISTICS OF EARTHQUAKE HAZARDS

M.V.RODKIN (Geophysical Center, Russ. Ac. Sci., 117296 Moscow, Molodezhnaya 3, email: rodkin@wdcb.rssi.ru); V.F.Pisarenko (Intern. Inst. of Earthquake Prediction Theory and Math. Geophysics, Russ. Ac. Sci., Moscow)

Earthquake tolls and economic losses in 1900-1996 years are examined in connection with earthquakes regime and economic conditions in different regions. It was shown that while the number of events with small and moderate number of victims and losses increase with time in a non-linear manner the large losses that constitute the major part of the total number of victims and losses have a linear increase with time. The non-linear increase with time of the total number of victims and losses is caused mainly by the Pareto-law distribution of losses from earthquakes, thus a high non-stationarity of regime of hazards assumed by a few authors is apparent. The limitations inherent to the Pareto-law distribution of losses are discussed and the value of maximum possible seismic hazard is evaluated. The connection of regime of seismic disasters with regional economic situation is discussed also. It was shown that while the losses from earthquakes have a tendency to increase with time, the number of victims and losses we normalised with the national income per capital have a tendency to decrease. A prognosis of number of victims and losses from earthquakes till 2020 year is presented.

INTERNATIONAL GPS TEST-AREA FOR DEFORMATION FORERUNNERS OF EARTHQUAKE STUDY

Mikhail PRILEPIN (United Institute of Physics of the Earth, B.Gruzinskaya Str., 10, 123810 Moscow, Russia, email: prilepin@uipe-ras.scgis.ru)

One of the reasons why the problem of earthquake prediction is far away from the solution stipulated is the lack of real international co-operation on experimental study and evaluation of significance of different forerunners. Many scientists today share the opinion that deformation forerunners are primary and their study can help in understanding the processes of preparation of earthquakes and prediction of event. The favorable factor nowadays is the availability of very effective GPS technology for the study of deformation forerunners on large territory with high accuracy and with the possibility for automatization of gathering and processing of the data. The next step in instrumentation is combining GPS with SAR interferometry, which is making the first but a very successful step toward the study of geokinematics. In the report discussed, the items dealing with the determination of the epicenter position, magnitude and time of shock using the data accumulated on GPS networks of different levels developed in seismically active areas. The consideration about the selection of place for a test-area, its status, sequence of development of the GPS networks, transition of data, gathering of auxiliary data and activity of the center for processing and analyzing the data are discussed. The consideration about the possibility of united study of different kinds of forerunners: seismic, geoelectromagnetic, variation of ground water level and emanation of noble gases are also presented shortly.

THE THREE STRONG EARTHQUAKES, NORTH CHINA, CHINA AND ITS STRUCTURAL SIGNIFICANCE

Lu PEILING (Centre for Analysis and Prediction, CSB, Beijing (l00036), China, Tel: 010-88015557, Fax: 010-68218604)

Abstract The seismic activities before and after strong earthquakes, the source mechanism of mainshocks, and the geological structure of the epicenter area of three strong earthquakes (the 1976(M7.8) Tangshan, the l989(M6.1)Datong-Yanggao and the 1998 (M6.2)Zhangbei-Shangyi earthquake) have been investigated. The structural significance of the three strong events is also discussed. The results show that 1. In according to the seismic activities before and after mainshocks, three strong events occurred in the north margin of North China faulting block area. The occurrence of three events was resulted from the most recent abrupt slip on a NE-trending Changdong fault zone, a NE-trending Shanxi grabon zone and a NWW-trending Zhangjlakou-Bohai fault zone, respectively. 2. In according to the mainsbock location, the events was in the intersecting area of the faults, therefor its sequences have the rich aftershock action, the most of strong aftershocks and the energy attenuation slow. 3. The source mechanism solutions of mainshocks are in agreement with the regional stress field with the P axis in the NEE-SWW direction of North China, but there are a difference in the fault motion type, 1976 event shows the northeastern striking high-angle strike-slip faulting

mechanism, 1989 event has the strike-slip with the normal faulting motion, and 1998 quake is the thrust fault type. Those might correspond upon the structure of the epicenter area. 4. The epicenters is in or near Cenozoic-aged faulting basins with the Cenozoic -aged baselts, the genesis of the strong earthquakes which are derived from baselts may is the rising model of the hot material. Due to an action of the local hot stress the earthquakes occurred. 5. the mainshock faults are not at a great active structure, even there is not active fracture in the surface of the epicenter area.

SEISMIC HAZARD ASSOCIATED WITH SUBMARINE NEOTECTONIC FAULTS IN GREECE

Joanna PAPOULIA (National Center for Marine Research, Agios Kosmas, Hellinikon, 16604 Athens, GR)

Seismic hazard analyses are associated with large uncertainties when historical data are insufficient to define seismicity rates. These uncertainties may be decreased however in areas where seismicity is shallow, and produced by Quaternary faulting, by incorporating geological data in the analysis of seismic hazard. A tool towards the integration of the so-called prior information of seismicity, obtained from geological data, with historical observations is the Bayesian probability theory. This theory is tested here to estimate the seismic hazard associated with submarine active fault zones in the area of Greece. Prior estimates of seismicity are developed from slip rate measurements obtained from offsets of geological formations. The analysis demonstrates the importance of uncertainty in the Bayesian estimate of seismicity, and subsequently in the estimate of seismic hazard.

GUAGUA PICHINCHA: MANAGING THE CRISIS

HUGO A. YEPES; Instituto Geofisico, Escuela Politecnica Nacional, P.O. Box 17-01-2759, Quito, Ecuador; e-mail: geofisico@accessinter.net

Guagua Pichincha is a dacitic volcano located 12 km west of Quito (pop. 1.2 M.), the capital of Ecuador. It has erupted five times in the last 1,030 years (970, 1560, 1575, 1582, and 1660), with a recurrence period of approximately 500 years during Holocene. In July/August 1998, there was a commencement of seismic and explosive activity at levels superceding those seen since the installation of the monitoring network in 1988. The increased activity, which peaked during late September, precipitated the declaration of a yellow alert by the city of Quito on 1 October.
The Geophysical Institute, drawing on its experience and expertise, acted as a catalyst for the city's actions given the city's lack of preparedness and inability to initially grasp the gravity of the situation. The initial step for the government in dealing with the crisis was the designation of the mayor of Quito as the overall response coordinator. The city established an operations/information center; determined populated areas at risk; identified public sectors likely to be affected; and cleared debris from flow areas and potential evacuation routes. Contingency planning included one evacuation drill; periodic meetings of governmental entities; solicitation of heavy equipment and medical supplies from foreign governments and NGOs; the development of ways to minimize impact to the water supply, power grid, and telecommunications; and the planning for ash removal, police deployment, evacuation of aircraft, ingress/egress of the city, and procurement of food and fuel. Educational efforts comprised press conferences, briefings, and press bulletins.
Any crisis has its difficulties. Some problems are unavoidable, some can be mitigated by adequate funding, and others are preventable. Problems encountered by the city have included the inability to control rumors, inability of the government to ameliorate the public's linkage of the alert declaration to local political events, poor management of the initial alert declaration, confusion over alert level definitions, difficulty in maintaining public interest over the long term, the release of overly technical information to the public, delays in developing contingency/evacuation plans, reluctance to disclose all available information on potentially affected areas, the ill-defined role of the operations center, inadequacies in the call-down list, a failure to publicize an alarm system, and insufficient funding. Yet despite these problems, the city has made great progress in recognizing the hazard and addressing the risk.

VOLCANIC HAZARD ASSESSMENT AT THE DENSELY INHABITED ISLAND OF ISCHIA

Sandro de VITA, Giovanni Orsi (Osservatorio Vesuviano, 80056 Ercolano -NA- Italy, email: devita@osve.unina.it) Fabio Sansivero (Dip. Geofisica e Vulcanologia. Un. "Federico II", 80138 Napoli, Italy)

Ischia is a volcanic island located in the north-western corner of the Gulf of Naples. Volcanism begun more than 150 ka B.P. and the last eruption took place in 1302 A.D. The largest caldera forming eruption generated the Mt. Epomeo Green Tuff and occurred 55 ka B.P. Resurgence of the central part of the caldera begun around 28 ka B.P. and caused a net uplift of about 900 m of the Mt. Epomeo block. It occurred through a simple-shear mechanism that determined the conditions for magma to rise to surface only along normal faults within the eastern sector of the resurgent block. Almost all the volcanic vents of the last period of activity (10 ka B.P.-1302 A.D.) are located in the eastern part of the island. During this period 46 eruptions, effusive and explosive, occurred mainly between 2.9 ka B.P. and 1302 A.D. Effusive eruptions produced lava flows and domes; explosive eruptions formed tuff-rings, tuff-cones, and variably dispersed pyroclastic deposits. Eruptions were separated by periods of quiescence that lasted up to few centuries. Slope instability, likely triggered by resurgence dynamics, generated landslides and mud-flows shortly before and after eruptions. The magmatic system is still active, as testified by the intense historical, volcanic and seismic activity, and by widespread thermal springs and fumaroles. The island is inhabited by about 50,000 peoples that greatly increases during summer. Farming, wine industries and a complex network of commercial exchanges with the near city of Naples, contribute to determine a high volcanic risk in this area.

EVIDENCE FOR VOLCANIC INFLUENCES ON MEXICO CITY AEROSOLS

G. B. RAGA (Centro de Ciencias de la Atmósfera, Universidad Nacional Autónoma de México, Ciudad Universitaria, 04510, México DF, México, email: raga@servidor.unam.mx), G. L. Kok (National Center for Atmospheric Research, Boulder, CO 80303, USA, email: kok@ucar.ncar.edu), D. Baumgardner, A. Báez and I. Rosas(all three at: Centro de Ciencias de la Atmósfera, Universidad Nacional Autónoma de México, Ciudad Universitaria, 04510, México DF, México, email: darrel@servidor.unam.mx)

In situ measurements of sulfur dioxide (SO2), carbon monoxide (CO) and sulfate mass provide evidence that aerosol composition in Mexico City is affected by emissions from the neighboring volcano, Popocatepetl. The data suggest that there are two distinct pathways by which SO2 is incorporated into particulates. Periods of high humidity, fog, and rain are accompanied by elevated sulfate mixing ratios, attributed to aqueous chemistry. Similarly, elevated sulfate concentrations in low humidity periods appear to be a result of adsorption onto existing particles. These two mechanisms are important for understanding the processes associated with particle formation in this highly polluted urban area. Under the influence of volcanic emissions, SO2 concentration is more than four times the average value and particulate sulfate is a factor of 2 larger.

SAN SALVADOR, EL SALVADOR, A HIGH RISK, MULTIPLE HAZARD MEGACITY

D J SOFIELD, J W Vallance, and W I Rose (Geological Engineering and Sciences, Michigan Technological University, Houghton, MI, 49931, email: djsofiel@mtu.edu)

Volcanism and earthquakes are the most dire geological hazards that threaten San Salvador, El Salvador's largest city (population, 1.7 million), with a rapidly growing population, and few plans or resources for hazard mitigation. Financial, transportation, and governmental centers of El Salvador all reside within San Salvador. The city lies on a plain within severe hazard zones of two active volcanoes (San Salvador to the W and Ilopango to the E) and also lies in a zone of major subduction earthquakes.
In the past 60 Ka, a caldera 12 km E of the city now occupied by Lake Ilopango erupted at least four significant pyroclastic deposits, each of which blanketed the valley that San Salvador now occupies. The last of these eruptions devastated all El Salvador in AD 260 and drove pre-Classic Mayan civilization northward into the jungles. A dome eruption in 1880 and small seismic swarms beneath the lake indicate continuing unrest. Neither San Salvador volcano nor its numerous flank vents has erupted catastrophically since European colonization, however numerous explosive eruptions occurred prior to that. San Salvador volcano erupted ash-rich tephra and pyroclastic flows 800 years ago and caused mudslides that would likely kill many thousands today. Because of the frequency of earthquakes, the people of San Salvador are much more aware of seismic risk than volcanic risk. The city has had to rebuild 7 times after earthquakes since 1712. The most recent devastating earthquake in 1986, killed 1500, injured 10,000 and left 100,000 homeless. Thick unconsolidated pyroclastic and tephra deposits amplify the effects of shallow-focus, moderate magnitude earthquakes beneath the city. Timely international involvement could provide the impetus that San Salvador needs to begin effective hazard-assessment, monitoring, and educational programs. A significant part of this work will be to make the population of a volcanic country more aware of its vulnerability to volcanic hazards. The recent occurrence of hurricane Mitch offers an opportunity to advance all hazard work in Central America.

METHODS OF EXTREME SEA LEVEL AND CURRENTS VALUES CALCULATION

Oleg ZILBERSTEIN, Guennady Safronov, Sergei Popov, Mikhail Chumakov (all at State Oceanographic Institute, Kropotkinski per. 6, 119838, Moscow, Russia, email: oleg@soins.msk.ru)

Hydrometeorological support for marine branches of the economy and safety of human activities on offshore regions requires knowledge of the main marine parameters (in particularly sea level and current extreme values). As a rule long-term observations in offshore regions are absent. The most dangerous rise and fall of sea level and also extreme currents are result from the combined effect of tides and storm surges. A special automated technology including hydrodynamic and probabilistic modelling was developed. On the basis of historical information and observation series analysis for region of interest, extreme storm cases with corresponding weather maps are selected. Following computation of earth-surface level wind and atmospheric pressure gradients are produced. On the base of this information the hydrodynamic calculation of storms and summary (accounting tides) sea level oscillations and currents are calculated with help of verified 2D and 3D hydrodynamic models. Baroclinic models are actively used last years. With the help of produced probability models, which are based on Gumbel low and Langbein relationship, the results of numerical modelling are processed and long-return period characteristics of sea level and currents at different horizons are determined. Produced complex of models and methods is successfully used within researches and survey for number of designing objects in Barents, Kara, Baltic, Caspian, and Sea of Okhotsk. This approach allows us to produce computer maps of long return period characteristics of sea levels and current

SEARCH FOR THE EARTHQUAKE PRECURSORY SIGNATURES BASED ON FRACTAL ANALYSIS OF THE ULF GEOMAGNETIC DATA

Natalia SMIRNOVA (Institute of Physics, St. Petersburg University, St. Petersburg, 198904, Russia, e-mail: nsmir@snoopy.phys.spbu.ru); Masashi Hayakawa and Tetsuya Ito (The University of Electro-Communications, Chofu, Tokyo 182-8585, Japan, e-mail: hayakawa@whistler.ee.uec.ac.jp)

An attempt to use fractal methods of time series analysis for searching the earthquake precursory signatures is fulfilled on the basis of ULF geomagnetic data obtained during Guam earthquake (EQ1) on August, 8 1993 (M=8) and Biak earthquake (EQ2) on February, 17 1996 (M=8). The observing places were situated both near the epicenters (Guam, 65 km off EQ1 and Biak, 100 km off EQ2) and far away (Darwin, 1200 km off Biak EQ). The chosen period covered a few months before and after the earthquakes in order to reveal the large-scale dynamics of scaling (fractal) characteristics of the pulsations. It is revealed that in the seismoactive region the ULF spectrum of emissions exhibits a power law behavior which is typical for self-organized critical dynamics. For Guam EQ the slopes of spectra and the fractal dimensions of ULF time series manifested stochastic fluctuations between values 2.5-0.7 with pronounced tendency for slope to decrease and for fractal dimension to increase in the process of the earthquake preparation.Taking into account the certain value of the critical slope we suggest that the gradual increase of the intervals with slopes less than this critical one prior to the earthquake may be considered as an earthquake precursory signature. The peculiarities revealed on the basis of ULF data of Guam EQ is verified on the materials of Biak EQ. The fractal properties of ULF emissions in seismoactive and seismoquiet regions are compared. The research was supported by Grant 98-05-65554 from Russian Foundation for Basic Research.

RESEARCH ON CORRELATION OF ASTRONOMIC FACTORS AND EARTHQUAKES

Hu HUI; Li Yongsheng (Yunnan Observatory, Academia Sinica, Kunming, 650011 China)

The effect of astronomical factors on the major earthquakes in China and the world is discussed in detail in this paper. The results show that the major earthquakes, especially the ones of above magnitude 7.0 are evidently affected by the astronomical factors, such as the Earth rotation, solar activities and lunar orbital motion. Only different seismotectonic belts or zones have different responses to an astronomical factor. The node of the lunar orbit with the earth's orbit

regresses towards the west on the ecliptic, with a period of 18.6 years. The precession of the lunar ascending node causes the inclination between the moon's path and the equator to change continuously from 18.28 to 28.58 degrees. The seismic activities of the main seismic belts in the world are obviously affected by the period of 18.6 years and only their active periods appear alternately, which shows that different locations of the moon correspond to different seismic belts or regions on the Earth. This bears analogy to the fact that the change Earth's climate with a period of a year is caused by the different quantities of arrival of solar radiation due to the inclination of the ecliptic to the equator.
In China, 8 seismic events over M 8.0 occurred since 1820 happened to be during the acceleration of the Earth rotation(DAER). Among the 106 events over M 7.0 occurred in the 20th century, 72% were during the DAER and 71% happened when the inclination changed from the maximum to minimum. Most of the events happened in the descending phases of solar activities.

POINT-LIKE PROCESSES AND CATASTROPHE PREVISION

Giovanni P. GREGORI (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy;
e-mail: gregori@atmos.ifa.rm.cnr.it)

A frequent approach when attempting at managing a natural catastrophe is in terms of a numerical model, by which we try at forecasting its occurrence in space and time. Sometimes this results to be difficult or even unrealistic. On a more pragmatic ground we can rather appeal to a formal analysis of the historical time series of every catastrophe of concern. Only approximately, however, such series can be likened to a point-like process, because the "detector-mankind" experienced substantial changes vs. time. Nevertheless, such algorithms can be approximately applied by means of a few suitable assumptions. Four basic viewpoints can be considered: (i) either by assuming that phenomena are periodic; (ii) or by assuming that an event occurs only whenever so m e energy threshold is attained (calorimetric criterion); (iii) or by assuming that it occurs only whenever the system experiences some abrupt change of its boundary conditions; or (iv), whenever no such algorithm is viable due to scanty observational inf o rmation, just by applying the box counting method, or some other more or less related and/or equivalent fractal algorithm. The mutual relations, advantages, and drawbacks of either one such approach are briefly discussed, with a few applications. They al r eady lead to an apparently successful long-range forecast of a large flood in northern Italy occurred in 1994, and to the prevision of the next explosive eruption of Vesuvius. But, the success of every such application is closely determined by the quality of the historical database, or by the physical information that is fed into the analysis, rather than by mathematics that per se have only to be concerned with avoiding that some arbitrary non-physical input is added, based only on the human need for simplicity.

PHASE OF MOON, INCLINATION OF MOON'S PATH WITH EQUATOR AND STRONG EARTHQUAKES IN YUNNAN

Li XIAOMING (Yunnan Observatory, Chinese Academy of Sciences, P.O.Box 110, Kunming; Yunnan Province, 650011, P.R.China)

Yunnan Province lies in the southwestern part of china, adjoining the juncture of the Eurasian plate and Indian plate, with the complicated geological structure, frequent seismic activities and the Mediterranean seismic belt passing through the province itself. It is found from the analyses that the rate of recurrence of earthquakes has close correlation to the position of the Moon at the last quarter and especially near the new Moon and the last quarter of the Moon earthquakes occur frequently. In the 19th and 20th centuries the rates of recurrence of the earthquakes with M 6.2 near the two phases of the Moon are respectively 6.2 times and 4.5 times as frequent as the average rate of recurrence, having a stripe-shaped distribution and the major earthquakes with M 7.0 almost occurred in the maximum and minimum year of the inclination and within two years after or before it in particular. As for the solar and lunar tidal forces, most of the earthquakes occurred in the time interval when the horizontal component of the tidal force made the greatest change. This shows that an earthquake can be excited by the position of the Moon and the tidal forces of the Sun and the Moon.

IMPACT OF THE HYDROLOGIC EXTREMES OVER THE WATER TABLE IN THE "PAMPA HUMEDA" (ARGENTINA) AND ITS RELATIONS WITH THE ENSO

Maria del Valle VENENCIO and Norberto O. Garcia (Facultad de Ingenieria y Cs. Hidricas - Univ. Nac. del Litoral, CC 495 - (3000) Santa Fe, Argentina. - E-mail: mvv@fich.unl.edu.ar)

This paper aims to create the bases in order to carry out, starting from seasonal and interannual climate prediction, a seasonal and interannual prediction of availability of groundwater resources coming from the unconfine acuifer in the productive areas of the "Pampa H=FAmeda" in the Argentine Republic.
The regional averages of the depth of the unconfined aquifer get rid suppose affected only for climatic variations. Also, the use of the groundwater resource is considered constant. Keeping in mind that the several water resources states in the region obeys several relationships between the variables precipitation, evaporation and evapotranspiration, it was carried out a serial water balance and correlations between the variability of the precipitation and the depth of the unconfined aquifer.
So, we can say that the precipitation produces decreasing or rising water level. As it was demonstrated the relationship between the ENSO and the precipitation on the Southeastern South America (SSA) by several authors, presently work was aimed to establish relationships between the water table and the ENSO. This correlation also provides useful information about the predictability of the future piezometric levels for sustainability of groundwater resources.
Then, the main conclusion of this work is that the water table level is predictable in function of a predictor like El Nino.

LONG REPOSE PERIODS IN THE ERUPTIVE HISTORIES OF RECENT KAMCHATKA VOLCANOES: WHAT VOLCANO CAN BE RECOGNIZED AS EXTINCT?

Vera PONOMAREVA, Olga Braitseva, Ivan Melekestsev (Institute of Volcanic Geology and Geochemistry, Piip Ave., 9, Petropavlovsk-Kamchatsky, 683006, Russia,
email: ponomareva@geology.ru) Leopold Sulerzhitsky (Geologic Institute, Pyzhevsky per., 7, Moscow, 109017, Russia, email: suler@ginran.msk.su)

Detailed studies of the eruptive histories of Kamchatka volcanoes, based on geologic mapping, tephrochronology and radiocarbon dating, allowed us to document main repose periods in the lives of most Holocene volcanoes and monogenetic volcanic fields, and to determine their duration. It appeared that dormant periods as long as 500-1000 years were common in the lives of the volcanoes of various morphology, types of activity, and composition of eruptives. The best known example is Bezymianny volcano which was silent for about 1000 years before the 1955-56 large eruption. Longer repose periods up to 2000-3000 years were not rare. The longest repose periods - about 3500 years - were recorded at Kikhpinych and Dikii Greben' volcanoes; after a long dormancy both volcanoes were able to resume their activity. These data suggest that at least in Kamchatka a volcano should be considered potentially active (and thus, potentially hazardous) if it was proved to produce at least one eruption within the last 3-4 thousand years. This approach has allowed us to add some more names to the list of active volcanoes: Taunshits, Khodutka, Dikii Greben', Khangar volcanoes, which have been considered extinct and were not included in any catalogues of active volcanoes, appeared to have large eruptions within the last 3000 years, as well as Tolmachev Plateau and some other volcanic fields.

THE CELLULAR AUTOMATA MODEL SCIARA FOR LAVA FLOW SIMULATION: APPLICATIONS AND RESULTS

G.M. CRISCI, A. Di Francia, S. Di Gregorio, F. Nicoletta*, R. Rongo, W. Spataro (Dip. di Scienze della Terra Dip. di Matematica *Dip. di Chimica ersità della Calabria, I 87036 Arcavacata, Italy)

Cellular Automata (CA) represent a parallel computational method in alternative to differential equations, for modelling very complex phenomena, whose evolution can be considered based exclusively on local interactions. The CA model SCIARA for the simulation of lava flow was developed and subsequently improved several times by our research group. A lava flow is described in SCIARA as a system with discrete time and space; the space is represented by regular cells (square or hexagonal) two-dimensional cells, whose specifications (substates) describe the main physical characteristics of the corresponding portion of space: altitude and, for each lava layer, lava thickness, temperature, lava outflows toward the adjacent cells; furthermore a division in lava layers can be considered in a refinement of the model. The CA evolves changing the state of all cells simultaneously at discrete times. Input for each cell is given by the states in the adjacent cells; the evolution of the phenomenon is mainly given by the computation of the outflow from the cells and the change of the remaining substates. SCIARA was applied in different times to 1986/7 and 1991/2 Mount Etna eruptions. The results were satisfying within limits to forecast the lava flow path, according to the surface covered by lava. The main parameters of the model for Etnean lavas were found; then simulations were performed in order to evaluate the risk in some inhabited Etnean area (the towns of Nicolosi, Pedara and S.Alfio) considering future catastrophic events. We consider the evolution of SCIARA, the main results and a critical discussion for a further improvement of the model, its limits in the application.

LAVINA - A COMPUTER TOOL FOR AVALANCHE FORECASTER

Pavel CHERNOUSS and Evgeny Mokrov (Center of Avalanche Safety, "Apatit" JSC, 33a, 50 years of October St., Kirovsk, Murmansk region 184230, Russia, e-mail: P.Chernous@apatit.murmansk.su); Alexander Perlikov (Institute of Ecology, Kola Science Centre of the Russian Academy of Sciences, 14a, Fersmana St., Apatity, Murmansk region 184200, Russia)

LAVINA is a software package which assist avalanche forecaster to evaluate avalanche risks. It is an integrated system consist of two main units permitting evaluate probabilities of avalanche occurrence and dynamical parameters of possible avalanches. Probability of avalanche occurrence is evaluated for a whole region or for a separate starting zone. In the first case standard meteorological data and snow drift measurements are used for different types of discriminant analysis and pattern recognition algorithms. Diagnostics is carried on each third hour as current measurements have being made. Probabilistic and categorical conclusions on avalanche releases are the results of data treatment. There is an opportunity to display ten situations closest to current one from archive. Statistical simulation applied to snow thickness, density and shear strength is used for evaluation of snow cover stability in a separate starting zone. The areas of instability of different probabilities are displayed at a computer monitor. The dynamical parameters of a probable avalanche – maximal speed and impact pressure, are calculated at any given point of the avalanche path. LAVINA as a part of computer assisted work place of an avalanche forecaster is in operation at the Center of Avalanche Safety since 1991. The results of its exploitation are discussed and the ways of its improving are considered.

INFLUENCE OF MACROSEISMIC INTENSITY ATTENUATION IN SEISMIC HAZARD EVALUATION FOR FAGARAS (ROMANIA) CRUSTAL SOURCES

IREN-ADELINA MOLDOVAN (IVAN) and Aurelian Pantea (National Institute for Earth Physics, P.O. Box MG-2, Bucharest-Magurele, Romania, e-mail: pantea@infp.ifa.ro and iren@infp.ifa.ro)

An important step for the correct assessment of seismic hazard is the interpretation of the macroseismic effects distribution from a given seismic zone, as well as the good evaluation of seismic intensity attenuation laws. The attenuation was analysed as a function of distance and azimuth, using nine attenuation laws.
The present paper is a study of macroseismic intensity attenuation laws, using 5 crustal earthquakes (MGR>4.0) occurred in Fagaras(Romania) seismic zone, along the following

azimuths: E, W, N,S,NE,SW,NW,SE. The evaluation of macroseismic intensity attenuation laws for Fagaras region was imposed by the necessity of seismic hazard assessment in this high seismic potential zone the largest event occurred in this zone: MGR =6.4; Io=IX).

COMPARISON BETWEEN TWO SYSTEMS OF BASE SEISMIC INSULATION

Federico BARTOLOZZI (Civil Engineer and Independent Researcher, via dei Carracci3, 21100 Varese, Italy, email: ciuciuzza@iol.it)

One of the proposed systems is with four rigid movable bearings and the other one with four elastic bearings. The two systems share the following characteristics: 1. self-centring of the building after an earthquake; 2. extreme economical competitiveness with all the existing anti-seismic systems, due to the considerable decrease of the seismic energy in the building, which makes possible the use of slenderer carrying structures. The differences between the above systems are: 1. a pendulous effect in the building, during an earthquake, in the system with rigid bearing. It is characterised by a very small vertical rotation of the building, which varies in average from a few seconds to some minutes with soil displacements included between some millimetres and about 150 mm. In addition, this effect is extremely limited and has no repercussions of psycho-physical character for the inhabitants of the building; 2. the verticality and the immobility of the building with respect to the horizontal translation of the foundation-soil complex n the system with elastic bearings. The vertical elastic strain of the springs compensates the variations of rigid deflection relative to the bearings, due to the inclination of their sliding surfaces. The vertical component of the of the motion, due to the sub-undulatory shock, varies only partially the building behaviour because of two phenomena: minor vertical translation of the building and resonance possibility. In order to prevent the resonance danger, each bearing is equipped with two or four frequency converters automatically started up when the emergency situation, defined by the equality between the vertical component of the earthquake frequency an the building vertical natural frequency, becomes imminent.

HIMALAYS CRUST DEFORMATION REGION, RADON EMANATION AND SEISMO WAVE EFFECTS

Vladimir ALEXEEV, Yury Mikhailov (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of Russia's Academy of Science, Troitsk, Moscow region, 142092, Russia, e-mail: yumikh@charley.izmiran.rssi.ru)

The Himalays form is available region for study of the deformation processes of continental crust during collision orogeny. Simple shear dominant strains have developed new fabrics parallel to the main thrust zone. Radon fields [1] and aerosols create anomalous electric fields, which may change properties of upper wall of wave-guide earth ionosphere. This process leads to change of penetration of ELF-VLF waves through lower ionosphere and evolution of spectral characteristics of electromagnetic emissions, registered on satellites [2].

PHENOMENOLOGICAL MODEL OF THE LARGE-SCALE EVOLUTIONARY PROCESSES IN A HAZARD SYSTEM OF THE EARTHQUAKE BASED ON THE SOC (SELF-ORGANIZED CRITICALITY) CONSIDERATION

Natalia SMIRNOVA, Vladimir Troyan (Institute of Physics, University of St.Petersburg, St.Petersburg 198904, Russia, e-mail: nsmir@snoopy.phys.spbu.ru); Masashi Hayakawa (The University of Electro-Communications, Chofu, Tokyo 182, Japan, e-mail: hayakawa@whistler.ee.uec.ac.jp); Thomas Peterson (TFPLAB, Cleveland, Ohio 44124-5441, U.S.A., e-mail: TFPLAB@aol.com), and Yury Kopytenko (St.Petersburg Filial of IZMIRAN, St. Petersburg 191023, Russia, e-mail: galina@admin.izmi.ras.spb.ru)

The concept of self-organised criticality (SOC) is now widely used for interpretation of the natural hazard system behaviour. That concept was included as one of the principal point in a complex approach proposed recently by the present authors for searching the earthquake precursory signatures. Here we develop consideration of the processes in the earthquake regions on the basis of SOC concept. We suggest a phenomenological model for large-scale evolutionary processes occurring between two violent earthquakes. Four principal phases of the evolution: random chaos, subcritical, critical and supercritical stages are proposed and analysed consistently. The external stimuli such as geomagnetic storms, sharp temporal and spatial variations of atmospheric pressure, ULF impulses and others are considered as a driving force for "cellular automata" process in a seismoactive region. The important fingerprints of SOC - fractal structures in space and time are analysed using seismicity data and the ULF electromagnetic data timed to violent earthquakes near Guam (August 8, 1993, M = 8.0) and Kobe (January, 16, 1995, M = 7.2). A possibility to use the fractal characteristics of signals to study critical dynamics of a hazard system is discussed.
The research was supported by NASDA (Japan) and Russian Foundation for Basic Research (Grants No. 98-05-65554 and 99-05-NNN).

DYNAMICS OF SELF-DEVELOPING NATURAL PROCESSES AND PROSPECTS OF ITS USE FOR THE FORECAST OF GEOPHYSICAL CATASTROPHES.

Alexander I. MALYSHEV (Institute of Geology and Geochemistry, Urals Branch of RAS, Pochtovy per 7, Ekaterinburg, SU-620151, Russia, email: root@igg.e-burg.su)

Study of patterns of fore-culmination activizations present a great interest for the forecast of geophysical catastrophes, such as disastrous earthquakes, strong volcanic eruptions, rock bumps, landslides etc. During the study of Bezymyannyi volcano eruptions in 1980-1987 the fact of hyperbolic activization before explosive-effusive eruptions was established. Further studying of the revealed regularities and their comparison with empirical dependencies of the development of various natural processes allowed to conclude that there is a wide class of self-developing natural processes, the dynamics of which is described by non-linear differential equation of the second order. The attempts of using these regularities for the forecast of eruptions were quite successful, however the accuracy of the forecast for the time of eruption did not exceed a semi-quantitative level. At present the methods, allowing confidently to reveal the laws of the development of natural processes, have been developed. As it is shown on the example of a number of Bezymyannyi and Shivelutch volcanic eruptions, for the class of eruptions, having stable fore-culmination preparation, this technique allows increasing accuracy of paroxysm time forecast up to a quantitative level.
The forecast of destructive earthquakes is more complicated. Ivan Tikhonov and me have analyzed the fore-shock-aftershock sequences of destructive earthquakes in southern Kuril arc area. It was established that the development of both of fore-shock, and aftershock sequences corresponds to the equation of the dynamics of self-developing natural processes. However the fore-shock sequences are more poorly expressed. Probably, some updating of seismic observations is required for getting more stable results. The obtained results make it possible to assume that the methods are a perspective for the forecast of these geophysical catastrophes.

EXCESS AND DEFICIENT RAINFALL YEARS OVER INDIA DURING 1871-1996: A BRIEF APPRAISAL

A. A. MUNOT (Indian Institute of Tropical Meteorology Dr. Homi Bhabha Road, Pashan, Pune-411 008, India, e-mail: munot@tropmet.ernet.in)

India, being an agricultural country has its economy closely linked with the performance of the summer monsoon (June-September) which gives 75-90 % of the total annual rainfall. Timely onset and normal distribution of rain in the summer monsoon season generate good amount of food production whereas erratic behavior of monsoon which leads to drought/flood over the country has an adverse effect on the food production and in turn on the economy of the country. Because of this, year to year variation of monsoon rainfall becomes the subject of immense importance. In view of this in this paper an attempt is made to study the inter-annual variability of summer monsoon rainfall for the period 1871-1996. On an average India as a whole receives 852.4 mm of monsoon rainfall with a standard deviation of 84.7 mm and coefficient of variation of 9.9 %. Excess and deficient rainfall years over the country are identified using suitable criterion. There are 22 deficient and 19 excess rainfall years during 1871-1996. The total area of the country under deficient rainfall conditions as well as under excess rainfall conditions have been computed for all the deficient/excess rainfall years. The mean area of the country under deficient rainfall condition in a deficient rainfall year is found to be 42.8% whereas the mean area of the country under excess rainfall condition in a excess rainfall year is found to be 35.7 %. Out of 22 deficient rainfall years, during four years viz. 1877, 1899, 1918 and 1987 more than 60 % area of the country suffered from deficient rain. Similarly out of 19 excess rainfall years during four years viz. 1892, 1917, 1961 and 1988 more than 40 % of the total area of the country was under excess rainfall conditions. Conditional probabilities have been computed for all-India rainfall to be deficient or excess on the basis of June, July and June + July rainfall. It is observed that by the end of July it is possible to anticipate with reasonable degree of accuracy how the performance of the monsoon will be at the end of September, whether it will be normal, deficient or excess. Based on these assessments precautionary measures can be taken in case of monsoon being abnormal.

SHORT-TERM EARTHQUAKE PREDICTION: METHODOLOGICAL ADVANTAGES AND WARNING SYSTEM.

Vitali A. MORGOUNOV (Institute of Physics of the Earth, Moscow 123810, B.Grusinskaya 10, Russia, email: vam@uipe-ras.scgis.ru)

What is preferable: to use a chance to win or full ignorance of impending hazard?! Are the cases of real predictions only a blind luck or it is a step to solve the problem? At what extend the uncertainty relation Cognoscibility/Unpredictability of Earthquakes could be improved? Between polar opinions like the dismal prospects for real improvement of the unpredictability (London, November. 7-8, 1996) and unique practical success in China in 1975,1997 there exist a optimum way to solve the most important part of the problem. Progress in the study of short/immediate precursors could be one of the possible path to get over the obstacle due to the following advantages. 1. The final stage of preparation of impending earthquake is characterised by a substantial activation of the process while it's strain rate increase by the orders of magnitude and considerably increase signal-to-noise ratio. That is favourable for identification of critical state of the focal zone through the ground measurements of geophysical fields, in particular by electromagnetic emission, generated by the stress-strain rate of the rock. 2. The avalanche creep process and the worked out instrument make possible to advance the effectivity of the method in relatively short period of time in seismic active areas during the background seismicity (M=3-4). 3. The short-term methods suggest the practical utilisation to prevent the casualties and ecological catastrophes. The EM method, experimental results, and Hardware-Software System "Alarm-Seismo" as an acceptable warning instrument are discussed. The System consists of the network of N slave controllers and master station, where in a real time regime the data is processing by PC computer. The distance between the slave stations is defined by the magnitude of expected earthquake, tectonic and geological peculiarities of the region, relief.

MONITORING OF NATURAL HAZARDS USING MULTI-SENSOR DATA

Ramesh P. SINGH, Sudipa Roy and N.C. Mishra (all at Department of Civil Engineering, Indian Institute of Technology, Kanpur - 208016, India, email: ramesh@iitk.ac.in)

The data recorded by the Special Sensor Microwave Imager (SSM/I), IRS-P3 MOS, IRS - LISS and NOAA AVHRR Data over India have been analysed. The brightness temperature deduced from SSM/I data over snow covered region show distinct behaviour which is attributed to the variable snow thickness and snow melting. The routine analysis of SSM/I data will give fairly good idea of snow avalanches and flooding of the river as a result of snow melting. The daily or weekly variations of brightness temperature, liquid water path (LWP) and total precipitable water (TPW) over Arabian sea and Bay of Bengal has given an anomalous characteristics of a tropical cyclone which hit the coast of Bangladesh. The normalised vegetation index (NDVI), vegetation condition index (VCI) and temperature condition index (TCI) deduced from NOAA-AVHRR give information about the vigor of the vegetation which can be used in monitoring of drought conditions. The IRS-P3 MOS data in 14 bands along path 95 of winter and summer seasons have been used in classifying water bodies. The spectral reflectance deduced in 14 bands give information about the water quality> The characteristic peaks in the spectral reflectance data give idea about the type and distribution of contamination in water bodies. The IRS-LISS data has been used for mapping of the lineaments which can be used for the evaluation of seismic hazards of any region. In the present paper the use of multi sensors data will be illustrated and discussed in monitoring various types of natural hazards.

GEOPHYSICAL HAZARDS: MITIGATION AND WARNING SYSTEMS IN INDIA

K.S. MURTY (E-3 Vishnukamal Apts., 160 Shivajinagar, Nagpur, 440 010 India)

In the last two decades, India was hit by several natural disasters of which the Andhra cyclone of 1977, the Uttarkashi earthquake of 1991, the Latpur earthquake of 1993 and the Andhra cyclone of 1996 are typical geophysical phenomena that caused destruction of property and loss of life on a large scale. Relief measures were taken up by government and non-government agencies, while long-term measures like construction of cyclone shelters and new villages to house the affected population were intiated. Cyclone warning systems, flood warning systems, and seismological network in areas that are prone to these geophysical hazards have been set up. Besides, improved infra-structures like road construction have been made part of the development programmes of the concerned areas. These steps have considerably reduced loss of life in some of the more recent natural disasters the country faced.

JSP23/E/12-B2 Poster **0830-05**

AN EMPIRICAL DISPERTION RELATION FOR SEISMIC SIGNALS AND EARTHQUAKE PREDICTIONS

Boris W. LEVIN (Shirshov Oceanology Institute of RAS and Russian Foundation for Basic Research, 32a Leninsky prosp, Moscow, 117334 Russia email: levin@rfbr.ru); Elena V. Sassorova (State Oceanographic Institute, 6 Kropotkinsky per., Moscow, 119838 Russia; email: sasor@geoph.ioras.msk.ru)

We show that faint seismic signals radiated from an earthquake source and acoustic signals foregoing a compression failure of laboratory rock samples can be written by common empirical relationship for waves of period T and length L, as follows T^2 = d L, where d is dimension coefficient. This leads us to some empirical dispersion relation for seismic signals that is defined by expression W^2 = 2*3.14* A k, where W is frequency, k – wave number, A-acceleration of stress force. The attempt to find such dispersion relation with theoretical way was made by L.Brevdo (1998) because similar function may, on his opinion, lead to an effective method of some earthquake prediction. We used special developed software package for data processing of 200 earthquake records and had found more than 30 events in which digital records the seismic foregoing signals were discovered. The period-length relation for these signals was well described by presented expression. Although the expression should been studied for using in condition of real seismic region, the presented method can sometimes be used to further improve earthquake disaster mitigation practices.

A VOLCANO MONITORING AND TSUNAMI WARNING SYSTEM FOR GRENADA AND THE SOUTHERN GRENADINE ISLANDS.

Lloyd L. LYNCH, John Shepherd, and Chandradath Ramsingh (Seismic Research Unit, University of the West Indies, St. Augustine, TRINIDAD, email: sru@wow.net).

We propose to develop and establish a volcano monitoring and tsunami warning system for Grenada and the southern Grenadine islands. This region is located close to the Kick 'em Jenny (KeJ) submarine volcano, which has erupted ten times since it, was first identified in 1939. Studies that have been done to assess the explosive potential of this volcano and to assess the vulnerability of the East Caribbean Islands to tsunamis, have identified it as a prime tsunami-genic source with Grenada and the southern Grenadines being most vulnerable to its hazards. The studies have also revealed that East Caribbean islands are exposed to tsunamis from other potential sources but to a lesser extent and that the existing regional seismograph and volcano monitoring efforts could be extended and reinforced to mitigate the effects of hazards from KeJ and tsunamis.
The primary aim objective of the volcano monitoring and tsunami warning system is therefore to maximise life safety by providing some level of advanced warning to the vulnerable population. The system is composed two critical components. The first is an integrated network of instruments to detect and rapidly evaluate the nature of increased volcanic activity at the KeJ and events of tsunami generating potential (such as sub-marine landslides or large earthquakes). An array of tide gauges will also be used to track the progress of any sea wave that may be generated. The second component of the system is a set of definitive procedures on how to respond to a tsunami-genic event. All data from the network will be tele-metered to a permanently manned monitoring and warning center to be established near the north coast of Grenada. Warning and alert activities will be co-ordinated through this center. Selected data channels will be relayed to the headquarters of the regional earthquake and volcano-monitoring agency - the Seismic Research Unit (SRU). This agency will widely support the warning center in the areas of equipment installation and maintenance, data processing and interpretation, and staff training. The SRU also plans to assist in educating vulnerable communities about other mitigation techniques that can be used to complement the proposed system.

TOWARDS UNDERSTANDING LAHAR-TRIGGERING MECHANISMS AT RUAPEHU

Vincent NEALL and Jerome Lecointre (Institute of Natural Resources, Massey University, Private Bag 11 222, Palmerston North, New Zealand, email: V.E.Neall@massey.ac.nz); Katy Hodgson (Natural Resources Engineering/Environmental Management and Design Division, Lincoln University, P.O. Box 84, Canterbury, New Zealand, email: Hodgsonk@kea.lincoln.ac.nz)

Over 20 major lahar deposits have been mapped and described from the past 2,000 year B.P. record at Ruapehu. In historical time, a number of different lahar-triggering mechanisms have been observed, so it is pertinent to ascertain how the prehistoric lahar record originated and how this relates to lahar magnitude. We are beginning to recognise specific signatures in the lahar/tephra record that fit models for lahar generation at this volcano. Lahar deposits immediately preceding tephra eruptions are consistent with volcanic activity emptying the crater lake until dry eruptions can occur with resultant ash showers as exemplified by the 1995 eruptions. Lahar deposits immediately following tephra eruptions are consistent with post-eruptive rain-triggering events mobilising tephra accumulations high on the cone. Lahar deposits containing fragile volcanic bombs are clearly indicative of explosion events and eruption-generation of the lahars. Others will be non-eruptive collapse events due to failure of the crater lake wall for a variety of reasons. Currently our programme seeks to: (1) use all sedimentological parameters to characterise the lahar deposits; (2) use petrological matching of lahar clasts to lava flows on the edifice; (3) integrate the complex lahar and tephra record and; (4) provide further precise dating, to elucidate how prehistoric lahars over the last 2,000 years were generated. We thereby hope to understand the environmental conditions one may expect to lead to, or cause any future laharic event.

ERUPTION FORECASTING AT CERRO NEGRO VOLCANO, NICARAGUA, USING TIME-VOLUME RELATIONSHIPS

Brittain HILL, Charles Connor (CNWRA, Box 28510 San Antonio TX USA 78228,
E-mail: bhill@swri.edu)

At the scale of sub-duction-zone tectonics, magma production rates appear constant relative to eruption recurrence rates. Differentiation and mixing processes obscure magma production rates in the mantle, making time-volume relationships complex at differentiated volcanic systems. Cerro Negro (CN) volcano in Nicaragua, however, has erupted relatively homogeneous high-Al basalt 22 times since forming in 1850 A.D. Small petrogenetic variations at CN are produced through minor crystal fractionation+accumulation. Waxing activity from 1850-1900 is followed by a steady-state eruption rate of 1.8x10^6 m^3/yr. Relatively constant petrogenesis of CN basalt suggests eruption rate is controlled by the mantle replenishment rate and thus may follow simple time-volume predictable patterns. Empirically, large-volume eruptions at CN since 1900 are followed by long quiescence, whereas short quiescence follows small-volume eruptions. The timing of CN eruptions >5x10^6 m^3 has a linear relationship (r^2=0.97) with cumulative volume at the time of each eruption. Eruptions in 1992 and 1995 are successfully forecast within 1 yr of the actual eruption using these relationships. The 1971 eruption occurred 12 yr earlier than expected, also earlier than forecast using a 95% confidence interval (1973-1996). The 1968 eruption occurred 8 yrs

GEODETIC MONITORING OF FOGO ISLAND (CAPE VERDE ARCHIPELAGO) FOR VOLCANIC HAZARD REDUCTION

Sandra I N HELENO, Joao L Matos and Joao F B D Fonseca (IST, Av Rovisco Pais, 1, 1049-001 LISBOA, Portugal, email: sisilva@alfa.ist.utl.pt); Jos N P Lima and J P Osorio (Centro de Geodesia, Instituto de Investigacao Cientifica e Tropical, Rua da Junqueira, 534, 1300 LISBOA, Portugal,
email: cgeod@www.iict.pt); Inocencio J M Barros and Arlindo Rosario (LECV, CP 114, Praia, Republic of Cape Verde, email: lec.mit@mail.cvtelecom.cv); Antonio Berberan (LNEC, Av. Brasil, 101, 1799 LISBOA, Portugal, email: berberan@lnec.pt); Simon J Day, Benfield Greig Hazard Research Centre, UCL, Gower Street,London WC1E6BT, UK, email: s.day@ucl.ac.uk)

As part of a broader hazard reduction project in Fogo Island, N Atlantic, (Fonseca et al., this issue), a programme of periodic GPS and levelling observations was initiated, with a view to the forecasting of impending eruptions by the detection of associated anomalous crustal deformations. In addition, the data will be used in the characterization of the possible flank instability of the volcanic edifice (Day et al., this issue), which may in itself constitute a significant hazard to the population of the island (33000 inhabitants).This poster describes the observational infrastructure built in the island (23 observation points), emphasising the volcanological criteria behind its design, the care taken in the selection of sites with adequate geology, and the stability requirements of the monuments. Results from the Zero Epoch campaign (September 98) are presented and discussed earlier than forecast, but within a 95% confidence interval (1967-1994). Several intervening small-volume eruptions before the 1968 and 1971 events likely triggered the larger eruptions before source replenishment was complete. The 8x10^6 m^3 of basalt erupted during 1995 activity at CN indicates the next significant eruption is most likely in 2000+/-1, with a 95% confidence interval to 2006 in the absence of intervening small-volume eruptions.
The work reported here was supported by the U.S. Nuclear Regulatory Commission (Contract NRC-02-97-009). This work is an independent product of the CNWRA and does not necessarily reflect the views or regulatory position of the NRC.

GLOSEISRISK: A SIMPLIFIED APPROACHING TOOL FOR GLOBAL SEISMIC RISK

QI-FU CHEN and Jie Liu (P. O. Box 166, Center for Analysis and Prediction, CSB,Beijing 100036, P. R. China, email: cqf@ip.cap.ac.cn); Yong Chen (No. 63, Fuxing Avenue, China Seismological Bureau, Beijing 100036, P. R. China, e-mail: yongchen@public.bta.net.cn); Ling Chen (Institute of Geophysics, CSB, Beijing 100081, P. R. China)

A simplified methodology of seismic hazard and risk assessment has been developed by IASPEI working group chaired by Prof. Yong Chen. The new approach includes two analysis methods: One is the seismic hazard analysis method by using earthquake catalogs as basic data and taking area model as potential earthquake sources. A technique is also developed providing the method for integrating individual influences of area sources, near and far, more active or less, into the probability distribution of seismic intensity or peak ground acceleration. Second method addresses exposure bypasses the data collection problems of the traditional method by employing a macroscopic indicator to represent the total exposure directly. The earthquake losses are assessed quickly and approximately by using social wealth represent by Gross Domestic Product and population data.
GloSeisRisk is application software based on Geographic Information System, which is designed to perform analysis and demonstration of seismic hazard and risk with the simplified methodology. The GIS-based GloSeisRisk offers a simplified approach modeling earthquake hazard assessment, loss estimation and earthquake scenario analysis. The GloSeisRisk includes the data analysis and processing programs for seismic catlogue, GDP and population and the seismic risk estimation functions respectively. It can also illustrate the data distribution and seismic risk maps for different print output. The data can be updated readily from available resources in this application tool and easy to update seismic risk analysis.

SCIENCE OR CHANCE? SCORING THE CHINESE ANNUAL EARTHQUAKE PREDICTION FROM 1990 TO 1997

Yaolin SHI (Graduate School, University of Science and Technology of China, Academia Sinica, Beijing 100039, China, email: shiyl@sun.ihep.ac.cn); Jie Liu and Guomin Zhang (Center for Analysis and Prediction, Chinese Seismological Bureau, Beijing 100036, China, email: liujie@cap.ac.cn)

China is the only country in the world that has an official institution dedicated to precursor monitoring and earthquake prediction. About 800 observational stations spread over China, where more than 1700 pre-cursorial elements are monitored on regular basis. Every January, the Chinese (State) Seismological Bureau holds a national consultation meeting on prediction of major earthquake of the year. Deterministic predictions are made in the meeting. Possible risk areas for the year are circled out. These predictions are reported in official documents to the State Council, though kept confidential during the predicted year to avoid unnecessary social panic. In this study, we apply a scheme of success rate score (R-score) to evaluate the disclosed annual predictions in the 90s. A random guess leads to an R-score of 0 and a complete successful prediction has an R-score of +1. The average R-score of the annual prediction in China in the 90s is about 0.10. The probability in achieving equal or better results by random guess for an averaged year is quite high, about 1/3. However, the probability for

random prediction to get equal or better scores in 8 successive years is very low, only 1.5X10^-4. In conclusion, we believe that earthquake prediction in China is not by chance, even though it is still in a very preliminary stage to fit the definition of science.

CONTRIBUTION OF GEOPHYSICAL INVESTIGATION TO SOLVE AN ENGINEERING PROBLEM, SOUTH EL-KHARGA OASES, EGYPT

Maher A. MESBAH (Department of Geological and Geophysical Engineering; Faculty of Pet. and Min. Eng., Suez, Suez Canal University, e-mail: mmesbah@frcu.eun.eg)

A severe subsidence in the ground has been occurred during the passing of heavy machines which are used in the foundation processes of the base and the sub-base of El-Kharga-Paris railway proposed site. The current geophysical study is directed to determine the causes of this civil engineering problem. Therefore, geoelectric resistivity measurements were done by measuring 25 vertical electrical soundings (VESes) along the proposed line. Also, the previous regional gravity and magnetic surveys were examined in order to obtain the maximum information content from the measured resistivity soundings. In the light of the previous geological, geophysical and geotechnical studies in the area, the measured VESes were manually and automatically processed and interpreted in the light of the drilled boreholes. The analysis and the interpretation of the obtained results should that the maximum monitored depth is 42 m. The resulted geoelectrical models reflects that 3 to 4 geoelectric layers can be determined. A dry surface inhomogeneous layer formed from alluvium deposits covers the investigated site. This surface layer is followed by a soft to hard clay layer. The second geoelectric layer is followed by a hard and compacted clay layer and it was monitored at the most of VESes and didn't at some of them. Therefore, the bedrock layer needed to be a sub-base (or a base) for foundation didn't monitored along the investigated site and special construction requirements are necessary to overcome this conditions of the base.

AUSTRALIA'S IDNDR PROGRAM FOR MITIGATION OF GEOPHYSICAL HAZARDS

Jack RYNN (Member Australian IDNDR Co-ordination Committee, Centre for Earthquake Research in Australia, PO Box 276, Indooroopilly, Queensland 4068, Australia. email: sally.brown@uq.net.au); Alan Hodges (Chair Australian IDNDR Co-ordination Committee, Director General Emergency Management Australia, PO Box 1020 Dickson, ACT 2602, Australia. Email: ahodges@ema.gov.au); Pip Marks, (Manager Australian IDNDR Coordination Committee, Emergency Management Australia, PO Box 1020 Dickson, ACT 2602, Australia. Email: pmarks@ema.gov.au)

Following the proclamation by the United Nations of the International Decade for Natural Disaster Reduction (IDNDR) 1990 - 2000, the Australian Committee was established within Emergency Management Australia (EMA) to pursue the ideals and goals of IDNDR pursuant to mitigation measures of natural disasters in Australia. More than 120 projects were successfully undertaken directly relating to the IDNDR targets of risk assessment, mitigation measures (awareness, disaster planning, education, dissemination of information, community involvement) and warning systems, natural hazards. The multi-disiplinary approach involved government agencies (national, state and local), NGO's, academia and the private sector. The Australian projects include tropical cyclone workstation, risk assessments for storm surge and tsunami, earthquake mitigation of cities, flood and landslide awareness, wildfire prediction and warnings, economic guidelines for loss reduction, medical training package, media campaigns, education curricula and community awareness campaigns. Co-operative efforts with 7 Pacific Island countries through the Pacific Region IDNDR (per 1994 Yokohama Statement) completed projects on cyclone, flood, earthquake, tsunami, landslide and volcano. Planning is in progress to continue the IDNDR concept into the 21st century.

VIGIL - A WARNING SYSTEM FOR VOLCANIC ERUPTIONS IN FOGO ISLAND, NORTH ATLANTIC

Joao F B D FONSECA and Sandra I N Heleno (both at Physics Department, IST, Av Rovisco Pais, 1, 1049-001 LISBOA, Portugal, email: fonseca@alfa.ist.utl.pt) Peggy Hellweg and Horst Rademacher (both at Geo Enterprises Orinda, 57 Overhill Road, Orinda, CA 94563-3122, USA, email: HRademacher@compuserve.com) Steve Pauly and Bruce Pauly (both at Digital Technology Associates Inc, USA, 1330A Galaxy Way, Concord, CA94520, USA, email: dta_pauly@compuserve.com) Nicolas dOreye (ECGS, Walferdange, G.D.L., email: nicolas.doreye@ecgs.lu) Inocencio J M Barros and Arlindo Rosario (both at LECV, CP 114, Praia, Republic of Cape Verde, email: lec.mit@mail.cvtelecom.cv)

The low-energy strombolian eruption of April 95 in Fogo Island (North Atlantic), following 44 years of quiescence, enhanced the awareness of the risk posed to its 33.000-strong population by the volcanic activity (average interval between eruptions of about 20 years). This created the conditions for the implementation of a volcanological monitoring routine, presently being tested.
This presentation will describe the main components of the monitoring instrumentation, namely, a combined network of broad-band (Guralp CMG-40T) and short-period (Guralp CMG-40T-1) seismic stations, and a network of resistive tiltmeter (AGI702) stations. All the data collected, both in Fogo Island and in the neighbouring Brava Island, are transmitted in realtime to the data acquisition and processing laboratory (located in Praia, Santiago Island) using spread-spectrum transceivers and combiner-repeater modules. Aditionally, a network of 23 high-precision geodetic monuments was built in Fogo Island to allow the periodic surveying with GPS receivers and EDM.

SPACE - GEODETIC MONITORING OF LANDSLIDE MOVEMENTS USING GPS TECHNIQUES

P.RUTIGLIANO, F. Vespe (Centro di Geodesia Spaziale P.O. BOX Aperta, 75100 - Matera ITALY, email: rutigl@asi.it); F. Cafaro, C. Cherubini (Politecnico di Bari - Istituto di Geologia Applicata e Geotecnica, Via Orabona 4, 74100 Bari, Italy)

The use of GPS techniques in monitoring natural hazards like volcanic deformations or landslide motions can be a powerful way to improve disaster mitigation. In this work the experimental setting up of a GPS-based system able to monitor landslide motions is reported. The first step of this work consists in evaluating how much a small simulated landslide movement can be mirrored by GPS data. The landslide simulation has been necessary to calibrate the hardware and the software used in this analysis. The experiment has been done using an array of six receivers placed in a small area around the CGS (Center of Space Geodesy) near Matera, Italy. One receiver has been assumed as reference, working permanently during the whole campaign. The other sites have been occupied for eight hours three times each, in order to obtain an evaluation, of the baseline length between all the receivers and the reference one before and after the displacement of the antenna of a known quantity (few cm). The main topics under investigation in this step have been:
a) The minimum observation time needed to obtain an estimation accuracy level suitable to this application (2-3 cm)
b) The possibility of using one frequency (L1) instead of two frequency (L1/L2) GPS receivers without loss of accuracy in the estimation of the movements
The second step of the work consists in the planning of a system to constrain solidly the GPS antenna to the ground, necessary to be sure that the possible motions detected with the GPS are representative of the real motion of the landslide.

COMPARISON OF SEASONAL VARIATION OF WATER/HEAT EXCHANGE AT LAND/ATMOSPHERE INTERFACE FOR THREE SITES IN EAST SIBERIA

Tetsuo OHATA, Yuji Kodama (Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan. email: ohata@pop.lowtem.hokudai.ac.jp, kodama@pop.lowtem.hokudai.ac.jp); Takeshi Ohta (Faculty of Agriculture, Iwate University, Morioka, Japan. Email: takeshi@msv.cc.iwate-u.ac.jp)

Within the GAME-Siberia project, three local sites were selected for study of local land surface processes in order to investigate the response characteristics of land surface to the annual atmospheric forcing cycle. These sites are Tiksi facing the Arctic Ocean (vicinity of Yakutsk called Spasskaya Pad where it is Taiga, and Mogot area in the hilly Taiga area. These three sites were selected from the standpoint of surface conditions (Tiksi-tundra, Spasskaya and Mogotarea) and difference in basic climate parameter, precipitation. All have cold winters. Summer temperature is low for Tiksi compared with other two. Precipitation is high for Tiksi and Mogot. Two former sites have already obtained full year data in 1997-1998, and latter one is planned for 1999-2000 but it has past data obtained by State Hydrological Institute in the 1970s to 1980s. These data will be used for preliminary analysis. Result on the comparison of general geographical/topographical/surface/climate conditions, seasonal variations in ground thermal/hydrological conditions, water/energy exchange at the surface and typical processes need to be considered at each sites will be presented. Furthermore, area of further study and needed observation will be discussed.

JSM24/W/04-B1 0930

MEASUREMRNT OF SENSIBLE AND LATENT HEAT FLUX ON THE TIBETAN PLATEAU

Hirohiko ISHIKAWA, Taiichi Hayashi (both at Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, 611-0011, Japan, E-mail: ishikawa@ssrs01.dpri.kyoto-u.ac.jp); Osamu Tsukamoto and Hironori Fudeyasu (both at Faculty of Sciences, Okayama University, 700-0082, Japan, E-mail: tsuka@ccews2.cc.okayama-u.ac.jp); Ichiro Tamagawa (Institute for Hydrospheric-Atmospheric Sciences, Nagoya University, Furo-cho, Chikusa, Nagoya, 464-0814, Japan); Jun Asanuma (Nagaoka University of Technology, Nagaoka, 940-2137, Japan); Yunquiao Qi (School of Agriculture, Kochi University); Shim Miyazaki (Tsukuba University, Tennouai, Tsukuba, 305-0006, Japan); Jiemin Wang, Yaoming Ma and Zeyong Hu (at Lanzhou Institute of Plateau Atmospheric Physics, Lanzhou, Gansu, 780000, P. R. China)

As a part of GAME (GEWEX Asian Monsoon Experiment), intensive observation of surface boundary layer of Tibetan Plateau (Amdo, 32 ° 14.468'N , 91° 37.507'E) was carried out from late May to early September in 1998. The intensive observation includes four components radiation, wind, temperature and humidity profile by a 14 m tower, precipitation and other meteorological parameters. Soil parameters such as ground surface temperature, soil temperature at three depths and soil heat flux at two depths was also monitored continuously. A 3d-sonic anemo-thermometer and an infrared hygrometer were used to measure atmospheric turbulence. The measurement was conducted almost continuously, and more than 4,500 runs of 30 min. 10Hz data were obtained.With these data the land surface-atmosphere interaction is investigated. As compared with other field data, the downward shortwave radiation is the stronger but the downward longwave radiation is the weaker at Amdo. The resultant net radiation is a little greater. The diurnal variation of the surface temperature exceeds 50 degrees in the dry season, which reduced to around 20 degrees after the onset of monsoon. The sensible heat flux was dominant in the dry season, but the latent heat flux becomes comparable with sensible heat flux in the wet season. The surface energy balance is assessed from net radiation, turbulent fluxes and the soil heat flux estimated from soil parameters. The balance is not well established so far. The estimated soil heat flux is smaller than the residual, Rn-H-LE.In addition to the intensive observation at Amdo, four automatic weather station have been collecting basic meteorological data since August, 1997. The data reveal the south-north contrast of the meteorological condition of the plateau including the winter time.

JSM24/E/06-B1 0950

IMPROVEMENT OF MICROWAVE REMOTE SENSING ALGORITHM FOR SNOW AMOUNT ESTIMATION USING GEOLOGICAL INFORMATION

Hiroyuki OHNO (Japan International Research Centre for Agricultural Sciences, 1-2 Ohwasi, Tsukuba, 305-8686, Japan, Email: ohno@jircas.affrc.go.jp); Tetsuo Ohata (Institute of Low Temperature Science, Hokkaido University, 19-8, KIta-ku, Sapporo, 060-0819, Japan, Email: ohata@pop.lowtem.hokudai.ac.jp); Hironori Yabuki (Frontier Research System for Global Change, Institute for Global Change Research, Seavance North 7F, 1-2-1 Shibaura, Minato-ku, 105-6791, Japan, Email: yabuki@frontier.esto.or.jp)

The methods to estimate the amount of deposited snow using microwave remote sensing technique have been studied by many researchers. Many of studies point out that an algorithm, with the form of a polynominal of brightness temperatures, does not have large appricable area. The reason is considered that the microwave emission is affected not only by

the layer of ice particle but also by snow wetness, depth hoar, forest cover and complex mountains terrain. We made linear regression analysis between ground measured snow depth and the difference of microwave brightness temperature (T19v-T37v) observed by SSM/I on DMSP satellite for the data from 1994 to 1998, over more than 500 points ranging eastern part of the Euro-Asian Continent. The result shows that both of the first order (slope) regression coefficient and the standard error of regression has a tendency and to be large in central part of East Siberia. In contrast, only standard error is significant in the area of lower altitude in East Asia, without a clear tendency in slope coefficient. Based upon the result above, we developed a new algorithm being simple and having wider applicable. In the algorithm, the amount of deposited snow is calculated from the linear combination of raster maps of the brightness temperature, slope coefficient and offset coefficient. This procedure has an advantage of representing regional distribution of the error of estimation. We created the maps of the coefficients and the error, by means of multi-valuable regression of geological information of elevation, ld.

JSM24/E/14-B1 1010

BOREAL FOREST SNOW INTERCEPTION AND SUBLIMATION FLUXES

POMEROY (1), J. Parviainen (2), N. Hedstrom (1, 2), D.M. Gray (2) (1): National Hydrology Research Centre, Environment Canada, 11 Innovation Blvd., Saskatoon, Sask. S7N 3H5 Canada; (2): Division of Hydrology, University of Saskatchewan, Saskatoon, Sask, S7N 0W0 Canada)

The accumulation, unloading and sublimation of intercepted snow in northern forest canopies is described mathematically and using empirical data. Using fractal mathematics, the physics of interception and sublimation are scaled-up from small-scales, where they are well understood, to forest stand or larger-scale calculations of intercepted snow sublimation. Sublimation rates reached 3 mm per day and could take up to 120 hours after a snowfall. Evaluation of results from the simulation against measured interception and sublimation in a Canadian boreal forest jack pine stand during late winter, found the coupled model provides reasonable approximations of both interception and sublimation losses on half-hourly, daily and event basis. Cumulative errors in estimate of intercepted snow load over 23 days of test were 0.06 mm SWE with a standard deviation of 0.46 mm SWE. Sublimation losses during the evaluation were high, approximately two-thirds of snowfall within this period. Seasonal intercepted snow sublimation as a portion of annual snowfall at the model test site was lower than sublimation during the tests, ranging from 13% for a mixed spruce-aspen, 31% for the mature pine and 40% for a mature spruce stand. The results indicate that sublimation can provide a significant transfer of water vapour from northern forests to the atmosphere and that the transfers can be estimated by application of process-based algorithms can provide a significant transfer of water vapour from northern forests to the atmosphere.

JSM24/W/02-B1 Poster 1030-01

SIMULATION OF PADDY FIELD USING THE SIB2 IN GAME-T

Wonsik KIM, Taikan Oki, Katsumi Musiake (Institute of Industrial Science, University of Tokyo, 7-22-1, Roppongi, Minato-ku, Tokyo 106-8558, Japan, Email: wonsik@iis.u-tokyo.ac.jp, taikan@iis.u-tokyo.ac.jp, prof@hydro.iis.u-tokyo.ac.jp)

At present it is being understood that the changes in water and energy cycle in Tropical Asian Monsoon (TAM) influence the water and energy balance of the other climatic systems. However, the changing of energy balance of land surface due to vegetation changes by deforestation in TAM is unknown. As one of the GEWEX Asian Monsoon Experiment-Tropics (GAME-T) projects, experiments to examine the above relationship were launched. One of the experiments was to monitor the energy balance of a paddy field in GAME-T area using a micrometeorological method. Micrometeorological parameters and variables of the paddy field were measured during the period of GAME-T project in Sukhotai, Thailand. Another experiment was performed to simulate the monthly energy balance of this site using the simple biosphere model (SiB2) proposed by Sellers et al.(1996). The leaf area index (LAI) of the vegetation was used as the indicating parameter for the vegetation changes. It was suspected that the changes in the LAI affects predominantly in changing the sensible heat flux and latent heat flux, which are important deciding factors of water and energy cycle.

JSM24/W/03-B1 Poster 1030-02

THE MONITORING OF GROUND HUMIDITY BY METHOD NMR OF THE EARTH'S FIELD

Anton SABANIN, Vladimir Sapunov, Alexey Denisov (Quantum Magnetometry Laboratory, Physics-Technical Department, Urals State Technical University, Mira 19 St., Ekaterinburg, 620002, Russia. E-mail: ants@dpt.ustu.ru)

NMR measurements are made by manipulating hydrogen protons in fluid molecules. Use of a method NMR gives exact amount of a free fluid, and does not depend on impurity. We have developed and assembled the working model of relaxometer. The relaxometer allows determining saturation of cores by a proton-containing fluid. In updating the equipment the application of the sensor on a surface of ground for monitoring humidity is supposed. Other opportunities of application are considered too.
The method of measurement – Packard-Varian, at which sample is exposed to initial magnetization with the subsequent registration of a signal free precession in the Earth's magnetic field. The times of the longitudinal relaxation time (T1) and the transverse relaxation time (T2) determine character of interaction of a fluid with a sample (ground, sand, etc.), and give the additional information on an opportunity and speed of discharge of water in a ground. Both are directly relate to a porous size. The amplitude of a free precession signal gives the information on amount of a fluid in a sample (Free Fluid index – FFI).
In the paper the accounts original of the noise proof proton sensor of a disk type are submitted. The received signal from such sensor does not depend on orientation of a magnetic field. The registration of a signal occurs in a homogeneous magnetic field of the Earth, that allows to characterize the large volumes of a sample not paying attention on heterogeneity its. In the same time the additional magnetic system is excluded and power consumption is lowered. The mode of accumulation and storage of a signal for case of low-saturated samples is stipulated.

JSM24/W/07-B1 Poster 1030-03

CHARACTERISTICS OF PLANETARY BOUNDARY LAYER STRUCTURE IN CENTRAL TIBET DURING SUMMER SEASON OF 1998

Nobuhiko ENDO (Frontier Research System for Global Change, c/o National Research Institute for Earth Science and Disaster Prevention, Tsukuba, Ibaraki 305-0006, JAPAN,
Email: endo@frontier.bosai.go.jp); Tetsuzo Yasunari (Institute of Geoscience, University of Tsukuba, Tsukuba, Ibaraki 305, JAPAN, Email: yasunari@atm.geo.tsukuba.ac.jp)

Many invesigators have previously been evaluated atmospheric heat source and moisture sink over the Tibetan plateau. One of the important processes on the energy and water circulation over the plateau is heat and water transportation mechanism in the planetary boundary layer. Although several special observations were made in Tibet, regional characteristics of the planetary boundary layer (PBL) are not so clear. The purpose of this paper is to describe the regional characteristics of the PBL structure at Amdo, Central Tibet, during summer of 1998.
Using data set is a GAME-TIBET IOP-98 special aerological data which were collected at Amdo (32.25N, 91.63E, 4700ASL) during the GAME-TIBET IOP from June 3 to August 20, 1998. The routine radiosounding observation was made at 00, 06, 12 UTC during IOP. We observed that vertical potential temperature gradient around middle of troposphere was rapidly decreased in June 10. It is coincided with a development of the Tibetan High. Atmospheric moisture content was suddenly increased at June 13. We considered that the monsoon season at Amdo was started around June 13 to June 21 to describe characteristics of the diurnal variation of PBL structure. Observed PBL diurnal variation was very clear. Most obvious character is the atmospheric moisture content was increased and easterly wind was simultaneously prevailed lower most 1000m depth of atmosphere during night. On the other hand, the mixed layer was developed during daytime. Its top reached around 2000m above the ground level. Shallow or deep convective cloud was developed during late afternoon. Those characteristics were almost similar to the CREQ93 radiosonde observation which made at northern side of the Tanggula mountain in 1993. However, the mixed layer depth at Amdo was larger than the case of CREQ93, and the precipitable water content was larger in Amdo. From GMS cloud imagery observation, it is obvious that cloud activity is more vigorous in southern side of the Tanggula mountains. Objective analysis data shows that there is a meridional gradient of water vapour over the plateau.

JSM24/C/U1/P/03-B1 Poster 1030-04

GROUND WATER RECHARGE IN NORTHERN UGANDA

JAMES MWAMI (Integrated Pastoral Development Project, PO. Box 964 MBARARA, Uganda, Tel/Fax: 256-485-21395 E-mail: kalisa@swiftuganda.com)

Provision of Potable water supply for Uganda's predominantly (>90%) rural population depends upon the development of ground water. Recent research into ground water resources of Apac District of Northern Uganda indicates that most ground water moves by way of shallow weathered soils (regolith) rather than the underlaying bedrock fractures which have traditionally been developed. Indeed, the Lango people have relied upon this shallow source through unprotected spring discharges and land dug "scoop wells". During the last three years a number of agencies (WATSAN-UNICEF, CPAR) have constructed shallow wells with competent yields in the regolith for domestic, hand pump obstruction rates up to 3m 3/day. However incidents of well failure and waning spring flow have been attributed to presumed fluctuations in the shallow water table and raised concerns over sustainability of ground water development programmes in this region. Nevertheless, studies of ground water recharge in Apac have shown that replenishmnent is in the order of 0.2m/year and occurs exclusively from intense (>I 0mm/day) rainfall during the monsoons. Monitoring of water levels in the unconfined, regolith aquifer was therefore initiated in June 1994 in order to investigate both the magnitude of water table dynamics in the regolith and the nature of the water table's response to recharge events predicted by developed models of ground water recharge.

JSM24/W/06-B1 1105

SCALES AND TRENDS OF OBSERVED SOIL MOISTURE VARIATIONS, AND PREDICTED FUTURE VARIATIONS OF SOIL MOISTURE

Alan ROBOCK (Dept. of Environmental Sciences Rutgers, The State University of New Jersey, 14 College Farm Road, New Brunswick, NJ 08901-8551 USA, email: robock@envsci.rutgers.edu); Konstantin Y. Vinnikov (University of Maryland, USA)

Soil moisture is an important variable in the climate system. Understanding and predicting variations of surface temperature, drought, and flood depend critically on knowledge of soil moisture variations, as do impacts of climate change and seasonal forecasting. An observational data set of actual in situ measurements is crucial for model development and evaluation, and as ground truth for remote sensing. We describe the Global Soil Moisture Data Bank, a web site http://www.envsci.rutgers.edu/~robock) dedicated to collection, dissemination, and analysis of soil moisture data from around the globe. The Global Soil Moisture Data Bank is a resource for the remote sensing, climate modelling, and climate analysis communities. We currently have soil moisture observations for over 400 stations from a large variety of global climates, including from the former Soviet Union, China, Mongolia, India, and the US. Here we describe the use of several of these data sets to analyse inter-seasonal, inter-annual and inter-decadal variations in soil moisture and determine the important scales of soil moisture variations. In the past, we have used these data to evaluate calculations of soil moisture by land surface models, including PILPS Phase 2(d), the ECMWF ERA-15 reanalysis, the Global Soil Wetness Experiment, to determine the representativeness of our current soil moisture network, to make recommendations about spatial and temporal scales of climate modelling and satellite remote sensing of soil moisture, and as ground truth for passive microwave remote sensing of soil moisture. The scale of temporal variation of soil moisture observed in Illinois, Russia, China, and Mongolia is about 2 months in all cases and the spatial scale in all these regions is about 500 km. We show these analyses and explain how these scales are controlled by atmospheric forcing. This has important implications for climate model evaluation, remote sensing, and design of surface observational networks of soil moisture. Summer desiccation is one of the most serious potential negative consequences of global warming.

JSM24/E/03-B1 1125

A FIELD STUDY OF ATMOSPHERIC FORCING OF THE SUBSURFACE WATER BUDGET

Gabriel ROONEY (Met. Research Unit (Field Site), Shortstown, Bedford, MK42 0SY, UK)

Results are presented from a continuing field study of subsurface and atmospheric moisture fluxes at a site near the main drainage stream of a shallow meso-scale (3 km lengthscale) sub-catchment near Bedford, UK. The study, carried out by the UK Meteorological Office Research Unit, began in May 1997 and collects data of precipitation, atmospheric moisture flux and water-table depth, and of subsurface moisture content using a buried vertical array of soil-moisture probes. Wind, radiation, and atmospheric, surface, and subsurface temperatures are also continuously measured.
The soil-moisture evolution is compared with simple force-restore methods for modelling precipitation recharge and drainage and evaporation/transpiration losses. The data show how the soil moisture contents at different depths depend to varying degrees on evaporation as well as precipitation, and how the deep soil moisture over-responds to the precipitation input because of drainage effects, effectively responding to the concentration of precipitation from a wider area. This indicates that one-dimensional modelling of subsurface moisture movement is insufficient in the saturated zone. In addition, it is demonstrated that the timescale for recovery from surface forcing also varies with depth.

JSM24/E/01-B1 1145

RETRIEVAL OF PLANT-AVAILABLE SOIL MOISTURE THROUGH SATELLITE DATA ASSIMILATION INTO A GLOBAL VEGETATION AND LAND SURFACE MODEL

Wolfgang KNORR (Max-Planck-Institut fuer Meteorologie, Bundesstrasse 55, D-20146 Hamburg, Germany, email: knorr@dkrz.de); Jan-Peter (Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark); Bernard Pinty and Michel Verstraete (Space Applications Institute, European Commission Joint Research Center, I-21020 Ispra, Italy); Martin Heimann (Max-Planck-Institut fuer Biogeochemie, Postfach 100164, D-07701 Jena, Germany)

Plants control much of the water balance over continental areas. Therefore, observations of vegetation distribution from satellites can be used as an indicator of the amount of plant-available soil moisture for land surfaces on a global scale. Here, we present a method of inferring land moisture status by a combination of land surface modelling, using observed climate and soils data, and satellite remote sensing. The Biosphere Energy-Transfer and Hydrology model (BETHY) is used to compute photosynthesis, energy and water balance, as well as plant distribution globally. Modelled fields of the fraction of absorbed photosynthetically active radiation (fAPAR) are then compared to satellite data from NOAA-11/AVHRR, and a number of model parameters are adjusted until the agreement reaches an optimum. The results indicate maximum plant available soil moisture of 1000 mm and higher for many parts of the tropics and the arid temperate zones. By a comparison with field measurements, we also demonstrate the importance of consistency between observed greenness and proper surface parameterisation. Modified fields of maximum soil water storage lead to rather large changes in the simulated surface temperature in a general circulation model for a number of regions.

JSM24/E/11-B1 1205

POSSIBLE ROLE OF SNOW-COVER ON VEGETATION IN ARID AND SEMI-ARID ASIA

Shao-Fen TIAN (Frontier Research System for Global Chadnge, IGCR, c/o Nat'l Inst. Earth Sci. & Disaster Prevention, Tsukuba, 305-006, Japan, e-mail: tian@frontier.bosai.go.jp); Tetsuzo Yasunari (Institute of Geoscience, University of Tsukuba, Tsukuba, 305-8571, Japan, e-mail: yasunari@atm.geo.tsukuba.ac.jp); Yuuya Adachi (College of Natural Science, University of Tsukuba, Tsukuba, 305-8571, Japan, email: adachi@etesia.geo.tsukuba.ac.jp)

This study examine role of snow-cover on the vegetation activities in arid and semi-arid Asia by comparing the spatial distributions and mean seasonal evolutions of the Normalized Differential Vegetation Index (NDVI), rainfall and snow-cover extent. Particularly, Gobi desert and the surrounding steppe regions are emphasised. Spatial distributions of annually-cumulated NDVI and snow-cover extent reveal that the boundary between Gobi desert and the northern steppe region coincides with the southern limit of regions with seasonal snow-cover. Seasonal evolutions monthly mean NDVI and rainfall shows that green-up in northern Mongolia (with snow-cover) precedes the onset of rainy season. However, the vegetation activity in Gobi desert and Ordos Plateau (without snow-cover) varies almost simultaneously or with a small lag to rainfall. The results suggest that the snow-cover in arid and semi-arid regions may be important for the vegetation activity there. It is implied that decrease in spring snow-cover associated the global warming may bring further northern expanding of the mid-latitude deserts.

JSM24/E/04-B1 1225

CALCULATION OF RUNOFF IN LPS WITH SUBBASIN GRIDDING METHOD

Suxia LIU (Department of Hydrology, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, P.R.China, email: liusx@sun.ihep.ac.cn)

Almost all of current schemes of land surface Parameterization (LPS) use longitude and Latitude to subgrid research areas for regional staudy. This paper uses sub-basin gridding method to calculate runoff for a region in a typical Yellow River Basin. The regional Climate model is used for the calculation. The results are compared with that by current gridding method which certainly cut off the basin. It is shown that sub-basin gridding method is more reasonable from the point of hydrological view in water fluxes calculation.

WATER BUDGET OF INTENSE CYCLONES IN THE BALTEX REGION

Burkhardt ROCKEL (Institute of Atmospheric Physics, GKSS Research Centre, Max-Planck-Straße, 21502 Geeshacht, Germany, email: rockel@gkss.de); Ute Karstens (Institute of Atmospheric Physics, GKSS Research Centre, Max-Planck-Straße, 21502 Geeshacht, Germany, email: karstens@gkss.de)

Extra tropical cyclones are one of the major forces driving the hydrological cycle transporting huge masses of moist air and water between different regions of the globe. Within the frame of the Baltic Sea Experiment (BALTEX) the water budget of three intense cyclones was studied. These cyclones occur during the period 28th of August 1995 to 5th of September 1995, which falls into the PIDCAP (BALTEX Pilot Study for Intense Data Collection and Analysis of Precipitation) period where an extended set of observational data was collected. These cyclones were investigated making use of several ground based (e.g. rainfall stations, rain radars, GPS stations) and satellite measurements (e.g. NOAA/AVHRR) as well as analysis data from ECMWF and the German Weather Service. Special emphasis was laid on the 3D-distribution of water components in the cyclones and their temporal development. One of the cyclones staid in the observed area from its formation to its decay, which made it possible to study its whole life cycle.Also the accompanied water transport into the BALTEX region will be shown in this presentation.Furthermore a regional forecast model with a horizontal resolution of less than 20 km was used to simulate these cyclones and compared to the measured and analysed data sets.

JSM24/W/10-B1 1420

RELATIONSHIP BETWEEN RAINFALL AND GSUT IN TIBETAN PLATEAU IN SUMMER MONSOON SEASON OF GAME/TIBET 1998

Taiichi HAYASHI (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto, Japan, email: hayashi@rcde.dpri.kyoto-u.ac.jp)

The Tibetan plateau is the third pole in the world, following the arctic and Antarctic poles, which affect the Asian monsoon. In the summer monsoon, Rainfall occurred in the afternoon almost everyday after the active development of cumulus in the morning. The wind speed increases suddenly from a few to more than 20-30m/s in only a few ten minutes. At the same time, the wind direction changes and the temperature falls abruptly. Strong solar radiation activates the convection and causes this diurnal variation in spite of the little humidity in the surface of the Tibetan Plateau. The observation of the turbulence in the atmospheric surface layer and clear the existence of the downdraft below the matured cumulus cloud. Enhanced aerological observation, the sensor was launched every 3 hourly, was made from June 7.

JSM24/E/02-B1 1440

GROUND VALIDATION OF THE TRMM PRECIPITATION RADAR AND MESOSCALE ANALYSES WITH AN X-BAND DOPPLER RADAR SETTLED ON THE TIBETAN PLATEAU

Shuji SHIMIZU (Earth Observation Research Center, National Space Development Agency of Japan, 1-9-9 Roppongi, Minato-ku, Tokyo 106-0032, JAPAN, email: shimizu@eorc.nasda.go.jp); Ken'ichi Ueno (School of Environmental Science, The University of Shiga Prefecture, 2500 Hassaka-cho Hikone, SHIGA, 522-8533 JAPAN, email: kueno@ses.usp.ac.jp); Hideyuki Fujii (Department of Civil and Environment Engineering, Nagaoka University of Technology, 1603-1 Kamitomioka-cho, Nagaoka, Niigata 940-2137, JAPAN, email: fujii@hydro.nagaokaut.ac.jp); Hiroyuki Yamada (Department of Earth and Planetary Science, Hokkaido University, Nishi-8, Kita-10, Kita-ku, Sapporo, Hokkaido 060-0810, JAPAN, email: yamada@metsun1.sci.hokudai.ac.jp); Ryuichi Shirooka (Department of Rural Development, Hokkaido National Agricultural Experiment Station, 1 Hitsujigaoka, Toyohira-ku, Sapporo, Hokkaido 062-0045, JAPAN, email: shirooka@cryo.affrc.go.jp); Liping Liu (Lanzhou Institute of Plateau Atmospheric Physics, Chinese Academy of Science, 196 Dong Gang Xi Lu, Lanzhou, PRC, email: wmail2@ns.lzb.ac.cn)

A field observation using an X-band Doppler radar for the ground validation of the TRMM satellite was carried out between May to September 1998 near Naqu, Tibet for the GAME-Tibet project. Midnight rainfall was frequently observed around Naqu area. Stratiform rain lasted for 7 hours from 1600 UTC 1 Aug. 1998. In this case TRMM passed over the radar observation area. The TRMM PR showed that the stratiform echo had small diameter (< 100km) and local rain around Naqu area. PR and ground radar have qualitati c In this case a bright band clearly existed at 0.8km from surface (5.3km above sea level). Time series of vertical profiles of horizontal winds calculated by VAD method shows that beginning time of the northerly wind near the surface coincided with start of rainfall. Then northeasterly wind and convergence dominated around the radar site. The convergence made rain strengthen. It showed that the wind and divergence fields contribute to change of stratiform precipitation.

JSM24/E/08-B1 1500

REASSESSMENT OF THE MOISTURE SOURCE OVER THE SAHARA DESERT

ALPERT Pinhas, Yuval Shay-El (Dept. of Geophysics and Planetary Science, Tel Aviv University, 69978, Ramat Aviv, Israel, e-mail: pinhas@cyclone.tau.ac.il)

The components of the moisture balance equation are calculated for the Middle-East North-Africa regions, based on NASA's GEOS-1 DAS multi-year dataset. The annual mean DIV (Q) corresponds well with NCEP analysis by Vitart et al (1996). Over the N. African Sahara desert the moisture flux was shown to converge through the northern and southern boundaries mainly at low levels (~900 hPa) and to diverge through the eastern and western boundaries at higher levels (~700 hPa). Starr and Peixoto(1958) have classified N. Africa as a net moisture source. Area averaging of DIV (Q) over a box with varying dimensions reveals that N. Africa can be classified as a NET SINK if the box is small enough and located over the center of the desert. It is suggested that the earlier finding of a net source might be due to smoothing of the water\land boundaries, or due to atmospheric diffusion processes such as the sea-breeze cycle or clouds intrusion and their dissipation.

JSM24/W/14-B1 1520

RELATIONSHIP BETWEEN RAINFALL AND DEFORESTATION IN THAILAND

Shinjiro KANAE, Taikan Oki, Katumi Musiake (IIS, University of Tokyo, 7-22-1 Roppongi Minato-ku Tokyo, Japan, email: kanae@iis.u-tokyo.ac.jp)

Observed monthly rainfall data for more than 40 years in Thailand are collected and analyzed, to extract the long-term trend which may reflect the effect of deforestation. Consequently, a remarkable characteristic is found in the analysis of September, which is the peak month on rainfall in Thailand. To investigate the cause of this characteristic, numerical simulations with a regional climate model are carried out. From the analysis of these numerical simulations, it is concluded that the deforestation in Thailand should be the cause of this long-term rainfall change. Also the mechanism how deforestation influence rainfall is discussed.

JSM24/W/15-B1 1610

WATER AND ENERGY CYCLES IN THE TROPICAL SOUTH EAST ASIA FROM THE INTENSIVE OBSERVATION OF GEWEX ASIAN MONSOON EXPERIMENT IN TROPICS IN 1998

Taikan OKI, Toshiyuki Nakaegawa, and Katumi Musiake (Institute of Industrial Science, University of Tokyo 7-22-1 Roppongi, Minato-ku, Tokyo 106-8558, Japan Email: taikan@iis.u-tokyo.ac.jp)

As a part of GEWEX Asian Monsoon Experiment (GAME), GAME-Tropics (GAME-T) is aiming the quantitative monitoring of vapor flux, precipitation, evapotranspiration, radiative flux, and their seasonal, intra-seasonal, and interannual variations in the south-east Asia, and also aiming their applications for water resources management in the region. In order to accomplish these objectives, various field observations and data collections has been planned and implemented. The year 1998 was set to be the Intensive Observation Period (IOP) of GAME and organized field observations and data collections were carried out through the target region. Even though the target area of GAME-T largely covers the warm humid region in the south-east Asia, observational activities were mainly focused in Thailand. Although subsequent or intermittent observations are associated, major IOP activities were done during these two periods; Phase I Monsoon onset: middle of April to middle of June, and Phase II Mature stage of monsoon: middle of August to middle of September. Comprehensive observations includes 4 times daily launch of rawinsonde at 4 sites within Thailand associated with continuous observation by GPS receivers for estimation of precipitable water, digital recording of three weather radars, detailed surface flux observations at three representative land scapes, and ground truth observations for satellite remote sensing such as soil moisture measurement by SAR. From these IOP observations, a hydro-meteorological dataset is being

developed and comparative studies between these two phases are being carried out. Characteristic differences of water and energy cycles between the onset and mature stage of monsoon season was found even in a preliminary summary of the IOP data. Data management, the future linkage with modeling, and the regional reanalysis in high resolution using the IOP data will be discussed as well.

JSM24/W/16-B1 1630

SEASONAL CYCLE AND INTERANNUAL VARIABILITY IN THE AMAZON HYDROLOGIC CYCLE

Dr Ning ZENG (UC Los Angeles, email: zeng@atmos.ucla.edu)

An analysis of the Amazon basin hydrologic cycle has been carried out using the NASA/GEOS-1 atmospheric reanalysis, observed rainfall of Xie and Arkin, and historical Amazon river discharge. Over a seasonal cycle, the precipitation is found to vary by 5 mm day, the runoff by 2 mm day while the evaporation largely remains constant. On interannual time scales, the hydrologic variability both in the atmosphere and at the land-surface is found to be closely related to ENSO. The correlation between the Southern Oscillation Index and Xie-Arkin precipitation is 0.8 for the period 1985-1993 and 0.56 for the period 1979-1996. The precipitation lags behind the Southern Oscillation Index by 3-4 months while the Amazon river discharge lags behind the precipitation by another 3 months. The lagged relationship suggests interesting dynamic mechanisms. The reanalysis moisture convergence and observed discharge are used to diagnose basin average soil water storage. The year to year variation in the annual mean soil water storage is about 200 mm, comparable to the change within a climatological seasonal cycle. In one case, the basin soil water storage increases by 462 mm from September 1987 to March 1989, suggesting the remarkable ability of the tropical rainforest environment to store and take up water.

JSM24/E/05-B1 1650

RECENT GCIP-SPONSORED ADVANCEMENTS IN COUPLED LAND-SURFACE MODELING AND DATA ASSIMILATION IN THE NCEP MESOSCALE ETA MODEL

Kenneth MITCHELL (National Centres for Environmental Prediction, NOAA/NWS, 5200 Auth Road, Camp Springs, MD 20746-4304, USA, email: Kenneth.Mitchell@noaa.gov); John Schaake (Office of Hydrology, NOAA/NWS, 1325 East-West Highway, Silver Spring, MD 20910-3283, USA, email: John.Schaake@noaa.gov)

With support from the GEWEX Continental-Scale International Project (GCIP), the Environmental Modeling Center (EMC) of NCEP joined with NWS hydrologists in the Office of Hydrology (OH) and satellite land-surface remote sensing experts in NESDIS to develop advancements in the land-surface subsystem (LSS) of the NCEP coupled mesoscale Eta model. Recent advancements include an increase from 2 to 4 soil layers, addition of an explicit vegetation canopy, sub-grid runoff treatments, and satellite-derived a) seasonal cycle of vegetation greenness and b) daily snow cover updates. The Eta LSS is a descendant of the LSS of Oregon State University (Pan and Mahrt, 1987). It carries multiple soil layers for which it predicts a) soil moisture using Richard's equation and soil temperature using the heat equation. In a major NCEP milestone on 03 June 98, the LSS state variables of soil moisture, soil temperature, canopy water, and snow water became fully and continuously cycled state variables in the coupled Eta model's 4-D Data Assimilation System (EDAS). Herein, LSS performance must be good on many time scales (hourly, daily, weekly, monthly, and annual). No nudging of the soil moisture is employed, neither to a soil moisture climatology or otherwise. A vivid example of EDAS soil moisture anomalies in the Texas and Oklahoma drought of summer 1998 will be shown. Additionally, this paper will present Eta LSS performance and validation studies, both from uncoupled intercomparison studies (e.g. PILPS 2a, 2c, 2d) and coupled Eta studies. For example, a new capability to validate LSS skin temperature against hourly 0.50-degree GOES-derived skin temperature will be shown.

JSM24/E/12-B1 1710

WATER FLUX AND WATER AVAILABILITY OVER CHINA

Xinguo MO (Environment and Ecotechnology Station, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, P.R.China, email: moxg@dls.iog.ac.cn); Suxia Liu (Department of Hydrology, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, P.R.China, email: liusx@sun.ihep.ac.cn)

The dataset of soil moisture and meteorological data over 102 agrometeorological stations has been collected over China. A simple regional evapotranspiration model is established which only needs the input from routine meteorological stations and soil moisture. Water flux and water availability is calculated by the model. Compared with the potent-evaporation distribution used currently to guide irrigation and other agriculture management, the results from the model is more accurate and reasonable.

JSM24/L/02-B1 1730

SPECIAL-SCIENTIFIC THINKING IN HYDROLOGY: A "LABORATORY" FOR UNDERSTANDING OUR PROSPECTS FOR TODAY?

Konstantin A.Sergeyev, Dr. Sci., Prof. (St.-Petersburg State University, History of Philosophy Department, 5 Mendeleyev Line, St.-Petersburg 191002, Russia, email: george@tetris.dux.ru); Natalia V.PENKOVA, Ph.D (State Hydrological Institute, Water Resources and Water Balance Department, 23 Second Line, St.-Petersburg 199053, Russia, email: george@tetris.dux.ru); George S.Penkov, Student (St.-Petersburg State University, Social Philosophy Department, 5 Mendeleyev Line, St.-Petersburg 191002, Russia, email: george@tetris.dux.ru)

Despite the Hydrology data and conclusions almost worldwide are raised now to the level of a state policy, the state of orthodox methodology of the science does not meet modern requirements: theoretical interpretation of Hydrologic problems lags strongly behind an accumulation of an actual material, and new facts frequently conflict with existing theories and hypotheses. Now the fast opening of new problem area - cross-disciplinary researches area in Hydrology (including the person and socio-historical conditions of her activity) is to be observed. Hydrologic researches methodology shifts from "system-ontological" concept to "system-gnosiological" one, which assumes an application of "subject-object" interactive methodology, a personalization of scientific search, a realization of cognitive potential of Hydrologic methods as "reflection, deflection, mental simulation". Thus, not only production of new knowledge, but also intensive "formation and reproduction of the altered subject of cognition" takes place.
At modern level of Hydrology progress all this as "dissolved in vision of a subject intuition" still remains. But an urgent necessity to express the premises, assumptions and consequences of subject cognition in social concepts is emerging. In the study the task on the basis of realizing the "heuristic structure" of the science, and of analysing of various historical and modern forms of human (natural-scientific) thinking experience as "archaetypes" that assist us to find "in the past tactics, way, method, which will help us to be kept in problematic tomorrow" (Ortega Y. Gasset, 1991) is suggested to be investigated.

LARGE SCALE BUDGETS AND FLUXES

JSM24/W/11-B2 0930

ANOMALOUS ATMOSPHERIC MOISTURE TRANSPORTS AND VARIATIONS IN THE SOUTHEAST ASIAN MONSOON

Ian SIMMONDS (School of Earth Sciences, The University of Melbourne, Parkville, Victoria, 3052, Australia, email: ihs@met.unimelb.edu.au); Daohua Bi (Antarctic CRC, University of Tasmania, Hobart, Tasmania, 7001, Australia, email: d.bi@utas.edu.au); Pandora Hope (School of Earth Sciences, The University of Melbourne, Parkville, Victoria, 3052, Australia, email: p.hope@met.unimelb.edu.au)

Twice-daily ECMWF/WMO analyses have been used to diagnose the summer moisture transport by the large-scale circulation over China. The horizontal flux of atmospheric water vapour and its divergence has been calculated over two target regions, namely, southeastern China (25-35oN, 110-120oE) and northeastern China (40-50oN, 120-130oE). The time-averaged fluxes show the southeastern Asian and Indian monsoon circulations bringing abundant moisture from the South China Sea and the Bay of Bengal, respectively, to southeastern China while the midlatitude westerlies dominate the moisture transport over northeastern China. The paper addreses the association between the interannual variations of moisture flux and rainfall over China. The comparison (for the period 1980 to 1990) of the fluxes for wet (1980, 1982, 1983) and dry (1981, 1985, 1988) years over the southeast showed there to be, for the former, much stronger moisture transport by the southeastern Asian monsoon through the southern boundary but little change associated with transport by the Indian monsoon. Furthermore, comparison between mean and transient eddy transport budgets in wet and dry years and in the climatological mean shows that the mean component is dominant in the total transport. The moisture convergence associated with the transient eddies assumes its largest values in the eastern part of the country and, for the most part, assumes a sign opposite to that of the moisture flux convergence associated with the time-mean circulation and moisture fields. Our results suggest that the transient eddies do not play a significant role in the initiation and maintenance of the abnormal climate events over our two domains.

JSM24/W/12-B2 0950

NONLINEAR REACTIONS OF AUSTRALIAN REGION CIRCULATION AND RAINFALL PATTERNS TO NEAR-SURFACE CONTINENTAL WETNESS CHANGES

Ian SIMMONDS, Pandora Hope (School of Earth Sciences, The University of Melbourne, Parkville, Victoria, 3052, Australia, email: ihs@met.unimelb.edu.au)

We have used GCM experiments to examine the interaction of large scale soil moisture anomalies and the atmospheric circulation. The suite of GCM experiments were performed in which the soil was instantaneously saturated and desiccated over the entire Australian continent. These conditions were imposed on the first day of each of the 12 calendar months and anomaly simulations integrated for four months. We discuss the substantial asymmetry in the transient response of the climate system to these Australian wet and dry soil moisture conditions. A significant amount of the asymmetry in the 'wet' and 'dry' cases is seen to be associated with the propagation of surface thermal anomalies into the troposphere. In January the warm anomaly (in the dry case) propagates more rapidly than does the cool anomaly, due to the switch on of convective processes. Hence the troposphere is influenced more rapidly in the dry case and induces at an earlier stage feedbacks associated with anomalous circulation and moisture transports, and cloud cover. By contrast, in the 'dry' July experiment the warming is to a great extent confined to the lower troposphere. This seasonality of the response may be explained in terms of the behaviour of vertical mixing and convection. In general, the vertical stability of the atmosphere is much greater in winter. Hence, any surface warming would be expected to be confined to lower levels. By contrast, in summer conditions are more conducive to deep cumulus and vigorous mixing and thermal anomalies are able to propagate through greater depths of the atmosphere. The presentation will address some of the many nonlinear processes in the land-atmosphere system and the complex roles played by convection, cloud, circulation regimes (including the monsoon), thermal conditions, and horizontal moisture transports.

JSM24/L/01-B2 1010

THE IMPACT OF CLIMATE CHANGE ON THE WATER RESOURCES OF EASTERN AND SOUTHERN AFRICA

J.R. MEIGH, F.A.K. Farquharson (Institute of Hydrology, Wallingford, Oxfordshire OX10 8BB, UK)

The Institute of Hydrology have taken a novel approach to the problem of assessing the likely impacts of climate change on water resources in Africa and have applied the method to assessing water scarcity. The approach used is believed to offer a realistic and consistent procedure which has been applied across many countries. Water demands, surface flows and groundwater availability were estimated on a gridded basis, and various water availability indices were derived comparing the resource with the projected demand. Surface flows were estimated using a conceptual rainfall-runoff model linking climate to runoff and, in the major river basins, the runoff estimates for individual grid cells were accumulated to give estimates for the total flows at all points of interest. Groundwater availability was derived from hydrogeological maps based on estimates of the potential yield that can be expected from a borehole and the likely maximum borehole density. Estimates of potential groundwater recharge derived from the surface water model were also taken into account. Water demands were based on current and projected population and livestock numbers, and information on irrigation schemes and industrial water use. Results are presented for the application of the model to a region covering the whole of eastern and southern Africa. The main scenario considered includes the combined impact of climate change, population growth and improved living standards to the year 2050. The climate change scenarios applied were those from recent IPCC reports. The results for this scenario show that water scarcity is likely to increase in many countries in the region, with particular problems in the countries around Lake Victoria and in the southernmost parts of the pilot region.

JSM24/E/07-B2 1055

ON THE MACKENZIE BASIN WATER CYCLE DURING TYPICAL AND UNUSUAL WATER YEARS

Ronald E. STEWART (Atmospheric Environment Service 4905 Dufferin Street Downsview, Ontario Canada M3H 5T4)

The atmospheric, surface, and hydrological components of the Mackenzie Basin's water cycle are described and interpreted in this presentation. Particular attention is paid to the 1994/95 water year that was characterized by slightly below-average precipitation and slightly above-average temperature, but the lowest discharge over the past 40 years.
In general, the water cycle of the Mackenzie Basin is characterized by annual precipitation of approximately 400 mm and about 170 mm of equivalent discharge into the Arctic Ocean. The integrated amount of water vapour over the basin averages about 10 mm and snow covers about 55% of the basin on average. The basin's water cycle appears to become more efficient as its overall temperature decreases in that the fraction of the integrated water vapour that results in discharge is actually higher with lower overall temperature as a result of several feedback processes.
In comparison with long-term averages, the 1994/95 water year resulted in very low discharge. The autumn of 1994 was quite dry, almost no rain fell, and much of the initial snowpack was laid down within one episodic lee cyclogenesis event; the snowpack therefore formed over a dry surface. During the spring melt starting in April 1995, there was a persistent high pressure system covering the basin that was linked with sunny skies, no precipitation, strong winds, and rapid snowmelt. Much of the snowmelt percolated into the dry soil and this is believed to be the major factor (along with enhanced evaporation) leading to the greatly decreased runoff and discharge into the Arctic Ocean, and to some of the lowest lake levels ever experienced over Great Slave Lake. In addition, there was a near normal frequency of summer convection during 1995 but dry surface conditions limited local moisture sources and consequently the amount of rainfall. For this cold climate system, features as surface dryness and atmospheric circulations therefore have immediate as well as long-term impacts on the water cycle.

JSM24/W/13-B2 1115

PLATEAU- AND MESO- SCALE ENERGY AND WATER CYCLE EXPERIMENTS ON THE TIBETAN PLATEAU: GAME-TIBET

Toshio KOIKE (Nagaoka University of Technology, Nagaoka, 940-2188, Japan, email: tkoike@nagaokaut.ac.jp); Tetsuzo Yasunari (Institute of Geoscience, University of Tsukuba, Tsukuba, 305-8571, Japan, email: yasunari@atm.geo.tsukuba.ac.jp); Jiemin Wang (Lanzhou Institute of Plateau Atmospheric Physics, Chinese Academy of Sciences, Lanzhou, Gansu 730000, China, email: jmwang@lzu.edu.cn); Tnadong Yao (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou, Gansu 730000, China, email: tdyao@public.lz.gs.cn)

To clarify the interactions between the land surface and the atmosphere over the Tibetan Plateau in the context of the Asian monsoon system by taking into account the importance of seasonal variations in key processes, experiments at two different scales, the plateau-scale experiment and the meso-scale experiment, were carried out during the Intensive Observing Period (IOP) from May to September in 1998. For the purposes of improving the quantitative understanding of land-atmosphere interactions over the Tibetan Plateau and developing process models and methods for applying them over large spatial scales, the following measurement systems were deployed and operated continuously during the IOP: the 14 AWSs, PBL tower, two turbulent flux measurement systems, radio-sonde system, 7 barometers, 20 rain gauges, 3-D Doppler radar, snow particle measurement system, microwave radiometer, GPS receiver, 9 soil moisture and temperature measurement systems, and two river water level gauges. To develop and validate satellite-based retrieval methods and to understand characteristics of spatial and seasonal distributions of surface hydrological parameters, soil moisture and temperature, surface roughness and spectral reflectance were measured at 8 areas in the scale of 60m by 60m with 10m interval and in the scale of 1km by 1km scale with 1 km interval once a moth during the IOP. For the Isotope studies on the origin of precipitation and its recycling, and formation processes of stable isotopic composition, samples of precipitation, river and lake water and soil water were regularly or temporally taken along the north-south and east-west transects in the plateau-scale and the meso-scale experimental fields.

JSM24/W/05-B2 1135

THE ROLE OF ATMOSPHERE, LAND-SURFACE INTERACTIONS IN HYDROCLIMATOLOGICAL PREDICTABILITY

Bob OGLESBY (Purdue Univ., W. Lafayette IN 47907, Email: roglesby@purdue.edu); Susan Marshall (Dept. Geog. &Earth Sci., UNC-Charlotte, Charlotte, NC 28233, Email: susanm@uncc.edu); John Roads (Scripps Institution of Oceanography, UCSD-0224, La Jolla, CA 92093, Email: jroads@ucsd.edu) Franklin Robertson (NASA/Marshall Space Flight Center, Global Hydrology and Climate Center, Huntsville, AL 35806, Email: pete.robertson@msfc.nasa.gov)

Wet and dry seasonal composites have been constructed for three separate regions of the Western Hemisphere using long climate model simulations made with the NCAR CCM3 and reanalysis products from NCEP and NASA/DAO. The regions include (1) the high-latitude Mackenzie Basin in northern Canada; (2) the mid-latitude GCIP region of the central US; and (3) the low-latitude LBA region of Brazil. Seasonal anomalies of soil moisture and precipitation are used to construct the composites. Each set of composites is diagnosed to identify the key factors responsible for the wet and dry periods and then the three composites are cross-compared to identify similarities and differences in wet and dry anomalies for these three disparate regions. Our initial emphasis has been on the role of land-surface interactions in accounting for the wet or dry conditions. Predictability experiments using these land surface anomalies are also being developed and will be compared to predictability experiments using sea-surface temperature anomalies. Our ultimate goal is to determine the relative roles of the local land surface forcing and the remote forcing due to SST anomalies.

JSM24/W/08-B2 1155

EVALUATION OF INTERANNUAL VARIATIONS IN RUNOFF FROM LARGE RIVER BASINS

Andrey B. SHMAKIN (Geophysical Fluid Dynamics Laboratory/NOAA, P. O. Box 308, Princeton, New Jersey 08542, USA, email: abs@gfdl.gov); P. C. D. Milly (U.S. Geological Survey and Geophysical Fluid Dynamics Laboratory/NOAA, P. O. Box 308, Princeton, New Jersey 08542, USA, email: pcm@gfdl.gov)

A methodology is proposed and applied for temporal "downscaling" of monthly mean atmospheric data for use as inputs to a land-surface water- and energy-balance model. The general approach, for any model gridpoint, is to modulate 1-year reference input time series of high (e.g., hourly to daily) temporal resolution by multi-year observed monthly means of one or more of the input variables (e.g., precipitation rate). Because the reference inputs are derived from model-based analyses of atmospheric observations, they express the natural temporal and spatial variability of the inputs, including their space-time correlation structure. The modulation by historical monthly observations allows for temporal and spatial representation of actual historical monthly anomalies. A test of the methodology was conducted using the International Satellite Land Surface Climatology Project (ISLSCP) Initiative I data set (1987-1988) and a simple bucket-type land-surface model for the evaluation of water- and energy-balance components on a global 1-degree grid. Usage of 6-hourly inputs for 1987, modulated by monthly average values of all variables from 1988, gave annual runoff sums, averaged over major river basins, close to those obtained by use of 6-hourly 1988 inputs. The same good correlation was obtained with the years reversed. Furthermore, much of the interannual variability could be reproduced by modulating precipitation and radiation only. In an application of the technique, estimated monthly mean global fields of precipitation and radiation for an eight-year period were used for modulation of the ISLSCP reference time series. The modeled annual basin-mean runoff anomalies were well correlated with observed discharge anomalies for several large river basins.

JSM24/W/09-B2 1215

EVALUATION OF INTERANNUAL VARIABILITY OF RIVER RUNOFF IN EASTERN EUROPE USING ATMOSPHERIC CIRCULATION STATISTICS

Valeria V. POPOVA (Institute of Geography, Russian Academy of Sciences, Starometny St., 29, Moscow, 109107, Russia, e-mail: climat@ipcom.ru); Andrey B.Shmakin (Geophysical Fluid Dynamics Laboratory, NOAA/Princeton University, e-mail: abs@gfdl.gov); Natalia L.Shuvaeva (Institute of Geography, Russian Academy of Sciences, Starometny St., 29, Moscow, 109107, Russia, email: climat@ipcom.ru)

The daily air temperature and precipitation data for 1950-85 at 24 stations in Eastern Europe, as well as archive of daily atmospheric circulation types have been used for establishment of statistical relationships between meteorological anomalies and atmospheric circulation patterns. The circulation types archive is based on a classification of large-scale atmospheric processes in the extratropical zone of Northern hemisphere developed by Prof. B.L.Dzerdzeevsky. The relationships were obtained to be various in different regions of the territory according to the direction of main circulation streams, while the strongest negative temperature anomalies (5-7 degrees) extend throughout the whole subcontinent. The absolute values of anomalies averaged for each circulation pattern and for each of four seasons, as well as their statistical confidence and probability of occurrence for all regions were determined. In Eastern Europe, 29 of 41 atmospheric circulation types provide statistically confident deviations of meteorological parameters from the average climatic regime (from 4 to 16 each season in one of 5 large river basins). There were no statistically confident anomalies of precipitation in summer for the studied region. These anomalies were used for evaluation of water/energy exchange by a simple bucket-type land-atmosphere scheme. The meteorological forcing variables for 1987 with 6-hour temporal and 1-degree spatial resolution (ISLSCP Initiative I data set) were transformed according to the occurence of circulation types during 1950-1985 as compared to 1987. The interannual and decadal variability of river runoff for 5 large basins (Wisla, Neva, Northern Dvina, Pechora and Volga) were reproduced in good agreement with observed data. The approach allows one to obtain interannual variations of river runoff in Eastern Europe (as the main part of runoff there is formed by snow melting, and the absence of relationships between summer precipitation and atmospheric circulation patterns is of less importance).

OCEAN/ATMOSPHERIC VARIABILITY-ENSO EFFECTS, ENSO DECADAL VARIABILITY

JSP25/W/24-B1 0850

THE EFFECTS OF ENSO ON INDIVIDUAL LARGE-SCALE WEATHER EVENTS

Joseph J. BARSUGLI, Jeffrey S. Whitaker, Prashant D. Sardeshmukh, Andy Loughe,(all at: NOAA-CIRES Climate Diagnostics Center, University of Colorado, Campus Box 449, Boulder, CO, 80302, USA, email: jjb@cdc.noaa.gov), and Zoltan Toth (NCEP/EMC, 5200 Auth Rd., Camp Springs, MD, 20746, USA, e-mail: zoltan.toth@noaa.gov)

What is the link between ENSO and individual weather events in the extratropics? This question is addressed quantitatively using ensembles of medium-range weather forecasts made with and without tropical sea surface temperature anomalies during the winters of 1997-8 (a record El Nino event) and 1998-9 (a substantial La Nina event).
We find statistically robust sub-seasonal variations in ENSO teleconnections over North America. These sub-seasonal effects can depart dramatically from the seasonally-averaged extratropical pattern classically associated with ENSO. For example, a large tropical influence was detected in the case of the devastating ice storm that hit Canada in January 1998, apparently involving an anomalous atmospheric wavetrain along the Atlantic Coast of North America. Some (though not all) of the variations in the heavy California rains of February 1998 also are associated with sub-seasonal variations in the strength of the ENSO teleconnections. Interesting cases for winter 1998-9 will also be shown.
Some mechanisms, including Rossby wave propagation on time-varying flows, and the effects of transient tropical convective forcing are discussed, as well as the implications for improving medium range forecasts. The inherent limitations of attributing individual weather events to specific causes in a chaotic system is also addressed.

ENSO WESTERN PACIFIC OSCILLATOR PARADIGM AND THE 1997-98 EL NINO

Chunzai WANG and Robert H. Weisberg (both at Department of Marine Science, University of South Florida, St. Petersburg, FL 33701, USA, email: wang@marine.usf.edu)

A western Pacific oscillator paradigm has been proposed for the El Nino-Southern Oscillation (ENSO). This paradigm emphasizes the importance of western Pacific interannual anomaly patterns for the evolution of ENSO, in addition to eastern Pacific anomaly patterns. During the warm (cold) phase of ENSO, off-equatorial cold (warm) sea surface temperature (SST) and high (low) sea level pressure (SLP) anomalies in the western Pacific produce equatorial easterly (westerly) winds in the western Pacific. These winds force oceanic upwelling (downwelling) responses that evolve eastward tending to decrease (increase) SST in the east, providing a negative feedback for the coupled ocean-atmosphere system to oscillate. Thewestern Pacific oscillator paradigm may work in conjunction with the delayed oscillator paradigm that emphasizes wave reflection at the western boundary as a negative feedback. Observations show that evolution of the 1997-98 El Nino is consistent with the western Pacific oscillator paradigm. From November 1996 to January 1997, the eastern Pacific is characterized by equatorial cold SST and high SLP anomalies, while the western Pacific is marked by off-equatorial warm SST and low SLP anomalies. Corresponding to this distribution are high outgoing longwave radiation (OLR) anomalies in the equatorial central Pacific and low OLR anomalies in the off-equatorial far western Pacific. The off-equatorial low SLP anomalies in the western Pacific are associated with a switch in the equatorial winds over the western Pacific from easterly to westerly. These equatorial westerly anomalies then appear to initiate early SST warmings around the dateline in January/February 1997 and around the far eastern Pacific in March 1997. Subsequently, both the westerly wind and the warm SST anomalies, along with the low OLR anomalies, grow and progress eastward. The eastward propagating warm SST anomalies merge with the slower westward spreading warm SST anomalies from the far eastern Pacific to form large-scale warming in the equatorial eastern and central Pacific. The anomaly patterns in the eastern and central Pacific continue to develop reaching their peak values around December 1997

JSP25/W/30-B1 0930

A MODELLING STUDY OF THE INFLUENCE OF THE 1997/1998 ENSO ON THE ATLANTIC OCEAN

Stephen JEWSON and Rowan Sutton (both at the Centre for Global Atmospheric Modelling, Department of Meteorology, University of Reading, PO Box 243, Earley Gate, Reading, RG6 6BB, UK, email: steve@met.reading.ac.uk)

The observational record shows us that one of the remote effects of ENSO can be to warm the waters of the northern sub-tropical Atlantic. The recent strong ENSO event was accompanied and followed by large sea surface temperature (SST) anomalies in other parts of the Atlantic as well. This raises the question as to whether these anomalies were also a response to ENSO, and hence whether they might have been predicted in advance. We address this question, and also evaluate the performance of a state of the art coupled model in simulating the whole of the Atlantic response to ENSO.
We have performed ensemble integrations of a global coupled model for the period 1997/1998. Over the tropical Pacific and Indian oceans the model SST is contrained with artificial heat fluxes to follow either the observed evolution for 1997/1998 or climatological SSTs. In the Atlantic, however, the ocean and atmosphere interact freely. In this way we can study the coupled response to a particular ENSO event. The model shows some deficiencies in simulating the observed evolution of Atlantic SST during 1997/1998, while some features are simulated correctly. This leads to insight into both the performance of the model and the role played by ENSO in creating SST anomalies in the Atlantic.

JSP25/W/60-B1 0950

MECHANISMS FOR THE INDIAN OCEAN WARMING DURING THE 1997-98 EL NINO

Lisan YU (Department of Meteorology, University of Maryland, College Park, MD 20742, USA, email: lyu@atmos.umd.edu); Michele Rienecker (NASA/Goddard Space Flight Center, Greenbelt, MD 20771, USA, email: rienecke@mohawk.gsfc.nasa.gov)

Two major climate events took place in 1997-98: the greatest El Nino of the century in the tropical Pacific Ocean and a record-breaking broad-scale warming in the Indian Ocean. In this study, we examine the primary mechanisms that gave rise to the basin-wide change of the sea surface temperature (SST) in the Indian Ocean during this period and their relationship with the El Nino - Southern Oscillation (ENSO) event in the Pacific. The evolution of some key atmosphere-ocean variables, as revealed in our analyses of multi-source data sets, indicated that the changes of SST in the Indian Ocean were largely attributable to the ENSO impact on the large-scale atmospheric circulation. During June-December 1997, when the El Nino in the Pacific was maturing, the Indian Ocean experienced the reversal of the Walker Circulation and the prolonged equatorward displacement of the southeast trades. The resultant changes of surface wind influenced the SST through the following means. In the equatorial region, the easterly winds associated with the reversed Walker Circulation forced equatorial Kelvin/Rossby waves, which then affected the equatorial ocean heat balance (mainly through upwelling/downwelling) and eventually led to the reversal of the zonal SST gradient in the fall of 1997. The negative SST anomalies in the east and positive anomalies in the west in turn helped maintain and prolong the equatorial easterlies, indicating coupled atmosphere-ocean interactions in operation. Outside of the equatorial waveguide, the broad-scale warming was induced mainly by the changes of latent heat flux associated with the anomalies in wind speed. The most intensive surface warming occurred in the southern Indian Ocean during the summer/fall of 1997 when the southeasterly trade winds weakened significantly, leading to a dramatic reduction of the latent heat release and subsequently a rapid surface warming.

JSP25/W/14-B1 1010

MJO TRIGGERED 1997/98 ENSO

Tetsuo Nakazawa (Meteorological Research Institute, Tsukuba, Japan 305-0052,
Email: nakazawa@mri-jma.go.jp)

The onset phase of the 1997/98 ENSO is described by using several remote-sensing datasets including the ADEOS/NSCAT surface wind data, the NOAA/OLR data, the TOPEX/POSEIDON sea surface height data) as well as the TOGA/TAO buoy data. These data shows that the 1997/98 ENSO is triggered by the Madden-Julian Oscillation with a period of 30-60 days, which is originated in the equatorial Indian Ocean in February 1997 and propagated into the western Pacific in March 1997. Under the warmer condition of the upper ocean in the western Pacific, the strong and persistent westerlies assosiated with the MJO was favorable to generate the oceanic Kelvin wave in middle of March. This Kelvin wave propagated to the eastern Pacific end of April or early May when the ENSO was initiated.

DYNAMICS OF TROPICAL DROUGHTS DURING THE 1997-98 EL NINO

J. David NEELIN, Ning Zeng, Chia Chou and Hui Su (University of California at Los Angeles, Dept. of Atmospheric Sciences, UCLA, Los Angeles, CA 90095-1565 USA, e-mail: neelin@ucla.edu)

An intermediate complexity atmospheric model is used to analyse radiative-convective-dynamical interactions in the response to the 1997-98 El Nino sea surface temperature anomalies. The atmospheric model, QTCM1 (quasi-equilibrium tropical circulation model) makes use of properties of the quasi-equilibrium convective closure in the Betts-Miller convective scheme to produce efficient solutions that are accurate in convective regions and reasonable elsewhere. It is coupled to a one-layer land-surface model with interactive soil moisture, and simulates its own tropical climatology. The model is able to reproduce many tropical features in observed anomalies of precipitation, outgoing long-wave radiation, land surface temperature and winds associated with the recent El Nino. The radiative-convective-dynamical balances associated with the subsidence regions around ENSO convective heating regions are examined. We compare the feedbacks over land involved in the Amazon drought with those over the western Pacific/Indonesian ocean region. In both, cloud-radiative interaction affects the dynamics of relative descent in the convection zone. Over parts of the ocean region, ocean dynamical effects are inferred to have played some role. Over land regions adjacent to the SST anomaly, land feedbacks actually simplify the analysis via the surface energy balance condition. The surface temperature response is relatively passive from the dynamical point of view, adjusting to satisfy this condition, and is significantly associated with cloud feedbacks. The convective-radiative-dynamical feedbacks identified in this case likely play a role in most tropical teleconnections involving suppression of convection zones by remote SST anomalies.

JSP25/E/05-B1 1110

WHAT ROLE DID THE MJO AND ASSOCIATED WESTERLY WIND BURSTS PLAY IN THE DEVELOPMENT OF THE 1997/98 EL NINO

M.K. DAVEY, S. Ineson (both at Hadley Centre for Climate Prediction and Research, UK Met. Office, Bracknell, UK. Email: sineson@meto.gov.uk), J.M. Slingo and R. Brugge (both at Centre for Global Atmospheric Modelling, Department of Meteorology, University of Reading, Reading, UK.)

The growth of the 1997/98 El Nino was dramatic and significantly faster than normal. It developed in association with strong atmospheric intraseasonal variability, characterised by a series of MJOs with strong Westerly Wind Bursts (WWB) embedded in the active phase of the MJO.
A series of experiments with the UK Met. Office Tropical Pacific OGCM, forced with ECMWF operational analyses for 1996/97, have been made to investigate the impact of the intraseasonal variability in the atmosphere and oceans on the evolaution of El Nino. The aim is to test the hypothesis that a series of MJOs and/or WWBs are required to precondition the ocean to El Nino.

JSP25/W/58-B1 1130

THE BMRC SEASONAL-TO-INTERANNUAL PREDICTION MODEL

Richard Kleeman, Guomin Wang and Neville SMITH (all from the Bureau of Meteorology Research Centre, Melbourne Vic. 3001, AUSTRALIA, email: N.Smith@BoM.GOV.AU)

A global coupled general circulation model has been developed for forecasts of the El Nino-Southern Oscillation. The atmospheric model is an R21L9 version of the BMRC atmospheric climate model. The ocean component is a global general circulation model with resolution focussed in the tropical region and 20 vertical levels. A univariate statistical interpolation method, with 10 day data ingestion windows, is used to assimilate temperature data and initialize the coupled model. Hindcasts have been carried out for the period 1981-1995 for each season (60 in all), for up to 12 months lead-time. This paper will describe these initial experiments and show that the skill comparable to, and in some cases exceeds, that of the present operational intermediate model, and is comparable to that of other published models. The skill of the model is focussed in the central Pacific, which suits seasonal forecasting in the Australian region, but is generally weak in the far eastern Pacific and outside the tropical Pacific. Some of the other attributes and weaknesses of the model will also be discussed. The hindcasts have been extended to the present with a view toward quasi-operational trials.

JSP25/W/66-B1 1150

A CONCEPTUAL EQUATORIAL OCEAN RECHARGE OSCILLATOR MODEL FOR ENSO

FEI-FEI JIN and Soon-Il An (School of Ocean and Earth Science and Technology, University of Hawaii at Manoa, Honolulu, Hawaii, USA, e-mail: jff@soest.hawai.edu)

Through the dynamical coupling between ocean and atmosphere, the vertical advection of anomalous subsurface temperature by the mean upwelling and zonal advection of mean sea surface temperature (SST) by anomalous current constitute the so-called the thermocline and zonal advective feedbacks which are essential for El Niño / Southern Oscillation (ENSO) coupled dynamics. In this paper, we demonstrated that these two feedbacks are dynamically linked because of the semi-geostrophic balance the upper ocean zonal current and meridional gradient of thermocline. Both feedbacks thus play important and similar roles in the growth and phase transition of ENSO. We further proposed a new version of the conceptual recharge oscillator model for ENSO by including these two feedbacks. The new model retains the simplest possible form of a harmonic oscillator, yet presents a more complete description of slow physics for ENSO. Moreover, it also provides the reconciliation between the biased emphases in the ENSO theories on the thermocline and zonal advective feedbacks.

JSP25/W/36-B1 1210

ASSESSMENT OF THE DIABATIC HEATING DISTRIBUTION AND GLOBAL TELECONNECTION ERRORS IN THE UKMO UNIFIED MODEL DURING ENSO

RICHARD NEALE and Julia Slingo, (CGAM, Department of Meteorology, University of Reading PO BOX 243, Earley Gate, Reading, RG6 6BB)

Interannual variability in tropical sea surface temperatures (SSTs) is able to influence the atmospheric circulation in more remote regions. This is achieved due to a succession of processes, beginning with the generation of convection anomalies through to the impact of global teleconnection patterns. The major source of interannual variability in tropical SSTs is due to ENSO.
AMIP II integrations using the UKMO Unified Model (UM) (version HadAM3) reveal that the global response during ENSO conditions is exaggerated compared to observations. Analyses of these integrations are performed in order to determine the major sources of error in the

model. In particular, the ability of the model to reproduce the correct magnitude and spatial distribution of the tropical diabatic heating anomalies in response to ENSO sea surface temperature (SST) distributions will be discussed.
ENSO also influences the more remote tropical climate through known global teleconnection patterns. In the tropics a remote response to ENSO is observed in the tropical Atlantic, primarily through changes in the Walker circulation. During El Nino conditions, increased descent is seen over the tropical Atlantic tending to result in a warming of SSTs. The intensity of this response gives rise to stronger than observed coupling between tropical Pacific and tropical Atlantic SSTs.
The impact of vertical resolution on model skill will also be assessed, with a comparison of 19 level and 58 level versions of the AMIP II UM integrations.

OCEAN/ATMOSPHERIC VARIABILITY-ENSO EFFECTS, ENSO DECADAL VARIABILITY

JSP25/W/22-B1 1400

FLUCTUATIONS IN INDIAN OCEAN SST DIPOLE PATTERNS

Robert J. ALLAN (CSIRO Atmospheric Research, Aspendale, Victoria 3195, Australia, email: rob.allan@dar.csiro.au); Ian N. Smith (CSIRO Atmospheric Research, Aspendale, Victoria 3195, Australia, email: ins@dar.csiro.au); Chris J.C. Reason (School of Earth Sciences, University of Melbourne, Parkville, Vic., 3052, Australia, email: cjr@buster.unimelb.edu.au).

Indian Ocean sea surface temperature (SST) dipole patterns are examined in the context of historical, global mean sea level pressure (MSLP) and SST anomalies during the evolution of major El Niño and La Niña events. These SST dipoles occur at various stages during the life cycles of both the more 'canonical' and protracted of El Niño Southern Oscillation (ENSO) phases. When seasonal MSLP and SST fields are filtered on interannual ENSO time scales, the resulting quasibiennial 2-2.5 year and 'classical' ENSO 2.5-7 year bands often both display SST dipoles, but they may not always be spatially aligned. Superposition of these bands can lead to the annulment of such SST signals. However, if either or both of the above bands is dominant, and carrying SST dipole signals, then an important modulation for rainfall producing systems in various regions of the Indian Ocean basin can emerge. In general, south west-north east oriented dipoles develop during the onset and cessation phases of El Niño or La Niña episodes. During the mature stage of strong ENSO phases a north-south oriented SST dipole structure is usually evident on both bands.
Filtering on lower frequency time scales reveals the presence of additional SST structures, particularly during protracted ENSO phases. This indicates that interannual SST dipoles are modulated further by decadal to interdecadal fluctuations in Indian Ocean SST dipole patterns.

JSP25/W/65-B1 1420

DECONSTRUCTING CORRELATIONS: USING PATH ANALYSIS TO DIAGNOSE OCEAN-ATMOSPHERE INTERACTIONS

NEVILLE NICHOLLS, Wasyl Drosdowsky, (both at Bureau of Meteorology Research Centre, PO Box 1189K, Melbourne 3001, Australia. E-mail: n.nicholls@bom.gov.au); Tahl Kestin, (CRC for Southern Hemisphere Meteorology, Monash University, Clayton 3168, Australia)

The number of tropical cyclones affecting the Australian region each year is related to the El Niño - Southern Oscillation. The correlation between year-to-year changes in tropical cyclone numbers and year-to-year changes in September-November NINO3.4 sea surface temperature (SST) is -0.62 (n = 48; significant at 1%). Year-to-year changes in tropical cyclone numbers are also correlated with SSTs around northern Australia (r = 0.71) and these SSTs, in turn, are correlated with NINO3.4 SSTs (r = -0.83). Does NINO3.4 SST have an effect on tropical cyclone numbers separate from that arising from acting in concert with local, north Australian SSTs? Path analysis allows us to deconstruct the observed correlations between SSTs and cyclone activity into unique and common effects, ie to separate the unique effect of NINO3.4 SSTs on tropical cyclones from the common effect involving both NINO3.4 and north Australian SSTs. This analysis indicates that the NINO3.4 SST only affects tropical cyclone activity through its common effect with the local, north Australian SSTs. Path analysis, and its more complex relation Structural Equation Modelling, allow us to investigate the underlying correlation structure in situations where there are several inter-related predictor variables all correlated with one or more predictand or response variables. These techniques appear not to have been used in the study of relationships between SSTs and climate variables, despite their obvious utility in such studies. They could, for example, allow the correlation between Indian Ocean SSTs and Indian rainfall to be separated into the contribution arising from the unique effect of Indian Ocean SSTs on rainfall, and the contribution arising from the common relationship of Pacific Ocean and Indian Ocean SSTs with rainfall (through the El Niño - Southern Oscillation). We will illustrate the use of these techniques in separating the effects of Indian and Pacific Ocean SSTs on Indian and Australian rainfall, as well as on tropical cyclone activity, and discuss their relationship to climate model experiments.

JSP25/E/23-B1 1440

THE CONNECTION BETWEEN ENSO AND PRECIPITATION IN ISRAEL

Colin PRICE, Pinhas Alpert and Yitzhak Carmona (all at Department of Geophysics and Planetary Sciences, Tel Aviv University, Ramat Aviv, 69978, Israel, email: cprice@flash.tau.ac.il, pinhas@cyclone.tau.ac.il, carmona@cyclone.tau.ac.il); Lewi Stone and Amit Huppert (both at Department of Zoology, Tel Aviv University, Ramat Aviv, 69978, Israel, email: lewi@lanina.tau.ac.il, amit@lanina.tau.ac.il); Balaji Rajagopalan (Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY 10964-8000, USA, email: rbala@rosie.ldgo.columbia.edu)

Recent analysis of hydrological data in Israel has revealed some interesting connections between the ENSO phenomenon and weather in Israel. The precipitation season in Israel is during the winter months from October-April, with the maximum precipitation coinciding in phase with the maximum of the ENSO cycle. Hence the anomalous circulation patterns in the atmosphere due to ENSO coincide with the rainy period in Israel.
For this study we used rainfall data from nothern Israel, streamflow data from the Jordan river, and lake levels from the Sea of Galilee. The rainfall drains into the watershed of the Jordan river which then flows into the Sea of Galilee. Rainfall data were available from 1922, streamflow from 1967 and lake level data from 1927. We analysed the data on a seasonal basis, and compared the anomalies with both the NINO3 sea surface temperatures and the southern oscillation index, during the same winter months. A highly significant statistical correlation was found between all the hydrological parameters and the ENSO indices. During El Nino years there is generally above average rainfall in the northern parts of Israel, while during La Nina years the opposite is true. By analysing archived data related to global circulation patterns we have noticed that the subtropical jetstream shifts approximately 100-200 km southwards/northwards during El Nino/La Nina years.
It is interesting that the strong connection between ENSO and rainfall in Israel exists only since the 1970s, with little connection before this period. Whether this is due to a change in the teleconnection patterns since the 1970s is still uncertain. However, it is clear that there has been a change in the frequency and intensity of ENSO events since the 1970s.

JSP25/W/39-B1 1500

SEASONAL, DECADAL, AND ENSO RESPONSES OF THE UPPER LAYERS IN THE NORTHERN GULF OF ALASKA

Thomas C. ROYER (Center for Coastal Physical Oceanography, Department of Oceanography, Old Dominion University, Norfolk, VA 23529 USA, email: royer@ccpo.odu.edu)

Temperature and salinity versus depth to 250 m at the mouth of Resurrection Bay, Alaska (60 N, 149 W) (GAK 1) have been measured since December 1970 with various temporal sampling intervals, ranging from hours to months. The ocean climatology suggests that, seasonally, the temperature and salinity signals propagate downward from the surface to about 100 m.The influences of local upwelling, regional and global atmospheric circulation forcing can be seen in the temperature anomalies along with SOI (Southern Oscillation Index) influences. In contrast with temperature anomalies observed off the California coast, these are coherent with depth. This suggests a barotropic forcing rather than a vertical propagation or baroclinic influence. Amplitudes of the interdecadal temperature fluctuations decrease from more than 6 C at the surface to about 3.6 C at 250 m with those in the lower 150 m being coherent with their greatest variance at low frequencies (15-21 years).. Using a threshold level of one standard deviation, positive temperature anomalies at 150 m and deeper since 1974 have corresponded to ENSO events. The 1997-8 ENSO event was accompanied by the largest temperature anomaly yet seen at 250 m (1.43 C) (Feb. 1998), more than 3 SD (1 SD = 0.45 C) above normal. This signal first appeared in Jan. 1998 but by May 1998 had subsided to 0.29 C, below the ENSO threshold. Surface salinity anomalies have significant periods of a 4-5 years whereas the deeper waters (10-100 m) have a decadal periodicity (9-11 years) shifting to 12-15 years for 150-250 m.

JSP25/P/06-B1 1520

NUMERICAL SIMULATION RESEARCH ON THE CYCLIC RELATIONSHIP BETWEEN ANOMALOUS EAST-ASIAN WINTER MONSOON AND ENSO

MINGQUAN Mu and Chongyin Li(The Key Laboratory of Numerical Modelling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG), Institute of Atmospheric Physics (IAP), Chinese Academy of Sciences, P.O.Box 2718, Beijing 10008, China E-mail: mmq@lasgsgi4.iap.ac.cn)

This study includes two parts. The first part gives general observational features about mutual relationship between ENSO and anomalous East Asian winter monsoon. On the one hand, stronger (weaker) East Asian winter monsoon can excite happening of El Nino (La Nina) through forced anomalous westerly (easterly) wind and stronger (weaker) convective activity over the tropical Pacific Ocean; on the other hand, the occurrence of El Nino (La Nina) weakens (enhances) East-Asian winter monsoon through the atmospheric teleconnection. Power spectral analyses imply that this cycle mainly locates in the 3-5 years; and quasi-biannual cycle is also clear. The second part mainly focuses on numerical simulations with tropical Pacific ocean model (OGCM) and coupled ocean-atmospheric general circulation model (CGCM). Both of the results reveal that stronger (weaker) winter monsoon is able to lead to El Nino (La Nina) event. The simulation results also indicate that the anomalous oceanic Kelvin waves and atmospheric intraseasonal oscillation, caused separately by anomalous westerly (easterly) and stronger (weaker) convective activity over the tropical Pacific, play an important role in the occurrence of ENSO (El Nino and La Nina). So, both of the observation and simulation have one consistent conclusion: The relationship between anomalous East Asian winter monsoon and ENSO is two-way interaction

JSP25/W/37-B1 1600

ENSO VARIABILITY OF THE HYDROLOGICAL CYCLE DERIVED FROM RAINFALL ISOTOPE MEASUREMENTS

Ahmet S Kayaalp and John A T BYE (Faculty of Science and Engineering, Flinders University, GPO Box 2100, Adelaide Australia 5001, email: John.Bye@flinders.edu.au)

Stable isotope measurements in precipitation have been used to obtain the ratio (f) of precipitation to evaporation for 104 stations in the International Atomic Energy Agency archive. The global annual oceanic precipitation fields predicted from published evaporation fields are found to be realistic in comparison with other methods, e.g. from coastal rainfall and MSU satellite data.
The results show that f is well correlated with the wet bulb temperature (Tw) which occurs during rainfall, and in particular that f becomes very large when Tw exceeds about 26oC. This diagnostic has been used to investigate changes in the global hydrological cycle which occur during ENSO.
It is found that the very high MSU derived oceanic rainfall in the central equatorial Pacific Ocean is consistent with the existence of positive Tw anomalies due to positive sea surface temperature anomalies. During the El Nino phase, a corresponding reduction in f occurs in the extra tropical regions. Associated changes in the global hydrological cycle will be discussed.

JSP25/P/07-B1 1620

A MODELING ENSO/DECADAL VARIATIONS IN THE NORTH DURING 1975 TO 1998

Tomonori MATSUURA and Satoshi Iizuka (both at National Research Institute for Earth Science and Disaster Prevention, 3-1 Tennodai Tsukuba, Japan, email: matsuura&ess.bosai.go.jp)

'The El Niño and decadal scale simulation, which is long run from 1975 to 1998, is conducted using an ocean general circulation model (MOM 2). As surface forcings, we used daily fluxes obtained from Louis et al. (1982)'s formulae and NCEP data. We could successfully simulate the El Niño (1976 1979, 1982/83, 1986/87, 1991/92, 1997/98) and the decadal variation, the phase of which changes in 1982, 1989, and 1997. Both the El Niño and decadal signals appear in the North Equatorial Current region (145°E-180°, 10°N-20°N) and the decadal variability of heat content in the subpolar front (145°E-180°, 35°N-45°N) correlated inversely with the North Equatorial Current region. We show that the strong El Niño and La Niñas may play an important role in changing the phase of decadal variability.

JSP25/W/11-B1 1640

DECADAL MODULATION OF ENSO VARIABILITY IN THE ECHO-G MODEL

Keith RODGERS (Max Planck Institut fuer Meteorologie, Bundesstrasse 55, D-20146 Hamburg, Germany, Email: rodgers@dkrz.de); Mojib Latif (Max Planck Institut fuer Meteorologie, Bundesstrasse 55, D-20146 Hamburg, Germany, Email: latif@dkrz.de); Stefanie Legutke (DKRZ, Bundesstrasse 55, D-20146 Hamburg, Germany, Email: legutke@dkrz.de)

The global coupled ECHO-G (ECHAM4/HOPE) model is examined in order to identify those oceanic processes which modulate the decadal behavior of ENSO. The focus is on inter-gyre exchange of thermocline water between the subtropical Pacific and the upwelling regions of the eastern equatorial Pacific. Three processes which can contribute to changing the thermal structure of the equatorial pycnocline on decadal timescales are considered: Variability in ocean circulation fields, temperature anomalies which subduct in the extratropics and advect equatorward, and changes in diapycnal fluxes within the equatorial pycnocline. Special attention is given to the role of the South Pacific. The growing database of oceanic measurements strongly suggests that the South Pacific plays at least as important a role as the North Pacific in equatorial thermocline ventilation. The ocean model's performance is discussed within the context of hydrographic and tracer measurements.

JSP25/W/87-B1 1700

TIME SERIES OF SST, SEA-LEVEL PRESSURE, SURFACE WINDS, AND RAINFALL

Todd MITCHELL, (University of Washington, USA, Email: mitchell@atmos.washington.edu)

Time series of SST, sea-level pressure, surface winds, and rainfall are presented to document ENSO variability in the tropics from the 1850s through 1998. The series are derived from area-averages of very large regions and as such emphasize the tropics-scale nature of ENSO-related climate variability. This approach is a complement to the pioneering studies of Quinn and collaborators, which emphasized the historical record of El Nino at the Peru coast. Intercomparison of the series for the different variables will corroborate the identification of the major ENSO episodes and interdecadal variability in the tropics. The resultant series are useful to clarify the relationship between interdecadal variability and the frequency of ENSO episodes.

WATER VAPOR TRANSPORT OVER THE INDIAN OCEAN AND WESTERN PACIFIC DURING THE WARM AND COLD EVENTS OF EL NINO

Nataly A. VYAZILOVA (Russian Research Institute of Hydrometeorological Information - World Data Center 6, Korolyov St., Obninsk, Kaluga region, 249020, Russia, e-mail: vjaz@meteo.ru)

Using mean monthly and climatic upper-air data of the objective analysis during the period 1982-97,made by the U.S. National Meteorological Center which are presented at the points of the 2.5 step regular grid, the following characteristics of the tropical atmosphere have been calculated for the centers of the 5*5 squares: mean monthly water content in the atmospheric column, water content anomalies for individual months (water content is expressed in percent relative to mean climatic values), mean monthly values of the zone, meridional and resulting water transfer, cross-equatorial water vapour flux. Peculiarities of a space - time distribution of water exchange characteristics are studied in the Tropical Indian ocean and Western Pacific during the summer monsoon in accordance with a type of the monsoon circulation. Four types of the monsoon circulation have been considered as compared to the mean climatic year:- Weakened monsoon circulation when an intensive development of El Nino is observed (warm events in 1982,1987 and 1997);- Weakened monsoon circulation when the El Nino development did not reach its peak (warm event in 1986);- Developed monsoon circulation (cold events in 1988 and 1996);- Normal monsoon circulation (1989).

JSP25/P/04-B1 1740

THE ROLE THE INDIAN OCEAN SSTA TAKSE IN THE ENSO TO ASIAN CLIMATE

XIAO Ziniu and Sun Jihua (both at Yunnan Meteorological Observatory, 73 Xichang Road, 650034, Kunming, Yunnan, China); Li Chongyin (LASG, The Institute of Atmosphere Physics, Box 2718, Beijing 100080, China)

During the ENSO event period, the Indian Ocean SST will be anomalous almost simultaneously. But the space structure of the SSTA in the Indian Ocean is not same from time to time. The seesaw structure is a typical pattern of the Indian Ocean SSTA. Based on the IAP-GCM9L model, which is developed in Institute of Atmospheric Physics, the SSTA pattern with warm SST in the western Indian Ocean and cold SST in the eastern India Ocean is simulated during an ENSO period. And its effect to the Asian climate is studied. The results indicated that the Indian Ocean SSTA would mainly influence the climate in Bengal, Indo-China, Indonesia, India and China. During the ENSO period, the SSTA pattern with warm west and cold east SST in India Ocean will enhance the climate anomalous brought by the eastern Pacific Ocean SSTA. Especially, it makes Indo-China more dry and reduce the precipitation over northern China. But it increases the precipitation over the area from southwest China to southeast China obviously. So that, the precipitation will be concentrated in a zonal region around in Changjiang River drainage area and forms zonal drought and flood pattern which is similar to the fact. Therefore, during ENSO period, the Indian Ocean SSTA is important to Asian climate especially to the anomalous precipitation pattern in China.

IMPACT OF GLOBAL WARMING ON VARIABILITIES OF THE CLIMATE MODES IN A CGCM

Z.-Z. HU, L. Bengtsson, E. Roeckner, M. Christoph, A. Bacher (MPI for Meteorology, Bundesstrasse 55, D-20146 Hamburg, FRG, e-mail: hu@dkrz.de); J. M. Oberhuber (DKRZ, Bundesstrasse 55, D-20146 Hamburg, FRG)

In this study, we investigated the impact of global warming on the linear trend and standard deviation of geopotential height at 500 hPa (H500) in the NH winter, and on the variabilities of the large scale interannual and interdecadal climate modes and the teleconnection patterns with two long term integrations of the ECHAM4/OPYC3 CGCM. One is the control (CTRL) run with fixed present-day concentrations of greenhouse gases. Another experiment is a simulation of transient greenhouse warming, named GHG run.
In the global warming, the standard deviation of H500 over the tropics is enhanced (reduced) remarkably on the interdecadal (interannual) time scales. Except for the interdecadal mode related to the Southern Oscillation (SO) in the GHG run, the spatial variation patterns are similar for different (interannual+interdecadal, interannual, and interdecadal) time scales both in the GHG and CTRL runs. Spatial distributions of the teleconnection patterns in the GHG run are also similar to those in the CTRL run. But some teleconnection patterns manifest the linear trends and changes of the variances and the frequencies in the global warming scenario. The ENSO cycle has the most significant nonlinear response to the global warming. Besides the linear increasing trend of the SO, the interdecadal modulation to the ENSO cycle is enhanced during the GHG 2040~2099. This is the result of enhancement of the Walker circulation during that period. La Nina event will intensify and El Nino event relatively weaken during the GHG 2070~2090. It is also suggested that the growth of the greenhouse gas concentrations will trigger off the unstable correlation between the SO and the PNA pattern both on the interdecadal and interannual time scales.

JSP25/W/55-B2 0950

SEA SURFACE TEMPERATURES AND THE MEXICAN MONSOON: MECHANISTIC IMPLICATIONS

DAVID L. MITCHELL (Atmospheric Sciences Center, Desert Research Institute, P.O. Box 60220, Reno, NV 89506, USA; email: mitch@dri.edu); Dorothea Ivanova and Timothy J. Brown (Same address; dorothea@dri.edu, tbwrcc@dri.edu)

The North American or Mexican monsoon is responsible for roughly 40% of the annual precipitation in Arizona and New Mexico, USA, and about 60% for northern Mexico. It's regular occurance in summer also effects precipitation patterns in the mid-western and eastern United States, as well as the North American radiation budget. Recent studies indicate the heat content of the upper layer (e.g. 70 m) in the Gulf of California during spring/summer is primarily due to horizontal advection from the south, allowing sea surface temperatures (SST) to be higher than solar insolation alone would permit. Other studies show the Gulf of California (henceforth the gulf) to be the dominant moisture source for the monsoon. Our study is unique in that it quantiatively relates gulf SSTs to the timing, amount and regional extent of monsoon rainfall.
A detailed three season empirical study was conducted based on satellite SST data at 18 km and weekly resolution, along with satellite SSM/I pentad (5 day) precipitation data having a spatial resolution of 0.25 x 0.25 degrees. Four coastal ocean regions (three in the gulf) were evaluated for SSTs, and four land regions northwest of each ocean region (consistent with known moisture transport) were evaluated for rainfall amount. The main results were:1) Monsoon rainfall did not occur prior to the onset of gulf SSTs exceeding 26 C.2) The incremental advance of SSTs > 26 C up the mainland coast of Mexico appears necessary for the northward advance of the monsoon. 3) In the southern gulf region, an SST parameter was lag-correlated with rainfall amount in adjacent land regions (r = 0.78) occurring during the 5-15 day period after an SST increase. 4) Relatively heavy rainfall in Arizona and New Mexico depended on two factors: (1) northern gulf SSTs exceeding 29 C, and (2) a neutral or positive along-gulf SST gradient (positive means higher SSTs in the N. gulf). Periods meeting both criteria accounted for 75% of the monsoon rainfall in this region.

JSP25/W/15-B2 1010

INTERANNUAL VARIABILITY AND PREDICTABILITY IN THE MARITIME CONTINENT

JOHN L MCBRIDE Bureau of Meteorology Research Centre Melbourne Australia and Paulus Winarso, Dodo Gunawan, and Soetamto Meteorological and Geophysical Agency, Jakarta, Indonesia, e-mail: jmb@bom.gov.au

Interannual variability is studied for the maritime continent through analysis of seasonal rainfall data for 102 seasonal forecast districts across Indonesia. These data have been assembled from the records of the Meteorological and geophysical Agency in Indonesia, and form the basis of their seasonal forecasts. Four parameters are available for the 102 districts over the period 1961 to 1998: Onset date for the wet season, onset date for the dry season, total wet season rainfall, total dry season rainfall. From these, two additional derived parameters can be constructed: length of wet season and length of dry season.
Linear correlations are calculated for each parameter with the Southern oscillation Index and with amplitudes of various rotated EOFs of global sea surface temperature data. The largest correlations are with the SOI, and these are in the magnitude range of 0.4 to 0.7 across most of the country during the dry months of June to November. Parameters relevant to those months include dry season rainfall and wet season onset, and based on 3-month lag correlations with the SOI, these parameters have a high degree of predictability. Conversely the relationships are quite small in the wet months of December to May; and the predictability is low for parameters whose timing occurs in that half-year, viz: wet season rainfall and dry season onset.
These relationships are studied further through calculating correlations with Sea surface temperature patterns as well as cross correlations between the 102 forecast districts. It turns out the parameters related to the SOI are also related to the SST patterns, with smaller but statistically significant correlations with amplitudes of several EOF's. On the other hand parameters occurring during the wet season are not well related to the SST patterns; and they also have close to zero coherence in interannual variations across the domain. The implication is that in this region association with the Southern Oscillation is related to a large scale for spatial coherence in interannual variations. It also suggests that the monsoon or wet season rainfall does not have large scale coherence and is inherently unpredictable.

TROPICAL VARIABILITY

JSP25/W/08-B2 1110

THE INFLUENCE OF SST PERTURBATIONS ON INTRASEASONAL VARIABILITY OF TROPICAL CONVECTION

Steven WOOLNOUGH and Julia Slingo (Centre for Global Atmospheric Modelling, Department of Meteorology, Univeristy of Reading, Earley Gate, PO Box 243, Reading, RG6 6BB, UK. email: s.j.woolnough@rdg.ac.uk); and Brian Hoskins (Department of Meteorology, University of Reading, Earley Gate, PO Box 243, Reading, RG6 6BB, UK)

Results from TOGA-COARE and other studies haveshown that convection associated with theintraseasonal oscillation can affect the upperlayers of the ocean through changes in thesalinity, mixed layer depth and SST.However, the ways in which these changes in SSTmay feedback on the the convection associated withthe intraseasonal oscillation are not wellunderstood. A better representation of theintraseasonal oscillation may lead to improvementsin seasonal forecasting and the prediction of theonset of El Nino.
Results from integrations of an aqua-planet GCMwill be presented to demonstrate the sensitivityof intraseasonal variability in convection to SSTperturbations. The implications for modelling ofthe intraseasonal oscillation will be discussed.

JSP25/E/03-B2 1130

A THREE-DIMENSIONAL SIMULATION OF THE SOUTH CHINA SEA CIRCULATION

QINYU LIU, Haijun Yang (Institute of Physical Oceanography, Ocean University of Qingdao, Qingdao, 266003, P.R.China Email: liuqy@ouqd.edu.cn)

A three-dimensional, sigma-coordinate primitive equation model(Princeton Ocean Model) with a free surface is used to simulate the monthly mean circulation in the South China Sea(SCS). The model has a resolution of 0.5° in the horizontal and 10 sigma layers in the vertical in a region from equator to 27°N and from 98°E to 125°E. There are four openings in the model region, where the inflow and outflow in the Kuroshio, through the Taiwan Strait and Karimata Strait are obtained from the model output of the Parallel Ocean Climate Model(POCM). At the sea surface, the model is forced by monthly averaged climatological wind stress, heat and salinity flux. Several important features are reproduced in the model results. First, for the vertical integrated circulation(VIC), there is a large cyclonic gyre dominated the whole basin in winter, in which a meso-scale cyclonic eddy named Luzon cold eddy(LCE) appears to the northwest of the Luzon island. In spring the large cyclonic gyre becomes weak due to weak wind stress forcing and the LCE moves northwestward. A weak anticyclonic gyre begins to appear in the central SCS(10°N-14°N) in March. In summer, the VIC is cyclonic in the north half basin and anticyclonic in the south half and the LCE disappears. In fall, the cyclonic gyre expands southward and then occupies the whole basin. Second, the surface current represents the Ekman transport, which direction is nearly perpendicular to that of surface wind. From the sea surface temperature (SST) distribution, there is upwelling between 11°N to 13°N off the Vietnam in summertime. Third, in the lower layer, the thermal-wind relation is nearly met between the temperature distribution and the circulation pattern due to relatively weak influence of the surface wind and solar radiation. For example, the LCE is corresponding to a strong upwelling whose center temperature is lower than that of the surroundings by about 2 to 3 degrees. In winter and spring, there is warm water appearing in the central SCS, which corresponds to an anticyclonic gyre there. While in the south of the SCS, there is a cycloni gyre corresponding to cold water. Finally, the LCE can reach at depth of 200m. Its generation and maintenance should be mainly due to the local wind stress curl. The Kuroshio can not flow directly into the SCS interior but forms an anticyclonic loop in the Luzon Strait, where a small part of Kuroshio water can flow out of the Taiwan Strait along the west coast of the Taiwan island.

ONSET CHARACTERISTICS OF THE 1998 SOUTH CHINA SEA SUMMER MONSOON

Yongguang Wang, JOHNNY C. L. CHAN and Jianjun Xu (Dept. of Physics & Materials Science, City University of Hong Kong; Email: Johnny.Chan@cityu.edu.hk)

The South China Sea Monsoon Experiment (SCSMEX) was conducted in May and June 1998 to study the South China Sea Summer Monsoon (SCSSM). This paper presents the results of a preliminary study of the characteristics of the synoptic-scale conditions related to the SCSSM onset and its maintenance. The onset and break are defined using gridded zonal winds at 850 hPa and observed daily rainfall at Xisha (112.33°E, 16.83°N) and Yongshujiao (112.88°E, 9.53°N). Four sets of meteorological parameters are examined using the gridded data sets from the Beijing Data Center of SCSMEX: 1) surface and 850-hPa temperatures, 2) mean sea-level pressure (MSLP), 3) surface relative humidity, and 4) surface and upper-level winds. The results show that the summertime meridional temperature gradient and meridional wind circulation as well as high relative humidity are already established before May over the South China Sea (SCS). On the other hand, reversals of the meridional MSLP gradient and the zonal wind circulation occur only at the onset. An active tropical cyclone in the Bay of Bengal is apparently responsible for "leading" the strong southwesterly Somalia jet to the SCS. A vortex over the northern SCS causes a weakening of the subtropical high to change the meridional MSLP gradient over the SCS, and enhances the cross-equator-flow at 105°E. Westerly flow then sets in at the low levels. The enhanced Southern Asia high at 200 hPa and an upper tropospheric trough over northeastern SCS are related to the establishment of easterly flow at the upper levels.

INTERANNUAL RAINFALL VARIABILITY

RICHARD WASHINGTON and Martin Todd (School of Geography, University of Oxford;1 Mansfield Rd, OX! 3TB UK)

The primary mode of interannual rainfall variability over southern Africa and the Southwest Indian Ocean during the austral summer and its relationship with oceanic and atmospheric fields are examined in this paper. Empirical Orthogonal Functions (EOFs) of the Xie-Arkin satellite derived rainfall data are used to determine modes of interannual variability for austral summer months between November and March. In all months it is shown that tropical-temperate troughs linking tropical convection with quasi stationary or propagating transients are the primary mode of rainfall variability. Further analysis of model rainfall from an AGCM (HADAM2A) forced with historical sea surface temperatures from 1904-1994 indicates a similar mode of variability on both interannual and interdecadal time scales.
Sea surface temperatures, moisture fluxes, sea level pressure and other fields are examined to determine the characteristics of oceanic and atmospheric anomalies accompanying extreme years of tropical-temperate trough activity. The NCEP re-analysis data is used in conjunction with the Xie-Arkin (observed) rainfall EOFs and the model data with the model rainfall analysis.
The analysis of both model and observed circulation data focuses on anomalous anticyclonic gyres in near surface atmosphere of the southwest Indian Ocean. Near surface water vapour flux anomalies associated with the anomalous gyres and with extremes in tropical-temperate trough variability are highlighted.

Asian Monsoon

JSP25/W/89-B2 1400

MONSOON-ENSO RELATIONSHIP ON INTERANNUAL AND INTERDECADAL TIME SCALES

B N GOSWAMI, Centre for Atmospheric and Oceanic Sciences Indian Institute of Science Bangalore 560012, India e-mail: goswamy@caos.iisc.ernet.in and V. Krishnamurthy Center for Ocean-Land-Atmosphere Studies Institute of Global Environment and Society, Inc. 4041 Powder Mill Road, Suite 302, Calverton, MD 20705, USA e-mail: krishna@cola.iges.org

Empirical evidence is presented to support a hypothesis that the interdecadal variation of the Indian summer monsoon and that of the tropical sea surface temperature (SST) are parts of a tropical coupled ocean-atmosphere mode. The interdecadal variation of the Indian monsoon rainfall (IMR) is strongly correlated with the interdecadal variations of various indices of El Nino and the Southern Oscillation (ENSO). We also show that the interannual variances of both IMR and ENSO indices vary in phase and follow a common interdecadal variation. However, the correlation between IMR and eastern Pacific SST or between IMR and Southern Oscillation Index (SOI) on the interannual time scale does not follow the interdecadal oscillation. The spatial patterns of SST and sea level pressure (SLP) associated with the interdecadal variation of IMR are nearly identical to those associated with the interdecadal variations of ENSO indices. As has been shown earlier inthe case of ENSO, the global patterns associated with the interdecadal and interannual variability of the Indian monsoon are quite similar. The physical link through which ENSO is related to decreased monsoon rainfall on both interannual and interdecadal time scales has been investigated using National Centers for Environmental Prediction/National Center for Atmospheric Research reanalysis products. The decrease in the Indian monsoon rainfall associated with the warm phases of ENSO is due to an anomalous regional Hadley circulation with descending motion over the Indian continent and ascending motion near the equator sustained by the ascending phase of the anomalous Walker circulation in the equatorial Indian Ocean. We show that, to a large extent, both the regional Hadley circulation anomalies and Walker circulation anomalies over the monsoon region associated with the strong (weak) phases of the interdecadal oscillation are similar to those associated with the strong (weak) phases of the interannual variability. However, within a particular phase of the interdecadal oscillation, there are several strong and weak phases of the interannual variation. During a warm eastern Pacific phase of the interdecadal variation, the regional Hadley circulation associated with El Nino reinforces the prevailing anomalous interdecadal Hadley circulation while that associated with La Nina opposes the prevailing interdecadal Hadley circulation. During the warm phase of the interdecadal oscillation, El Nino events are expected to be strongly related to monsoon droughts while La Nina events may not have significant relation. On the other hand, during the cold eastern Pacific phase of the interdecadal SST oscillation, La Nina events are more likely to be strongly related to monsoon floods while El Nino events are unlikely to have a significant relation with the Indian monsoon.

JSP25/E/18-B2 1420

POST-MONSOON SST ANOMALIES OVER INDIAN AND PACIFIC OCEANS

C. A. BABU and P. V. Joseph (Department of Atmospheric Sciences Cochin University of Science and Technology Cochin - 682 016, INDIA)

We have studied the Sea Surface Temperature (SST) anomalies over the Indian and Pacific Oceans in association with DRY Indian monsoons accompanied or not with El Nino during the period 1961-1985, over the following three seasons September-November (SON), Decemmber-February (DJF) and March-May (MAM). The domain studied is between latitudes 25 S and 25 N and longitudes 40 E to 160 W. In general, a DRY monsoon is followed by a warm SST anomaly over the tropical Indian Ocean and cold SST anomaly over tropical west Pacific ocean. Those DRY monsoons which are co-existing with El Nino are associated with larger SST anomalies.
Examining 3 monthly moving averages, it is found that warm SST anomaly first appear over the western Indian Ocean during JJA and expand in area northward and intensify during the Asian Summer Monsoon (JAS, ASO and SON). During OND this anomaly weakens and spreads to the east and south while a new and stronger SST anomaly appears over the eastern Bay of Bengal and South China Sea, apparently in association with the Asian Winter monsoon. This anomaly intensifies and spreads towards theAustralian waters over the following few months. By March to May (MAM) season the entire Indian Ocean about 10-15 degrees latitude either side of the equator, has a warm SST anomaly.

JSP25/W/73-B2 1440

A MODEL OF THE INTRASEASONAL FLUCTUATION OF THE INDIAN MONSOON

MR BRETT SCONCIA and Prof. Brian J. Hoskins, Department of Meteorology, University of Reading, 2 Earley Gate, Whiteknights, PO Box 239, Reading, UK, e-mail: swr96bcs@reading.ac.uk

The dominant mode of intraseasonal variability of the Indian summer monsoon is associated with an alternating position of the tropical convergence zone (TCZ). An "active" period of the monsoon occurs when the TCZ persists over the Indian sub-continent, contrasting with a "break" period that occurs when the TCZ is found in a more southerly position over the equatorial ocean. The heating structures of the atmosphere associated with a typical active and break period are produced from ERA data and are used as forcings to drive a simple numerical model. With the two heatings kept constant, resultant atmospheric flows are consistent with those seen in ERA data. The model is then made time-dependent with a linear combination of the active and break heatings used to drive the model. Characteristics of the low-level flow that are significantly different for the two regimes are used to determine the relative amounts of the two heatings. Results from a 1000-day integration show an apparently chaotic system with some evidence of bi-modality in the probability density function (PDF). Experiments with the time-dependent model to investigate the sensitivity of the PDF distribution to external forcing will be presented.

JSP25/P/03-B2 1500

IMPACT OF ENSO ON ASIAN MONSOON: NEW PERSPECTIVES

R.H.KRIPALANI and Ashwini Kulkarni (both at Indian Institute of Tropical Meteorology, Pashan, Pune 411008, India, email: rhksup@tropmet.emet.in)

El Nino Southern Oscillation (ENSO) phenomenon is now recognised as the single most important mode of the earth's year-to-year climatic variability. It has been well documented that majority of the ENSO warm (cold) extremes are associated with below (above) normal rainfall over the Asian domain.
Our recent analysis of the 128-year (1871-1998) data reveals that the Indian monsoon rainfall (IMR) exhibits epochal variability. The periods 1880-1895 and 1930-1963 are characterised by above normal rainfall while the periods 1895-1930 and 1963-1990 are characterised by below normal rainfall. Further the impact of El Nino (La Nina) on IMR is more severe during the below (above) normal rainfall epochs. Rainfall data analysis also reveals that the IMR is entering into an above normal epoch with a turning point around 1990 suggesting that the impact of El Nino (La Nina) on IMR may not (may) be severe. This may be a possible reason for India not experiencing a drought during the El Ninos after 1990s. In spite of the severe 1997 El Nino the IMR was 102 % of the long-term average. The equatorial Pacific entered into a La Nina phase during the Monsoon of 1998. The IMR for 1998 was 106 % of the normal.
Such phase-locking between the ENSO episodes and epochal variability is also seen over other regions of Asia. Implications of these results on the impact of ENSO during the coming decade will be discussed.

JSP25/E/36-B2 1520

THE OCEANS' ROLE IN LOW-FREQUENCY VARIABILITY OF THE INDIAN MONSOON

ROXANA C. WAJSOWICZ (Dept. of Meteorology/JCESS, University of Maryland, College Park, MD 20742, U.S.A., e-mail: roxana@atmos.umd.edu); Paul S. Schopf (Institute of Computational Sciences and Informatics, George Mason University, Fairfax, VA 22030, U.S.A., e-mail: schopf@cola.iges.org)

It is proposed that the southern tropical Indian Ocean (STIO) plays an important role in variability of the strength of the Indian summer monsoon. During years of a strong monsoon, its influence is either direct in providing more moisture to precipitate over India, or indirect in draining less heat from the Arabian Sea and so promoting a more energetic atmospheric circulation. Direct influence is supported by analysis of COADS, which shows that the evaporation rate over the STIO is increased as is the cross-equatorial moisture transport by the Findlater jet during boreal summer in strong years. Interestingly, the corresponding SST anomalies in the STIO are positive. In years of below average monsoon rainfall, the opposite is found. Indirect influence occurs because vigorous evaporation over the STIO is sustained during the boreal summer by heat transport from the Arabian Sea and from the western equatorial Pacific Ocean via the Indonesian throughflow. Whereas the heat exchange between the Arabian Sea and STIO has an annual period with a maximum southward transport in boreal summer, that between the western equatorial Pacific and the STIO has a strong semi-annual period with a maximum southwest transport over the upper thermocline during the monsoon transition seasons. Hence, the Indonesian throughflow preconditions the STIO for the ensuing monsoon season. The mutual interactions between these three components, namely the Arabian Sea, STIO and western equatorial Pacific, are illustrated with differently configured GCMs of the seasonal cycle and the last decade.

CLIMATIC ANOMALIES DURING THE BOREAL WINTER OF 1997-98: THE ROLE OF ATLANTIC SST

R.T. SUTTON, S.P. Jewson, C. Jones, J. Slingo Centre for Global Atmospheric Modelling, Department of Meteorology, University of Reading, PO Box 243, Earley Gate, Reading RG6 6BB, U.K.

During the boreal winter of 97/98 there were major climate anomalies in many parts of the world. Many of these anomalies were attributed to the El Nino conditions that prevailed at the time, implying a link to SST anomalies in the tropical Pacific. There were, however, significant SST anomalies elsewhere in the world: in the Indian and Atlantic oceans. There is considerable evidence that the Indian Ocean SST anomalies had a major impact on climate. We are investigating the less studied role of the Atlantic Ocean SST anomalies.
We have performed ensemble integrations of an atmospheric General Circulation Model with various SST fields used as lower boundary condition. Our results show that the Atlantic SST anomalies had a significant impact on both the tropical and extratropical atmospheric circulation during DJF 97/98. Our model suggests that this impact included a contribution to a predictable signal over Europe. The response to the Atlantic SST anomalies in the tropics involves intensification of the local Hadley Circulation. Over the North Atlantic an anomalous low is forced. An important question is whether this mid-latitude response is forced by the local Atlantic SST anomalies or is a remote response to the tropical Atlantic SST anomalies. We are presently addressing this question through further experimentation.

JSP24/W/45-B2 1640

TROPICAL-EXTRATROPICAL CONNECTION IN THE ATLANTIC ATMOSPHERE-OCEAN VARIABILITY

Masahiro WATANABE and Masahide Kimoto (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro, Tokyo 153-8904, Japan, email: hiro@ccsr.u-tokyo.ac.jp)

Observations for the recent 40 years show two dominant modes of variability in the tropical Atlantic SST anomalies. One has a monopole structure associated with the El Ni\~no-like signal in the tropical Pacific SST anomalies, while another reveals a north-south dipole straddling the equator. These modes accompany 500-hPa height and SST anomalies in the North Atlantic.
To investigate the physical relationship between the tropical SST variations and the North Atlantic atmosphere-ocean system, a 60-yr long integration was conducted with an AGCM coupled to a 50-m-deep slab ocean except for the tropics where the SST is prescribed to observations (TOGA-ML run). The TOGA-ML run well reproduced the extratropical height and SST anomalies, suggesting an impact of tropical SST anomalies on the North Atlantic air-sea variations. However, linear responses of the dynamical operator of the AGCM to the heating in the tropical Atlantic corresponding to the two modes of SST variability are weak in the North Atlantic and moreover less similar to the observed height anomalies. The height responses resemble the anomalies when associated transient eddy forcing is included. This result implies that the tropical SST variations indirectly influence the North Atlantic atmosphere through changes in the eddy activity. A comparison of the TOGA-ML run with a GCM run coupled to the global slab ocean indicates that the tropical SST variability increases the variance in the extratropical atmosphere, selectively for the North Atlantic Oscillation.

JSP25/L/02-B2 1700

THE EQUATORIAL ATLANTIC OSCILLATION: A SELF-SUSTAINING CLIMATE OSCILLATION IN THE TROPICAL ATLANTIC

ITSUKI C. HANDOH (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, U.K., e-mail: i.handoh@uea.ac.uk); Grant R. Bigg (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, U.K., e-mail: g.bigg@uea.ac.uk)

The anomalous climate of the Atlantic of 1983-84 has been inferred as being triggered by the 1982/83 El Nino in the Pacific. Other such events have been observed in the tropical Atlantic, typically lagging El Nino events by 4-5 months, although there are not always clear links to such events, as in 1988. Here, using modelling, satellite altimetric and sea surface temperature data, we report an unusual equatorial Atlantic event, starting in autumn 1995 and continuing into the autumn of 1997, which does not seem to be connected to the El Nino ending in early 1995. This Atlantic event contained both a warm and a cold phase, with the latter seemingly being generated, through air-sea coupling, by the former. The propagating signal within each phase is identified in the sea surface height and temperature signatures as both equatorial and off-equatorial Rossby waves in the ocean, with coupling to atmospheric convection. The two-phased climate event appears to have been associated with internal atmospheric and oceanographic variability within the Atlantic basin and hence have been independent of the Pacific climate.

JSP25/W/83-B2 1720

A LINKAGE FOR DECADAL CLIMATE VARIATIONS IN THE LABRADOR SEA AND THE TROPICAL ATLANTIC OCEAN

Jiayan YANG (Dept. of Physical Oceanography, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA, email: jyang@whoi.edu)

The Labrador Sea Water (LSW) thickness, according to observations, varies significantly on decadal time scales in response to atmospheric forcing and fresh-water flux from the Arctic Ocean. Sea surface temperature (SST) in the tropical Atlantic also exhibits considerably interannual to decadal changes. A distinct mode, as identified in previous studies, is the so-called tropical Atlantic SST dipole -- a cross-equator pattern. Analyses of observations and modeling results indicate that the SST dipole and variations of LSW thickness are linked through the Meridional Overturning Circulation (MOC). Southward transport of LSW along deep western boundary must be compensated by northward flow in the upper ocean. Once the LSW pulse enters the tropics, it affects the cross-equator heat transport and the upper ocean response generates a dipole pattern in the SST field. The correlation between observed LSW thickness and SST is significant with a lag of 5 years. The best correlation occurs in areas off the western boundary where the main cross-equator transport takes place. Results from an ocean model indicate that the time lag between LSW and tropical SST is set by coastal Kelvin waves that propagate from the Labrador Sea to the tropics along the western boundary.

SEASONAL-DECADAL VARIABILITY

NAO Related Variability

JSP25/E/12-B3 0830

NORTH ATLANTIC OCEAN VARIABILITY ON DECADAL TIMESCALES IN THE HADLEY CENTRE COUPLED MODEL

Claire COOPER and Chris Gordon (both at Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SY, UK.
Email: ccooper@meto.gov.uk)

The simulation of decadal variations in the North Atlantic Oscillation (NAO) and related ocean phenomena in a multi-century integration of the latest Hadley Centre coupled model which does not use flux adjustment will be described. Where possible the model simulation is compared with available observations. The ocean component of the model has a 1.25 deg resolution which allows a better representation of the North Atlantic Current (NAC) than in many of the earlier coarser resolution climate models. It has also enabled the relationship between the NAO, high latitude convection and the strength and path of the NAC to be explored in detail. It is shown that the model realistically simulates the NAO in both spatial pattern and time variability and, in addition, the ocean component confirms the observed relationship between convection in the Labrador and Greenland Sea and the phase of the NAO. The model also has propagating decadal timescale sea surface temperature anomalies, similar to those found in the historical observations. The mechanisms of propagation of these anomalies in the coupled model will be discussed.

JSP25/W/53-B3 0850

FLUCTUATIONS OF THE NAO AND NORTH ATLANTIC STORM TRACK ACTIVITY IN THE ECHAM4/OPYC3 COUPLED AOGCM

M. CHRISTOPH and U. Ulbrich, (Institut für Geophysik und Meteorologie der Universität zu Köln, Kerpener Straße 13, D-50923 Köln, Germany)

In a 300-year control integration of a coupled ocean_atmosphere GCM (ECHAM4 + OPYC3), a close relation of the North Atlantic Oscillation (NAO) and the eastern part of the Atlantic storm track is confirmed both for the interannual (< 10 years) and the decadal (> 10 years) time scales. Positive anomalies of the NAO are associated with a northward shift and intensification of the storm track, and increased freshwater fluxes into the Iceland and Norwegian Seas. On the other hand, the mean flow anomaly in the atmosphere induces Ekman pumping into the central parts of the subtropical North Atlantic during the positive NAO phase. This contributes to a spin up of the subtropical gyre circulation and thus to northward transports of warm and salty waters within the Gulf stream system. While the existence of such relations on the decadal time scale suggests that the dynamical ocean is important for the NAO and the associated storm track variability, an additional experiment using a 50 m fixed-depth mixed layer ocean proves the contrary. The NAO has very similar space-time behaviour as in the coupled run and amplitudes are only about 10% smaller than using the dynamical ocean. The second EOF of eddy activity over the Atlantic represents the variation of activity in the center of the Atlantic storm track, again both on the interannual and the decadal time scales. This variation exhibits a very weak connection to the NAO or to other coherent SLP variability patterns. Potential factors influencing this region are discussed.

JSP25/E/24-B3 0910

LONG-TERM CHANGES OF INTERANNUAL SEA LEVEL VARIABILITY IN THE BALTIC SEA AND RELATED CHANGES OF WINTER CLIMATE

Martin EKMAN (Summer Institute for Historical Geophysics Bomarsund Åland Islands)

The world's longest sea level series, that of Stockholm commencing 1774, has earlier been used by the author to study the eustatic rise of sea level. Here, the interannual sea level variability of the Baltic Sea and its relation to climate is studied using the same sea level series, together with equally long temperature and wind series. Long-term changes of the sea level variability are found to be closely related to changes of winter climate. The interannual sea level variabilty and the interannual winter temperature and winter wind variabilities have all decreased significantly from the end of the 1700s to the beginning of the 1900s; after that they have all increased significantly again. The common origin of these long-term changes turn out to be two consecutive wind processes over the North and Baltic Seas, especially the Baltic entrance: From the end of the 1700s to the beginning of the 1900s there is a rapidly decreasing number of dominating winter winds from northeast, after that there is an increasing number of dominating winter winds from southwest.

JSP25/E/06-B3 0930

IS THE NORTH ATLANTIC OSCILLATION A RANDOM WALK?

Dr. David B. STEPHENSON (Labo. de Statistiques et Probabilites, Universite Paul Sabatier, 118, route de Narbonne, 31062 Toulouse, France. E-mail: stephen@cict.fr); Dr. Valentina Pavan (CINECA, via Magnanelli 6/3, 40033 Casalecchio di Reno, Italy. E-mail: pavan@cineca.it)

A principal component analysis of the Jones gridded land/sea temperature data set reveals that year-to-year differences in global land/sea wintertime surface temperatures are dominated by a) the North Atlantic Oscillation (NAO) and b) the tropical biennial oscillation. The NAO indices exhibit long-memory fluctuations that can be modelled using a simple non-stationary random walk model. The model accounts for both year-to-year reversals and trends in the NAO, and has some slight yet encouraging skill at forecasting the NAO one year ahead. Decadal trends and cycles simulated by this non-stationary stochastic model resemble those in the observed NAO and offer a possible explanation for recent NAO variability.

JSP25/W/59-B3 0950

SEASONAL DEPENDENCE AND TIME EVOLUTION OF THE INTERANNUAL SEESAW BETWEEN THE ALEUTIAN AND ICELANDIC LOWS

HISASHI NAKAMURA (IGCR, Frontier Research System for Global Change, Tokyo/Dept. Earth, Planetary Physics, Univ. Tokyo, 113-0033, JAPAN; email: hisashi@geoph.s.u-tokyo.ac.jp), Meiji Honda (IGCR, Frontier Research System for Global Change, Tokyo; email: meiji@ frontier.esto.or.jp), and Jinro Ukita (IARC, Frontier Research System for Global Change, Tokyo;
email: qpee@frontier.esto.or.jp)

It is known that the surface Aleutian and Icelandic lows (AL and IL, respectively) exhibit a seesaw-like oscillation in winter. We examined seasonal dependence of this interannual seesaw by recording the minimum within each of the North Atlantic and North Pacific in the 31-day moving-averaged sea-level pressure (SLP) for each day over 1973-1994 based on the NMC analyses. The correlation coefficient between the 22-year timeseries of thus-defined AL and IL intensities was evaluated for each calendar days. The correlation was found to be strongly negative only in the late winter (February through mid-March). In the rest of the year it is weakly negative or even slightly positive. A similar seesaw is also evident in the SLP field from which ENSO- related anomalies as inferred from a linear regression analysis with SOI were removed.
We defined AI (AL-IL) index as the IL-center pressure subtracted from the AL-center pressure in the 45-day mean SLP for January 31-March 16. In the recognition of the equivalent barotropic structure of the seesaw, we investigated seasonal evolution of the seesaw in the linear lag regression maps between AI index and the mean of the 250-hPa height for each of the fourteen 45-day periods, whose central calendar days are mutually 15 days apart. In the following, we focus on a winter of the weaker AL with the stronger IL. After positive height anomalies gradually develop over the eastern North Pacific in December, a PNA-like wavetrain emanates from the positive anomalies in early January (Dec. 17-Jan. 30) with negative and positive anomalies appear over western Canada and the southeastern US, respectively. Then, another wavetrain emanates from the latter with negative and positive centers to the east of Newfoundland and over northern Europe, respectively. As these wavetrains gradually weaken by early February (Jan .16-Mar. 1), positive anomalies over the North Pacific fully mature and cover the entire North Pacific, which correspond to the weak AL. At the same time the negative anomalies over the North Atlantic further develop while shifting northward until they mature in the "peak period" (Jan. 31- Mar. 16), when the AL-IL seesaw is the most apparent.

JSP25/W/52-B3 1010

LONG-TERM CHANGES OF THE WINTER SEA LEVEL PRESSURE FIELDS AND RELATED SYNOPTIC ACTIVITY OVER THE NORTH ATLANTIC

Igor ZVERYAEV (IPRC, SOEST, University of Hawaii, MSB, Room 227, 1000 Pope Rd., Honolulu, HI 96822, USA, email: igorz@soest.hawaii.edu)

Long-term climatic changes of the winter synoptic activity over the North Atlantic are studied in relation to changes of the winter mean sea level pressure (SLP) fields. Analysis of linear trends has revealed a good agreement between long-term (interdecadal) changes of the intensity of synoptic processes and variations of the winter SLP. On the contrary, there was not such agreement found between detrended and low-pass filtered anomalies. There are periods, which are characterized by the enhanced (reduced) synoptic activity attributed to the low (high) index of the North Atlantic Oscillation (NAO). It appears that low-passed anomalies of intramonthly root mean square deviations of SLP are negatively correlated with NAO and East-Atlantic teleconnection patterns over the most of the North Atlantic.
The low-passed winter SLP anomalies demonstrate both propagating and standing patterns. The latter have a period of about 8 years. While meridional dipole-like structures formed by the winter SLP anomalies are shifted to the west (east) of the North Atlantic, related anomalies of synoptic activity tend to be located in the eastern (western) part of the region. When decadally averaged, anomalies in the intensity of synoptic activity are strongly linked to the North Atlantic storm track position. Exception is 1980-1990 decade, characterized by the very high NAO index. During this decade enhanced synoptic activity is observed to the south of the North Atlantic storm track.

Predictability

JSP25/W/04-B3 1110

HYDROCLIMATOLOGICCAL PREDICTABILITY OVER THE AMERICAS

John ROADS (Scripps Institution of Oceanography, UCSD-0224, La Jolla, CA 92093, Email: jroads@ucsd.edu); Susan Marshall (Dept. Geog. & Earth Sci., UNC-Charlotte, Charlotte, NC 28233, Email: susanm@uncc.edu); Bob Oglesby (Purdue Univ., W. Lafayette IN 47907, Email: roglesby@purdue.edu); Franklin Robertson (NASA/Marshall Space Flight Center, Global Hydrology and Climate Center, Huntsville, AL 35806, Email: pete.robertson@msfc.nasa.gov)

Hydrologic variations over the Americas associated with interannual sea-surface temperature (SST) anomalies have been identified in long simulations made with the National Center for Atmospheric Centers (NCAR's) community climate model (CCM3) and in the National Centers for Environmental Prediction (NCEP) reanalysis. Corresponding variations in global precipitation climatology project (GPCP) precipitation anomalies provide additional validation of the strength and magnitude of the anomalies. These hydrologic variations are also being compared to the variations associated with local soil moisture anomalies.
The extent to which the response of the CCM3 atmosphere to SST anomalies differs from the response to local soil moisture anomalies serves as the basis for climate predictability experiments using various combinations of SST and soil moisture anomalies. Preliminary results indicate that in the Mississippi River basin and in the Mackenzie River basin, both soil moisture and SST anomalies have significant influences on monthly to seasonal predictions. By contrast, hydroclimatological variations over the Amazon are governed much more strongly by SST anomalies.

JSP25/E/33-B3 1130

LONG-RANGE PREDICTION OF UK WINDSTORMS

S. E. GEORGE and M. A. Saunders (both at Department of Space and Climate Physics, Benfield Greig Hazard Research Centre, University College London, UK, Email: seg@mssl.ucl.ac.uk)

For the UK and NW Europe, winter storms and floods are the largest cause of economic damage and insurance loss. The skillful prediction of such events several months in advance would allow damage limitation procedures to be implemented. Current dynamical weather forecast models have a limit of predictability measured in weeks rather than months, and are therefore not suitable for such a task. We present a new statistical model for the long range prediction of UK windstorms. Initial results for winter storminess in the South East of England for the period 1958-1996, have shown 70% of the year-to -year variance in storminess can be predicted six months in advance. Physical mechanisms linking the climate predictors we use with UK windspeed several months later will be suggested.

JSP25/E/08-B3 1150

IMPACT OF THE ENSEMBLE SIZE ON MULTIMODEL SEASONAL FORECASTS

Francisco Javier DOBLAS-REYES and Michel Deque (CNRM, Meteo-France, 42, Av. G. Coriolis, 31057 Toulouse Cedex, France)

In the framework of the PROVOST project, the European seasonal prediction experiment, four long-lead ensemble forecast experiments with prescribed SST have been carried out. Each experiment has been run with a different GCM: the ECMWF, CNRM (with two different horizontal resolutions), and UKMO atmospheric models, all integrated from common initial conditions.
The performance of the combination of the different models in a whole ensemble has been compared with the performance of the individual models. The combination increases the ensemble size, providing a good test field for checking the feasibility of probabilistic forecasts in seasonal forecasting. Furthermore, the multimodel forecasts present the advantage of taking into account the role of the model in the forecast divergence. All the models exhibit some skill in the seasonal range in winter. This is also evidenced for the other seasons except for the European region. The hypothesis of a significant gain in skill for multimodel probabilistic forecasts independently of the ensemble size has been tested. Results show that multimodel represents a clear improvement over the tropics.

SEASONAL-DECADAL VARIABILITY

Air-Sea Interaction and the Mixed-Layer

JSP25/E/32-B3 1400

THE INFLUENCE OF MIDLATITUDE AIR-SEA INTERACTION ON CLIMATE VARIABILITY

MICHAEL ALEXANDER and James Scott (CDC-CIRES, University of Colorado Boulder, CO 80309, USA e-mail: maa@cdc.noaa.gov)

A coupled atmosphere-ocean model is used to examine the role of air-sea interaction in climate variability. The coupled model consists of the Geophyscial Fluid Dynamics Lab (GFDL) atmopsheric general circulation model (AGCM) coupled to a grid of independent mixed layer ocean models which is nearly global in extent. The ocean model simulates vertical processes which makes it appropriate for studying aspects of the climate system which operate on interannual time scales in the extratropics. The coupled model has been integrated for 50 years and has been compared to a 50-year control AGCM simulation in which sea suurface temperatures (SSTs) corresponding to the long term mean in the coupled run are specified as boundary conditions.
Here we will focus on processes which create SST anomalies and how these anomalies influence the atmospheric circulation. The net surface heat flux is the dominant term in creating SST anomalies over most of the year except in fall when entrainment plays an equal or greater role over parts of the North Pacific and North Atlantic. This allows for the winter-to-winter recurrence of SST anomalies as thermal anomalies created by the net heat flux in late winter, remain below the mixed layer in summer and are then returned to the surface by entrainment in the following winter. Preliminary results indicate that air-sea interaction in the Atlantic influences the storm track and the circulation at 500 mb downstream over Europe.

JSP25/E/21-B3 1420

ERROR PROPAGATION ACROSS THE AIR-OCEAN INTERFACE

Peter C. CHU, (Naval Postgraduate School, Monetary, CA 93943, USA, Email: chu@nps.navy.mil) Shihua Lu, W. Timothy Liu, and Yuchun Chen

Error propagation across the air-ocean interface is an important factor to determine the ocean/atmosphere predictability. First, we use the Lorenz system (Lorenz, 1963) to show the propagation of boundary error. Second, we use the latest version of the NCAR Community Climate Model (CCM3) to study the propagation of tiny surface temperature error into the model atmosphere. The model was integrated from 1 September 1977 observational data over the globe for 16 months with and without SST disturbances. A time-scale of 20-day is found such that the response increases rapidly within this time-scale and then oscillates at high values. Third, we study the propagation of wind error into ocean model. Finally, some theoretical discussion will also be included.

JSP25/W/35-B3 1440

TESTING THE INFLUENCE OF THE SST ANOMALIES IN THE TROPICAL ATLANTIC UPON THE ATMOSPHERIC CIRCULATION AT 500 HP

AIleana Mares, C. MARES, Mihaela Mihailescu (National Institute of Meteorology and Hydrology, Bucuresti-Ploiesti 97, Bucharest 71552, Bucharest, RomaniaFax : 00-40-1-2303143, E-mail: imares@meteo.inmh.ro

We have started from the hypothesis that there is a dependence of Markov chain type of the main interaction types between the ocean state and the atmospheric state. The classification

with four states has been used : blocking circulation conditioned by SST negative anomalies, blocking circulation conditioned by SST positive anomalies, zonal circulation conditioned by SST positive anomalies and zonal circulation conditioned by SST negative anomalies.
The probability matrix of the transformations from one state to another, is estimated from monthly mean values of the geopotential at 500 hPa and of the SST in the Atlantic Ocean area, during the period 1965-1987. The geopotential has been considered over the sector: 500W-400E and 350N-650N. The SST data in COADS in the same period have been considered in our processing for the sector: 370S-390N, 740W-100E. The limiting matrix of the Markov chain has become stabilised after 23 steps (months), indicating a measure of the predictability of the supposed interaction. The statistical significance of the elements of the transition matrix has been established by the Monte Carlo simulation method.

JSP25/W/94-B3 1500

THE SEASONAL AND INTERANNUAL VARIATION OF THE HEAT BUDGET OF THE MIXED LAYER EVALUATED BY SATELLITE-DERIVED HEAT FLUX AND THE NUMERICAL MODEL VELOCITY FIELD

Masanori KONDA, Miho Toyoda, Taiyo Kobayashi, Norihisa Imasato (Department of Geophysics, Graduate School of Science, Kyoto University); Kitashirakawa-Oiwake, Sakyo, (Kyoto 606-8502, Japan, E-mail: konda@kugi.kyoto-u.ac.jp) , and Akira Shibata (NASDA/EORC, 14F, Roppongi-firt Buld., 1-9-9 Roppongi, Minato, Tokyo 106-0032, Japan, E-mail: ashibata@eorc.nasda.go.jp)

We evaluate the heat budget in the mixed layer in the global ocean from satellite-derived surface heat flux and the numerical model velocity field, and discussed the seasonal and the interannual variability of it. The surface heat flux data is the sum of the satellite-derived turbulent heat flux and the radiation flux from July 1987 to June 1991, and the seasonal cycle of the surface velocity field is computed by the robust diagnostic model (Kobayashi and Imasato 1998) without the interannual variation. The thermal response of the ocean to the surface heat exchange is very important in the point that the seasonal and the interannual climate changes largely depend on the thermal air-sea interaction.In careful consideration for the validity of using together different types of the data sources as imported from the numerical model computation and the satellite observation, the heat flux at the bottom of the mixed layer is computed as the residual of the surface and the horizontal heat flux and the change of the heat content in the surface layer with a constant depth in the global ocean. The distribution of the heat flux at the bottom of the mixed layer indicates the existence of the significant heat exchange between the surface and the subsurface layer. The seasonal change of the bottom heat flux suggests that the oceanic heat transport by the strong current has relatively greater effect during the season when the sea surface temperature (SST) is increasing, and the surface heat flux when the SST decreasing. Correlation analysis is done to examine how the result of the air-sea heat exchange can be induced to the subsurface ocean, and it is suggested that the change of the thermal condition in the remote area can teleconnectively contribute to the local heat budget through the horizontal heat transport, adding to the local effect of the surface heat flux.

JSP25/E/17-B3 1520

MIXED-LAYER HEAT BALANCE AND NET SURFACE HEAT FLUX ON A SEASONAL SCALE

S.A.B. KIM (Satellite Technology Research Center. 373-1, Kusung, Yusung, Taejon, S. KOREA 305-701. email: sbkim@krsc.kaist.ac.kr. Also at Korean Meteorological Administration)

Heat balance within an ocean mixed layer is important since it describes whether ocean-atmosphere interactions occur locally or remotely. The heat balance mechanism is analysed over the Kuroshio Extension region to identify the significance of the jet, seasonally from October 1992 to September 1995. The horizontal geostrophic heat advection is obtained using current velocities from satellite altimetry. The errors in the monthly and spatial mean values of the zonal and meridional geostrophic heat advection reach respectively 150 % (46 W/m**2) and 300 % (61 W/m**2) of the signal. The entrainment heat advection is estimated rigorously on a climatological monthly scale. The heat storage rate is computed using subsurface temperature records. The horizontal Ekman heat advection is derived using ECMWF model wind speeds. The seasonal heat advection by the Kuroshio Extension is <10 % of the heat storage rate in the basin-scale heat balance. The horizontal Ekman heat advection is also insignificant. It is concluded that the heat balance is achieved locally. Monthly net surface heat fluxes are derived from the sum of the heat balance terms. Errors in these fluxes are estimated thoroughly by developing formulae on how errors in the basic fields propagate into the flux. A value of 30 W/m**2 is obtained for the error in the three-year mean net surface heat flux over the basin. This is smaller in percentage terms than that achieved by the best bulk-formulae method. Horizontal heat advection (Ekman plus geostrophic) contributes 21 W/m**2 to the error in the three-year mean net surface heat flux.

JSP25/W/43-B3 1620

INTERNALLY GENERATED MODE WATER VARIABILITY

Wilco HAZELEGER (KNMI, Oceanogr. Res. Div., PO Box 201, 3730 AE De Bilt, The Netherlands, Email: hazelege@knmi.nl) Sybren Drijfhout (KNMI, Oceanogr. Res. Div., PO Box 201, 3730 AE De Bilt, The Netherlands, Email: drijfhou@knmi.nl)

Mode Water formation in the subtropical gyre of the North Atlantic exhibits substantial decadal variability. Here, we present results that indicate a large role of internal oceanic variability in generating this variability. The results are obtained with an isopycnic ocean model, with idealised geometry and forcing. The horizontal resolution is sufficiently high and the friction/diffusion sufficiently low for the flow to become unstable.
Two modes of low frequency variability are found. Both modes consist of westward propagating thickness anomalies. The anomalies have a first baroclinic modal structure. One mode has a time scale of 8 years and a basin wide spatial scale, the other has a time scale of 4.5 years and smaller spatial scale. The modes are damped when the diffusion is increased. In that case, the 8 yr mode can be excited by a spatially coherent stochastic wind stress, but the amplitude is much smaller. The modes are maintained by a release of energy of the mean flow in the thermocline. The instability of the mean flow is determined by the basic stratification, in particular the slope across the midlatitude jet. Finally, it is shown that coupling to the atmosphere and a parameterization of surface mixing are necessary for the low frequency variability to appear in the mixed layer.

JSP25/E/01-B3 1640

INTER-DECADAL VARIATIONS IN JAPANESE SARDINE AND THE KUROSHIO EXTENSION

ICHIRO YASUDA (Univ. of Tokyo/ Frontier Research System for Global Change, Hongo 7-3-1, Bunkyo, Tokyo 113-0033,Japan, E-mail: ichiro@geoph.s.u-tokyo.ac.jp); Masayuki Noto (Hokkaido Univ., E-mail: noto@geoph.s.u-tokyo.ac.jp); Tomoki Touzuka (Univ. of Tokyo, E-mail: s72620@vsiron.geoph.s.u-tokyo.ac.jp)

Japanese sardine is known to greatly vary in inter-decadal time sacles. In 1988, the catch was over 4 million tons; it declined abruptly since 1989 and was below 1 million tons in 1995. We found the winter-SST in the Kuroshio Extension and its southern recirculation area (KESA: 30-35N, 145-180E) significantly correlates with the mortality coefficient of the Japanese sardine. The warming in the KESA since 1988 possibly causes the collapse of the sardine. The SST variations in the KESA and south of Japan were different from those in the Kuroshio-Oyashio frontal regions in the western/central Pacific (40-45N 145-180E) where a regime-shift around mid-1970s was known: the SSTs in the Kuroshio regions have a longer time scale of over 50 years than in the frontal regions (25 years), and the jump of the Kuroshio SSTs around late-1980s occurred two years earlier in 1988 than in the frontal regions. The shift around mid-1970s in the frontal regions was not observed in the Kuroshio and the KESA where the SST anomalies were already negative in early-1970s. These SST variations well corresponds to sardine catch records. Analyses of heat flux and wind before/after the late-1980s SST jump indicate that the warming since 1988 was caused partly by the decrease in the net heat flux and in the mixed layer depth due to the reduction of wind over the Kuroshio south of Japan and over the Kuroshio Extension regions.

JSP25/W/72-B3 1700

RECENT VACILLATIONS IN THE SURFACE PRESSURE SEMIANNUAL OSCILLATION

Ian SIMMONDS (School of Earth Sciences, The University of Melbourne, Parkville, Victoria, 3052, Australia, email: ihs@met.unimelb.edu.au); David A. Jones (Bureau of Meteorology Research Centre, 150 Lonsdale Street, Melbourne, Victoria, 3001, Australia, email: d.jones@bom.gov.au)

We present a climatology of the Southern Hemisphere semiannual oscillation of surface pressure and mid tropospheric baroclinicity compiled from 21 years of numerical analyses. In addition, long time series of this feature derived from pressure data from a number of mid and high latitude stations are presented. The results confirm that the oscillation is an important feature of the annual cycle of pressure and meridional temperature gradient. The pressure half-yearly wave attains its greatest amplitudes in the mid latitude ocean basins and on the Antarctic periphery, with a minimum near 55oS. The semiannual oscillation of the temperature gradient is strongest near 60oS, where it explains about 50% of the mean annual variance of monthly data, and the harmonic maxima (strongest gradients) occur during the transition seasons.
We document the extent to which the half-yearly wave exhibits variability on interannual to decadal time scales, and consider the extent to which recent changes may be seen as part of such overall variability. In both the mid and high latitudes the temporal variability of the semiannual oscillation of pressure has been found to be statistically related to the variability in the oscillation of the high latitude temperature gradient. Changes in the latter seem to be associated in the greater part with temperature changes at the higher latitudes.

JSP25/E/19-B3 1720

NATURE OF ATMOSPHERIC VARIABILITY OVER THE NORTH ATLANTIC OCEAN FROM INTERANNUAL TO DECADAL TIME SCALE

Christophe CASSOU, Laurent Terray, Sophie Valcke (CERFACS, Climate Modelling and Global Change Team, 42, Avenue Gustave Coriolis 31057 Toulouse, FRANCE, EMAIL: cassou@cerfacs.fr)

Predictability is considerably reduced at mid-latitudes especially over the Atlantic Ocean where the variability is mainly controlled by internal atmospheric processes which mask Sea Surface Temperature (SST) influences. In order to quantify and explain the response of the atmosphere to observed SST variability, the ARPEGE-Climat Meteo-France Atmospheric Global Circulation Model is used through 2 types of experiments : a 100-year simulation with a prescribed monthly climatological SST is carried out together with an ensemble of 8 50-year simulations forced by GISST month to month SST changes from 1948 to 1997 (GOGA simulations hereafter). Predictability is first investigated using ANOVA techniques applied on the ensemble experiment for different seasons. This statistical tool allows to separate in the total variability, the part forced by the SST from the part explained by internal dynamics. The North Atlantic Oscillation (NAO) is then more precisely studied in both experiments. The frequency analysis of the NAO related signal shows a weak 2.5-year peak in the climatological run whereas in GOGA simulations, the same analysis exhibits more energy concentration at longer time scale and a significant 3.7-year peak related to ENSO. This suggests important teleconnections and atmospheric linkages between the Atlantic and the Pacific. The SST impact is then examined using classification techniques in weather regimes; emphasis will be laid on differences between the climatological and the GOGA experiments in terms of spatial weather patterns, their occurences and transitions. Optimal filter methods finally allow to determine the spatial and time characteristics of the SST pattern which plays a role in setting up the simulated forced atmospheric response. Some preliminary results will also be presented on shorter sensitivity experiments using the detected SST signal superimposed on the climatological background as a new forcing.

GLOBAL VARIABILITY

JSP25/W/61-B4 Invited 0930

PATTERNS OF LARGE-SCALE CLIMATIC VARIABILITY IN THE INSTRUMENTAL ERA

Chris K. FOLLAND (Hadley Centre, Met Office, London Road, Bracknell, Berkshire, RG12 2SY, UK, Email: ckfolland@meto.gov.uk); Rob J. Allan (CSIRO Atmospheric Research, Aspendale, Victoria 3195, Australia, Email: rob.allan@dar.csiro.au); Michael E. Mann (Department of Geosciences Morrill Science Center, University of Massachusetts, Amherst, MA 01003, Email: mann@snow.geo.umass.edu); Scott B. Power (National Climate Centre, Melbourne, Victoria 3001, Australia, Email: s.power@bom.gov.au)

An empirical orthogonal function (EOF) analysis of ocean surface temperature, filtered to highlight periods greater than about 13 years, has been used to identify patterns of low frequency variability. These include a secular pattern of global warming, a 70-80 year interhemispheric pattern associated with interdecadal variations in Sahel rainfall, and a pattern reminiscent of El Nino but with a somewhat different structure that modulates high frequency ENSO influences on Australian climate. More insight can be obtained by carrying out joint EOF

analyses of pressure at mean sea level (PMSL) and SST for different spectral bands, and multi-taper singular value decomposition analyses of joint SST and PMSL data. These highlight significant low frequency bands and the secular band, and provide patterns of variability that are mostly consistent between the analyses.

JSP25/W/49-B4 Invited **0950**

QUASI-PERIODICITY AND GLOBAL SYMMETRIES IN INTERDECADAL UPPER OCEAN TEMPERATURE VARIABILITY

Warren B. WHITE and Daniel R. (Cayan1 Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California, e-mail: wbwhite@ucsd.edu)

Abstract Recent studies find interannual (i.e., 3 to 7 year), decadal (i.e., 9 to 13 year), and interdecadal (i.e., 18 to 23 year) periodicities, and a trend dominating global sea surface temperature (SST) and sea level pressure (SLP) variability over the past hundred years, with the interdecadal signal dominating sub-El Niño-Southern Oscillation (ENSO) frequencies. We isolate interdecadal frequencies in SST and SLP records by band passing with a window admitting 15 to 30 year periods. From 1900 to 1989, the rms of interdecadal-filtered SST and SLP anomalies is largest in the extratropics and eastern boundaries. First-mode empirical orthogonal functions (EOFs) explain about half the interdecadal variance in both variables, with the tropical warm phase peaking near 1900, 1920, 1940, 1960, and 1980. From 1955 to 1994, EOF spatial patterns of interdecadal SST, SLP, and 400m temperature (T400) anomalies reveals global reflection symmetries about the equator and global translation symmetries between ocean basins, with tropical and eastern ocean SSTs warmer (cooler) than normal, covarying with stronger (weaker) extratropical westerly winds, cooler (warmer) SSTs in western-central subarctic and subantarctic frontal zones (SAFZs), stronger (weaker) subtropic and subarctic gyre circulations in North Pacific and North Atlantic Oceans, and warmer (cooler) basin and global average SSTs of 0.1°C or so. Evolution of interdecadal variability from the tropical warm phase to the tropical cool phase is propagative, also characterized by reflection and translation symmetries. During the tropical warm phase, cool SST anomalies along western-central SAFZs are advected slowly eastward to the eastern boundaries and subsequently advected poleward and equatorward by the mean gyre circulation, the latter conducting extratropical SST anomalies into the tropics. A delayed action oscillation model is constructed that yields the quasiperiodicity of interdecadal variability in a manner consistent with these global symmetries in both pattern and evolution.

INTERANNUAL-TO- DECADAL VARIABILITY OF THE TEMPERATURE-SALINITY STRUCTURE OF THE WORLD

SYDNEY LEVITUS (NODC/NOAA, E/OC5, 1315 East West Highway, Room 4362, Silver, Spring MD 20910-3282, Email: slevitus@nodc.noaa.gov)

Analysis of historical upper ocean temperature data suggests the existence of a global mode of upper ocean heat storage. Additional analysis suggests that in the North Atlantic Ocean, both the first (NAO) and second (EAO) modes of sea level pressure are correlated with upper ocean thermal structure demonstrating the existence of coupled modes of oscillation for this ocean. Variabiliy of the temperature-salinity structure of the intermediate and deep waters of various regions of the world ocean will also be described.

Presiding Chair: Chris K. Folland (Hadley Centre, UKMO, Bracknell, UK)

RELATIONSHIPS AMONG RECENT ATMOSPHERIC CIRCULATION CHANGES, GLOBAL WARMING, AND SATELLITE TEMPERATURES

Jim HURRELL, (NCAR, USA, email: jwhurrell@meto.gov.uk)

There is much debate about our ability to detect a human influence on climate. Part of the problem is that the Earth's climate record includes both natural variability as well as human-induced effects, and the presence of the former makes it difficult to isolate possible anthropogenic signals. This is illustrated by changes in the atmospheric circulation over the past two decades which have contributed strongly to observed global warming patterns. Differences in the vertical structure of the temperature anomalies associated with the circulation changes largely account for discrepancies between temperature trends from surface and satellite-derived lower-atmospheric records. The circulation changes are related to variations in modes of natural variability over the North Atlantic and North Pacific basins. The question of the physical relationship between the variations in these two circulation modes on low frequency time scales, and furthermore their relation to secular changes in ENSO, will be discussed.

JSP25/W/09-B4 Invited **1110**

GLOBAL AND REGIONAL TELECONNECTIONS IN ATLANTIC BASIN SST VARIATIONS

YOCHANAN KUSHNIR, Balaji Rajagopalan, Yves Tourre, and Jennifer Miller, (Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY 10964, USA)

To address the extent to which Atlantic climate variability (ACV) is governed by processes internal to the Atlantic Basin, we apply various multivariate analysis methods to a long record of sea surface temperature anomalies. We find evidence for both local and global influences on the leading modes of ACV. Tropical and South Atlantic SST variability appears to be mainly associated with global patterns of SST variability, namely ENSO and an almost-global SST warming trend, between 1930 or so and the present. North Atlantic SST variability appears to be regional with little evidence to other oceanic regions. The characteristic pattern of regional SST variability is its "tri-polar" structure where subpolar and subtropical SST are fluctuating in phase with one another, and out of phase with midlatitude SST. The spectrum of the regional SST fluctuations displays distinct decadal and multi-decadal peaks and a hint of propagating behavior. We compare these results with other recent findings on ACV and discuss their implication.

JSP25/W/31-B4 Invited **1130**

DECADAL VARIABILITY IN THE EXTRATROPICAL OCEAN-ATMOSPHERE SYSTEM

Stephen P. MEACHAM, (Atmospheric and Environmental Research Inc., 840 Memorial Dr., Cambridge, MA 02139, USA. Email: smeacham@aer.com)

In the last four decades, a variety of mechanisms have been suggested as potential contributors to decadal variability of the extratropical atmosphere and ocean. It is difficult to unambiguously distinguish individual mechanisms in the complex behavior of a "full" climate model. We describe results from a pair of studies that focus on low frequency variability associated with redistribution of potential vorticity within the ocean. In the first, a simple baroclinic ocean with an adiabatic interior, forced with a specified double gyre wind stress, is shown to exhibit strong variability on decadal time scales. This variability is associated with the storage and release of potential vorticity in inertial recirculations embedded within the subtropical and subpolar gyres. A necessary condition for this mode of variability is the resolution of mesoscale eddies which are intimately connected with the episodic breakdown of the inertial recirculations. The inter-gyre eddy potential vorticity flux exhibits strong decadal variability. In the second study, a pair of mid-latitude ocean basins is coupled to a quasigeostrophic tropospheric model. The ocean is equipped with an active mixed layer that can store and transport heat. The interior of the ocean is essentially adiabatic. The oceans and atmosphere are coupled primarily through the transfer of potential vorticity: the atmosphere induces Ekman pumping in the ocean while the air-sea heat flux induces atmospheric heating and cooling anomalies which modify the potential vorticity budget of the atmosphere. The active atmosphere exhibits a moderately realistic planetary-scale and synoptic-scale wave regime, with quasistationary subtropical highs over the oceans, and drives subtropical and subpolar gyres in both oceans. Both the atmosphere and ocean exhibit significant low frequency variability. Part of this is the result of potential vorticity accumulation and discharge in the ocean gyres analogous to that seen in the ocean-only model. Another part of the variability can be attributed to coupled "modes" of the ocean-atmosphere-mixed layer system.

INTERDECADAL OSCILLATIONS WITH A LOW DEGREE OF FREEDOM MODEL OF THE OCEAN-ATMOSPHERE

Alain COLIN DE VERDIERE (Laboratoire de Physique des Oceans, Universite de Bretagne Occidentale,BP 809, 29285 Brest cedex France, email: acolindv@univ-brest.fr); Thierry Huck (Geophysical Fluid Dynamics Laboratory, NOAA, Princeton, NJ 08542 USA, email: tnh@GFDL.GOV)

Oceanic GCMs have been observed to oscillate on time scales in a large number of studies. Under the simplest situation of a temperature dependent equation of state, two conditions are necessary to produce the oscillations for a fixed strength of the overturning: a weak enough damping of SST anomalies (through constant heat flux for instance) and a low enough background eddy diffusivity. We suggest that baroclinic instability in western boundary current outflow regions governs the generation of the oscillations. In the complicated geometry of an oceanic GCM (as compared to an atmospheric channel), the large scale instability is local, driving planetary waves in the interior that set the period of the oscillations. The situation is not different when the oceanic GCM is coupled to an Atmospheric Energy Balance Model. This is used to construct a two degree of freedom climate model that reproduces a number of features of the coupled Ocean-EBM model such as the Hopf bifurcation to the limit cycle and the damping effect of restoring boundary conditions. It quantifies the relative weight of the various dissipation processes against the instability that feeds on available potential energy. Significant differences appear, however, when the oscillations are in the finite amplitude regime.

JSP25/W/01-B4 Invited **1210**

ON THE USE OF WAVELET COHERENCY FOR ANALYZING DECADAL CLIMATE VARIABILITY

TORRENCE, Christopher (National Center for Atmospheric Reasearch/Advanced Study Program, PO Box 3000, Boulder CO 80307-3000 USA, e-mail:torrence@ucar.edu)

The method of wavelet coherency is developed and applied to time series of climate variability. In particular, decadal changes in the El Nino-Southern Oscillation (ENSO) are linked to changes in Indian monsoon rainfall. The wavelet coherency provides a measure of the strength of the ENSO-monsoon connection and how the connection has varied over the last 125 years. Statistical significance tests are used to test the robustness of the results.

Thursday 29 July PM

VARIABILITY OVER THE ATLANTIC OCEAN

JSP25/W/47-B4 Invited **1400**

SIMULATION OF QUASI-DECADAL AND INTERDECADAL VARIABILITY IN THE ATLANTIC OCEAN ASSOCIATED WITH THE NORTH ATLANTIC OSCILLATION

George Halliwell, (MPO/RSMAS, University of Miami, USA)

Over the last several decades, the North Atlantic Oscillation (NAO) index has varied with two distinct time scales, a quasi-decadal oscillation and an interdecadal oscillation with a period of about 50 years. Since high NAO index is associated with anomalously strong Westerlies and Trade Winds, NAO variability is expected to drive Atlantic Ocean climate variability. Properties of this ocean climate variability at both quasi-decadal and interdecadal periods are investigated through analysis of a primitive-equation ocean general curculation model driven by forcing fields derived from the NCEP/NCAR atmospheric reanalysis for 1946-1998. At both time scales, the strong Westerlies and Trade Winds associated with high NAO index generate an SST anomaly pattern characterized by anomalously cold water over the open ocean in both the Westerly and Trade Wind belts and anomalously warm water over the western Sargasso Sea. Model analysis reveals that anomalous SST is driven by local thermodynamical forcing in the two wind belts, and by anomalous heat advection associated with the spin-up of the North Atlantic subtropical gyre in the western Sargasso Sea. The opposite pattern is observed for low NAO index. A two-year time lag is observed in the western Sargasso Sea relative to the basin-wide atmospheric forcing resulting from the baroclinic adjustment of the subtropical gyre. Results suggest that at quasi-decadal periods, the atmosphere is predominantly driving the ocean. An additional time lag between SST anomaly patterns and the NAO index at interdecadal periods suggests that more complicated coupled variability between the atmosphere and ocean occurs at the longer time scales.

JSP25/W/07-B4 Invited **1420**

THE FORMATION AND EVOLUTION OF NORTH ATLANTIC HEAT CONTENT ANOMALIES

Graham GLADMAN and Rowan Sutton (Department of Meteorology, University Of Reading, PO BOX 243, Earley Gate, Reading, RG6 6BB, Email: swr97gjg@reading.ac.uk)

Observations of the North Atlantic Ocean over the past century reveal decadal timescale fluctuations in heat content and related variables. Many aspects of these fluctuations are intriguing and require explanation. In particular, the mechanisms responsible for the formation and propagation of heat content anomalies are not understood. While such anomalies may be generated by processes internal to the ocean, forcing by the atmosphere is likely to play a key role.
We are investigating the role of atmospheric forcing in the formation and evolution of heat content

anomalies by experimentation with an Atlantic ocean isopycnic GCM. In the first phase we have performed experiments to explore how heat content anomalies develop in response to forcing by idealised windstress anomalies. The interaction between the barotropic response and topography leads to very interesting, and sometimes surprising, behaviour. We will present analyses of both this short timescale response and also the longer timescale baroclinic response. In the second phase of our work we will be investigating the development of specific heat content anomalies observed in the North Atlantic this century.

JSP25/E/16-B4 Invited 1440

DECADAL VARIATIONS IN TROPICAL ATLANTIC CLIMATE IN OBSERVATIONS AND IN A GLOBAL OCEAN-ATMOSPHERE MODEL

VIKRAM M. MEHTA, (NASA-Univ. of Maryland Joint Center for Earth System Science, Department of Meteorology, Univ. of Maryland, College Park, Maryland 20742, U.S.A); Tom Delworth, (NOAA/Geophysical Fluid Dynamics Laboratory, P.O. Box 308, Princeton, New Jersey 08542, U.S.A.)

Decadal-multidecadal climate variations are receiving increased attention from the research community in the last one or two decades. It is very important to study decadal-multidecadal climate variability in its own right and also because of its potential to interact with interannual climate variability and anthropogenic climate change. Observed decadal climate variability in the tropical-subtropical Atlantic region and its statistical predictability will be described in this oral presentation. The mechanisms of such climate variability in the GFDL coupled ocean-atmosphere model will also be described.

JSP25/W/03-B4 1500

INTERDECADAL MODES OF VARIABILITY IN A SIMPLIFIED COUPLED MODEL

Thierry HUCK and Geoffrey Vallis (GFDL, Princeton University AOS, Forrestal campus, Route 1, Princeton NJ 08542, USA, email: tnh@gfdl.gov gkv@gfdl.gov); Alain Colin de Verdiere (Laboratoire de Physique des Oceans, Universite de Bretagne Occidentale, BP 809, 29285, Brest cedex, France, email: acolindv@univ-brest.fr)

A simplified coupled model is constructed including an ocean general circulation model (MOM3, GFDL) and an atmospheric Energy Balance Model with physical parameterizations for horizontal heat transport and zonal winds. The external forcing comes from constant insolation at the top of the atmosphere (no seasonal cycle). In various idealized and realistic configurations, the model produces interdecadal variability. One mode is clearly related to the thermohaline circulation in the North Atlantic and its sensitivity to parameters and parameterizations is analyzed: it compares very well with the ocean mode under constant surface heat flux. Other modes of variability, involving changes in the subtropical gyres intensity and mid-latitude winds, are investigated. Finally, comparisons are drawn with the observations.

JSP25/W/20-B4 1520

DECADAL VARIATIONS OF THE THERMOHALINE CIRCULATION IN MODELS OF THE ATLANTIC OCEAN FORCED BY OBSERVED SURFACE FLUXES

Carsten EDEN, Juergen Willebrand (both at Institut fuer Meereskunde, Duesternbrooker Weg 20, 24105 Kiel, Germany, Email: ceden@ifm.uni-kiel.de, jwillebrand@ifm.uni-kiel.de) and Rene Redler (Alfred Wegener Institut fuer Polar- und Meeresforschung, Bgm.-Smidt Str. 20, 27568 Bremerhaven, Germany, Email: rredler@AWI-Bremerhaven.DE)

The variation of the thermohaline circulation (THC) in the Atlantic Ocean on decadal time scales due to atmospheric surface flux variability is investigated.
A medium-resolution model (4/3 degree horizontal mesh) of the Atlantic Ocean, forced with observed surface fluxes taken from the NCEP-reanalysis dataset, was used to study the induced variations of the THC. Several experiments show that the model THC was sensitive to heat flux anomalies in the Labrador sea, where mixed layer depth variations are correlated with THC-anomalies, which propagate southwards into the subtropical gyre, resembling a first baroclinic mode boundary wave like structure.Atmospheric freshwater flux anomalies seem to be unimportanteven under mixed boundary conditions, whereas reshwater fluxanomalies originating from sea-ice variability do.
Experiments with a eddy-permitting model (1/3 degree horizontal mesh) of the North Atlantic Ocean were performed to study the impact of the resolution on the variation of the circulation. First results suggest that increased horizontal resolution does not significantly change the oceanic response on the flux variability.

JSP25/E/10-B4 1620

THE INFLUENCE OF SEA SURFACE TEMPERATURES ON THE NORTH ATLANTIC OSCILLATION AND EUROPEAN CLIMATE IN WINTER

Mark RODWELL, Chris Folland and David Rowell (Hadley Centre, UK Met Office, London Road, Bracknell, RG12 2SY, UK, Email: mjrodwell@meto.gov.uk)

Observational studies have shown that there is a relationship between the North Atlantic Oscillation (NAO) and North Atlantic sea surface temperatures (SSTs). Some of the mechanisms by which the NAO can influence these SSTs are fairly well understood but the opposite link, from SSTs to the NAO, has been unclear. We show for the first time that an atmospheric general circulation model (AGCM), forced with real SSTs and sea-ice extents, can reproduce much of the observed multiannual to multidecadal variations of the NAO over the last half century. The direct effects of greenhouse gases on the atmosphere were not required to achieve this. The SSTs highlighted as important for this NAO simulation are confined to the North Atlantic region and form a tripole pattern, similar to observed correlation patterns between the NAO and SST. We demonstrate that a realistic magnitude of this SST pattern results in local changes to evaporation and atmospheric convective heating that tend to enhance the thermal structure of the NAO. In agreement with observations, there is also a strong modulation of the modelled North Atlantic storm track. NAO-forced Ekman transport appears to provide a positive feedback onto the SST anomaly pattern and this may slow down its rate of damping. Significant multiannual predictability of North Atlantic SSTs has recently been proposed. Our results are therefore encouraging for the prediction of European winter climate features, such as temperature, precipitation and storminess, up to several years ahead.

JSP25/W/57-B4 Invited 1640

ARCTIC SEA ICE VARIABILITY AND ITS RELATION TO THE NAO

CLARA DESER (National Center for Atmospheric Research, P.O. Box 3000, Boulder, Colorado, USA, e-mail: cdeser@ncar.ucar.edu)John Walsh (University of Illinois, Champaign-Urbana, IL, USA)Michael Alexander (University of Colorado, Boulder, Colorado, USA)Michael Timlin (University of Colorado, Boulder, Colorado, USA)

Forty years (1958-1997) of gridded monthly sea ice concentration data are used to document variability of Arctic sea ice coverage and its association with atmospheric circulation changes. The dominant pattern of wintertime sea ice variability exhibits out-of-phase fluctuations between the western and eastern North Atlantic, together with a weaker dipole in the North Pacific. This mode is dominated by decadal-scale variations and a longer-term trend of diminishing ice cover east of Greenland and increasing ice cover west of Greenland. The changing sea ice margin, which we suggest is driven by recent trends in the North Atlantic Oscillation (NAO), induces large perturbations (several hundred Watts per square meter) in the surface energy exchange between the atmosphere and ocean. The enhanced upward surface energy flux in the area of ice retreat east of Greenland may have contributed to the observed increase in the number of cyclones over the Greenland Sea during the last 40 years. An ensemble of atmospheric GCM experiments forced by observed trends in sea ice coverage are used to investigate the sensitivity of the circulation to sea ice anomalies.

JSP25/W/16-B4 Invited 1700

INTER-HEMISPHERE RELATION OF DECADAL CLIMATE VARIATIONS IN ATLANTIC

Youichi TANIMOTO (Institute for Global Change Research, FRSGC, Shibaura 1-2-1, Seavans N Bldg.7F, Minato-ku, Tokyo 105-6791, Japan, email: tanimoto@frontier.esto.or.jp); Shang-Ping, XIE (Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060-0810, Japan, email: xie@ees.hokudai.ac.jp

Sea surface temperature (SST) and Sea Level Pressure (SLP) anomaly fields with an equatorial anti-symmetric dipole structure in the tropical Atlantic affects on precipitation in surrounding areas. But zonal mean tropical SST anomalies have decorrelated scatters between 10-20 degree latitudes. The same observation applies to SLP anomalies. Therefore, it seems that there are, at least, two modes in the air-sea coupled field in the tropical Atlantic. The purpose of the present study provides dominant modes, which are physically reasonable, from statistical analyses by taking advantage of the spectral gap between decadal and interannual SST variability in the tropical Atlantic. After we divide the Atlantic basin into two independent parts, north and south of the equator, we compute empirical orthogonal functions (EOFs) for SST and SLP anomalies. Then anomalies are averaged for the boreal winter and filtered through the decadal band (8-16 year). These EOFs of SST (SLP) anomalies explain 44.2% and 43.2% (36.4% and 50.2%) of the band-passed variance on the Northern and Southern Hemispheres, respectively.Two EOFs (spatial patterns) of SST anomalies present meridionally lined up five centers of action. In two EOF of SLP anomalies, we realize subtropical centers of action with opposing polarities in either side of equator. The PCs (time series) of these four EOFs are highly correlated. In the present study, the two subdomains and the two fields are statistically independent and there is no a priori reason for them to be correlated. This indicates that tropical Atlantic SST and SLP anomalies are not always independent in either side of equator, at least on decadal variations, and further that the tropical dipolar oscillation is associated with the inter-hemispheric decadal variability in the Atlantic.

JSP25/E/14-B4 Invited 1720

RECONSTRUCTIONS OF NORTH ATLANTIC OSCILLATION INDICES

ROSANNE D'ARRIGO, Edward Cook, Heidi Cullen (all at: Lamont-Doherty Earth Observatory, Palisades, NY 10964, TEL 914-365-8617, FAX 914-365-8152, email: druidrd@ldeo.columbia.edu) and Michael Mann (Dept. of Geosciences, Morrill Science Center, University of Massachusetts, Amherst, MA 01003, TEL 413-545-9573, FAX 413-545-1200, email: mann@snow.geo.umass.edu)

The North Atlantic Oscillation (NAO) is one of the dominant features of climate for the North Atlantic and surrounding land areas (Van Loon and Rogers 1978, Rogers and Van Loon 1979, Rogers 1990). Longer records are needed to provide a long-term context for the variability of the recent instrumental record of the NAO (e.g. the persistently high index values of recent decades). Tree-ring width records from North America and Europe have been used to reconstruct the NAO and related time series of North Atlantic climate for the past several hundred years. These include the first reconstruction of the winter (DJF) NAO sea-level pressure (SLP) index (Cook et al. 1998).
We have also produced a reconstruction of a winter (DJFM) NAO sea-surface temperature (SST) index in order to derive a more complete picture of the NAO system. This index is based on SST averaged over five Atlantic regions which are best correlated with NAO SLP, from the Kaplan et al. (1998) analysis. This reconstruction extends from AD 1701 to 1979 and is based on North American and European tree-ring data as well as the long (335 year) Central England instrumental temperature series (CET) (Plaut et al. 1995). The NAO SST reconstruction accounts for 47% of the variance over the calibration period and is well verified using statistical tests typically used to evaluate dendroclimatic reconstructions (Cook and Kairiustis 1990). We have compared the NAO SLP (Cook)and SST (D'Arrigo) reconstructions to several other relevant time series, including an NAO reconstruction (Appenzeller) based on a Greenland ice core record (Appenzeller et al.1998), and an NAO SST reconstruction based on a network of tree-ring data and other proxies as well as long instrumental temperature records (Mann) Principal components analysis (PCA) scores based on the 4 NAO reconstructions covering 1750-1979 and 3 NAO reconstructions covering the period 1701-1979 (excluding Mann) show verification results that are improved relative to the individual series. The PCA scores of these reconstructions, when compared to global SST, SLP and surface air temperature fields, reflect the characteristic patterns of the NAO.

JSP25/W/90-B4 1740

THE PURPOSE OF THIS STUDY IS TO INVESTIGATE THE TEMPORAL STRUCTURE OF TEMPERATURE VARIABILITY

Marina V. SHABALOVA, (Royal Netherlands Meteorological Institute, P.O.Box 201, 3730 AE De Bilt, the Netherlands, email: shabalov@knmi.nl)

The purpose of this study is to investigate the temporal structure of temperature variability on timescales longer than 50 yr, as reflected in a number of long paleo records located in Europe and North America, using a combination of statistical techniques including uni- and multivariate singular spectrum analysis. Two statistically significant modes of temperature variability are identified, one on multidecadal and one on centennial timescales. The first mode is oscillatory, with a timescale ~60-80 yr. Its geographic pattern suggests a connection to the North Atlantic Oscillation. The second mode, confined to high latitudes, describes temperature variations on timescales longer than 100 yr; in the longest records a weak ~120 yr oscillation can be identified with confidence. We show that the temporal pattern of centennial mode is season-dependent in Europe. We also show that paleo records representing the same season and region (e.g. N.Urals versus Fennoscandia) may exhibit a striking difference in their temporal structures on centennial timescales, which is likely to indicate unreliability of centennial timescales in one/both record(s). In a number of seasonally homogeneous records the centennial components of variability are coherent, showing a multiple-phase 'Little Ice Age' and a 'Medieval Warm Period'. We assume that only those centennial signals which are

coherent in a number of independent paleo series and are statistically significant against the red noise surrogates at the 95\% confidence level represent a genuine mode of temperature variability.

VARIABILITY OVER THE PACIFIC OCEAN

JSP25/W/46-B5 Invited 0830

ON PACIFIC DECADAL VARIABILITY IN THE CSIRO COUPLED OCEAN-ATMOSPHERE MODEL

Anthony C. HIRST (CRC for Southern Hemisphere Meteorology CSIRO Atmospheric Research PMB 1, Aspendale, Vic., 3196 Australia) Scott B. Power and David Walland (Bureau of Meteorology GPO Box 1298K, Melbourne, Vic., 3001 Australia Dan Vimont Dept of Atmospheric Sciences University of Washington - JISAO Box 351640, Seattle, WA 98195)

A 1000 year integration of the CSIRO coupled ocean-atmosphere general circulation model is used to study low frequency (decadal to centennial) climate variability. An EOF analysis is applied to selected model fields to show some of the major statistical modes of low frequency variability. The first EOF bears considerable resemblance to observational estimates, it is centered in the Pacific and extends well into the extratropics in both hemispheres. The EOF has a time evolution that appears to be more than just red noise. It modulates both precipitation and temperature globally. In particular, a link to Australian decadal rainfall variability is evident which is of similar character to (though moderately weaker than) that observed. The talk focuses on defining the character of this mode and examining the mechanisms by which it comes about. Comparison is made to both the observed variability and to the patterns of variability found in other coupled general circulation models.

JSP25/W/91-B5 Invited 0850

DECADAL TO INTERDECADAL OCEAN-ATMOSPHERE INTERACTION IN THE PACIFIC BASIN

FEI-FEI JIN, Masahide Kimoto*, Xiao-Chun Wang School of Ocean and Earth Science and Technology University of Hawaii at Manoa, Honolulu, Hawaii, USA * Center for Climate System Research University of Tokyo, Tokyo, Japan.

Slow exchanges of mass and heat between the tropical and subtropical ocean gyres, attributed to subtropical oceanic Rossby waves, play a key role in the decadal to interdecadal ocean- atmosphere interactions in the Pacific basin. In this report, with supporting simulations of a global coupled model and analysis of observational data, we developed a simple model to delineate the main physical mechanisms of the decadal to interdecadal oscillations. The subtropical oceanic Rossby waves are found to play a key role in forming a distinct coupled decadal to interdecadal mode and enabling it to modulate the ENSO. Model simulations and observational analysis consistently show that the tropical, and extratropical ocean atmosphere interactions and the teleconnection between the tropics and- extratropics in these interactions are responsible for co-variations of the decadal to interdecadal climate fluctuations in the tropical and extratropical Pacific.

JSP25/W/51-B5 Invited 0910

A DECADAL SALINITY MODE IN THE TROPICS

Niklas SCHNEIDER (Scripps Institution of Oceanography, University of California, San Diego, Mail Code 0224, 9500 Gilman Drive, La Jolla, CA 92093-0224, USA, email: nschneider@ucsd.edu)

Dynamics of a climate mode in a simulation of a sophisticated coupled ocean-atmosphere model are explored. The mode stems from an interplay in the Pacific of the low-latitude circulation, of advection of thermal and haline anomalies along isopycnal surfaces and of atmospheric wind stress changes due to anomalies in the western equatorial Pacific of the relative importance of temperature and salinity in determining oceanic density. The time scale of the mode is ten years.
In the equatorial region, the arrival in the western Pacific of warm and salty anomalies on isopycnal surfaces slightly increases the across Pacific east-west temperature difference, thus enhances of the trade winds and leads via positive feedbacks to a state of the upper ocean resembling a La Nina. Associated with the strengthening of the wind stress, the North Equatorial current accelerates and, at 10 to 15N in the central Pacific, leads to the generation by anomalous advection across a mean gradients of cool and fresh anomalies on isopycnal surfaces. The anomalies are advected with the mean circulation via the western boundary currents and arrive in the equatorial western Pacific approximately five years later. The arrival there of cool and fresh anomalies decrease the east-west temperature gradient along the equator, reduce the trade winds and flip the system to the opposite phase that resembles El Nino. The associated spin-down of the North Equatorial currents then initiates again warm and salty anomalies at 10 to 15 N whose arrival at the equator five years later close the cycle.

JSP25/W/88-B5 Invited 0930

AN ISOPYCNAL PRIMITIVE EQUATION OCEAN MODEL

Guillermo AUAD, (Scripps Institution of Oceanography, UCSD, USA, email: guillo@ucsd.edu)

An isopycnal primitive equation ocean model is used to represent the physics of the Pacific Ocean. Observations of winds and surface heat fluxes are used to force the model from 1951 through 1997. The goal of this integration is to detect and understand major decadal and interdecadal changes in both tropics and midlatitudes. Preliminar results show a good agreement with observations of heat content of the upper 400 m of the Pacicif Ocean. The central North Pacific and the western equatorial area show maximum variability for oscillations with period between 10-20 y. Additional results and comparisons with observations will be presented at the meeting for sea surface temperature, heat content and thermocline and mixed layer depth.

JSP25/W/13-B5 Invited 0950

THE IMPACT OF NORTH PACIFIC DECADAL CLIMATE FLUCTUATIONS ON THE EQUATORIAL PACIFIC

S.VENZKE (MPI fuer Meteorologie, Bundesstr.55, 20146 Hamburg, Germany, email: venzke@dkrz.de); N. Schneider (Scripps Institution of Oceanography, La Jolla, USA, email: niklas@moana.ucsd.edu); M. Latif (MPI fuer Meteorologie, Bundesstr.55, 20146 Hamburg, Germany, email: latif@dkrz.de)

It has been hypothesised that decadal climate variability is caused by the coupling of the central North Pacific to the equatorial thermocline via thermal anomalies that propagate in the oceanic thermocline. While an interpretation of observed upper ocean temperature anomalies appears to provide evidence in support of this hypothesis, consideration of wind stress anomalies using simple steady-state models of the oceanic circulation indicates that tropical variability is mainly driven by low-latitude winds.
To resolve this controversy simulations with the Hamburg Ocean Primitive Equation model (HOPE) driven by different atmospheric forcing conditions have been performed. It is shown that decadal variability within the tropics is largely independent of the arrival of thermal anomalies from midlatitudes.

JSP25/W/28-B5 Invited 1010

A DYNAMIC COMPARISON OF CLIMATE VARIABILITY IN THE TROPICAL PACIFIC AND ATLANTIC

SHANG-PING XIE, Hideyuki Noguchi (Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060-0810, Japan, E-mail: xie@ees.hokudai.ac.jp); Taroh Matsuno, Youichi Tanimoto (Frontier Research System for Global Change, Tokyo 105-6791, Japan)

How to characterize the tropical Atlantic sea surface temperature (SST) variability has been highly controversial. New observational evidence is emerging in favor of a dipole-monopole decomposition (Tanimoto and Xie, this volume). Here we examine the physical basis for such an empirical decomposition and address an important question of why such a latitudinally anti-symmetric dipole mode is most pronounced in the Atlantic but apparently not in the Pacific.
For this purpose we develop a coupled ocean-atmosphere model that includes both the feedbacks by ocean dynamics and by surface heat flux. Consistent with observations, an interannual equatorial and a decadal dipole mode emerge from the model and are supported by the Bjerknes and a wind-evaporation-SST feedbacks, respectively. The equatorial and the dipole modes exhibit distinctive growth curves, with the former peaking at the size of the Pacific Ocean while the latter decreasing monotonously with wavenumber. It thus follows that the equatorial mode will dominate the Pacific whereas it will co-exist with a zonally uniform dipole mode, a theoretical outcome that explains observations. Having emphasized the difference between the tropical oceans, we will present evidence for interaction between extratropical North Atlantic and North Pacific, an inter-oceanic link that is particularly pronounced on the quasi-decadal time scale.

OBSERVATIONS AND THEORIES OF PACIFIC OCEAN DECADAL VARIATIONS

ARTHUR J. MILLER (Scripps Institution of Oceanography, La Jolla, CA 92093-0224.
E-mail: ajmiller@ucsd.edu)

Physical fields of the Pacific Ocean are observed to vary over decadal time scales. Different physical mechanisms have been proposed to explain the diverse basin-scale patterns of SST, thermocline depth and horizontal currents, which are linked in various ways. Although observations of upper-ocean temperature and sea-level pressure are limited in temporal and spatial resolution, they can help to put constraints on the various theories. Ocean model hindcasts can also be used to reconstruct the ocean's importance in decadal variations. Various recent theories of Pacific Ocean decadal variability will be summarized and discussed in the context of observations and model hindcasts to attempt to determine which mechanisms are the most plausible.

RESONANCE IN BIDECADAL AND PENTADECADAL CLIMATE OSCILLATIONS OVER THE NORTH PACIFIC: ROLE IN CLIMATIC REGIME SHIFT

SHOSHIRO MINOBE (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, Sapporo, 060-0810, Japan, Email: minobe@neptune.sci.hokudai.ac.jp)

The roles of interdecadal oscillations in climatic regime shifts, which are observed as rapid strength changes in the Aleutian low in winter and spring seasons in the 1920s, 1940s, and 1970s, have been analyzed. A regime shift results from simultaneous phase reversals between pentadecadal and bidecadal (about 17-years period) variations, which synchronize with one another at a relative period of three. The pentadecadal variation, which is observed in both winter and spring seasons, provides the basic timescale of regime shifts, while the bidecadal variation, which is observed only in winter, characterizes the rapidity of the shifts.
A Monte-Carlo simulation has shown that the simultaneous phase reversals or resonance between the pentadecadal and bidecadal variations reflect a physical linkage between them and do not coincide accidentally. If the synchronization feature continues until the next regime shift, which is likely to occur in the coming decade. The mechanisms of the regime shifts or resonance might be understood by a simple delayed-oscillator model with an external forcing on the bidecadal timescale.

JSP25/W/48-B5 Invited 1130

THE NORTH PACIFIC DECADAL CLIMATE VARIABILITY AND OCEANIC FRONTS

HISASHI NAKAMURA (IGCR, Frontier Research System for Global Change, Tokyo/Dept. of Earth, Planetary Physics, Univ. of Tokyo, Tokyo, 113-0033, JAPAN; email: hisashi@geoph.s.u-tokyo.ac.jp); Alexander S. Kazmin (IGCR, Frontier Research System for Global Change, Tokyo; email: kazmin@frontier.esto.or.jp)

Decadal/interdecadal climate events (DICEs) observed in the North Pacific over the last several decades are documented. Except in the tropics, the observed wintertime decadal SST variability in the basin is concentrated in the subarctic and subtropical frontal zones (cited to as SAFZ and STFZ, respectively). The decadal SST fluctuations in STFZ, accompanied by the anomalous surface subtropical high, exhibit strong negative simultaneous correlation with the tropical fluctuations, whereas those in SAFZ do not and hence they cannot be attributed to the direct tropical influence via the Òatmospheric bridgeÓ. The decadal SST anomalies in SAFZ are accompanied by the anomalous Aleutian Low and PNA pattern aloft. A wave-activity flux associated with that pattern is strongly divergent over SAFZ, suggesting that the pattern is forced there. It is suggested that the observed DICEs in the subpolar gyre and the atmospheric circulation above may be associated with internally-generated variability in the coupled atmosphere-ocean system, although the associated wind anomalies could influence the subtropical gyre. In fact, lag regression analysis indicates a tendency of SST anomaly development in STFZ several years after the maturity of the anomalies in SAFZ, as simulated in coupled GCMs. The decadal SST fluctuations in SAFZ occurred in conjunction with substantial changes in the front. It is evident in high-resolution SST data based on ship measurements that the frontal axis tends to shift equatorward during a cool period and poleward in a warm period. The equatorward shift is associated with the stronger penetration of the Oyashio along the Japanese coast and the cooling in SAFZ and in the northern part of the Kuroshio extension. The decadal shift of SAFZ is confirmed in satellite-derived SST data.

Furthermore, they indicate that the cross-frontal SST contrast tends to be stronger when the front is shifted polowad in a warm period.

JSP25/W/67-B5 Invited **1150**

A 31-YEAR ANALYSIS (1968-1998) OF THE ALASKA SUBPOLAR OCEAN GYRE

Gary LAGERLOEF (Earth and Space Research, 1910 Fairview Ave E, Suite 102, Seattle, WA 98102-3620 USA, email: lagerloef@esr.org)

Surface dynamic topography over the recent three decades is used to assess interdecadal circulation variability of the Alaska Gyre, a cyclonic subpolar gyre in the northeast Pacific Ocean. The data are a composition of conventional upper ocean hydrographic stations for the first 2.5 decades (objectively analyzed), and appended with recent satellite altimetry. The principal mode (positive phase) coincided with elevated dynamic height and SST in the eastern part of the gyre, a weaker circulation, and a slight displacement of the gyre WSW. These features in turn, were coherent with the cold phase of the decadal North Pacific (NP) SST mode and intensified Aleutian Low. The gyre generally exhibited its negative phase for most of the 1970s and 1990s, and positive in the 1980s, with episodic reversals of a few years duration. The dynamics of these decadal variations, including stochastic wind stress curl forcing and heat fluxes, will be discussed along with the relationships of the Alaska gyre varitions and other climate indices in the North Pacific sector.

JSP25/E/01-B5 Invited **1210**

INTER-DECADAL VARIATIONS IN JAPANESE SARDINE AND THE KUROSHIO EXTENSION

ICHIRO YASUDA (Univ. of Tokyo/ Frontier Research System for Global Change, Hongo 7-3-1, Bunkyo, Tokyo 113-0033,Japan, E-mail: ichiro@geoph.s.u-tokyo.ac.jp); Masayuki Noto (Hokkaido Univ., E-mail: noto@geoph.s.u-tokyo.ac.jp); Tomoki Touzuka (Univ. of Tokyo, E-mail: s72620@vsiron.geoph.s.u-tokyo.ac.jp)

Japanese sardine is known to greatly vary in inter-decadal time sacles. In 1988, the catch was over 4 million tons; it declined abruptly since 1989 and was below 1 million tons in 1995. We found the winter-SST in the Kuroshio Extension and its southern recirculation area (KESA: 30-35N, 145-180E) significantly correlates with the mortality coefficient of the Japanese sardine. The warming in the KESA since 1988 possibly causes the collapse of the sardine. The SST variations in the KESA and south of Japan were different from those in the Kuroshio-Oyashio frontal regions in the western/central Pacific (40-45N 145-180E) where a regime-shift around mid-1970s was known: the SSTs in the Kuroshio regions have a longer time scale of over 50 years than in the frontal regions (25 years), and the jump of the Kuroshio SSTs around late-1980s occurred two years earlier in 1988 than in the frontal regions. The shift around mid-1970s in the frontal regions was not observed in the Kuroshio and the KESA where the SST anomalies were already negative in early-1970s. These SST variations well corresponds to sardine catch records. Analyses of heat flux and wind before/after the late-1980s SST jump indicate that the warming since 1988 was caused partly by the decrease in the net heat flux and in the mixed layer depth due to the reduction of wind over the Kuroshio south of Japan and over the Kuroshio Extension regions.

VARIABILITY OVER THE ARTIC REGION

JSP25/W/44-B5 Invited **1400**

DECADAL AND LONGER-SCALE VARIABILITY OF THE ARCTIC SEA ICE COVER AND OVERLYING ATMOSPHERIC CIRCULATION

Lawrence A. MYSAK, Dingrong Yi and Silvia A. Venegas (McGill University, Dept. of Atmospheric and Oceanic Sciences, 805 Sherbrook Street West, Montral, OC H3A 2K6 Canada. E-mail: mysak@zephyr.meteo.mcgill.ca)

The relationship between the Arctic and subarctic sea ice concentration (SIC) anomalies and the overlying atmospheric circulation fluctuations is investigated using the singular value decomposition (SVD) and composite map analysis methods. The data analyzed are monthly SIC and sea level pressure (SLP) anomalies poleward of 45 N which extend over the 38-year period 1954-1991. The association of the SIC anomalies with the decadal-scale "Ice and Salinity Anomalies " (ISAs) observed in the Greenland and Labrador seas during the late 1960s/1970s (by Dickson et al.), the late 1970s/1980s and late 1980s/1990s (by Belkin et al.) is also explored.The SVD1 (first) mode of the coupled variability, which accounts for 54% of the square covariance, is mainly an atmosphere-to-ocean forcing mode characterized by the decadal timescale. The aforementioned ISAs are clearly captured by this mode. We also show that there exists a significant correlation between the decadal SIC variability associated with SVD1 and the North Atlantic Oscillation, whose spectrum also exhibits a quasi-decadal signal.The SVD2 mode accounts for 16% of the square covariance and shows no evidence of a dominant forcing field. This mode exhibits very low frequency variability and reveals that the co-variability of the SIC and SLP fields is mainly concentrated in the northern North Pacific. This is in contrast to SVD1 mode whose variability occurs mainly in the North Atlantic sector.

JSP25/W/63-B5 Invited **1420**

DECADAL VARIABILITY OF THE ARCTIC CLIMATE

ANDREY PROSHUTINSKY (Institute of Marine Science, University of Alaska Fairbanks, P.O, Box97725-7220, Fairbanks, USA, email: prosh@ims.alaska.edu)

Arctic navigation, oil and gas exploration, andarctic pollutant transport depend on arctic environmental conditions. Existing atlases, manuals, and reference books contain multi-year mean environmental variables and their multi-year mean seasonal variability; however, uncertainties sometimes result from the existing atlases because they do not take into account climate change and climate variability. This presentation is motivated by the recent finding of two regimes (or two climate states) of arctic atmosphere--ice--ocean circulation described by Proshutinsky and Johnson [1997]. Our results show that wind-driven ice and water motion in the Arctic alternates between anti-cyclonic and cyclonic circulation, with each regime persisting for 5-7 years (period is 10-15 years). Based on this work, we demonstrate that seasonal variations in the ice concentration, ice thickness, and ice drift; ocean currents, ocean temperature, and salinity; horizontal and vertical heat fluxes; atmospheric pressure, wind speed, cloudiness, and precipitation; river discharge; and permafrost temperatures are different for cyclonic and anticyclonic arctic climate states. We analyze observational and model data to document decadal variability of the arctic system. The model simulations are validated and aided by oceanic, meteorological,and terrestrial data sets collected over the past 100 years throughout the arctic.

JSP25/W/82-B5 Invited **1440**

HYPERSENSITIVE DECADAL OSCILLATIONS IN THE COUPLED ATMOSPHERE-ICE-OCEANSYSTEM OF THE ARCTIC/SUBARCTIC REGIONS

M. IKEDA (Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, Japan, email: mikeda@ees.hokudai.ac.jp); J. Wang (International Arctic Research Center/ Frontier Research System for Global Change, Fairbanks, Alaska); J-P. Zhao (Institute of Oceanology, Chinese Academy of Sciences, Qingdao, China)

Decadal oscillations have become remarkable in the Arctic climate only for last three decades, being superimposed on the global warming trend. The variability is often called the Arctic Oscillation (AO) and characterized by an oscillation between the intensified Polar Vortex connected with the warmer Arctic, having a center of action over Siberia, and the opposite tendency. The air temperature over the Greenland Sea has a reversed phase with that over Siberia. The intense Polar Vortex matches with the lower ice cover in summer and fall over the Canadian Basin, with a two-year lag (ice leads the atmosphere), and the year-round lower ice cover over the Atlantic sector. A conceptual model is developed with a basis on water exchange between the upper layers of the Arctic Ocean, the Greenland-Iceland-Norwegian (GIN) Seas and the Atlantic Ocean. Only the upper-layer volumes (or thicknesses) are considered. Those of the Arctic Ocean and GIN Seas are time-dependent variables, while the Atlantic Ocean is prescribed. An atmosphere-ocean feedback mechanism relates the Arctic Ocean thickness with the flow from Arctic to GIN: i.e., the thinner Arctic upper layer causes warmer Arctic and more intense Polar Vortex, which contributes the flow from Arctic to GIN, or the opposite direction. The other key component is the enhancement of deep water convection caused by the flow from Atlantic to GIN: i.e., the GIN box water is expelled by thermohaline circulation and deep convection, whose rate is increased by the inflow of the more saline Atlantic Water.
The solution is convergent, oscillatory or divergent, depending on efficiencies of the atmosphere-ocean feedback and the deep convection. The higher (lower) efficiency yields divergence (convergence), whereas an oscillation exists only within the limited ranges of these two parameters. The occurence of the recent AO may be related to the changes in the parameters.

JSP25/W/27-B5 Invited **1500**

DECADAL VARIABILITY OF THE NORTH POLAR VORTEX

Julian X.L. WANG and James K. Angell (NOAA/Air Resources Laboratory,1315 East-West Highway, Silver Spring, MD 20910, E-mail: julian.wang@noaa.gov).

Using 51 years (1948-1998) of NCEP/NCAR Reanalysis, an assessment on intensity and size of the north polar vortex is made. Three dimensional description of the vortex structure and its decadal variation are shown in geopotential height and surface pressure fields. Premarily results indicates that the decadal variations of the vortex are closely linked to global tropics, and are associated essentially to the eccentricity of the vortex.

JSP25/P/05-B5 Invited **1520**

MULTIDECADAL VARIABILITY OF NORTHERN HEMISPHERE FUNDAMENTAL CIRCULATION MODES IN A 1.800 YEAR OCEAN-ATMOSPHERE MODEL RUN: IMPLICATIONS FOR CLIMATE CHANGE ASSESSMENT

Hans-F. GRAF and Judith Perlwitz, (Max-Planck-Institute for Meteorology Bundesstr. 55. D-20146 Hamburg, Germany, email: graf@dkrz.de)

The leading mode of coupled stratospheric variability in winter combines the strength of the circumpolar stratospheric vortex with characteristic pressure, temperature and precipitation anomalies in the northern hemispheric troposphere. The loading of this mode has changed significantly from the 1960s to the 1990s towards a stronger polar vortex. Basic features of this mode are also found in climate models. However, there the pattern structure is slightly different and locally explained variance does not reach such large values as in observations. Sensitivity experiments show that the leading variability mode can be exaggerated by external forcing like volcanic aerosol, greenhouse gas concentration and probably ozone changes induced by solar forcing. We studied the similarity between the pattern of observed 40 year circulation trends in the Northern Hemisphere and the corresponding circulation trends in both a 1800-year control run and a IIPCC (1996) Scenario A run, carried out with a coupled atmosphere-ocean climate model. We found that even an unforced coupled ocean-atmosphere climate model produces secular variability (in the specific case of a mean period of 76 years), which is strongly pronounced in patterns that resembles the observed trends of the recent 40 years. With greenhouse forcing according to EPCC (I 996) Scenario A the leading variability mode becomes exaggerated and remains so. Thus we have to expect an enhanced NAO in the future with mild winters over mid-latitude and northern Eurasia drought in the Mediterranean and a strong, cold and stable stratosphere polar vortex negatively affecting the Arctic stratospheric ozone concentration. The consequences of these results for climate change assessment will be discussed.

DECADAL TO MLTIDECADAL CLIMATE VARIABILITY IN THE INDIAN OCEAN REGION

Chris J.C. Reason (School of Earth Sciences, University of Melbourne, Parkville, Vic., 3052, Australia, email: cjr@met.unimelb.edu.au); Robert J. ALLAN (CSIRO Atmospheric Research, Aspendale, Vic., 3195, Australia, email: rob.allan@dar.csiro.au)

Decadal to multidecadal climate variability in the Indian Ocean region and potential links with the El Nino Southern Oscillation (ENSO) are examined using observational and modelling approaches. One prominent mode of variability in this region involves a strengthening and weakening of the South Indian Ocean anticyclone and warming and cooling across the southern midlatitudes of the basin. Atmospheric and ocean modelling suggests that local air-sea interaction may play a significant role in the generation of this mode, although evidence also exists of a possible relationship with ENSO.
Band pass filtering of seasonal mean sea level pressure (MSLP) and sea surface temperature (SST) fields for ENSO years on quasidecadal and interdecadal time scales (11-13 year and 15-20 year bands) is used to explore links between ENSO and the lower frequency variability manifested in the Indian Ocean region. This analysis reveals that quasidecadal and interdecadal signals in the climate system provide a modulation of the ENSO phenomenon that may lead to 'protracted' El Nino and La Nina episodes. In the Indian Ocean basin, interactions between these signals can result in periods when SST patterns and rainfall relationships are out-of-phase with 'protracted' ENSO responses across the central-eastern tropical Pacific Ocean.

JSP25/W/95-B5 Invited **1620**

WHAT CAUSES INTER-DECADAL CHANGES IN AUSTRALIAN SEASONAL RAINFALL PREDICTABILITY?

S. POWER (National Climate Centre, email: S.Power@bom.gov.au; GPO Box 1289K, Melbourne, VIC 3001, AUSTRALIA); T. Casey (BMRC), C. Folland and A. Colman (UKMO) and V. Mehta (NASA GSFC).

The success of an ENSO-based statistical rainfall prediction scheme and the influence of ENSO on Australia are shown to vary in associaion with a coherent, inter-decadal oscillation in surface temperature over the North and South Pacific Oceans. When this Inter-decadal Pacific Oscillation (IPO) raises temperatures in the tropical Pacific Ocean, there is no robust relationship between year-to-year Australian climate variations and ENSO. When the IPO lowers temperature in the same region, on the other hand, year-to-year ENSO variability is closely associated with year-to-year variability in rainfall, surface temeprature, river flow and the domestic wheat crop. The contrast in ENSO's influence between the two phases of the IPO is quite remarkable. This highlights exciting new avenues for obtaining improved climate predictions.

JSP25/E/15-B5 **1640**

DECADAL-MULTIDECADAL VARIATIONS IN TROPICAL CLIMATE AND ENSO

VIKRAM M. MEHTA (NASA-Univ. of Maryland Joint Center for Earth System Science Department of Meteorology, Univ. of Maryland College Park, Maryland 20742, U.S.A.)

Decadal-multidecadal climate variations are receiving increased attention from the research community in the last one or two decades. It is very important to study decadal-multidecadal climate variability in its own right and also because of its potential to interact with interannual climate variability and anthropogenic climate change. Observed decadal-multidecadal climate variability in the tropical-subtropical Pacific region, and its influence on long-term modulation of interannual ENSO variability and predictability will be described in this oral presentation. The influence of decadal-multidecadal climate variability in modulating interannual ENSO-global rainfall relationship will also be described.

JSP25/W/56-B5 **1700**

INTERDECADAL MODULATION OF INTERANNUAL ATMOSPHERIC AND OCEANIC VARIABILITY OVER THE NORTH PACIFIC

SHOSHIRO MINOBE (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan, Email: minobe@neptune.sci.hokudai.ac.jp); Nathan Mantua (Joint Institute of Sciences of Atmosphere and Ocean, University of Washington, Seattle, WA 98195-4235, USA, Email: mantua@atmos.washington.edu)

The interdecadal modulation of interannual variability of the atmosphere and ocean is examined over the North Pacific by using Wavelet Transform combined with EOF or SVD analysis. The interannual variability of the wintertime Aleutian Low, identified by either the North Pacific Index or the EOF-1 of North Pacific sea level pressure (SLP), exhibits an interdecadal modulation. Interannual variance in the strength of the Aleutian Low was relatively large from the mid-1920's to mid-1940's and in the mid-1980's, but relatively small in the periods from 1899 to the mid-1920's and from the mid-1940's to the mid-1970's. The periods of high (low) interannual variability roughly coincide with pentadecadal regimes having a time averaged relatively intense (weak) Aleutian Low. The SLP EOF-2, which is related to the North Pacific Oscillation, exhibited a strengthening trend from the beginning of this century to the mid-1960s, and significant weakening after that. Consistent changes are observed in the 500 hPa height and SST fields.

JSP25/W/19-B5 **1720**

INTERACTIONS OF DECADAL CLIMATE MODES IN THE NORTH ATLANTIC

A. GROETZNER and M. Latif (Max-Planck-Institut fuer Meteorologie, Bundestr.55, D-20146 Hamburg,Germany); A. Timmermann (KNMI, Postbus 201,3730 AE De Bilt, the Netherlands)

Two distinct climate modes of the North Atlantic climate system with decadal timescales have been identified in a millennium integration with the coupled GCM ECHAM3/LSG. Both oscillations rely on a feedback loop between the atmosphere, in particular the North Atlantic Oscillation, and the ocean, which represents the memory of the coupled system. One mode with a period of about 15 years is connected to the wind driven gyre circulation, while the other has a period of about 30-40 years and involves the thermohaline circulation. Since the latter mode has been described already elsewhere, we shall discuss the structure and dynamics of the wind driven mode and its interaction with the thermohaline mode. Since the dynamics of both modes involves large scale SST anomalies in the subtropical North Atlantic and he period of the wind driven mode appears to be roughly half of that of the thermohaline mode, an interaction between the two modes seems to be plausible. By applying various statistical techniques like singular spectrum and wavelet analyses we shall investigate the interactions between the two modes and discuss some implications for climate predictability on decadal timescales.

Monday 26 July AM

OCEAN/ATMOSPHERIC VARIABILITY AND PREDICTABILITY– ENSO VARIABILITY

THE INFLUENCE OF THE DECADAL-SCALE VARIABILITY OF SUMMER RAINFALL ON THE IMPACT OF EL NIÑO AND LA NIÑA EVENTS IN SOUTH AFRICA

A. C. KRUGER, (South African Weather Bureau, Private Bag X097, Pretoria, South Africa)

Regions of correlation between South African late summer rainfall and sea-surface temperature (SST) in the NINO3 region were identified. Regions identified for late summer showed a much better spatial coherence than was the case for early summer. These regions were then compared with eight homogeneous rainfall regions in South Africa. For the period 1955-1991, near-decadal epochs of above- and below-normal late summer rainfall were identified, with Cramer's t-test and cumulative deviations, for five of the eight homogeneous regions, which possessed areas with rainfall correlated with the NINO3 SST time-series. According to these tests, the 1960's and 1980's are characterised by below-normal rainfall, while the 1950's and 1970's are characterised by above-normal rainfall. Turning points between these epochs are around 1959/60, 1970/71, 1980/81 and 1991/92. This corresponds to cycles in summer rainfall in South Africa identified by other authors. To estimate rainfall anomalies without the effect of El Niño/La Niña, rainfall anomalies due to NINO3 were estimated by a linear regression of rainfall against NINO3 SST's. These were subtracted from the standardised rainfall anomalies to obtain the residual anomalies that give an indication of the rainfall without the effects of El Niño/La Niña. From these time series similar epochs and turning points were evident. El Niño seasons during epochs of below- and above-normal rainfall were compared. The same was done with La Niña seasons. The impact of El Niño and La Niña is influenced in such a way that during an epoch of above-normal rainfall a moderating effect is evident on the severity of El Niño events so that even rainfall above the normal rainfall is experienced on average during such events. The opposite is also true in that an epoch of below-normal rainfall will have a negative effect on the enhancement of rainfall usually associated with a La Niña event. Extreme events of rainfall (droughts and floods), usually occur when an El Niño event occurs during an epoch of below normal rainfall and when a La Niña event occurs during an epoch of above normal rainfall.

ENSO PREDICATION WITH WAVELET METHOD

Lintao LIU (Institute of Geodesy and Geophysics, Chinese Academy of Sciences, 54 Xudong RD, Wuhan 430077, P. R. China, email: llt@asch.whigg.ac.cn) H. T. Hsu (Institute of Geodesy and Geophysics, Chinese Academy of Sciences, 54 Xudong RD, Wuhan 430077, P. R. China, email: hsuh@asch.whigg.ac.cn)

In this contribution, we introduce a new data-analyzing technique: the modified continuous wavelet transform (MCWT). The MCWT technique performs very well in the extraction of instantaneous amplitude and phase of the non-stationary signals. We make time-frequency analyses on the Enso Data (SOI and SST anomaly), resorting to the MCWT technique. The wavelet spectrums of SOI and SST anomaly suggest that the extremes of the Enso circle result from the couplings of the interannual quasi-periodic modes in the Enso circle. The predications of SOI and SST anomaly are made according to their wavelet spectrums, respectively. Our study shows that the wavelet method can play an important role in the predication of the Enso circle.

ON THE SHORT-TERM VARIABILITY OF NORTHERN HEMISPHERE CLIMATE IN CONJUNCTION WITH EL-NINO SOUTHERN OSCILLATION

Byshev V.I, NEIMAN V.G., Aleynik D.L., Lebedev M.M. (all at P.P.Shirshov Institute of Oceanology, 117851, Nahimovski pr. 36, Moscow, Russia, email: dmitry@clime.ioran.msk.ru)

The main aim of the study was a detection as atmosphere so oceanic in mediate recall for the events of El-Nino Southern Oscillation. It was carried out an analysis of the atmospheric pressure fields at sea level and air temperature and altitude of the H-500 geopotential surface over entire Northern Hemisphere for 20-th century. In results it was acknowledge that certain type variability of processes in ocean and atmosphere appears in obvious temporal correlation with ENSO. Particularly, such variability demonstrates itself by arising of some prominent anomalies in the fields of atmospheric pressure at sea level and air temperature, also by changes of global longitudinal and latitudinal (ocean - continent) termal gradients as well as variations of lateral temperature shear at sub-polar (Atlantic and sub-arctic Pacific fronts). Taking into account the generally established specific of ocean - atmosphere interrelation during the ENSO it was retraced some regional differences in recall of the climatic system for the event. Thus, in the Pacific and Siberian regions the meteorological fields were found the most sensitive in that respect, while Atlantic and European regions shown relatively much weaker signals. Some interesting additional information can be followed up by face intercomparison of Gulfstream and Kuroshio transport fluctuations with those of quasi-permanent atmospheric highs and lows. Analysis of hydrographic data obtained in 1997-1998 by Russian expeditions in Barents Sea revealed appreciable decrease of its average heat content that conforms eventually with active stage of the last ENSO. Another case of El-Nino related behaviour of atmosphere was traced in phenomenon of Polar anticyclone forcing which controls in turn the hydro-meteorological conditions over whole Arctic area and in the neighbour territories.

CHARACTERISTICS OF THE PLANETARY-SCALE CIRCULATION OVER THE ASIA-PACIFIC REGION DURING A TRANSITION FROM A WARM TO A COLD STATE OF THE ENSO

Jianjun Xu and JOHNNY C L CHAN (Department of Physics and Materials Science, City University of Hong Kong, Email: APXUJJUN@cityu.edu.hk; and Johnny.chan@cityu.edu.hk)

Based on the transition of a significant sea-surface-temperature anomaly (SSTA) over the central equatorial Pacific (the Nino3.4 region) from 0.5ºC to -0.5ºC after an El Niño episode, three types of transition episodes can be identified: the spring type (SP) in which the SSTA first falls below -0.5ºC in April or May after the termination of an El Niño episode; the summer type (SU) in which the SSTA does not reach this threshold until July or later; and no La Niña occurrence type (NON) in which the SSTA never reaches the threshold. A composite of the SSTAs in each type suggests that the SP is generally stronger but the SU has two negative peaks during the entire La Niña episode. In the NON type, the positive SSTA gradually damps off. The strength of easterly anomalies over the central equatorial Pacific (CEP) appears to play an active role in the transition from a warm to a cold state of the ENSO cycle. If the easterly anomaly is non-existent or very weak, La Niña will not occur, such as in NON. Convergence over the western equatorial Pacific and divergence over the CEP and eastern equatorial Pacific near the surface appear to be necessary conditions for the development of the easterly anomalies, but their roles are apparently different in the two types of La Niña episodes. The transition from a warm to a cold state of the ENSO cycle is also closely related to anomalies in the Asian-Australian monsoon.

JSP25/E/34-B1 Poster **0830-05**

TOWARDS NONLINEAR IDENTIFICATION OF THE ATMOSPHERIC RESPONSE TO ENSO

A. HANNACHI (Atmospheric Oceanic & Planetary Physics, Clarendon Laboratory, Parks Road, Oxford OX1 3PU, UK, email: han@atm.ox.ac.uk)

The question of estimating the nonlinear atmospheric response to ENSO is addressed here using state-of-the-art General Circulation Models (GCMs) and focussing on the interannual, mainly winter, geopotential height at 500-mb. A set of multidecadal integrations of the Hadley centre GCM model, HADAM1, is used for this purpose. The model is forced by the observed sea surface temperature (SST) and is integrated for 45 years with different initial condition for each run. Simple EOF analysis indicates that the response over the North Pacific is close to being quasi-linear where the internal mode namely Pacific North American (PNA) pattern gets `synchronized' to the ENSO, while the response over the North Atlantic sector is more likely nonlinear.
A probabilistic approach is then introduced to detect this response based on maximizing and

minimizing the respective probability density functions (pdfs) of the ensemble mean and the noise given an estimate of the latter. The method demands that the ensemble mean be split intoclusters according to the phase of the southern oscillation (SO) and then the signal pattern in each cluster found. It is then shown in particular that over the North Pacific, in winter, negative phases of the nino3-SST anomaly (La-Nina) appear to trigger the negative PNA pattern while during positive phases of ENSO (El-Nino) the response bears some similarities to a zonally stretched PNA-like pattern with a weak signature of North Pacific Oscillation, but is not precisely the inverse of the response corresponding to La-Nina ($-$PNA). Over the North Atlantic the two response patterns are different where a dipolar structure with north-south seesaw tilted north-east/south-west is obtained during El-Nino whereas during the opposite phases a tripole response pattern emerged. Finally, investigations of the relationship between the spring atmospheric variability and the ENSO during the spring and the winter, using signal-to-noise ratios and cononical correlations, reveal that the spring atmospheric response is more related to the winter, rather than the spring, east tropical Pacific SST.

PREDICTING THE 1997/98 EL NINO USING A COUPLED GCM

S.INESON and M.K.Davey (both at U.K. Meteorological Office, London Road, Bracknell, RG12 2SZ, U.K. Email: sineson@meto.gov.uk)

The U.K. Met. Office Tropical Pacific/Global Atmosphere CGCM is being used for experimental seasonal predictions. Hindcasts have been made for various periods since the mid-1980's; however, this talk will focus on the recent major El Nino. Six month forecasts have been made at three month intervals with a small ensemble for each start time since December 1997. The forecast system consists of initialisation of the component models followed by the CGCM forecast. The present strategy has been to initilise relative to the coupled model climatology, and to predict anomalies relative to that climatology, with the aim of mimimising initial shock on coupling.
In general the onset of the 1997/98 El Nino was forecast well, although the initialisation scheme gave a relative cold bias in the central-east equatorial pacific SST at this time. Many of the observed regional changes in precipitation in the tropics were captured. Forecasts of the subsequent decline and transition to weak La Nina conditions have not been so successful and have revealed shortcomings in the initialisation technique.

ENSO ACCOMPANYING AND LAGGED VARIATIONS IN THE EXTRATROPIC NORTH PACIFIC SST, METEOROLOGICAL CHARACTERISTICS AND ICE EXTENT

Vladimir PONOMAREV, Olga Trusenkova, Serge Trousenkov, Dmitry Kaplunenko, and Vladimir Plotnikov (all at Pacific Oceanological Institute, Vladivostok, 690041, Russia, e-mail: archer@linkor.ru, ponomarev%dan86@poi.marine.su)

The ENSO accompanying and lagged variations of the extratropic North Pacific SST and atmospheric circulation patterns, as well as air temperature, precipitation and sea ice extent in the Northwest Pacific margin were studied. The time series of monthly mean SST fields for 32 years were analyzed using Complex EOF method to reveal anomaly development and movement. The linear lagged/unlagged relations between SST anomaly principal components, ice extent, meteorological characteristics and El Nino/Southern Oscillation Indexes were estimated. The extratropic atmospheric circulation patterns were presented by six principal synoptic situations over the North Pacific based on the SLP (Sea Level Pressure) daily field classification developed by Polyakova (1997). These situations are associated mainly with different positions of cyclone tracks and of high/low pressure over the North Pacific and adjacent land areas. Particular classes correspond to known atmospheric circulation patterns over the North Pacific area, namely particularly as Pacific - North American and Subtropical - Zonal. We used time series of frequency of occurrence (days/month) of the mentioned synoptic situations to determine their variations of ENSO-decadal scale related to annual cycle anomalies of the ice extent, air temperature and precipitation over the Northwest Pacific margin. Findings and results imply possible feedbacks between low-frequency variations in Tropic and Extratropic Pacific.

GEARING BETWEEN THE INDO-MONSOON CIRCULATION AND PACIFIC-WALKER CIRCULATION AND THE ENSO

Wen MENG, (Chinese Academy of Meteorological Sciences, Bejing, 100081, China
E-mail: men@lasgsgi4.iap.ac.cn); Guoxiong Wu, (State key Laboratory of Numerical Modeling for Atmospheric Geophysical Fluid Dynamics,Insititute of Atmospheric Physics, Beijing, 100080, China
E-mail: gxwu@lasgsgi4.iap.ac.cn)

Most of the existing theories explain the formation of El Nino/Southern Oscilation events in terms of air - sea interaction in the tropical Pacific domain. Prediction of their formation and evolution is still a big scientific challenge. Here we show that air- sea interaction in the equatorial Pacific Ocean and that in the equatorial Indian Ocean are linked to each other due to the close coupling between the monsoonal zonal circulation over the equatorial Indian Ocean and the Walker circulation over the equatorial Pacific Ocean. The coupling of these two circulation cells works in a way much like a pair of gear operating over the equatorial Indian and Pacific: anomalies in the monsoonal zonal flow over the Indian Ocean can affect the air-sea interaction over the central and eastern equatorial Pacific and trigger the occurrence of El Nino/Southern Oscilation events. The finding that El Nino/Southern Oscilation events can be traced back to the origin over the Indian Ocean may enable improved predictions of ENSO formation and evolution.

THE IMPACT OF THE LATEST ENSO EVENTS ON TEMPERATURE AND PRECIPITATION IN ROMANIA

C. MARES and Ileana Mares (both at National Institute of Meteorology and Hydrology, Bucuresti-Ploiesti, 97, Bucharest,71552, Romania, E-mail: cmares@meteo.inmh.ro)

Temperature and precipitation in Romania defined in 31 and 33 stations respectively were filtered by EOF 1, for the interval 1950-1991. In order to quantify the ENSO impact, the SOI values were considered as the measure of this event. Thus, for the interval 1950-1991 simultaneous correlations and of 1 to 12 months delay between the monthly values of the first EOF component of temperature and precipitation in Romania and SOI were taken into account. Usual, biserial and tetrachoric correlations were performed and only the high significant results (1% or more) were considered.For the simultaneous correlations the results showed that the impact of the ENSO event was significant only in July and December for temperature and in August and September for precipitation. For the correlations with up one year delay it resulted that in Romania for the precipitation of April and October the SOI values of March and August might have been predictors.For temperature, the most significant results were obtained for the months of January, June (with 12 months delay), July (10 months delay) and August (7 months delay). The performed verifications of the last two years in order to assess the impact of the ENSO on the monthly behaviour of temperature and precipitation in Romania, showed that precipitation responded better than temperature to this extreme forcing. Thus, the months extremely rich in precipitation (as compared with normal values), i.e. August 1997 (with monthly anomalies up to 150 mm) and October 1998 (twice exceeded the normal values), could have been forecast taking in account this study.Thus, there are periods when the ENSO influence is significant and can be used in the forecast of monthly temperature and precipitation in Romania.

ENSO OCCURRENCE AND SUB-SURFACE OCEAN TEMPERATURE ANOMALIES IN THE PACIFIC WARM POOL

Li CHONGYIN, Mu Mingquan, Zhou Guangqing (LASG, Institute of Atmospheric Physics, CAS, PO. Box 2718, Beijing 100080, China, email: lcy@lasgsgi4.iap.ac.cn)

The close relationship of the ENSO occurrence with the sub-surface ocean temperature (SOT) anomalies in the Pacific warm pool region is studied through data analyses and numerical simulation with a CGCM. It is clearly shown that there are continued positive (negative) anomalies of SOT in the warm pool region prior to the El Nino (La Nina), and the outbreak of El Nino (La Nina) is directly associated with the eastward propagation and expanding to the sea surface of positive (negative) SOT anomalies. It is also clear that the eastward propagation of anomalous SOT in the warm pool region is closely related to the zonal wind anomalies over the equatorial centre-western Pacific, which are earlier than the eastward propagation of SOT. A lot of studies have shown that the zonal wind anomalies over the equatorial centre-westem Pacific result mainly from anomalous winter monsoon in East Asia. This indicated again that there is close interaction between Asian winter monsoon and the ENSO cycle

EMPIRICAL SEASONAL FORECAST OF THE NORTH ATLANTIC ATMOSPHERIC ANOMALIES

Emilia SANCHEZGOMEZ and Maria Jose OrtizBevia (Universidad de Alcala de Henares, Alcala, Madrid 28871, Spain, email: emi@pc41.fsc.alcala.es)

In this work an empirical forecast of North Atlantic atmospheric anomalies is carried out using the statistical scheme given by the Singular Value Decomposition (SVD). The goal of SVD is to find linear combinations of two different sets of variables such that this linear combinations explain the maximum possible covariance.
In order to perform our statistical forecast, different meteorological fields are used as predictor and predictand. The predictive potential of these fields is investigated through several experiments: Sea Surface Temperature (SST) anomalies as predictor and 850-mb height air temperature anomalies as predictand and then the predictand field itself.
The air temperature anomalies field is built from the NCAR reanalysis set (Kalnay et al. 1995) and the SST field is built by merging the COADS and the IGOSS datasets. The predictor and predictand spatial domain is restricted to the same geographical region (North Atlantic). These fields both are filtered in time before performing SVD of the covariance matrix at time lag required for the forecast, and subsequently they are spatially filtered taking into account the most representative patterns obtained (20).
The first forecast experiment was carried out for the 90's and the skill (correlation between the predicted and observed field) has significant values in an extended oceanic region, including the subtropics and the central part of midlatitude ocean, while most of the coastal region, east and west, presents negative forecast skill. Other forecast experiments have been performed in order to investigate the spatial and temporal dependence of the correlation skill. The results obtained in these experiments will be discussed, specially those related with the spatial dependence of the skill.
The empirical forecast presented here were intended as the benchmark for the PROVOST project integrations.

SCALE INTERACTIONS IN THE VARIABILITY OF THE TROPICAL ATLANTIC

Maria Jose OrtizBevia, William CABOSNARVAEZ, Francisco AlvarezGarcia

We analize the variability of the tropical Atlantic sea surface temperature as simulated in a 250-years time slice of an OPYC-ECHAM coupled model integration, carried out at DKRZ, Hamburg. The statistical methods developed in (OrtizBevia at al., Beyond El Nino: Decadal and interdecadal variability, ed A. Navarra, Springer, 1998) are used to identify the relevant patterns of the interannual variability. Special attention is paid to decadal and ENSO related time scales. Then,we analyse the heat budgets and the dynamics of the mixed layer to seek out the physical mechanisms responsible for the observed patterns. The mechanisms are compared with the ones acting in the case of theseasonal variability. These last are identified by applying the same statistical techniques to the seasonal cycle of the same variables. For a better understanding of the decadal variability of the tropical Atlantic,we study the subsurface circulation of a 50-year period and the relationship between the tropical Atlantic and the tropical RPacific and tropical Indian Oceans, to see their contribution to the Atlantic SST variability. With this communication we make un attempt to contribute to the clarification of the question about the possible modes of variabity in the Tropical Atlantic.

TROPICAL-TEMPERATE TROUGHS IN SOUTHERN AFRICA AND THE SOUTH WEST INDIAN OCEAN

MARTIN TODD (School of Geography, University of Oxford, Mansfield Road, Oxford OX1 3TB, U.K., email: martin.todd@geog.ox.ac.uk); Richard Washington (School of Geography, University of Oxford, Mansfield Road, Oxford OX1 3TB, U.K., email: richard.washington@geog.ox.ac.uk)

Daily rainfall variability over Southern Africa (SA) and the Southwest Indian Ocean (SWIO) during the austral summer months is described objectively using new satellite products. The principle mode of variability in all months is a dipole structure with bands of rainfall orientated north west to south east across the region. These represent the location of cloud bands associated with tropical temperate troughs (TTT). Events characterised by such TTTs occur relatively infrequently with marked inter-annual variability, and contribute disproportionately to total rainfall.

On the basis of composites of NCEP reanalysis data the associated atmospheric structure is described. The 2 phases of the rainfall dipole are associated with markedly contrasting circulation patterns. There are also pronounced intra-seasonal variations in the position of the temperate trough and TTT cloud band.
Events in which the TTT cloud band lies primarily over the SWIO, are associated with large scale moisture flux anomalies, confirming TTT events as a major mechanism of poleward transfer of energy and momentum. Moisture is advected from 3 principal sources; (1) the northern or central Indian Ocean (where anomalous fluxes extend eastward to the Maritime Continent), (2) south equatorial Africa and the equatorial Atlantic, (3) from the south within a cyclonic flow around the extratropical trough. Thus, synoptic scale TTT events over SA/SWIO often appear to result from large scale planetary circulation patterns.
TTT development coincides with enhanced tropical convection between 10°-30°E (itself exhibiting periodicty of around 5 days), and often with convergence of eastward and westward prapogating convection around 40°E. Harmonic analysis of 200hPa geopotential anomalies show that TTT features are forced by a specific zonally asymmetic wave pattern, with wave 5 dominant or significant in all months except February when quasi-stationary waves 1, 2 and 3 dominate. The relationship of TTT rainfall over SA/SWIO with similar rainfall dipole structures observed in the South Pacific and South Atlantic convergence zones is also analysed. These findings illustrate the importance of tropical and extratropical dynamics in understanding TTT events. Finally, the relationship bewteen patterns of rainfall variability at daily, intra-seasonal and interannual scales, and the implications for predictability are discussed.

STUDIES OF OCEAN-ATMOSPHERE VARIABILITY AND ITS IMPLICATIONS FOR THE CLIMATE SYSTEMS IN WEST AFRIA DURING 1997-98 RAINY SEASONS

OJO O. and Gbuyiro S.(Department Of Geography University Of Lagos, Lagos, Nigeria)

This study applies the use of remote sensing technique to study the variability characteristics of ocean-atmosphere systems during the rainy season of 1997-98 using remote sensing technique. The study begins by examining the climatic background of West Africa with particular reference to the characteristics and significance of the ocean factor of climate in the region. The paper then discusses the elements and factors of climate in the region as they relate to the ocean-atmosphere variability in the region, especially as this relates to the characteristics and consequences of the tropical Atlantic sea-air interactions on the weather and climatic systems in the study region. In this regard, the paper discusses the patterns of migration and pulsation of the Intertropical Convergence Zone (ITC) (commonly known in West Africa as the Inter Tropical Discontinuity (ITD)) with its accompanying maritime Tropical (mT) air and the continental Tropical (cT) air along with their respective south-westerly and north-easterly winds. The paper discusses the macro-, meso- and micro-scale ocean-atmosphere variability as they relate to the Pacific and the Indian oceans and as they affect weather and climatic systems in the study region.
The paper then illustrates the characteristics of the variability in the ocean-atmosphere interactions in the tropical Atlantic Ocean and their impacts on weather and climatic processes during the rainy season of 1997-98 using the satellite photographs. The paper also relates also relates the variability in the air-sea interactions to the general characteristics of the elements and factors of weather and climate in the region, and especially as they affect rainfall and rainfall variability characteristics. The paper finally discusses the significance of this study for predictability of the weather systems and their consequences in the region, emphasise the need for adequate and regular information on satellite data, and advocates for co-operation and co-ordination, more effective monitoring and warning systems, and education and training.

TIME VARIABLE SPECTRA OF SEA LEVEL ANOMALIES COMPUTED BY TOPEX / POSEIDON ALTIMETRY

Wieslaw KOSEK (Space Research Centre, Polish Academy of Sciences, Bartycka 18A, 00-716 Warsaw, Poland, Email: kosek@cbk.waw.pl)

In this paper short period oscillations with periods ranging from 20 to 180 days of sea level anomalies determined from Topex/Poseidon altimetry are presented. The amplitude spectra computed by the Fourier Transform Band Pass Filter (FTBPF) for the whole ocean, equatorial regions, northern and southern hemispheres show that besides the annual oscillation there are oscillations with periods of 182, 120, 90, 60, and 30 days. The mean and variable amplitudes of these oscillations computed by the FTBPF depend on geographic latitude and longitude and are also variable in time. The 182 day oscillation has the biggest amplitude in the Indian and the equatorial Pacific Oceans. The 120-day and 90-day oscillation are very active in the equatorial regions of the Pacific and Indian Oceans as well as at the western parts of each Ocean. The biggest amplitudes of the 60-day oscillation, sometimes of the order of 15 cm, show mostly geographic regions where the M2 tide amplitude is not modelled correctly. In the case of a 30-day oscillation the equidistant spots with amplitudes of the order of 1-2 cm in the Pacific ocean above the equator were detected. These spots can be attributed to the instability waves in the equatorial Pacific. All these oscillations are also very energetic near the east coast of Argentina. In the mentioned geographic regions there are also the biggest changes of amplitudes of these short period oscillations.

ON STRUCTURAL CAUSES OF THE GENESIS OF INTERANNUAL SCALES OUT OF INTRASEASONAL DYNAMICS

Peter CARL (Climate Dynamics Project, c/o Forschungsverbund Berlin, Hausvogteiplatz 5-7, D - 10117 Berlin, Germany, email: pcarl@spclim5.wias-berlin.de)

Of the three types of climate variability found in a conceptual AGCM, a solution is studied in a 200 year run that is dynamically shaped by a torus segment in phase space which imprints a helical winding on the system's trajectories during boreal summer. The geometrical nature of this seasonal cycle bears interannual anomalies that structurally relate to intraseasonal motion systems of the 30-60 days band. The latter are maintained via interhemispheric synchronisation for which two discernible mechanisms are discussed. 2-, 4-, 6-year and longer quasiperiodicities are partially bom in three types of re-adjustment in autumn to the annual forcing by the fading summer monsoon. Further structural sources of interannual variability include a generically intraseasonal Southern Oscillation, found as a degenerate monsoon oscillator or as an irregular wander between summer and winter fixpoints in autumn. All these dynamics are reflected in the model's integrals of motion.
To pose the results into perspective, local and global time series of the real world have been studied using methods of time-frequency analysis. The data bear evidence of structured bands, frequency drifts, secular trends and conceptually essential amplitude modulations that altogether point to organised, nonstationary dynamics throughout the century. This leaves the space for variability modes as found, in addition to those not traced back to phase space geometry of a model's atmosphereland dynamics.

INTERANNUAL AND DECADAL CHANGES IN POLEWARD HEAT TRANSPORT BY THE EAST ASIAN WINTER MONSOON AND PACIFIC STORMTRACK

HISASHI NAKAMURA (IGCR, Frontier Research System for Global Change, Tokyo/Dept. Earth, Planetary Physics, Univ. Tokyo, 113-0033, JAPAN; email: hisashi@geoph.s.u-tokyo.ac.jp), and Takuya Izumi (Dept. Earth, Planetary Physics, Univ. Tokyo)

Interannual variability in the lower-tropospheric poleward sensible heat fluxes over the Northwestern (NW) Pacific associated with migratory baroclinic waves and with standing waves in bimonthly fields is investigated based on the NCEP/NCAR reanalyses for 1979-1995. The former is defined as the covariance (VhTh) of 8-day highpass-filtered temperature and meridional wind, and the latter (VsTs) can be regarded as heat transport by the northwesterly East Asian winter monsoon. Although the climatological-mean VhTh is suppressed in midwinter (Nakamura 1992), its interannual variability is the largest. The first EOF of January-February VhTh, which accounts for nearly 50% of the total interannual variance over the NW Pacific, represents anomalous VhTh along the climatological-mean stormtrack. The linear regression map of VsTs with the first principal component (PC1) timeseries of VhTh shows that the enhanced VsTs tends to be accompanied by the suppressed VhTh along the stormtrack and vise versa. Around 45N anomalous VsTs tends to be largely compensated by anomalous VhTh in the opposite sense, which leaves rather small changes in the total atmospheric sensible heat transport from one winter to another. Associated seasonal-mean circulation anomalies are identified in the linear regression maps with PC1. The enhanced VhTh is associated with anticyclonic SLP (sea-level pressure) anomalies that cover almost entire midlatitude North Pacific and weaker cyclonic anomalies over Siberia; in other words, the weakening of the Aleutian Low and Siberian High. These surface anomalies are accompanied by a PNA-like pattern over the North Pacific in the upper troposphere, and its anticyclonic ÒtailÓ extends into northern China that is in seesaw with cyclonic anomalies over Siberia. This baroclinic structure is consistent with anomalous VsTs over the Far East. Nakamuraand Yamagata (1998) pointed out that two of the three dominant modes of the decadal wintertime SST variability over the NW Pacific changed drastically in the second half of the 1980Ős. One is the Òmidlatitude modeÓ characterized by SST anomalies along the subarctic front with the anomalous Aleutian Low and PNA pattern aloft, and the other represents decadal modulation of the East Asian winter monsoon

SOME STUDIES ON THE VARIABILITY OF SURFACE FIELDS OVER THE INDIAN OCEAN DURING ABOVE AND BELOW NORMAL MONSOONS

P.K. Mohanty1 and S.K. Dash2 (1). Marine Science Department, Berhampur University, Berhampur - 76007, Orissa, India (2)Centre for Atmospheric Sciences, Indian Institute of Technology, Delhi, Hauz Khas, New Delhi - 110016, India

Surface fields over the tropics experience oscillations due to solar radiative forcing which contains strong periodicities at annual and semiannual frequencies. Therefore, spectral analysis, an illustrative climate diagnostic tool, and variance, a well known statistical indicator of space-time variability have been employed on sea surface temperature, mean sea level pressure, zonal and meridional wind stress, latent and sensible heat fluxes for four regional domains in the Indian ocean, viz; 1) Arabian Sea, 2) Bay of Bengal, 3) South China Sea and 4) Southern Indian Ocean. Composites of monthly mean, variance, power spectra and cross spectra (Coherence and phase) of the above mentioned surface fields
are computed for the below normal (1985, 1986, 1987) and normal/above normal (1988, 1989, 1990) monsoon years. Data for this study consist of the daily uninitialised data (0 UTC) of European Centre for Medium Range Weather Forecasts (ECMWF) for the period 1985 to 1990, FSU observed ship data and NCAR COADS climatology. Time series of surface fields for the composite years of below and above normal monsoons shows the evolution of the surface fields during the course of the annual cycle. However, the contrasts in the monsoons are not well reflected in the composite time series of the surface fields except for latent and sensible heat fluxes. The characteristics of the composite time series are consistent with composite power spectra of the surface fields. Power spectra show that oscillations of the surface fields are explicitly in the annual andsemiannual bands in the four regional domains except over the Southern Indian Ocean, where the oscillations are confined to the annual band only and with relatively weak amplitude. Semiannual cycle is predominant in the latent and sensible heat fluxes while the rest of the surface fields exhibit strong annual cycle. The amplitude of annual and semiannual cycles differ from one regional domain to the other and thus there is a distinct role of each regional domain in the monsoon variability.Interestingly, the contrasts in the monsoons are very well reflected in the variance of the surface fields.

VARIABILITY OF THE KUROSHIO VIEWED BY TWO-YEAR-LONG DIRECT CURRENT MEASUREMENTS SOUTH OF JAPAN

Shin-ichiro UMATANI, Motohiko Kashima, Shiro Imawaki (all at Research Institute for Applied Mechanics, Kyushu Univ., Kasuga, 816-8580, Japan, email: umatani@riam.kyushu-u.ac.jp) Hiroshi Uchida (Japan Science and Technology Corporation, Japan), Hiroshi Ichikawa (Kagoshima Univ., Japan), Masao Fukasawa (Tokai Univ., Japan) and ASUKA Group

The Kuroshio, the western boundary current of the North Pacific subtropical gyre, is known as one of major components controlling the earth climate system. A group called ASUKA (Affiliated Surveys of the Kuroshio off Cape Ashizuri) carried out oceanographic observations of the Kuroshio to obtain a long time series of the transport on the basis of direct current measurements. The survey was carried out along a line called ASUKA-line, crossing the Kuroshio from Shikoku coast to 25 °N, during 1993 - 1995. Nine mooring stations were maintained along the line. The shallowest current meter of each station was set nominally at 700 m depth. We also set current meters nominally at depths of 1500 and 3000 m and near the bottom on continental slope. CTD observations were carried out 42 times along the ASUKA-line during the period.
Velocity records from current meters at 700 m nominal depth show remarkable variability which well agrees with north-south movement of the Kuroshio, related to eastward propagation of a small meander of the Kuroshio observed by hydrographic surveys in the upstream region. Temperature of the Kuroshio axis at 650 m depth is estimated to be about 8 °C from temperature and velocity records. The variation of volume transport per unit depth of the Kuroshio, integrated from the coast to the offshore edge of the eastward Kuroshio surface flow, is estimated at depths of 650, 1500 and 3000 m. The shallower two are correlated in some extent with each other but are not correlated with the deepest.

INTERCOMPARISON OF THE CLIMATIC AND FLUX-DERIVED TEMPERATURE AND SALINITY UPPER LAYER FIELDS IN THE NORTH ATLANTIC

L.E. AMETISTOVA (1), S.K. Gulev (2), S.A. Dobroliubov (1) (1) Department of Oceanology, Moscow State University, email: diord@ocean.geogr.msu.su (2) (2) P.P. Shirshov Oceanology Institute, Moscow, Russia

The role of air-sea interaction in heat and water budgets in the North Atlantic is examined using temperature and salinity data derived from Levitus Atlas'98 and flux fields from NCEP/NCAR Reanalysis data. Four regions in the North Atlantic were taken to represent Gulf Stream (subtropical gyre), Labrador Sea (subpolar gyre), area between the two gyres and the region of Norwegian Current. Mean water temperature TLEV and salinity SLEV of a layer of 250 m were compared to the temperature TCOMP and salinity SCOMP derived from heat and (evaporation-precipitation-river runoff) fluxes on seasonal and interannual scales. TCOMP follows the pattern of TLEV but with greater amplitude. Warmer winters and cooler summers would be observed in all four regions (especially in the Labrador Sea) in case of air-sea interaction as the only term in heat energy budget equation. Heat advection and heat storage changes smooth temperature seasonal cycle. Time-series of salinity and (evaporation-precipitation-river runoff) flux have strong negative correlation in the two gyres. It is most vividly expressed during the Great Salinity Anomaly with smaller values of salinity and predominance of precipitation over evaporation in the subtropical gyre.

JSP25/W/32-B3 Poster **0830-03**

WAVELET ANALYSIS OF LOW FREQUENCY GLOBAL OCEAN VARIABILITY FROM MULTIPLE DATA SOURCES

O. ANDERSEN (National Survey, Geodetic Division, Copenhagen, Denmark, email: oa@kms.dk) N. L. Bindoff (Antarctic CRC, Hobart, Tasmania, Australia); R. Coleman(University of Tasmania, Hobart, Tasmania, Australia, and at CSIRO Marine Research, Hobart, Tasmania, Australia)

Long period, long-wavelength variations in sea level can be investigated by expanding the sea level variations in low degree spherical harmonic terms. have then been investigated for their using wavelet analysis. The complex Morlet wavelet enables an investigation of characteristics in time of the low degree spherical harmonic terms. The wavelet analysis technique enables a study of the evolution of scales and frequencies with time, and can be used for the identification of the driving forces and their changes with time. The most important physics contributing to the annual and semi annual changes in sea-level change on global space scales, appear to be the wind driven barotropic response and steric sea level changes caused by seasonal solar radiation in the mixed layer.
For the present investigation the low frequency sea level changes have been investigated using the first 6.5 years of TOPEX/POSEIDON altimetry spanning 230 repeats of altimetry. By comparing with long-wavelength height field calculated from NCEP SST and heatflux data, height fields calculated from surface wind data using a simple Sverdrup model, and finally SSH fields of the 1/4 degree WOCE Parallel Ocean Climate Model (Semtner/Chervin) (Stammer, et al., 1996) information on the role of the wind and the heat fluxes on this time and space scales can be gained.

JSP25/W/34-B3 Poster **0830-04**

ANNUAL AND INTER-ANNUAL VARIATIONS IN SEA LEVEL, ATMOSPHERIC PRESSURE AND SEA SURFACE TEMPERATURE FROM SATELLITES

Per Knudsen and Ole Baltazar Andersen (both at National Survey and Cadastre, Copenhagen NV, Denmark, email: pk@kms.dk, oa@kms.dk)

The sea level is monitored globally from satellites. Five years of atmospheric pressure observations, sea surface temperature data and sea level height for the same period is analysed. Altimetry from the TOPEX/POSEIDON satellite will be used along with low resolution averaged sea surface temperature data from the ATSR 1 and 2 sensor onboard the ERS satellites and AVHRR data from the NOAA satellites.
Global and regional characteristics of annual and interannual variations in sea level, atmospheric pressure and surface temperature during the period from 1992-1997 are investigated. Spatial and temporal correlation between the variations in sea level, atmospheric pressure and sea surface temperature are investigated to decide whether the changes in sea level are related to changes in the heat content of the ocean. Similarly, a bivariate coherency analysis of the sea level together with the atmospheric pressure and sea surface temperature observations is carried out at different spatial scales.

JSP25/W/42-B3 Poster **0830-05**

SEASONAL AND YEAR-TO-YEAR OCEANOGRAPHICS VARIABILITY IN THE NORWEGIAN-GREENLAND REGION

A. KORABLEV, (Arctic and Antarctic Research Institute, 38, Bering str., St Petersburg, Russia 199397. E-mail: aakor@aari.nw.ru.)

Mean seasonal and year-to-year oceanographic characteristics time series were obtained from historical data base for six regions in the Norwegian-Greenland Seas. Irregularity of the characteristics variability is under the influence of large-scale anomalies and convection activity. The water salinity distribution in the upper layer of the Norwegian and the Greenland Seas is the most typical indicator of the spreading influence of Atlantic and polar water. During GSA'70s passing the mean salinity of upper layer decreasing and not reach the previously value that has a profound influence on the convection activity reduction. Large salinity anomaly were registered early but have not such global consequences. Current system and interannual variability comparison allow to make conclusion that GSA"70s propagation was by to ways: along frontal system and with Norwegian current. Speed of movement and depth level with high anomaly intensity were different. Distributions of temperature, salinity, dissolved oxygen concentration and density seasonal changes for different regions of the Norwegian and Greenland Seas indicate the time of extremums approach at depth levels. Dissolved oxygen concentration and saturation can be used as an index of convection stage. Interannual variability of the oxygen concentration in the different layers of the southern part of the Norwegian Sea is a useful parameter for convection intensity estimation in the Iceland and Greenland Seas.

INTERANNUAL VARIABILITY OF WATER MASS DISTRIBUTION AND WATER AND HEAT TRANSPORTS ON 37-N OBSERVATION LINE

Shin-ichi ITO, Osamu Kato and Yugo Shimizu (all at Tohoku National Fisheries Research Institute, Shinhama Shiogama 985-0001, Japan, email: goito@myg.affrc.go.jp); Tomomi Takayama (Shin-Nippon Meteorological & Oceanographical Consultant Co. Ltd., Tamagawa Setagaya, Tokyo, Japan, email: tomomi@notes.metocean.co.jp); Hiroshi Yoshinari and Kensuke Takeuchi (both at Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060-0810, Japan, email: utatane@ees.hokudai.ac.jp); Ichiro Yasuda (Faculty of Science, Tokyo University, Hongo, Bunkyo 113-0033, Japan, email: ichiro@geoph.s.u-tokyo.ac.jp)

To clarify the interannual variability of water mass distribution and water and heat transports in the Inter-frontal Zone between Oyashio and Kuroshio Fronts in the North Pacific, we analyzed a hydrographic data along the 37-N observation line (extends to 164-E at least) during 1983-1996. Mean structure showed warm water region at 144, 148, 152, 157, 165-E and the variability is relatively high in the warm water region. We applied EOF analysis for historical temperature data and as a result EOF1 (27.2%) showed high amplitude at 144-E and its time variability is consistent with that of 1st crest of the Kuroshio Extension. EOF3 (13.0%) showed whole domain variation and its time variability showed longer period variation with transitions in 1988-1989. After 1989, the zonal inclination of main thermocline lost the steepness.We also estimated the water and heat transports on 37N in 1992-1996 and 1998. Both transports increased rapidly in 1998. The increase of transports again associated with the increase of the zonal inclination of the main thermocline.

CLIMATIC CHANGES OF SEASONAL CYCLE OF SST IN THE NORTH PACIFIC

Igor ZVERYAEV (IPRC, SOEST, University of Hawaii, MSB, Room 227, 1000 Pope Rd., Honolulu, HI 96822, USA, email: igorz@soest.hawaii.edu) Konstantin Selemenov (P.P.Shirshov Institute of Oceanology, RAS, Nakhimovsky Ave. 36, Moscow 117851, RUSSIA, email: selko@gulev.sio.rssi.ru)

Climatic changes in seasonal cycle of sea surface temperature (SST) in the North Pacific during 1951-1995 are studied. These changes are discussed in terms of pentadal anomalies of characteristics of annual and semiannual cycles as well as of anomalies of annual, winter and summer means. Anomalies of annual and seasonal means clearly indicate North Pacific climate shift of mid 70-ties. Quasi-decadal changes are more noticeable before climate shift.
Before 1971, anomalies of annual amplitudes tend to result in anomalies of annual means of the same sign, later - in anomalies of opposite sign. It is found out that these changes are due principally to different roles of seasonal anomalies in the formation of the annual cycle of SST. Before 1971, anomalies in annual cycle are defined by summer anomalies. Later, winter anomalies play a leading role in the formation of annual cycle. We note that this switch from the governing role of summer anomalies to that of winter anomalies takes place prior to the North Pacific climate shift.
Comparative analysis of anomalies of annual and semiannual cycles has revealed that enhanced (reduced) annual cycle does not necessarily result in enhanced (reduced) semiannual cycle. I.e. positive anomalies of semiannual cycle can be related both to positive and negative anomalies of annual cycle. The same is true about negative anomalies of the semiannual cycle.

INTRA-ANNUAL VARIABILITY IN THE DEEP BOTTOM BOUNDARY LAYER OF THE NORTH TROPICAL PACIFIC OCEAN

Tatiana Demidova (P.P.Shirshov Institute of Oceanology, Moscow, RUSSIA email: evita@redline.ru)

Intra-annual (synoptic and seasonal) current variability and estimates of horizontal mean and fluctuating kinetic energy (MKE and FKE) in the deep-water bottom boundary layer of the Tropical Pacific ocean are considered on the basis of 1 to 2-year time-series from groups of subsurface moorings within two test areas. Data were collected in frameworks of international projects during 1991-1995. The work was fulfilled as a part of the baseline studies aimed to evaluation and prediction of long-term hydrodynamic conditions in the near-bottom layer and in the upper water column in the region of planned deep-water mining.
Quite a stable long-term direction of the near-bottom water flow, controlled, in most cases, by main floor topographic elements, is found. Intraannual-scale spectra were analyzed. Contribution of synoptic as well as and meso-scale components in the total fluctuating kinetic energy are estimated. From filtered data, time series of MKE and FKE components are constructed, and time variability of synoptic components of kinetic energy at various levels and in space are analyzed and discussed. Peaks of synoptic-scale fluctuating energy are associated with specific seasonal time periods varying from area to area, and very often they are related to the late fall-winter seasons. . There is evidence that high level of synoptic variability in the bottom layer closely associated with synoptic activity on the surface. The comparison of the evaluating current velocity and kinetic energy parameters for different moorings and levels above the bottom contributes in parametrization of synoptic and seasonal processes in high resolution circulation models.

DECADAL- CENTENNIAL OCEAN/ATMOSPHERIC VARIABILITY

JSP25/W/68-B4 Poster **0930-01**

DECADAL VARIABILITY IN A COUPLED ATMOSPHERE-OCEAN CIRCULATION MODEL OF MODERATE COMPLEXITY

Dörthe HANDORF, Klaus Dethloff, and Antje Weisheimer (all at Alfred Wegener Institute for Polar and Marine Research, Telegrafenberg A43, 14473 Potsdam, Germany, e-mail: dhandorf@awi-potsdam.de); Vladimir K. Petoukhov (Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow)

In order to improve our knowledge of the influence and extent of internal processes in generating atmospheric variability on time scales of years and decades two 1000 year long integrations of a coupled atmosphere-ocean circulation model of moderate complexity have been performed. This model resolves explicitely the basic features of the large-scale long-term atmospheric and oceanic variables, including the tropo-, strato- and mesosphere, whereas all synoptic-scale processes are parameterized. The main large-scale features of atmospheric circulation have been simulated in agreement with observations. The first run has been performed with the fully coupled model, whereas in the second run the atmosphere is driven by prescribed seasonally varying sea surface temperatures (SST). The combined analyses of both runs reveal strong decadal and interdecadal atmospheric climate variations especially about 9 and 30 years, which show a significant shift from century to century. These modes of variability have been determined by investigations of fields of streamfunctions and

temperatures and of the North Atlantic oscillation by means of methods of multivariate statistics and of sophisticated time-frequency analyses (wavelettransformation). The comparison of the coupled with the SST-forced run leads to the conclusion, that the decadal and interdecadal climate variations are forced by nonlinear atmospheric processes and reinforced by oceanic processes.

IS THE ADJOINT METHOD AN APPROPRIATE TOOL TO STUDY CLIMATE VARIABILITY ?

M.JUNGE and T.W.N.Haine, AOPP, University of Oxford, Atmospheric, Oceanic and Planetary Physics, Clarendon Laboratory, Parks Road, Oxford OX1 3PU, UK, e-mail: mmj@atm.ox.ac.uk

A focus of current research in understanding decadal climate variations is the interaction between the atmosphere and the ocean. In order to disentangle these connections we study sensitivities of the upper ocean to the overlying atmosphere on all time scales up to decades. To do so we employ an OGCM (MICOM) in the North Atlantic Domain. Scalar functions such as SST, thermocline depth, upper ocean heat content and gulf stream transport, that comprise the ocean state, are calculated. The adjoint of the OGCM then gives the change in atmospheric conditions due to a change in the scalar function, i.e. the sensitivity of this scalar function to changes in atmospheric forcing.

DECADAL VARIABILITY OF THE ATMOSPHERE IN A COUPLED GLOBAL CIRCULATION MODEL

Antje WEISHEIMER, Klaus Dethloff and Dörthe Handorf (all at Alfred Wegener Institute for Polar and Marine Research, Telegrafenberg A43, 14473 Potsdam, Germany, e-mail: weisheim@awi-pots-dam.de)

Variations of the atmospheric circulation can be caused by external and internal processes. Whereas recently the meaning of external factors had been investigated in detail, the influence and extent of internal processes in generating natural low-frequency atmospheric variability on time scales of years and decades is not very well understood yet.
In this paper we are going to show the results of a 1000-year integration of the coupled general circulation model ECHAM3-T21-/LSG without time dependent external forcing except the seasonal cycle in solar insolation. The long-term run was carried out at the MPI for Meteorology in Hamburg. The study is based on monthly mean data of stream functions and temperatures at the surface, in the free troposphere and the lower stratosphere. The structure of the ultra-low-frequency variability with and without seasonal cycle has been investigated by means of EOF and wavelet analysis. The most important EOFs reproduce the spatial structure of the standard deviations, whereas the EOF of higher order reflect the influence of teleconnection patterns on generating atmospheric variability. The power and wavelet spectra of the PC which describe the temporal behaviour of the corresponding spatial patterns have been calculated. They show well pronounced variability on the decadal time scale. Preferred periods exist, especially around 11, 18 and 35 years, changing within the centuries.

JSP25/W/38-B4 Poster **0930-04**

LOW-FREQUENCY VARIABILITY IN LOW-ORDER-MODELS OF THE ATMOSPHERE

Antje WEISHEIMER, Klaus Dethloff, Dörthe Handorf and Annette Rinke (all at Alfred Wegener Institute for Polar and Marine Research, Telegrafenberg A43, 14473 Potsdam, Germany, e-mail: weisheim@awi-potsdam.de); Mikhail V. Kurgansky (Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow)

Besides the study of external influences on the climate system an improved understanding of atmos-pheric long-term variations requires also the investigation of internally generated, mostly nonlinear mechanisms of atmospheric dynamics. Because of the limited length of direct measurements of cli-mate variables and temporal as well as spatial inhomogeneities in paleoclimatic data series, long-term integrations of appropriate models with fixed external forcing, however, seem to be one possible way to approach this problem. Analyses of the model's natural low frequency variability on time scales of decades up to centuries might give hints on the behaviour of the real atmosphere.We investigated this problem by running three quasi-geostrophic Low-Order-Models (LOM) of the atmosphere: a one-, a two- and a three-layer LOM with different horizontal resolutions. Thesemodels consider nonlinear interactions between the zonal flow, thermally and orographically forcedplanetary waves and short baroclinic waves. They have been integrated over 1,000 to 10,000 years. The structure of low-frequency variability has been analysed by means of EOF and wavelets. The models reproduce variability on intraseasonal, decadal and even centenary time scales suggesting that the multiscale natural variability is caused by deterministic interactions between the modelcomponents and internally driven by short time-scale instabilities and nonlinearities connected withlarge-scale atmospheric processes.

TEMPERATURE VARIABILITIES IN THE NORTH PACIFIC GENERATED BY MOVEMENTS OF WIND-STRESS ZERO LINE

Yoshio MASUDA and Moto Ikeda (Division of Ocean and Atmospheric Science, Graduated School of Hokkaido University, Sapporo, JAPAN, email: masuda@ees.hokudai.ac.jp)

One and a half layer PE and QG models are used to study decadal temperature variabilities in the north Pacific. In the previous studies southward Ekman transport, air-sea heat flux, and mixed-layer development were suggested to be important for the decadal variabilities. In this study, the effects of curl Tau=0 line movement on the decadal temperature variabilities is investigated. The models are driven by the wind stress which forces the symmetric double-gyre circulation in a rectangular domain. The models retain two mechanisms which can infer temperature variability in the Pacific. One is an interface movement, propagating as a forced Rossby wave, whose zonal wavelength is as long as the longitudinal lengths of the model domains. This wave has some similarity with the observed SST variabilities reversed between the central Pacific and more eastern region. The other mechanism is a cross-gyre transport, which is realized by passive tracers left in the models. When the curl Tau=0 line moves southward, some tracers flowing eastward cross the gyre boundary and penetrate into the subarctic gyre, in particular, near the eastern boundary. This northward movement is consistent with a warm anomaly observed in the Gulf of Alaska. The oscillation of the curl Tau=0 line is the most effective to the temperature variabilities at decadal time scales.

THE THREE-CENTURY CLIMATIC UPHEAVAL OF C. 2000 BC, AND REGIONAL RADIOCARBON DISPARITIES

Douglas J. KEENAN (The Limehouse Cut, London E14 6NQ, U.K.; email: doug.keenan@virgin.net)

Several researchers have previously identified a severe climatic up heaval in tropical North Africa that began just over 4000 years ago and lasted for about three centuries. The upheaval is known to have occurred shortly after a volcanic eruption, and companion work proposes that this eruption was colossal. Here, we suggest how the eruption acted as a trigger for the upheaval: by forcing changes in ocean circulation; although the initial (atmospheric) forcing lasted only a few years, the ocean required three centuries to regain equilibrium. The suggested triggering mechanisms supported by palaeoceanographic, palaeoecological, andarchaeo-historical data and by related experiments with a (coupled general-circulation) climate model. We argue that the changes in ocean circulation forced changes in sea-surface temperatures that led to a weakening of the south-west North African monsoon. The upheaval has been proposed to have also encompassed south-western Asia. We argue that it encompassed most of the Northern Hemisphere: we present a variety of palaeoecological and palaeoceanographic evidence and describe the principal underlying climatology. In some areas the upheaval was the most severe since the ice ages. The full scope of the upheaval has previously been missed in part because radiocarbon dates from some areas are centuries too early: palaeoclimatic events in different areas thus appeared asynchronous. (The erroneous radiocarbon dates also misled searches seeking ice-core and tree-ring evidence of the eruption.) The cause of the radiocarbon- dating disparities is identified as a regional deficiency in 14C, and we locate s source of 14C-deficient carbon. (An extended version of this abstract will be at http://freespace.virgin.net/doug.keenan.).

TRANSPORT IN THE LOWER STRATOSPHERE

R. Alan PLUMB (Massachusetts Institute of Technology, Cambridge, MA, USA)

Exchange between troposphere and stratosphere is to a large degree controlled by the large-scale circulation, even though individual transport "events" may occur on smaller scales. Factors controlling the mean meridional circulation will be discussed, especially those that might determine the structure and intensity of lower stratospheric upwelling. Subtle, and poorly understood, aspects of the tropical angular momentum balance may be crucial in determining the relative importance of extratropical wave drag, tropical wave drag, and diabatic heating (in both stratosphere and troposphere). I will also discuss what observations of lower stratospheric tracers, including "age", might tell us about the impact of local (extratropical) stratosphere-troposphere exchange on tracer budgets in the lowermost stratosphere.

JSM26/W/06-B1 **0900**

LONG-LIVED FLUORINATED COMPOUNDS AS TRACERS OF THE AGE OF STRATOSPHERIC AIR

WT STURGES, DE Oram, SA Penkett (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, UK, email: w.sturges@uea.ac.uk) PJ Fraser (Division of Atmospheric Research, CSIRO, Private Bag 1, Mordialloc, Victoria 3195, Australia, email: pjf@dar.csiro.au) A Engel (Institute fur Meteorologie und Geophysik, J.W.Goethe Universitat Frankfurt, D 60325 Frankfurt, Germany, email: an.engel@meteor.uni-frankfurt.de)

Long lived halocarbons have been measured in air collected with a balloon-borne cryogenic sampler at altitudes from the tropopause to 7 hPa (c. 33 km) during flights from the Arctic and Northern mid-latitudes. The compounds measured include C2F6, C3F8, c-C4F8-, CFC-13, CFC-114, CFC-115, SF6 and HFC-23. These compounds have estimated stratospheric lifetimes between several hundred years and ten thousand years, making them potentially ideal tracers of transport to the stratosphere. Shorter-lived HFCs were also measured. Corresponding measurements of the same gases in the Cape Grim, Tasmania air archive allow a direct comparison between stratospheric and tropospheric measurements. C2F6 appears to be an ideal age-of-air tracer in the stratosphere, and agrees well with SF6-derived dates. Air ages at and just above the tropopause appear to be almost contemporaneous with the troposphere. Ages then rapidly increase up to about 20hPa, above which there is little further change in age. Ages at 20hPa are around six to seven years. Atmospheric trends for the other compounds can be reconstructed from the stratospheric profiles to give histories covering more than 10 years (from 1987). The trends are not always consistent with the Cape Grim archive (notably HFC-23 and c-C4F8) suggesting larger stratospheric loss terms than given by current estimates. (This replaces abstract Reference 011528)

TRANSPORT INTO THE NORTHERN HEMISPHERE LOWERMOST STRATOSPHERE REVEALED BY IN SITU TRACER MEASUREMENTS

Eric A. Ray (1), (2), Fred L. Moore (1), (2), James W. Elkins (1), Geoffrey S. Dutton (1), (2), David W. Fahey (3), Holger Vömel (1), (2), Samuel J. Oltmans (1) and Karen H. Rosenlof (2), (3) (1) NOAA/Climate Monitoring and Diagnostics Laboratory, Boulder, CO (2) Co-operative Institute for Research in Environmental Science (CIRES), Boulder, CO (3) NOAA/Aeronomy Laboratory, Boulder, CO.

The Lightweight Airborne Chromatograph Experiment (LACE) has made in situ measurements of several long-lived trace gases in the upper troposphere and lower to middle stratosphere as part of the Observations of the Middle Stratosphere (OMS) balloon platform. The tracers measured by LACE include several photolytic species (CFC-11, CFC-12 and halon-1211) as well as SF6. LACE measurements of these long-lived tracers as well as nearly simultaneous measurements of water vapor and CO2 are used to investigate transport into the lowermost stratosphere, a region where few in situ measurements exist. The measured photolytic species and water vapor are used in a simple mass balance calculation to estimate the mixture of

tropospheric and overworld (theta > 380 K) air in the lowermost stratosphere. In the northern mid-latitudes during September 1996 most of the air in the lowermost stratosphere sampled at the flight location (34.5N) was transported quasi-isentropically from the troposphere. Measurements from both a May 1998 mid-latitude flight and a June 1997 high latitude flight (64.5N) revealed the air sampled in the lowermost stratosphere to be dominated by downward advection from the overworld. SF6 and CO2 can uniquely reveal time and spatial scales of transport due to these species' large growth rates and subsequent latitudinal surface and free tropospheric gradients. Measurements in the lowermost stratosphere from the September northern mid-latitude flight coupled with surface measurements of these species revealed a transport time scale of no more than 1.5 months from the surface to the lowermost stratosphere. The SF6 and CO2 mixing ratios were also consistent with mostly Northern Hemisphere tropospheric air in the lowermost stratosphere. These results point out the usefulness of high-resolution in situ measurements of long-lived tracers to help determine time and spatial scales of transport in the region of the upper troposphere and lowermost stratosphere.

JSM26/W/11-B1 0940

TRANSPORT CHARACTERISTICS AND AGE OF AIR IN THE LOWER STRATOSPHERE: SIMULATIONS WITH A 3-D MODEL

W. GROSE, R. Eckman, J. Al Saadi, R. Pierce (NASA LaRC, Hampton,VA, 23681,USA, email: w.l.grose@ larc.nasa.gov), D. Fairlie (STC, Hampton,VA 23681, USA) G. Lingenfelser (SAIC, Hampton,VA,23681, USA)

A multi-year simulation has been conducted with a general circulation model (IMPACT) with coupled radiation, chemistry, and dynamics. IMPACT is a primitive equation, spectral model extending from the surface to approximately 90 km (34 levels). Gas-phase and heterogeneous chemical reactions have been incorporated with 24 species (families) explicitly transported. Discussion will focus on age of air and transport in the lower stratosphere based upon analysis of the model distributions of long-lived species. The age of air spectrum from the model will be compared with that deduced from observations. Diagnosis of the model transport will focus on a modified Lagrangian-mean analysis (developed by Nakamura) of the long-lived species, calculating "equivalent length" distributions for the tracer. Minima in equivalent length occur in polar and subtropical "barrier" regions where the lateral mixing is inhibited. Seasonal evolution of these minima will be presented. Correlation between long-lived species in the model will be compared with similar results from ER-2 airborne data to further evaluate the model transport.

JSM26/W/12-B1 1000

A THREE-DIMENSIONAL MODEL SIMULATION OF TRANSPORT OF SEASONALLY VARYING AND LONG-LIVED TRACERS INTO THE LOWER STRATOSPHERE

Lori BRUHWILER(Climate Monitoring and Diagnostics Laboratory, R/E/CG1 325 Broadway, Boulder CO, 80303, USA, email: lbruhwiler@cmdl.noaa.gov); Kevin Hamiliton (Geophysical Fluid Dynamics Laboratory, Princeton Forrestal Campus, Rt.1, Princeton, NJ 08540, USA, email: kph@gfdl.gov)

Due to its seasonal variation, CO2 is an excellent tracer of transport from the troposphere to the lower tropical stratosphere, and subsequently to the extratropics. Three-dimensional model calculations of CO2 and other long-lived trace species will be used to quantify the lower stratospheric transport properties of the GFDL SKYHI general circulation model. The responses of the model circulation and transport to parameterisations of momentum forcing due to gravity wave drag and the equatorial stratospheric quasi-biennial oscillation will also be discussed as well as implications for stratospheric photochemical models.

JSM26/E/08-B1 Invited 1040

THE EXTRATROPICAL TROPOPAUSE AS A TRANSPORT BARRIER

Peter HAYNES, (Centre for Atmospheric Science, DAMTP, Silver Street, Cambridge, CB3 9EW, United Kingdom, email: phh@damtp.cam.ac.uk)

It has been suggested that there are useful analogies between the extratropical tropopause and the edge of the polar vortex in the stratosphere, in that both are marked by a sharp gradient in potential vorticity and that both appear to act as a partial barrier to transport. These analogies will be discussed in this talk and the implications for our current understanding of the tropopause and stratosphere-troposphere exchange assessed. Two particular aspects will be discussed.
Numerical simulations (performed in collaboration with J. Scinocca) have shown that a quasi-realistic, statistical equilibrium tropopause may form in a simplifed numerical model solely through the spatially inhomogeneous stirring of the baroclinic eddies, without any contribution from convection, for example (The mechanism is much the same as that which forms a sharp edge to the polar vortex through the action of Rossby-wave breaking.). At upper levels the stirring is confined in latitude and a sharp edge forms in the potential vorticity field. This is seen as corresponding to the subtropical tropopause. At lower levels there is no latitudinal limit to the stirring. There is a sharp jump in the vertical between the two stirring regimes and this gives rises to a quasi-horizontal tropopause at higher latitudes.
Analysis of the transport properties of isentropic velocity fields from observational datasets, using the 'effective diffusity' diagnostic (work in collaboration with E. Shuckburgh), has clearly shown the tropopause as a partial barrier to transport on isentropic surfaces and revealed its vertical structure and seasonal evolution. The definition of the tropopause as a transport barrier, e.g. through effective diffusivity, is argued to be the most general and natural definition and is contrasted to more conventional definitions such as by a particular value of potential vorticity.

JSM26/W/30-B1 1110

NONLINEAR INTERACTION OF SYNOPTIC-SCALE ROSSBY WAVES AND THE GEOGRAPHIC DISTRIBUTION OF LATERAL TRANSPORT CHANNELS IN THE LOWERMOST STRATOSPHERE

HORINOUCHI, T (Department of Atmospheric Science, University of Washington, Seattle, Washington 98195-1640 USA, email: horinout@atmos.washington.edu)

The equatorial westerly duct over the central and eastern Pacific, where the upper tropospheric wind is westerly due to the Walker circulation, is known to allow cross-equatorial propagation of synoptic-scale Rossby waves. By using the middle atmosphere version of the NCAR CCM3 GCM, synoptic scale waves are shown to vigorously propagate to reach the equator through the stratospheric tail of the Pacific westerly duct. Similar propagation is also active though the other westerly duct over the Atlantic. The interaction between these waves and the Walker circulation creates an interesting east-west asymmetry of the potential vorticity (PV) anomalies flanking the westerly flow of the ducts. While persistent wave breaking blurs the PV gradient on west side of an anomaly, the gradient is intensified on the east side. The result is an opening of a PV window which allows airmass exchange between the tropics and the subtropics. This exchange is explained theoretically and demonstrated with a barotropic model. Trajectory calculations over a boreal winter reveal that the lateral transport between the tropics and the subtropics in the lowermost stratosphere is confined to the vicinity of the westerly ducts especially in the northern hemisphere. On the west-side of the PV anomalies are channels for transport from higher to lower latitudes, while on the east side are those from lower to higher latitudes. These features are consistent with the time-averaged flow, the geographical distribution of wave breaking, and the typical time-dependent flow pattern associated with breaking.

JSM26/W/22-B1 1130

STRATOSPHERIC INFLUENCE ON TROPOPAUSE HEIGHT

John THUBURN and George C Craig (Department of Meteorology, University of Reading, Whiteknights, Reading, RG6 6BB, UK, email: swsthubn@met.rdg.ac.uk)

Assuming an approximate balance between absorption of thermal IR radiation upwelling from the troposphere and local emission near the tropopause leads to a minimal quantitative model relating tropopause height to other factors such as tropospheric lapse rate and surface temperature. This minimal model, however, neglects solar heating and dynamical warming or cooling near the tropopause. An extended version of the minimal model including these non-IR warming processes will be presented. It predicts a sensitivity of tropopause height to non-IR warming of a few km per (K/day), with positive warming leading to a lower tropopause. Sensitivities comparable to this are found in GCM experiments in which imposed changes in the ozone distribution or in the driving of the stratospheric residual mean circulation lead to changes in tropopause height.

JSM26/W/32-B1 1150

DIAGNOSING STRATOSPHERE-TROPOSPHERE EXCHANGE

Andrew GETTELMAN and Adam H. Sobel, (Department of Atmospheric Sciences, University of Washington, Seattle, WA, USA, email: andrew@atmos.washington.edu)

This study discusses the direct diagnosis of stratosphere-troposphere exchange using different methods. The method introduced by Wei (1987) is applied to the GEOS-1 assimilated data set. A global picture of stratosphere-troposphere exchange for three complete years is presented, from the synoptic scale to the monthly averaged global flux. The same data is also used to derive the net stratosphere-troposphere exchange using monthly averaged mass budgets. We make a detailed comparison with the results of other studies using the same methods and different data sets, as well as comparisons with other methods of estimating stratosphere-troposphere exchange. Sensitivity tests and theoretical considerations indicate that the instantaneous two-way exchange may be significantly exaggerated by the Wei method, due to its being rather sensitive to the noise that is invariantly present in observed or assimilated data sets. The method becomes somewhat better conditioned as the results are more heavily averaged, but this also reduces the method's ability to diagnose two-way exchange. Additionally, when the flux across various surfaces is averaged over the globe and the entire year, the result implies unrealistically large imbalances in the annually averaged mass budget of the stratosphere. This could be caused by modest biases in the model used to perform the data assimilation. Since pure model simulations have an internal dynamical consistency that is lacking in observed or assimilated data sets, the analysis appears to explain the fairly large discrepancies between the two way fluxes obtained in studies using models and assimilated data sets. It may also explain the discrepancies between the net fluxes obtained by the Wei method and those obtained by other methods.

JSM26/E/22-B1 1210

SEASONAL VARIABILITY OF MIDDLE LATITUDE OZONE IN THE LOWERMOST SRATOSPHERE DERIVED FROM PROBABILITY DISTRIBUTION FUNCTIONS

R B ROOD, M C Cerniglia, A R Douglass, L C Sparling, J E Nielsen (NASA's Goddard Space Flight Center, Greenbelt MD, 20771, email: rrood@dao.gsfc.nasa.gov)

We present a study of the distribution of ozone in the lowermost stratosphere with the goal of understanding the relative contribution to the observations of air of either distinctly tropospheric or stratospheric origin. The air in the lowermost stratosphere is divided into two population groups based on Ertel's potential vorticity at 300 hPa. Conditional probability distribution functions are used to define the statistics of the mix from both observations and model simulations. Two data sources are chosen. First, several years of ozonesonde observations are used to exploit the high vertical resolution. Second, observations made by the Halogen Occultation Experiment [HALOE] on the Upper Atmosphere Research Satellite [UARS] are used to understand the impact on the results of the spatial limitations of the ozonesonde network. Despite the differences in spatial and temporal sampling, the probability distribution functions are similar for the two data sources. Comparisons with the model demonstrate that the model maintains a mix of air in the lowermost stratosphere similar to the observations. The model also simulates a realistic annual cycle. By using the model, possible mechanisms for the maintenance of mix of air in the lowermost stratosphere are revealed.

LONGITUDINAL VARIATIONS OF THE TROPOPAUSE STRUCTURE IN TROPICS REVEALED BY THE GPS OCCULTATION DATA (GPS/MET)

Toshitaka TSUDA and Masahiro Nishida (Radio Atmospheric Science Center, Kyoto University Uji, Kyoto 611-0011, Japan, email: tsuda@kurasc.kyoto-u.ac.jp, nishida@kurasc.kyoto-u.ac.jp)
Christian Rocken and Randolph H. Ware (GPS/MET Project, GPS Science and Technology (GST) Program, UCAR, Boulder, CO 80307-3000, email: rocken@unavco.ucar.edu, ware@unavco.ucar.edu)

Temperature profiles in the upper troposphere and stratosphere have been obtained by means of a radio occultation observation of GPS (Global Positioning System) signals (GPS/MET; GPS Meteorology) during April 1995 and February 1997. The GPS/MET profiles have been found to resolve detailed temperature structure, including sharp inversions and the step-wise increase of the temperature gradient near the tropical tropopause. Taking advantage of the global coverage of the GPS/MET data, we have investigated the longitudinal distribution of the tropopause height and the minimum temperature. The results have strongly suggested that GPS/MET have significant potential to contribute to weather prediction and climate change studies.

HIGH-RESOLUTION MEASUREMENTS AND MODELLING OF A SUMMER-TIME TROPOPAUSE FOLD

Andrew O. LANGFORD (NOAA Aeronomy Laboratory, 325 S. Broadway, R/E/AL6, Boulder, Colorado 80303, email: langford@al.noaa.gov) Stephen J. Reid (National Research Council, Washington, DC and NOAA Aeronomy Laboratory, email: sreid@al.noaa.gov) Jean-François Lamarque (National Center for Atmospheric Research, PO Box 3000, Boulder, Colorado 80307, email: lamar@acd.ucar.edu)

Ground-based lidar measurements of ozone and aerosol backscatter vertical profiles above Fritz Peak Observatory near Boulder, Colorado (39.9° N,105.3°W) are used in conjunction with radiosonde profiles and satellite water vapor imagery to investigate the structure of a stratospheric intrusion over the western United States on July 11-14, 1997. A high-resolution transect of the equatorward-sloping fold is constructed from 2-minute profiles obtained over nearly 24 hours of continuous lidar operation. These data provide a highly detailed view of the cross-sectional structure of the southward sloping fold and show evidence of small-scale mixing of the intrusion with the surrounding tropospheric air. The observations are compared with potential vorticity analyses obtained from ECMWF data and with model output from the NCAR MM5 mesoscale model.

JSM26/W/27-B1 1440

EVIDENCE OF EXCHANGE BETWEEN THE TROPOSPHERE AND STRATOSPHERE IN THE REGION OF THE SUBTROPICAL JET STREAM

C. Timmis, G.Vaughan (Physics Department, University of Wales, Penglais Hill, Aberystwyth, UK, SY23 3BZ. email: crt@aber.ac.uk, gxv@aber.ac.uk), E.Cuevas (INM, email: ecuevas@inm.es), Z. Xiangdong (Chinese Meteorlogical Administration, China. email: tangj@public.intercom.com.cn)

The ECMWF T106 31 level model analyses indicates the presence of potential vorticity layering in the latitude band of 30N - 40N. This layering occurs between the isentropic levels of 360K - 380K, which lies above and to the north of the subtropical jet wind maxima (350K). Ozonesondes launched within the subtropical region and in particular from Japan are used to determine whether this feature is a real atmospheric phenomenon. To further verify these results, radiosonde profiles are used to detect this feature as layering in static stability. Results indicate that this layering becomes greatest during the spring when the strength of the subtropical jet stream is strongest and thus suggests that the jet stream may be instrumental in the development of this layering and thus possibly may contribute to irreversible mixing between the stratosphere and troposphere.
During July 1996 Tenerife (28.03N, -16.34E) and Xining (36.43N, 101.45E) launched 21 and 27 ozonesondes respectively. Both of these stations are sub-tropical during the summer months and between the isentropic levels of 340K - 400K the increase of ozone is gradual and no clear ozone tropopause is present. The ozonesondes and the model analyses are used to determine the recent origins of the air in the subtropical upper troposphere and lower stratosphere during the summer months. Trajectory analyses indicates that the Asian summer monsoon is important in the subtropical dynamics during the summer.

JSM26/W/07-B1 1500

INTERCOMPARISON OF MOZAIC O3 DATA WITH A CTM: SENSITIVITY TESTS

Hubert Teyssedre, Martyn Chipperfield, Kathy Law & Paul-Henri Plantevin (University of Cambridge, Department of Chemistry, Lensfield Road, Cambridge, CB2 1EW, UK,
email: hubert.teyssedre@atm.ch.cam.ac.uk, Telephone No: +44-1223 336 524, Fax No: +44-1223 336 362)

An ozone tracer has been included in the TOMCAT chemical transport model and the results compared against in-situ MOZAIC measurements obtained from 5 long-range aircraft. TOMCAT is forced by ECMWF analyses for the year 1996 and uses a simple parametrization for ozone chemistry. An ozone climatology is also prescribed at the top and bottom of the model. The agreement between modelled results and MOZAIC observations is generally good, both in the absolute amount of ozone and the spatial/temporal variability. We have performed several sensitivity experiments to evaluate their effect on the comparison. The effect of the O3 top-boundary condition used in the model, the ozone chemistry parametrization itself and the horizontal resolution have been investigated and the results will be presented.

JSM26/W/20-B1 1520

RANDOM-WALK ESTIMATION OF A MEAN VERTICAL DIFFUSIVITY IN THE STRATOSPHERE USING TURBULENT PATCHES STATISTICS

J. Vanneste(1), J.-R. ALISSE(2) and P. Haynes(3) (1) Dept of Mathematics & Statistics University of Edindurgh Mayfield Road, King's Buildings, Edinburgh EH9 3JZ, UK, (2) Service d'Aeronomie du CNRS BP 3 91371,Verrieres-le-Buisson France, email: alisse@aerov.jussieu.fr (3) DAMTP University of Cambridge Silver Street, CB3 9EW Cambridge UK

Small-scale mixing in the stratosphere is mainly concentrated in isolated patches of three-dimensional turbulence, surrounded by nearly laminar flows. This mixing may lead on average to a diffusive effect in the vertical direction on the large-scale tracer fields. However, the spatially intermittent distribution of the mixing makes the computation of a mean vertical diffusivity somewhat delicate. We present here a theoretical derivation of such a mean vertical diffusivity, following the approach suggested by Dewan (1981) and refined in Vanneste & Haynes (1998). The vertical diffusivity is shown to be related to the variance of the vertical displacements of particles of fluids inside the turbulent patches. Taking into account the observational evidence of imperfect mixing inside the patches, we improve the Dewan's approach by introducing a measure of the mixing efficiency inside each patch. Using high-resolution stratospheric profiles of velocities and temperatures obtained from a balloon-borne experiment, we then estimate this diffusivity, as a function of the hypothetical mean life-time of the patches, which is unknown. For plausible values of the lifetime (between 100 and 100000 s), the mean vertical diffusivity typically lies between 0.01 and 0.02 m*m/s. These values are of the same order as those recently estimated from aircraft measurements.

JSM26/E/14-B1 1540

TRAJECTORY STUDIES OF LOW LATITUDE CROSS TROPOPAUSE TRANSPORT USING MODEL AND ANALYSED WIND FIELDS

D.R JACKSON (UK Meteorological Office, Bracknell, UK, email: drjackson@meto.gov.uk) J. Methven (Dept. of Meteorology, University of Reading, Reading, UK), V.D Pope (UK Meteorological Office, Bracknell, UK)

Simulations made with a 30-level version of the UK Meteorological Office climate model (HadAM3) show that the model simulation of water vapour near the tropical tropopause is in reasonable agreement with Halogen Occultation Experiment (HALOE) observations. These results suggest that HadAM3 realistically simulate troposphere to stratosphere transport in the tropics. Accordingly, a detailed examination of such transport is made using an off-line trajectory model driven by model winds. Trajectories were run for ten boreal winter seasons. For each season, a cluster of parcels were initialised in the upper troposphere over the main regions of tropical deep convection (Indonesia, central Pacific, South America and Africa), and forward trajectories over a five day period were calculated. Parcels from all four regions ascend over areas of deep convection, and in addition most are transported rapidly in the horizontal by the Hadley circulation to the subtropics, where they subside. An exception is the central Pacific trajectories, which tend to get transported eastwards by the Walker circulation. Interannual variability is predominantly associated with El Nino and La Nina events, and is greatest in the Pacific. Comparison of HadAM3 trajectories with similar experiments in which the trajectories are driven by ECMWF re-analyses (ERA) shows reasonable agreement, although the ERA experiments show more troposphere to stratosphere transport in deep convective regions.

JSM26/W/33-B1 Invited 1620

PHOTOCHEMICAL AND TRANSPORT STUDIES IN THE HIGH-LATITUDE SUMMER STRATOSPHERE

D. W. FAHEY, (NOAA Aeronomy Laboratory, 325 Broadway, Boulder CO 80303 USA, email: fahey@al.noaa.gov, Telephone No: 303-497-5277 Fax No: 303-497-5373)

Changes in ozone abundance in the Arctic summer stratosphere were addressed as part of the NASA Photochemistry of Ozone Loss In the Arctic Region in Summer (POLARIS) field campaign in 1997. Significant ozone loss occurs in the Arctic summer stratosphere as a result of continuous solar illumination. A wide variety of stratospheric measurements were made from Alaska with balloon and aircraft platforms between spring and fall of 1997. The measurements included reactive species within the nitrogen, hydrogen, and halogen families; longer-lived species such as N2O, ClONO2, and O3; and aerosol size and number. The data have been used along with photochemical models to address the partitioning within the reactive families and the in situ loss rates of ozone. The use of new laboratory measurements of the reaction rate constants of OH with NO2 and HNO3 improve the comparison of modelled and measured NO2 values. Chemical-transport models were also used to examine the contribution of transport to the observed ozone changes. Results from several of these interpretative studies will be given along with a brief overview of the mission.

JSM26/W/02-B1 1650

MODELLING THE BREAKUP OF THE ANTARCTIC OZONE HOLE

SHUHUA LI, Eugene C. Cordero and David J. Karoly (CRC for Southern Hemisphere Meteorology Monash University, Australia, email: sli@vortex.shm.monash.edu.au)

Understanding the distribution and evolution of stratospheric ozone is important for assessing the springtime break-up of the Antarctic ozone hole. A three-dimensional chemical transport model developed at the Co-operative Research Centre for Southern Hemisphere Meteorology is used to study stratospheric constituent distribution and transport. The model is driven by winds from the GASP (Global Assimilation and Prediction system, Bureau of Meteorology, Australia) global analyses, while chemical processes are parameterised using production and loss rates calculated from a two-dimensional photochemical model. A case study for October 1994 is presented to demonstrate model performance in simulating the vortex structure and ozone evolution in the Southern Hemisphere. Preliminary results indicate good correspondence between modelled ozone fields and observations during the springtime break-up of the polar vortex over Antarctica. Mass flux calculations in the lower stratosphere and upper troposphere will be shown to quantify the exchange rates between the polar vortex and mid-latitudes, as well as the tropical/mid-latitude exchange.

JSM26/W/36-B1 1710

MIDDLE ATMOSPHERIC TRANSPORT PROPERTIES OFASSIMILATED DATASETS

STEVEN PAWSON (1) and Richard Rood (2) (1)USRA, NASA GSFC, Code 910.3, Greenbelt MD 20771, USA. email: pawson@polska.gsfc.nasa.gov (2)NASA GSFC, Code 910.3, Greenbelt MD 20771, USA

One of the most compelling reasons for performing data assimilation in the middle atmosphere is to obtain global, balanced datasets for studies of trace gas transport and chemistry. This is a major motivation behind the Goddard Earth Observation System-Data Assimilation System (GEOS-DAS). Previous studies have shown that while this and other data assimilation systems can generally obtain good estimates of the extratropical rotational velocity field, the divergent part of the dynamical field is deficient; this impacts the 'residual circulation' and leads to spurious trace gas transport on seasonal and interannual timescales. These problems are impacted by the quality and the method of use of the observational data and by deficiencies in the atmospheric GCM. Whichever the cause at any place and time, the 'solution' is to introduce non-physical forcing terms into the system (the so-called incremental analysis updates); these can directly (thermal) or indirectly (mechanical) affect the residual circulation. This paper will illustrate how the divergent circulation is affected by deficiencies in both observations and models. Theoretical considerations will be illustrated with examples from the GEOS-DAS and from simplified numerical experiments. These are designed to isolate known problems, such as the inability of models to sustain a quasi-biennial oscillation and sparse observational constraints on tropical dynamics, or radiative inconsistencies in the presence of volcanic aerosols.

JSM26/W/23-B1 1730

CHAOTIC MIXING IN QUASI-PERIODIC FLOWS OF AN IDEALIZED CIRCUMPOLAR VORTEX OF THE STRATOSPHERE

Ryo Mizuta and Shigeo YODEN (both at Department of Geophysics, Kyoto University, Kyoto, 606-8502, Japan, email: yoden@kugi.kyoto-u.ac.jp)

A high-resolution two-dimensional spherical model is used to investigate the fundamental process of large-scale horizontal mixing in and out of the circumpolar vortex in the winter stratosphere. Concept and analysis method of the chaotic mixing, which were first introduced to geophysical flow by Pierrehumbert(1991) with a simple kinematical model, are applied to some quasi-periodic and non-periodic solutions obtained in the dynamical model. Ishioka and Yoden(1995) obtained quasi-periodic and non-periodic solutions in an idealised stratospheric model of two-dimensional non-divergent fluid with zonally symmetric zonal-flow forcing and Newtonian-type damping. The forced flow is a barotropically unstable polar-night jet and the obtained solutions mimic the eastward travelling planetary waves in the southern hemisphere upper stratosphere. Some of the typical solutions are analysed in this study.
Poincare sections for several particles are used to distinguish the regions of chaotic mixing. Dispersion of lots of particles placed in an limited area in the chaotic region shows the

characteristics of two-dimensionalisation from large scales; fractal dimension (correlation dimension) is estimated to describe the time dependence of the mixing process quantitatively. Stagnation points in the stream function field in the co-moving frame with the dominant wave play an important role in the chaotic mixing. Finite-time Lyapunov stability analysis is also done to obtain quantitative confirmation of the role.

WATER VAPOR AND CLOUDS

JSM26/L/01-B2 Invited 0930

WATER VAPOR IN THE UPPER TROPOSPHERE AND LOWER STRATOSPHERE IN THE CONTEXT OF DEEP CONVECTION

Dieter KLEY (Institut fur Chemie und Dynamik der Geosphare, Forschungszentrum Julich D-52425 Julich, Germany, email: d.kley@fz-juelich.de)

Water vapor in the upper troposphere and lower stratosphere (UT/LS) is of fundamental importance for atmospheric chemistry and the radiative budget of the atmosphere. The fact that the water substance occurs in all three phases, gas, liquid, solid, together with a strong temperature dependence of its vapor pressure, causes water vapor to be extremely variable in the troposphere and to exhibit a strong negative gradient in the vertical. UT/LS water vapor is difficult to measure with high-precision, accuracy and low uncertainty. The fundamental question, which is not answered to the presence, is whether the control of atmospheric water is by thermodynamic or dynamical principles.
The presentation will review published measurements of water vapor in the tropopause region and in the LS, both from in-situ and satellite instrumentation in the context of data precision and accuracy. Long-term measurements of water vapor in the stratosphere by frost point hygrometers reveal that the concentration in the LS increases at a higher rate than can be explained by methane oxidation alone.
We will also report on H2O measurements in the UT from instrumentation on board of commercial aircraft from the ongoing MOZAIC project from which four years of water vapor and ozone data are available. The analysis that will concentrate on the tropical UT over the Atlantic ocean and the extra tropical North Atlantic region shows pronounced seasonal variabilities of mixing ratio and relative humidity.
Using simultaneously measured ozone mixing ratios as a quasi-conservative tracer of deep convection we will discuss deep convection in the context of moistening the UT and transport of water vapor to the stratosphere.

JSM26/E/10-B2 1000

ON A SOURCE OF ERROR IN THE MEASUREMENT OF UPPER TROPOSPHERIC HUMIDITY BY THE FLUORESCENCE WATER VAPOUR SENSOR ONBOARD THE BRITISH C-130 AIRCRAFT

Iphigenia KERAMITSOGLOU, John E. Harries, David J. Colling (Department of Physics, Blackett Laboratory, Imperial College of Science Technology and Medicine, London SW7 2BZ, UK. email: i.keramitsoglou@ic.ac.uk, j.harries@ic.ac.uk, d.colling@ic.ac.uk), Rod A. Barker and John S. Foot (Meteorological Office, Meteorological Research Flight, Building Y46 DRA, Farnborough, Hants GU14 6TD, UK. email: ralbarker@meto.gov.uk, jsfoot@meto.gov.uk)

Water vapour is the most important greenhouse gas in the cloud-free atmosphere. Therefore, the ability to assess and predict any climate change strongly depends on accurate observations of water vapour and its representation in models. However, water vapour's extreme variability on all time and space scales makes accurate measurement a very complicated and difficult task.
The purpose of this study is to analyse and evaluate the performance of the Fluorescence Water Vapour Sensor (FWVS) onboard the British C-130 aircraft. The sensor was built by the Meteorological Research Flight, UK Met. Office, to fulfil the need of fast and accurate in-situ water vapour measurements in the upper troposphere. However, inter-comparisons of coincident flight data with a frost-point hygrometer have shown that the FWVS systematically overestimates humidity by 10-20%, depending on pressure, in comparison to the frost-point instrument. An in depth analysis of the possible sources of error has led to the design of laboratory experiments to better characterise the FWVS instrument. These included the measurement of the source spectrum, and of the effective oxygen absorption cross-section using the sensor itself. Most importantly, though, an original model of the FWVS has been developed, which proved to be a powerful tool in understanding the sensor's behaviour. The laboratory experiments confirmed the emission of wavelengths other than Lyman-alpha by the FWVS source. This result along with the outcome of the sensitivity tests carried out using the new model revealed that a source of error that accounts for up to half of the observed differences is the contaminated lamp spectrum and the underestimation of the oxygen absorption cross-section in the post-flight data processing.

JSM26/E/02-B2 1020

WATER VAPOUR TRANSPORT INTO THE LOWER STRATOSPHERE

Antje DETHOF, Alan O'Neill and Julia Slingo (CGAM, Department of Meteorology, University of Reading, RG6 6BB, UK, email: antje@met.rdg.ac.uk)

The climatology of the lowermost stratosphere is not well understood. Tracer distributions in this part of the atmosphere are governed by complicated interactions of dynamical, chemical and radiative processes. In this talk, case studies of isentropic stratosphere-troposphere exchange in the region of the middleworld are presented, and a method is developed, by which isentropic transport of mass and moisture between the tropical troposphere and the extratropical lowermost stratosphere can be quantified.

JSM26/W/37-B2 Invited 1100

CHLORINE ACTIVATING HETEROGENEOUS REACTIONS

Stephan BORRMAN, (Institute for Strathospheric Chemistry, Germany,
email: s.borrman@fz-juelich.de)

Chlorine activating heterogeneous reactions has been suggested to occur on cirrus clouds as well as in layers of enhanced numbers of small particles, on supercooled cloud droplets and on background aerosol in the tropopause region. The high water content, low temperatures, and slow photochemical recovery times near the tropopause make this region susceptible to heterogeneous processing, just as the extreme cold temperatures over the poles do for dryer air at higher altitudes. Detailed model studies by Solomon et al., 1997, and Hendricks, 1997, revealed that heterogeneous chemistry on the aerosol in the tropopause region could significantly contribute to the ozone depletion in northern mid-latitudes. Input for the model calculations by Solomon et al., 1997, are climatological SAGE II satellite observations of cirrus cloud optical depths and cloud occurrence frequencies from 1988 and 1989, i.e. years of relative volcanic quiescence. Because of variations in observed cloud occurrence frequency and in photochemical and dynamical time scales, the presence of cirrus clouds likely has its largest effect on ozone near the northern hemispheric mid-latitude tropopause. There the low background ClO mixing ratios could be enhanced by heterogeneous reactions by factors of 30, according to the model results. Due to the lack of extended ClONO2, HCl, and ClO observations the processes discussed in this presentation still have to be considered as hypothetical. Measurements of clouds, subvisual cirrus, and recent developments are also discussed in this context.

JSM26/W/04-B2 1130

RETHINKING REACTIVE HALOGEN BUDGET IN TROPOSPHERE AND LOWER STRATOSPHERE: INPLICATIONS FOR MID-LATITUDE OZONE DEPLETION AND DIAGNOSTICS OF CONVECTIVE TRANSPORT

VICTOR L. DVORTSOV (1,2), Marvin A. Geller (3), Susan Solomon (1), Sue M. Schauffler (4), Elliot L. Atlas (4), and Donald R. Blake (5) (1) Co-operative Institute for Research in Environmental Sciences, University of Colorado, Boulder. (2) NOAA, Aeronomy Laboratory, Boulder, Colorado.(3) State University of New York at Stony Brook, Stony Brook, New York.(4) National Center for Atmospheric Research, Boulder, Colorado (5) Department of Chemistry, University of California, Irvine, California

Using bromine species as an example, we use models and observations to show that short-lived halocarbons are able to maintain significant concentration of reactive halogens (e.g., BrO) in the troposphere. Moreover, as evident from both observations and our modeling, at least some of these short-lived source species (e.g., bromoform, CHBr3) are present in non-negligible amounts in the upper troposphere. These findings contradict the current beliefs that the short-lived compounds are completely removed in the troposphere, the products being rained out. Therefore, as our modelling further shows, contribution from short-lived halocarbons significantly increases the amount of reactive bromine in the lowermost stratosphere, thus playing an important role in the ozone photochemistry in this region. Depending on the atmospheric humidity and the partitioning of inorganic chlorine, the contribution of bromoform alone increases the model estimates of the ozone trends in the mid-latitude lowermost stratosphere for 20 to 50\%. This work has other important implications. As well known, short-lived gases are good tracers of convective transport. For instance, 222 Radon is commonly used for diagnostics of climate model convective parameterizations. However, the utility of 222 Radon for these purposes is limited to the continental convection, as the only source of this gas is ice-free land. On the other hand, the primary source of bromoform and some other short-lived organic halocarbons is ocean, which makes these species useful for diagnostics of the maritime convection. We discuss our implementation of such on-line diagnostics using bromoform in the NCAR Community Climate Model (CCM) version 3.6.

JSM26/W/31-B2 1150

FACTORS AFFECTING THE FORMATION OF POLAR STRATOSPHERIC CLOUDS

H.M. STEELE (Dept. of Chemistry, University of Cambridge, CB2 1EW, UK. email: Helen.Steele@atm.ch.cam.ac.uk), K. Hoppel (Naval Research Laboratory, Washington DC 20375. e-mail: hoppel@poamb.nrl.navy.mil), K. Drdla (NASA Ames Research Center, Moffett Field, CA 94035. e-mail: katja@aerosol.arc.nasa.gov), R.M. Bevilacqua (Naval Research Laboratory, Washington DC 20375. e-mail: bevilacqu@map.nrl.navy.mil), R.P. Turco (Dept. of Atmospheric Sciences, UCLA, Los Angeles, CA 90095. e-mail: turco@atmos.ucla.edu).

The formation and development of polar stratospheric clouds are examined in case studies using a comprehensive microphysical model applied along air parcel trajectories. During Antarctic winter specific parcels are sampled over a time span of several days using extinction data from the POAM II satellite instrument. The observed evolution of polar stratospheric cloud spectral opacity is compared to predictions from model simulations. Hence, aerosol growth and decay in response to changing environmental conditions can be observed and interpreted. In some instances good agreement between observations and predictions has been obtained over periods of many days. This analysis suggests that temperature history has a possible role in cloud formation. In order to quantify this role, a statistical study of polar stratospheric cloud formation over three Antarctic winters is carried out using POAM II aerosol observations and back trajectories. Aerosol data are fitted to a theoretical model for cloud growth to retrieve best fit parameters for ambient water vapour concentration and the aerosol sulphate content, and to deduce the rate of dehydration and denitrification throughout the polar winter. An analysis of variance is used to assess the importance of factors such as cooling rate, time spent below the nitric acid trihydrate condensation temperature, and exposure to temperatures below the ice frost point, in the formation of clouds.

JSM26/W/16-B2 1210

CONVECTION, CHEMISTRY AND AEROSOLS AT THE TROPICAL TROPOPAUSE: THE APE-THESEO MISSION

ROB MACKENZIE(1), Leopoldo Stefanutti(2), Stefano Balestri(3), Stephan Borrmann(4), Marco Cacciani(5), Ken Carslaw(6, 12), Teo Georgiadis(7), Giorgio Giovanelli(7), Vyacheslav Khattatov(8), Valentin Mitev(9), Piero Mazzinghi(10), Kevin Noone(11), Thomas Peter(12), Wolfgang Renger(13), Vladimir Rudakov(8), Johan Ström(11), Guido Visconti(14), Michael Volk(15), and Vladimir Yushkov(8). APE-THESEO is the Airborne Platform for Earth Observation (APE) contribution to the Third European Stratospheric Experiment on Ozone (THESEO). APE is the facility that manages scientific missions of the Russian high-altitude aircraft, the M-55 Geophysica. The Geophysica is an exciting new platform, well suited to the study of mesoscale processes occurring from the tropopause to 21 km altitude. We describe first results from the deployment of the Geophysica to the tropical tropopause in February-March 1999.
The objectives of APE-THESEO are to measure cloud, aerosol, and trace gas distributions close to, and above, intense tropical convection, in order to understand the processes governing stratospheric dehydration, aerosol formation, and upper tropospheric-lower stratospheric transport. An important additional aspect of APE-THESEO is the collaboration with the Indian Ocean Experiment (INDOEX), which aims to investigate the effect of aerosols on climate in the Indian Ocean.

Tuesday 27 July PM

CHEMISTRY AND TRANSPORT

JSM26/L/02-B2 Invited 1400

CHEMISTRY IN THE UPPER TROPOSPHERE AND LOWER STRATOSPHERE

R.A.COX (Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, CB2 1EW, UK.)

Whilst the gas phase chemistry responsible for the catalytic destruction of ozone in the photochemically controlled regions of the upper stratosphere is now reasonably well known, there remains many interesting problems in the chemistry of the lower stratosphere and upper troposphere.
New observations point to higher fractions of radical species relative to reservoir species in the lower stratosphere, the most extreme examples being in the Polar vortices where essentially all the stratospheric is Cl is converted to ClO (or its weakly bound dimer Cl2O2). The causes of these perturbations are heterogeneous reactions in which stable reservoirs are converted to photolabile radical sources. These processes may also be important in the upper troposphere. Heterogeneous reactions occur on solid ice and NAT particles and on liquid sulphuric acid aerosols at low temperatures. Laboratory studies have provided much new information on the kinetics of these reactions and a picture is now emerging of the key physico-chemical factors affecting reactivity. There have recently been improved laboratory data for the rates and mechanism of several gas phase reactions that are important in the lower stratosphere and upper troposphere.
The presentation will survey recent developments in knowledge of the chemistry of the lower stratosphere and upper troposphere, relevant for ozone loss. Some new kinetics data from our laboratory relating to iodine and bromine chemistry will be used to illustrate the coupled role of gas phase and heterogeneous chemistry in the lower stratosphere.

JSM26/E/05-B2 1430

DETAILED ATTRIBUTION OF NITROGEN OXIDE SOURCES DETERMING UPPER TROPOSPHERIC CHEMISTRY IN SONEX

Robert B CHATFIELD (Earth Science/245-5, NASA Ames Research Center, Moffett Field, California 94035 USA, email: chatfield@clio.arc.nasa.gov) Zitian Guo (Research Foundation, San Jose State University,San Jose, Calfornia, USA, email: zguo@clio.arc.nasa.gov) Yutaka Kondo (Solar Terrestrial Environment Laboratory, Nagoya University, Honohara, Aichi 442 Japan,
email: kondo@stelab.nagoya-u.ac.jp)

We describe the sources of active nitrogen oxides, NOx, in the upper troposphere over the North Atlantic for the intensive study period of SONEX, the Subsonic Assessment Program Ozone and Nitrogen Oxide Exeperiment. Such NOx is central in determining the delicate balance determining radiatively important upper tropospheric ozone. Perhaps surprisingly, we find that lightning was frequently a dominant source of NOx even in this late fall period, October-November, 1997. Lightning NOx in the North Atlantic frequently had sources in from maritime lightning, extending thousands of kilometers off the North American Coast and in the tropical waters of the Gulf and Caribbean. Aircraft and surface sources on NOx were also important. Aircraft NOx was often more significant for the uppermost troposphere, and surface NOx for the middle troposphere. The NOx/O3 ratio associated with stratospheric injections was highly variable.
Our conclusions derive primarily from a tracer model following NOx with labeled origin in a model driven by hourly winds and cloud motions. A rich variety of transport processes was revealed. These were derived from MM5 synoptic model reconstructions which was nudged to follow the European Centre analyses. These were compared to the measurements of NOx implied by the NO measurements made aboard the NASA DC-8 by the Kondo group as processed by the SONEX data team at Harvard University. Measurements of ozone, hydrocarbons, peroxides, and particles made on the aircraft helped confirm attributions that we made. Aircraft NOx accounted for ~30% of upper tropospheric NOx. Our ongoing simulations and comparisons will allow us to check this attribution and extend it from the DC-8 flight track to the whole North Atlantic.

JSM26/L/03-B2 1450

CHANGING STRATOSPHERIC CIRCULATION, THE GREENHOUSE EFFECT AND OZONE LOSS

Hans-F. GRAF and Judith Perlwith, Max-Planck-Institute for Meteorology Bundesstr. 55, D-20146 Hamburg, Germany, email: graf@dkrz.de

Stratospheric climate has changed considerably during the last decades. After elimination of volcanic effects a global mean decreasing lower stratospheric temperature consistent with increased greenhouse effect is detectable. In higher northern latitudes this trend is strongest in spring (March). At this time the reduction in stratospheric ozone is also strongest. However, the trend patterns of stratospheric temperature and geopotential match the ozone trends in March not as well at polar latitudes as in middle latitudes.
Analysis of model runs with prescribed observed ozone changes and with prescribed increased greenhouse gas concentration show that the observed changes cannot be explained by these forcings individually. While reduced stratospheric ozone is responsible for cooling of the stratosphere beginning in April on the northern hemisphere, it does not explain the strengthening of the winter polar vortex. This, according to the results of the greenhouse gas experiment, may be due to initial warming of the troposphere in low latitudes which strengthens the hemispheric geopotential gradient and thus also the polar winter vortex. For realistic forcing the modeled individual effects are weaker than observed. The observed stratospheric changes therefore are suggested to result from a combination of natural and anthropogenic contributions mainly in the troposphere. Initial strengthening and cooling of the polar vortex changes the structure of ultralong planetary waves in the troposphere (including the stabilization of the North Atlantic Oscillation in its positive phase, i.e. with strong Iceland trough and Azores high). This determines the stratospheric ozone concentration mainly in middle latitudes. Inside the intensified vortex cooling sets the precondition for the formation of PSCs and ozone destruction by heterogeneous chemistry in early spring. The reduced ozone leads to negative temperature anomalies that help keeping the vortex stable.

JSM26/W/34-B2 1510

THE STRATOSPHERE-TROPOSPHERE EXCHANGE SEEN FROM THE SOWER/PACIFIC RESULTS

Fumio Hasebe (Ibaraki University, email: hasebe@mito.ipc.ibaraki.ac.jp), Holger Voemel (University of Colorado/CERES, email: hvoemel@cmdl.noaa.gov), MASATO SHIOTANI (Hokkaido University, email: shiotani@ees.hokudai.ac.jp), Noriyuki Nishi (Kyoto University, email: nishi@kugi.kyoto-u.ac.jp), Samuel Oltmans (NOAA/CMDL, email: soltmans@cmdl.noaa.gov), Toshihiro Ogawa (NASDA/EORC, email: t_ogawa@eorc.nasda.go.jp) Kenneth Gage (NOAA/AL, email: kgage@al.noaa.gov)

Two observational campaigns at San Cristobal, Galapagos (0.90S, 89.62W) as part of the Soundings of Ozone and Water in the Equatorial Region (SOWER)/Pacific mission, have been successfully carried out in March/April and September 1998 and profiles of ozone and water mixing ratio together with those of temperature were obtained. The former (latter) period corresponds to high (low) wave activity in the Northern middle and high latitudes, when extratropical pumping in the stratosphere leads to a higher (lower) and colder (warmer) tropopause in the tropics, though the two periods were highly affected by the end of the very strong El Nino and the condition of the developing cold phase, respectively.
The temperature and ozone profiles show fluctuations typical of those in profiles at other locations in the tropics. These features suggest that wave activity may be responsible for local mass exchange between the troposphere and stratosphere, although that cannot be determined from these data alone. The tropopause is generally colder in March than in September as expected, but its altitude is also likely modified by the waves mentioned above. It is also found that the presence of the upward propagation of the seasonal water vapor signal through the stratosphere, referred to as the tape recorder effect, though profiles are needed at other times of the year for the better definition.

UPPER TROPOSPHERIC PHOTOCHEMISTRY: SOME FINDINGS FROM RECENT AIRBORNE STUDIES

H. SINGH (NASA Ames Research Center, MS 245-5, Moffett Field, CA 94035-1000, USA, email: hsingh@mail.arc.nasa.gov); W. Brune, D. Tan and I. Faloona (Penn State Univ., PA), Y. Kondo (Nagoya Univ., Japan), L. Jaegle and D. Jacob (Harvard Univ., MA), D. Davis (Georgia Institute of Technology, GA), B. Heikes (U. Rhode Island, RI), H. Schlager (Wessling, Germany)

Recent airborne missions such as SONEX (SASS Ozone and NOx Experiment) and POLINAT (Pollution in North Atlantic Tracks) have provided substantial new data from the upper troposphere/lower stratosphere region of the atmosphere. For SONEX, new state of the art instrumentation has been used to provide measurements of a complete suite of reactive nitrogen (NOx, PAN, PPN, HNO3, alkyl nitrates, NOy, and aerosol nitrate), reactive hydrogen (OH, HO2, H2O, peroxides, alcohols and carbonyls), and tracer (CO, C2Cl4, NMHCs) and O3 measurements. These observational data are complemented by a suite of meteorological products that are useful for interpreting dynamical features of the atmosphere. With these observations and tools, an attempt is made to assess the sources and sinks of a number of key oxygenated species in the troposphere. Factors controlling the rates of ozone production (NOx, HOx radicals etc.) are examined. Atmospheric observations are compared with photochemical models to assess our knowledge of the photochemistry of the upper troposphere and evaluate the potential impact of anthropogenic perturbations on NOx and Ozone. Areas of significant uncertainties are identified. These studies have the potential to greatly enhance our knowledge of the upper tropospheric photochemistry.

GRAVITY WAVES AND TURBULENCE AROUND THE TROPOPAUSE ABOVE ABERYSTWYTH

E.G. PAVELIN and J.A. Whiteway (Department of Physics, University of Wales, Aberystwyth, Ceredigion, SY23 3BZ, U.K. email: egp98@aber.ac.uk)

The U.K. M.S.T. radar located near Aberystwyth in western Wales has been used to study gravity waves and turbulence in the troposphere and lower stratosphere. Radar velocity measurements have been used to investigate the velocity spectrum of the wind field in regions of varying wave activity and turbulence. Of particular interest are areas of turbulence associated with wave breaking at critical layers, which may be identified with layers of enhanced spectral width. The general objective is to determine whether this turbulence causes significant mixing of constituents (such as ozone and water vapour) near the tropopause; and whether this mixing is significant for exchange between the stratosphere and troposphere.

JSM26/E/19-B2 Poster 1700-02

THE DYNAMICS OF AIR MASSES SEGREGATED FROM THE SOUTHERN HEMISPHERE POLAR VORTEX IN THE LOWER STRATOSPHERE

Marcelo Behar, Pablo O. CANZIANI (Grupo de Atmosfera Media, Departamento de Ciencias de la Atmosfera, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Pabellon II, Ciudad Universitaria, 1428 Capital Federal, ARGENTINA)

The dynamics of the southern polar vortex in the lower stratosphere and of the segregated air masses from the vortex edge are studied, with a special interest on the local impacts to the ozone layer. The air masses the break off the edge of the polar vortex can transport ozone-poor air, with physical and chemical characteristics similar to those found in the inside of the vortez up to latitudes close to 40-35 degrees south. Even if perturbations that these air masses can generate are not significant from the perspective of the total ozone column, it could be possible that the local impacts to the lower stratosphere be significant enough so as to affect the ozone budget there and in consequence modify the energy balance and the characteristics of the tropopause. In this study the break offs from the polar vortex are analysed using a trajectory analysis code together with chemical tracer satellite data. The results are also compared with total ozone measurements. A number of events that took place over the South Atlantic and over Southern South America are discussed, and their evolution is studied.

HIGH SENSITIVITY OF THE POLAR LOWER STRATOSPHERIC PHOTOCHEMICAL SYSTEM TO VARIATIONS OF THE PARAMETERS AND INITIAL CONDITIONS

A. M. Feigin, I. B. Konovalov, M. Y. Kulikov, and A. Y. MUKHINA (Institute of Applied Physics of Russian Academy of Sciences, 46 Ulyanov Str., Nizhniy Novgorod, 603600, Russia, e-mail: etanya@appl.sci-nnov.ru)

The qualitative non-linear dynamic properties of the polar lower stratospheric photochemical system (PLS PCS) are investigated on the base of the zero-dimensional photochemical basic dynamical model [Feigin, and Konovalov, J. Geophys. Res., 101, 26,023-26,038, 1996 (FK)], which adequately simulates the ozone evolution during the Antarctic ozone hole formation. It is shown that the behaviour of the Antarctic photochemistry is very sensitive to values of concentrations of some chemical species at August, which are considered as initial conditions for our model. The most important result is the high sensitivity of the system to a few parameters: concentration of inorganic chlorine, temperature, surface area of sulphuric aerosol and some others. These results are shown to be a consequence of the nontrivial dynamic properties (NDPs) of PLS PCS [FK; Konovalov, Feigin, and Mukhina, J. Geophys. Res., in press], and are of special interest for forecast of the Antarctic photochemistry evolution. At present the question about the possibility of recovering of ozone abundance in polar area due to expected decrease of the chlorine compounds is widely discussed. It is rather understandable that due to NDPs, return of one parameter to the natural level doesn't necessary lead to return of the system to initial state with the other parameters being different. Possible scenarios of the future evolution of ozone hole are investigated for expected future values of other parameters under an assumption that concentration of inorganic chlorine returns to the value of the beginning of 1980s when the Antarctic ozone hole was absent.

CORRELATION OF OZONE AND PV AND OZONE PREDICTION USING MOZAIC MEASUREMENTS

Olaf MORGENSTERN (Centre for Atmospheric Science, Chemistry Dept., Cambridge University, Cambridge CB2 1EW, UK, email: Olaf.Morgenstern@atm.ch.cam.ac.uk)

Simplified mean ozone analyses are compiled in the equivalent-latitude - potential-temperature space using ozone measurements made within the Measurement of Ozone and Water Vapour by Airbus In-Service Aircraft (MOZAIC) project. The analyses exhibit tropospheric, stratospheric and intermediate tropopause domains. The standard deviations of ozone, relative to the mean, in this parameter space attain maxima south of the subtropical barrier, which is attributed to stratosphere-troposphere exchange. Ozone is inferred from these simplified, two-dimensional representations of ozone for the days following the analyses. It matches measured ozone to a fair degree of accuracy, indicating that in the tropopause region ozone may usefully be described as a function of potential temperature and equivalent latitude, with a seasonal modulation. Differences between inferred and measured ozone appear to be relatively large in regions of low confidence in meteorological analyses.

JSM26/E/04-B2 Poster **1700-05**

THE INFLUENCE OF THE STRATOSPHERIC SULFURIC AEROSOL ON THE NONLINEAR DYNAMIC PROPERTIES OF ANTARCTIC PHOTOCHEMICAL SYSTEM AND THEIR TO RELEVANCE IN THE PROCESSES OF THE ANTARCTIC OZONE HOLE FORMATION

A. M. Feigin, and M. Y. KULIKOV (Institute of Applied Physics of Russian Academy of Sciences, 46 Ulyanov Str., Nizhniy Novgorod, 603600, Russia, email: etanya@appl.sci-nnov.ru)

The influence of heterochemical reactions running on the surface of the stratospheric sulphuric aerosol (SSA) on non-linear dynamic properties (NDPs) of the Antarctic photochemical system (PCS) during winter-spring period is investigated. The minimum value of ozone concentration in the region of its season averaged- maximum (heights 17-18 km) is considered as an indicator of this influence. It is shown that the processes change significantly a phase space of the system. In particular, they lead to the appearance of both an additional equilibrium state, and a stable limit cycle. It was obtained that influence of these "aerosol" phase space objects on ozone concentration behaviour depends significantly on a few control parameters, namely, total surface area of SSA particles, prescribed temperature evolution, non-organic chlorine abundance, and power of both denitrification, and dehydration. It is shown that the "aerosol" NDPs may be in close connection with significant increasing of extent of the Antarctic ozone hole extent in the years following powerful volcanic eruptions (e. g., Mount Pinatubo eruption in1991). An influence of the enhanced SSA level on the NDPs of Antarctic PCS under expected in the future values of other control parameters is analysed. Possible manifestation of these NDPs in the future evolution of Antarctic ozone hole are discussed.

RECONSTRUCTION OF OZONE FIELDS USING PSEUDO-DIABATIC CONTOUR ADVECTION WITH SURGERY

B. JOSEPH (1), F. Lefevre (2), B. Legras (1) (1) Laboratoire de Meteorologie Dynamique du CNRS, 24 rue Lhomond, 75231 Paris, France (2) CNRS Service d'Aeronomie, Universite Pierre et Marie Curie, BP 102, 4 Place Jussieu, 75252 Paris Cedex 05, France

We explore the feasibility of directly reconstructing fine-scale features in ozone fields in the Northern Hemisphere lower stratosphere from the lower resolution daily output of the three-dimensional REPROBUS (reactive processes ruling the ozone budget in the stratosphere) chemistry transport model (CTM) using pseudo-diabatic contour advection with surgery (PCAS). The PCAS technique, which also assimilates tracer fields as an on-line correction to the advected fields, has been demonstrated in our earlier studies with the potential vorticity (PV) fields to give results, which are superior to the usual contour-advection with surgery (CAS) results, both in the extratropical lower stratosphere as well as in the subtropics. In order to illustrate only the major aspects of the reconstruction of ozone fields, we concentrate our study to the 475 K isentropic surface, typical of the lower stratosphere. When chemistry plays a major role in determining the model ozone fields, we also expect PCAS to play a fundamental role in the reconstruction procedure. We examine high-resolution PCAS reconstructions of both passive and reactive ozone fields from the REPROBUS output and attempt to learn more about the filamentary aspect of transport and its role in the ozone depletion process in the northern lower stratosphere. We will also present a performance evaluation of PCAS reconstructions of PV, passive ozone, and reactive ozone fields on 475 K by comparing with the corresponding observed values from ozone profiles collected during the intensive phase of METRO (MEridional TRansport of Ozone in the lower stratosphere) campaign during 1997-98 and 1998-99 winters.

JSM26/W/21-B2 Poster **1700-07**

AGE OF AIR IN THE SLIMCAT CTM: SENSITIVITY TESTS

Hubert Teyssedre & Martyn Chipperfield (University of Cambridge, Department of Chemistry, Lensfield Road, Cambridge CB2 1EW, UK, email: hubert.teyssedre@atm.ch.cam.uk Telephone No: +44 01223 336524 Fax No: +44 01223 336362)

Deducing the stratospheric age of air [Hall et al., 1999] is a powerful tool to diagnose the quality of the transport representation in an atmospheric model. We have included a tracer with a source (linearly increasing in time) in the tropical lower stratosphere in the SLIMCAT chemical transport model (CTM), which is forced by UKMO/UARS analyses. An initial simulation, at low resolution (7.5 x 7.5 degrees) using 1992 analyses, exhibits an age of air which is too old (by up to 3 years at 30 km) in comparison with values derived from atmospheric SF6 measurements (in contrast to many other reported models). To reduce this discrepancy between our CTM and observations, several sensitivity tests have been performed with SLIMCAT. We will discuss the effect of the model horizontal/vertical resolution, the interannual variability of the analyses used to force the model and the effect of two different radiation schemes (MIDRAD and CCM2) used to calculate the vertical motion, on the modelled age of air. Hall et al., J. Geophys. Res., (in press), 1999.

JSM26/E/03-B2 Poster **1700-08**

MULTIPLE EQUILIBRIUM STATES IN THE POLAR LOWER STRATOSPHERIC PHOTOCHEMISTRY

Igor KONOVALOV, Alexander Feigin, and Anna Mukhina (Institute of Applied Physics of Russian Academy of Sciences, 46 Ulyanov Str., Nizhniy Novgorod, 603600, Russia, e-mail: konov@appl.sci-nnov.ru)

Results of our investigations of the polar lower stratospheric photochemical system (PLS PCS) from the point of view of non-linear dynamics are reported. For the investigations the box model of PLS PCS, which includes all the most significant photochemical processes taking place in the polar (both Arctic and Antarctic) lower stratosphere in winter-spring period, and adequately simulates the evolution of the Antarctic ozone hole, has been used. It has been revealed, in particular, that the model can possess simulteneously three equilibrium states (multi-stability) under realistic conditions. Revealing of the origin of this property has allowed to insure that it is not not a consequence of any approximation used in the model but is a property inherent in nature of PLS PCS. It is demonstrated that the multi-stability can provide the qualitatively different scenarious of ozone evolution depending on both initial conditions and parameter values. The analysis of the role of the multi-stability in the Antarctic ozone hole phenomenon has shown that the presence of this property may be accounted for the observed steepness of the ozone destruction at 17-18 km of altitude at the mid of 1980s. The possible applications of the knowledge of the non-linear dynamic properties of PLS PCS for the investigations of behaviour of minor constituents in the Arctic region are discussed.

ION-MOLECULE REACTION SCHEMES FOR IN SITU DETERMINATION OF STRATOSPHERIC HNO3 AND HCL CONCENTRATIONS BY CHEMICAL IONIZATION MASS SPECTROMETRY (CIMS)

A.-M. VAN BAVEL, C. Amelynck, E. Arijs, E. Neefs, D. Nevejans, N. Schoon (Belgian Institute for Space Aeronomy, Ringlaan 3, B-1180 Brussels, Belgium, email: Mieke.VanBavel@bira-iasb.oma.be) V. Catoire, D. Labonnette, G. Poulet, C. Stépien (LPCE-CNRS, 3A, Avenue de la Recherche Scientifique, F-45071 Orléans, France) H.-P. Fink, U. Jenzer, E. Kopp, W. Luithardt (Universität Bern, Sidlerstrasse 5, CH-3012 Bern)

Laboratory measurements (Huey et al. 1995) have shown that CF3O- ions selectively react with several stratospheric minor gases by fluoride transfer. We therefore recently equipped our balloon borne chemical ionization mass spectrometer instrument (MACSIMS) with a new photoelectric ion source producing mainly CF3O- ions. However, flight results obtained with this new ion source revealed that the derivation of trace gas concentrations was complicated by the presence of large amounts of CF3O-H2O (and to a lesser extent CF3O-HF) in the flight spectra. The spectra also indicate that CF3O-H2O and CF3O-HF selectively react with several trace gases (such as HNO3, HCl, ClONO2) by ligand switching, making these ions good CIMS source ion candidates.
In order to adjust the originally proposed fluoride transfer reaction schemes for derivation of HNO3 and HCl concentrations, the gas phase ion-molecule reactions of CF3O-, CF3O-H2O and CF3O-HF with both HCl and HNO3 have been studied at 295 K using our laboratory flowing afterglow apparatus. Rate constants and product ions were determined in the pressure range [0.5-2.4] mbar. Recent HNO3 and HCl mixing ratio height profiles (Gap-Tallard, June 1997) obtained using the adapted reaction scheme are also presented and the usefulness of the applied method is discussed.

MST RADAR AND OZONESONDE OBSERVATIONS OF HIGH-LATITUDE STRATOSPHERE-TROPOSPHERE EXCHANGE

JOHAN ARVELIUS, Dave Hooper, Hans Nilsson, Sheila Kirkwood and Phil Chilson, (Swedish Institute of Space Physics, Box 812, 981 28 Kiruna,Sweden, email: johan.arvelius@irf.se)

The Esrange MST radar (ESRAD) together with ozonesondes has been used to study the high-latitude tropopause as well as other structures giving rise to strong radar echoes. Such other structures include fronts and the borders of stratospheric air extending deep into the troposphere. Ozonesonde data have been used to compare the radar backscatter data with in-situ measurements. It seems from the measurements made so far that two phenomena of importance for stratosphere troposphere exchange can be studied using the MSTradar. One is the characterization of the tropopause, allowing the identification of indefinite tropopause region and troughs, which are likely sites for exchange of stratospheric and tropospheric air. The other phenomenon is the possibility to monitor tongues of stratospheric air extending deep into the troposphere. The radar detects the border between the stratospheric and tropospheric air because of an abrupt change of the radar reflective index, mainly caused by an abrupt change of temperature. Ozonesonde data are required to identify the air-mass as stratospheric, but once identified the air-mass can be monitored by the MST radar.

MODIFIED LAGRANGIAN-MEAN ANALYSIS OF LOW-FREQUENCY VARIATIONS IN THE UPPER TROPOSPHERE OF A SIMPLE GLOBAL CIRCULATION MODEL

Koji Akahori and Shigeo YODEN (both at Department of Geophysics, Kyoto University, Kyoto, 606-8502, Japan, email: yoden@kugi.kyoto-u.ac.jp)

A modified Lagrangian-mean (MLM) diagnostics of tracer transport in the stratosphere developed by Nakamura(1995) is extended to study the low-frequency variations of the troposphere from a viewpoint of mass conservation. Our method describes the time variation of mass in a volume element enclosed by two nearby surfaces of potential vorticity (PV) and those of potential temperature in terms of non-conservative mass flux through these surfaces. A long time-mean of the MLM mass flux illustrates a direct meridional circulation without eddy flux contributions under the constraints of both dynamics and thermodynamics.
Low-frequency variations of the zonal mean zonal flow and baroclinic eddies in a simple global circulation model, of which dynamics were investigated in the previous paper by the authors (Akahori and Yoden, 1997), are diagnosed by the new method. A characteristic feature is a propagation of the MLM mass anomalies from the tropics to the polar region with a time-scale over 100 days, which sets in rather periodically with a shorter time-scale. The poleward propagation of the mass anomalies is related to that of the zonal-flow anomalies, already found in some observational and numerical studies.
In low latitudes, the mass anomaly is mainly induced by the convergence of the meridional mass flux through PV surfaces, which is related to anticyclonic Rossby-wave breakings in the upper troposphere. In mid-latitudes, on the other hand, it is largely induced by the convergence of the vertical mass flux through isentropic surfaces, which is related to the thermal relaxation. In high latitudes, cyclonic Rossby-wave breakings on the poleward flank of the jet stream become important for the mass anomaly. Rather periodic occurrence of such propagation of the mass anomalies are characterised by a kind of relaxation oscillation which consists of a phase of mechanical mixing by Rossby-wave breakings and a recovery phase due to thermal forcing.

MEASUREMENTS OF THE GROUND-LEVEL SOLAR ULTRAVIOLET RADIATION OVER EAST SIBERIA DURING THE TOTAL OZONE ANOMALY PERIOD

A.V. Mikhalev, M.A. Chernigovskaya, A.Yu. Shalin, A.B. Beletsky, and E.S. KAZIMIROVSKY (Institute of Solar-Terrestrial Physics, Russian Academy of Sciences, P.O.Box 4026, 664033, Irkutsk, Russia, email: mikhalev@iszf.irk.ru)

Results of spectral measurements of the Solar ground-level UV-radiation (295-345 nm) over East Siberia obtained for the spring time of 1997, are presented. This period was characterised by the greatest total ozone content (TOC) depletion for both the magnitude and the duration in eastern regions of Russia. It is shown that an anomalous ozone decrease in the spring of 1997 was coincided with the high ground-level the Solar UV-radiation as compared with the spring of 1998, when the TOC values were in agreement with long-term average values. However this high level of UV-radiation was smaller than the mean value of the ground-level Solar UV-radiation in the autumn of 1997 for the same Solar elevations when the TOC values were also in agreement with long-term average values.

JSM26/W/19-B2 Poster **1700-13**

DETECTING TROPOSPHERE-STRATOSPHERE EXCHANGE USING THE GLOBAL OZONE MONITORING EXPERIMENT (GOME)

Paul Thomas Quinn, University of Wales, Aberystwyth, Ceredigion, SY23 3BZ, UK (email: ptq94@aber.ac.uk) Richard Siddans(R.Siddans@rl.ac.uk), Brian Kerridge, (email: BJ.Kerridge@rl.ac.uk) both at Rutherford Appleton Laboratory, Chilton, Oxfordshire, OX11 OQX, UK

The observations presented are of a large intrusion of subtropical tropospheric air (3.6(10e15 kg) which was detected in the midlatitude lower stratosphere over Europe in early March 1997. ECMWF trajectory analyses showed that this air was advected isentropically northwards along the 365K surface from near the subtropical tropopause and contained a region with potential vorticity values (2 PVU, consistant with ozone mixing ratios of 80 ppbv observed at Aberystwyth (52.4N, -4E). The feature was seen as a "mini-ozone-hole" in the total ozone fields of both the TOMS and GOME instruments with ozone values <270 Dobson Units. Preliminary ozone profile data from GOME produced by the Rutherford Appleton Laboratory was used to sample the feature at the 12km level, enabling the simultaneous sampling of total column ozone and ozone profile data of a lower stratospheric feature from space. The preliminary data was capable of detecting filaments, which are not seen in T106 ECMWF analyses or the GOME total ozone data, and Reverse Domain Filling trajectories were used to confirm the presence of these features. The data was also able to detect the feature over the Atlantic where no in-situ measurements could be made, and when the feature was not resolved from the background total.

MODEL OF VERTICAL ATMOSPHERE DIFFUSIVITY IN THE UPPER TROPOSPHERE AND LOWER STRATOSPHERE

A. Belyaev, (Fedorov Institute of Applied Geophysics, Rostokinskaya ul. 9, Moscow, 129128, Russia. E-mail : belyaev@rc.msu.ru)

Height profiles of vertical diffusion coefficients are simulated for upper troposphere - lower stratosphere. Simulations using the original IGW parameterization allowing wave destruction on critical levels are effected in the framework of the one-dimensional atmosphere model with pyre zonal wind. In the framework of this parameterization vertical diffusivity values depend on the vertical profile. To demonstrate influence of the wind profile on atmosphere diffusivity two vertical diffusion coefficient profile were calculated. Calculations were done for jet similar and constant wind profiles. The main difference between these diffusivity profiles is the presence of the deep gap in the profile corresponding to jet.

JSM26/W/08-B2 Poster **1700-15**

CHLORINE ACTIVATION DURING THE EARLY 1995-1996 ARCTIC WINTER

STEVEN T. MASSIE, XueXi Tie, and Guy P. Brasseur (National Center for Atmospheric Research, Boulder, CO, email: massie@ucar.edu) Richard M. Bevilacqua and Michael D. Fromm (Naval Research Laboratory, Washington, D. C.) Michelle L. Santee (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA)

The coupling of temperature, aerosol area density, and chlorine activation is studied by comparing three-dimensional chemical transport model values with observed temperature, aerosol area density, and ClO values in the Arctic for the time period December 1, 1995 to January 9, 1996. The three-dimensional model uses United Kingdom Meteorological Office (UKMO) winds and temperatures, run on pressure surfaces between 316 and 0.31 hPa, and the model results are examined at 100, 68, 46, 31, and 21 hPa. Polar Ozone and Aerosol Measurement (POAM II) aerosol extinction values are transformed into area density values, and compared to model daily averaged time trends. The model is run in several modes: (i) with gas phase chemistry only, (ii) with gas phase plus sulphate aerosol chemistry, and (iii) the case where gas phase, sulphate aerosol, and polar stratospheric cloud chemistry is active. The study shows that sulphate aerosol is very effective in activating chlorine in the Arctic polar vortex. Furthermore, time trends of five-day averages of model and Upper Atmosphere Research Satellite (UARS) Microwave Limb Sounder (MLS) ClO over extended regions inside and outside the vortex at 21 and 46 hPa agree within the experimental error.

JSM26/L/04-B2 Poster **1700-16**

LARGE SCALE TROPOAUSE FOLDINGS AND EXCHANGES ACROSS THE SUBTROPICAL JET IN THE SOUTHERN HEMISPHERE.

DANIEL Vincent(1), Barray Jean-Luc(2), Legras Bernard(1), Ancellet Gerard(3). (1) Laboratoire de Meteorologie Dynamique, Ecole Normale Superieure deParis, France (2) Laboratoire de Physique de l'atmosphere, Universite dela Reunion, France (3) Service d'aeronomie, Universite Paris VI, Jussieu, France.

Ozone measurements done at La Reunion and in South Africa with lidars, ozone sounds and Mozaic profiles are showing that the presence of ozone layers is ubiquitous. These ones occur in the mid and upper troposphere on the North side of the Southern hemisphere subtropical jet during winter, in July 1998. Values of 50 to 100 ppbv are often observed at altitudes between 5 and 9 kilometers near 20-25 South. Meridional cross sections of potential vorticity reveal that these layers are related to tropopause folds beneath the jet. Folding appears as quasi permanent and extends over a considerable longitudinal range from mid-Atlantic to Australia. Analysis of divergence, deformation fields and frontogenesis vectors suggest that these structures are due to the stationary forcing of the upper branch of the Hadley circulation during monsoon.

TROPOPAUSE FOLDS AND IRREVERSIBLE MIXING

YAMAZAKI, Y. H. and W. R. Peltier (dept. Physics , University of Toronto, 60 St. George Street, Toronto, Ontario, Canada M5S 1A7: email: hiro@atmosp.physics.utoronto.ca)

To assess the significance of small-scale processes associated with the non-linear evolution of synoptic-scale baroclinic waves in the mid-latitudes, we have employed a dry non-hydrostatic anelastic model and executed a series of three-dimensional numerical simulations at very high spatial resolution which explicitly resolve the secondary structures that develop in the troposphere and lower stratosphere. In particular, we evaluate the sensitivity of the degree of tropopause deformation and irreversible mixing to the contrast of stratification between the stratosphere and the troposphere and to the intensity of small-scale turbulent mixing.
The amplitude of the "synoptic-scale deformation"of the tropopause is found to be strongly sensitive to the stratification contrast as one might expect, but the behaviour of the descending "tongue" of the air that constitutes the tropopause folds is found to be relatively insensitive to this influence. In contrast, the strength of the subrigid-scale turbulence that is represented in the model using simple first order closure has little influence on the deformation of tropopause, although it significantly alters the PV generation at the surface front. The degree of irreversible mixing in these non-linear life-cycles has than rigorously evaluated by examining the evolution of the " unavailable" component of the potential energy which reflects only thermodyamic state of the fluid. The intensity of the irreversible mixing was found to be very sensitive to the intensity of turbulent diffusion, as expected.

TRACER TRANSPORT IN THE TROPICAL LOWER STRATOSPHERE IN A CTM SIMULATION

Yvan J. ORSOLINI (Norwegian Institute for Air Research, Kjeller, Norway; email: orsolini@nilu.no) Martyn Chipperfield (Dept of Chemistry, Cambridge University, UK)

Tracer transport in the lower tropical stratosphere is diagnosed in a high vertical resolution simulation carried out with the isentropic chemical transport model (CTM) SLIMCAT, developed at the U. of Cambridge. The model has 20 levels, extending from the tropical tropopause to near 26 km. The simulation covers February 1996 to February 1998, and uses ECMWF analyses. A suite of 8 idealized tracers is transported, which are injected near the tropical tropopause. In particular, the tracers include two seasonally varying source tracers,an age of air tracer, a tracer with a constant source and two tracers which mimic N2O and CFCs. The later two are initialized with results of a photochemical 2D model, and are decaying with rates calculated from tabulated photodissocation rates as a function of zenith angle and pressure. The model results show a well-pronounced "tape recorder" signal, characterized by slow ascent of seasonally varying anomalies. It takes 10 months for tracer anomalies to rise from 100 mb to near 30 mb. We further examine regions of strong tracer meridional transport. A method for diagnosing regions of enhanced tracer eddy variability has been developed and tested for various seasons.

JSM26/E/13-B3 0850

RAPID QUASI-ISENTROPIC TRANSPORT IN THE STRATOSPHERIC OVERWORLD DURING WINTER

C. MARQUARDT, S. Leder and I. Fast, (Freie Universität Berlin, Institut für Meteorologie, Carl-Heinrich-Becker-Weg 6-10, 12165 Berlin, Germany, email: marq@strat01.met.fu-berlin.de)

It is now widely accepted that the transport regime in the "lowermost stratosphere" exhibits rapid meridional quasi-isentropic transport. It is also assumed that transport in this region is more effective than meridional transport in the mid and upper stratosphere: in contrast to the lowermost stratosphere, the tropical and mid-latitude stratosphere are thought to be relatively well seperated by a "subtropical transport barrier", which is caused by wintertime planetary wave activity.
By examining two case studies using high-resolution RDF calculations (during northern and southern hemisphere winter, respectively), it is shown that in the presence of sufficiently strong planetary waves quasi-isentropic transport in the stratospheric overworld can be significantly stronger that in the lowermost stratosphere at the same time for a period of several days. Inspection of time series of minimum potential vorticity and meridional transport coefficients indicate that such transport events occur regularly during wintertime on both hemispheres. Some aspects of the low-frequency variability of the transport characteristics are discussed.

JSM26/E/17-B3 0910

ISENTROPIC STRATOSPHERE-TROPOSPHERE EXCHANGE ACROSS THE SUBTROPICAL BARRIER USING PSEUDO-DIABATIC CONTOUR ADVECTION WITH SURGERY

B. JOSEPH (1), A. Mariotti (2), B. Legras (1), D. G. Dritschel (3)\\ (1) Laboratoire de Meteorologie Dynamique du CNRS, 24 rue Lhomond, 75231 Paris, France (2) ENEA National Agency - C.R. Casaccia, S.M. di Galeria - ROMA - 00060, Italy (3) School of Mathematical and Computational Sciences, University of St. Andrews, St. Andrews, Fife, Scotland KY16 9AJ, U. K.

We examine the isentropic stratosphere-troposphere exchange (STE) across the subtropical barrier in the Southern Hemisphere during the winter of 1998 (July) by employing pseudo-diabatic contour advection with surgery (PCAS) of potential vorticity (PV) using the ECMWF wind analyses.
PCAS is an extension of the usual contour-advection with surgery (CAS), which also assimilates the non-conservative component of the PV field evolution as an on-line correction to the purely advected PV field. It is demonstrated that PCAS can give superior results than CAS even within 10 days of integration period. One of the results from our study is that during the Southern winter, strong isentropic STE may also occur along uppermost isentropes ($\approx$ 370K) in the middleworld, in addition to that along lowermost isentropes ($\approx$ 330K) in the middleworld already noticed in earlier studies. In agreement with earlier studies, there is little STE along isentropes, which lie between the above two limits. A more stringent test of our results is provided by comparing the CAS and PCAS reconstructions of PV with ozone profiles over La Reunion and South Africa during a strong tropopause folding event, obtained as part of the TRACAS (TRansport of Chemical species Across the Subtropical tropopause) field experiment in the Southern hemisphere. Our results suggest that the ozone peaks observed in the middle troposphere are a consequence of isentropic descent of extratropical stratospheric air into the subtropical tropospheric air. Again, PCAS has been found to reconstruct filamentary extrusions of stratospheric air, which are expected from peaks in ozone profiles, more faithfully than the pure CAS.

JSM26/E/11-B3 0930

UARS MLS OBSERVATIONS OF CROSS-TROPOPAUSE WATER VAPOR TRANSPORT

John MCCORMACK and Rong Ru (Institute of Atmospheric Physics, University of Arizona, Tucson AZ 85721, USA, email: mcc@atmo.arizona.edu)

UARS MLS measurements of specific humidity at 215hPa provide an opportunity to examine the transport of water vapor between the tropical upper troposphere and the extratropical lower stratosphere. At this level, extratropical stratospheric air is characteriSed by water vapor mixing ratios of ~10 ppmv or less, while mixing ratios in the tropical upper troposphere range from 50 to 300 ppmv. Daily maps of MLS water vapor throughout northern winter and spring show the frequent redistribution of dry stratospheric/moist tropospheric air across 30 degrees N latitude associated with planetary wave activity. Four years of daily MLS upper tropospheric water vapor data (1991-1995) are combined with corresponding analyses of isentropic potential vorticity to create a composite description of this transport. MLS water vapor profile are used to determine the vertical extent of these stratospheric intrusions into the lower latitudes. The influence of equatorward propagating planetary waves on the distribution of water vapor, cloud s, and stability in the upper troposphere over the eastern tropical Pacific region is also examined.

JSM26/W/03-B3 0950

A ONE-YEAR CLIMATOLOGY OF EXTRA-TROPICAL STRATOSPHERE-TROPOSPHERE EXCHANGE

Michel BOURQUI and Henry Wernli (Institute for Atmospheric Science, ETHZ, CH-8093 Zuerich , Switzerland)

Stratosphere-troposphere exchange (STE) of mass, moisture and trace gases is a key factor of stratospheric chemistry and dynamics. Direct evaluation of such trans-tropopause exchange in the extra-tropics must take into consideration the (often) sub-synoptic scale and geographically-differentiated nature of the events that accomplish the interchange. In this study, a one-year climatology of the STE flux of air and ozone in the extra-tropics of the Northern Hemisphere is derived by combining (a) the six-hourly ECMWF analysis data (T213L31) for the period May 95 to April 96 and (b) ozone measurements derived in the MOZAIC and NOXAR projects. Exchange events are defined using a Lagrangian conception of the air-flow and a dynamical (PV-based) definition of the tropopause. Evaluation of the fluxes entails computing sets of three-dimensional trajectories starting from a regular 1*1 degree grid every six hours throughout the stipulated period and utilising the ozone measurements to obtain the accompanying flux transport. This procedure provides large-scale coverage but with sub-synoptic scale resolution. The results yield illuminating details of the geographical distribution and seasonal variation of the up- and downward trans-tropopause exchange. In addition consideration is given to the sensitivity of the procedure, and a comparison is made with results from other studies.

JSM26/W/10-B3 1010

ZONALLY SYMMETRIC MODES OF VARIABILITY IN THE ANTARCTIC UPPER TROPOSPHERE AND LOWER STRATOSPHERE AND THEIR INFLUENCE ON TOTAL COLUMN OZONE

Mark HARVEY (CRC for Southern Hemisphere Meteorology, Monash University, Clayton 3168, Australia, email: mark@vortex.shm.monash.edu.au) Prof. David Karoly (CRC for Southern Hemisphere Meteorology, Monash University, Clayton 3168, Australia, email: djk@vortex.shm.monash.edu.au) Simon Grainger (CRC for Southern Hemisphere Meteorology, Monash University, Clayton 3168, Australia, email: grainger@vortex.shm.monash.edu.au)

The intent of this study is to use the residual mean circulation as a diagnostic to examine the dominant modes of low-frequency variation of the Southern Hemisphere circulation in 1997. Zonal wind anomalies in the upper troposphere and lower stratosphere and their relationship to eddy fluxes of zonal momentum are also examined.
During the Austral winter and spring when planetary waves are able to penetrate into the stratosphere, these zonal mean zonal wind anomalies amplify with altitude into the lower regions of the polar stratosphere. Total column ozone is employed as a tracer to examine zonally symmetric oscillations between the tropics and higher latitude

JSM26/E/21-B3 1050

THE INFLUENCE OF THE QBO ON ISENOTRPIC MIXING AND TRANSPORT

EMILY SHUCKBURGH, Peter Haynes, Centre for Atmospheric Science, DAMTP, Silver Street, Cambridge, CB3 9EW, United Kingdom, email: efs20@damtp.cam.ac.uk Alan Iwi, Warwick Norton, Dept. of Atmospheric, Oceanic and Planetary Physics, Clarendon Laboratory, Parks Rd, Oxford OX1 3PU

A 6 year integration with a chemical transport model, using ECMWF winds from 1992-8 has been used to investigate interannual variability in isentropic transport and mixing, in particular the influence of the QBO. The mixing properties of a flow may be characterised by calculating the `effective diffusivity' (Nakamura: JAS 53 1524--1537 1996) of an advected tracer. The effective diffusivity characterises the geometric structure of a tracer, which is most complex where the mixing is strongest. Effective diffusivity calculated from passive tracer fields advected by observed winds has been used to produce a quantitative characterisation of the transport and mixing structure of the lower and middle stratosphere. This has shown the variation in height and latitude and the seasonal evolution, over the 6 years, of the stratospheric tropical reservoir and of the barrier to transport at the edge of the stratospheric polar vortex.
It is seen that in the tropics, mixing is inhibited when the QBO winds are easterly. When the QBO winds are westerly, the mixing structure suggests that wave disturbances are able to propagate from the extratropics in the winter hemisphere through the westerly winds in the tropics and then break in the weak winds in the tropics or subtropics of the summer hemisphere. The influence of the QBO on the extratropical transport and mixing is also investigated.
Comparison is made between time series of effective diffusivity calculated from ozone fields simulated by the chemical transport model and ozone fields measured by MLS.

JSM26/W/28-B3 1110

QBO MODULATION OF TROPICAL TRACER TRANSPORT IN THE LOWER STRATOSPHERE

A. IWI, W. Norton (AOPP, University of Oxford, Clarendon Lab,Parks Road, Oxford OX1 3PU, UK, email: iwi@atm.ox.ac.uk)

A six-year integration of a chemical transport model (CTM) forced by ECMWF analysis is examined as to its simulation of the tropical lower stratosphere. It is found that the quasi-biennial oscillation (QBO) produces marked interannual variability in the distribution of chemical tracers. This has a significant impact on many features including tropical vertical ascent rates, tropical "tape recorder" signal, age of air, and correlation of long-lived tracers. The annual cycle of the subtropical transport barrier will be discussed. Comparison will be made with available observed measurements and with results from other CTMs, which are a part of the EU-funded TOPOZ II project.

JSM26/E/16-B3 1130

QUANTIFICATION OF FILAMENTS IN THE NORTHERN HEMISPHERE TROPOPAUSE REGION

O. MORGENSTERN and G. Carver (both at Centre for Atmospheric Science, Chemistry Dept., Cambridge University, Cambridge CB2 1EW, UK, email: Olaf.Morgenstern@atm.ch.cam.ac.uk, Glenn.Carver@atm.ch.cam.ac.uk)

Contour advection simulations are performed of analyzed potential vorticity fields for every day of January and February of the years 1997 and 1998. Filaments are defined as structures of small cross-dimension penetrating in those simulations the finite-thickness tropopause in either direction. Statistics of such structures are derived; episodes of strong hemispheric-mean filamentation are related to the formation of tropospheric cut-off systems evolving in the later stages of Rossby-wave
breaking events. Zonal asymmetries occur as these waves favourably break near the end of the North-Atlantic storm track. The results hint at the role of filamentation in accounting for the interannual variability of ozone.

JSM26/W/24-B3 1150

MONITORING OF STRATOSPHERIC INTRUSIONS USING MST RADAR AND OZONESONDES AT ABERYSTWYTH

R.M. Worthington, G. Vaughan (Department of Physics, University of Wales, Aberystwyth, SY23 3BZ, U.K, email: rrw@aber.ac.uk, gxv@aber.ac.uk)

This study examines events since 1991 when stratospheric intrusions could be detected and tracked above Aberystwyth (52.4N, 4.1W), using extensive data from MST radar, and ozonesondes launched 5 km away. The radar measures height-time structure of wind and wind shear, and the occurrence of increased turbulent mixing shown by Doppler broadening of the radar echoes. The power and anisotropy of the echoes also give information about the static stability. Variability in the evolution of streamers of stratospheric air in the troposphere is studied in terms of their chemical compositions, their changing wind velocity structure, and the intermittency of the turbulent mixing of stratospheric and tropospheric air.

JSM26/W/01-B3 1210

APPLICATION OF 4D-VAR ASSIMILATION OF STRATOSPHERIC CHEMICAL SPECIES ON THE FIRST CRISTA FLIGHT

Q. ERRERA, D. Fonteyn (Belgish Instituut voor Ruimte Aeronomie, Institut d'Aeronomie Spatial de Belgique, 3 av. circulaire, Brussels, B-1180, Belgium, email: Q.Errera@bira-iasb.oma.be), and M. Rise (Physics Department, University of Wuppertal, Gauss-Str. 20, 42097 Wuppertal, Germany)

For the first time, comparison of model calculations with actual observations is performed by 4D-VAR assimilation. From a general point of view, variational assimilation consists in constraining a model to reproduce the observations and hence find the initial model conditions. In this paper, we present the results of variational assimilation of the stratospheric chemical species performed using CRISTA observations. The CRISTA observations were chosen due to the exceptional spatial data coverage. The 4D-VAR assimilation system and the measurements are briefly described. The chemical composition and its evolution, obtained by these analyses, are discussed as well as the predictive capability of the model. Two main aspects will be considered: from a modelling point of view the 4D-VAR assimilation allows a detailed comparison with observations and thus a validation of the 3D chemical transport model is discussed. The analyses make it possible to perform a predictive model calculation, this gives better a priori information about the composition of the stratosphere. Thus, retrieval algorithms will benefit from this information.

JSA27/P/05-B1 0900

A STUDY OF INTEGRATION METHOD OF REMOTE SENSING AND AEROMAGNETICS FOR TECTONIC PROSPECTING OF GOLD ORE DEPOSITS

Zhu ZHENHAI (Institute of Remote Sensing Applications, Chinese Academy of Sciences, Beijing, 100101, P. R. China, email: zhuzh@irsa.irsa.ac.cn); Hao Tianyao (Institute of Geophysics, Chinese Academy of Sciences, Beijing, 100101, P. R. China, email: tyhao@mial.c-geos.ac.cn); Huang Xiaoxia, Wang Hongmei (both at the Institute of Remote Sensing Applications, Chinese Academy of Sciences, Beijing, 100101, P. R. China, email: zhuzh@irsa.irsa.ac.cn)

According to the distribution characteristics of known gold deposits of mid-latitude area of Asia, the obvious regularity of preferentiality of the distribution od a serial of large, rich gold deposits has been discovered. The tectonic prospecting model of gold deposits duided mainly by transverse structures has been established. Because of its' diffuse characteristics, the transverse structures are hard to be found by using the conventional geology investigating method. In order to discriminate effectively the transverse structures, we put forward an analytic method of integrating remote sensing and aeromagnetics technology.
The experiment area is mineralization belt of Yin Mountain and Yanliao gold deposits located in northern margin of the northern China Plate. According to the macroscopic interpretation of remote sensing and the new method of "thin shield" for linear tectonics inversion by using aeromagnetic data, the regional distribution of transverse structures has been interpreted. Supporting by the information system of mineral resources, and integrating the analyse of regional strike structure and activity of magnetic rocks and geological background of mineralization, the exploration prospect of large and rich gold ore deposits of Yin Mountain and Yanliao mineralization belt has been put forward.

JSA27/W/02-B1 0920

GRID-INDEPENDENT ELECTRODE POSITIONING FOR 3D DC AND IP FORWARD MODELING IN MINERAL EXPLORATION

Klaus SPITZER (Joint Geoscientific Research Institute, Stilleweg 2, 30655 Hannover, Germany, email: klaus.spitzer@gga-hannover.de); Michel Chouteau (Ecole Polytechnique, Succ. Centre-Ville, PO Box 6079, Montreal (Qc) H3C 3A7, Canada, email: chouteau@geo.polymtl.ca)

Electric crosshole measurements in mineral exploration require flexible interpretation software because transmitters and receivers are lined up along boreholes that are generally not aligned with the axes of Cartesian coordinate systems. Therefore, we present a 3D DC and IP forward modeling code, which offers grid-independent electrode positioning, i.e. locations of transmitters and receivers may be detached from the grid nodes. This is possible through a singularity removal procedure which splits up the potential in a normal and an anomalous part. The normal part containing the singularity is calculated analytically and is thus independent from the finite difference grid. Consequently, source locations are literally arbitrary. The potential at the receiver positions is calculated via tri-linear interpolation of the anomalous potential. This is superior to interpolating the total potential because the anomalous potential is rather smooth compared with the total potential and shows less steep gradients. Therefore, the accuracy is considerably raised. The new code is applied to a crosshole survey at a gold mine and its advantages (reduction in grid size, decrease in run time) are presented.

JSA27/E/07-B1 0940

EULER DECONVOLUTION OF GRAVITY TENSOR DATA

Martin F. MUSHAYANDEBVU, Alan B. Reid, J. Derek Fairhead (School of Earth Sciences/GETECH, University of Leeds, Leeds LS2 9JT, UK, email: mushaya@earth.leeds.ac.uk); Changyou Zhang (117-401 Westview St., Coquitlam, B.C., V3K, 3W3, Canada); Mark Odegard (GETECH, 12946 Dairy Ashford, Suite 250, Sugar Land, Texas 77478, USA)

Conventional Euler deconvolution uses 3 orthogonal gradients of any potential quantity as well as the potential quantity itself to determine depths and locations of a source. Gravitational acceleration is a vector with 3 Cartesian components and the gradient is thus a 9 component tensor. Euler deconvolution is developed and modified for the interpretation of gravity tensor gradient data. Using all the measured tensor gradients puts additional constraints on the Euler solutions data forms. The method has also been tested on measured gravity tensor gradient data from the Eugene Island area of the Gulf of Mexico with gridded and profile data forms. The results from both model and real data show improved performance for the tensor Euler deconvolution.

JSA27/W/01-B1 1000

GEOLOGICAL DELINEATION OF THE MAIN STRUCTURAL TRENDS AS REVEALED FROM, TOPOGRAPHICAL, AEROMAGNATIC AND AREORADIOSPECROMETRIC DATA AND THEIR RELATION TO URANIUM REMOBILIZATION IN WADI UM-HAD AREA, CENTRAL EASTERN DESERT, EGYPT

Nasser HASSAN (Geophysics Dept., Fac. of Sc., Ain Shams Univ., Egypt
(email: aboashor@asunet.sahams.eun.eg); Magdy A. Gouda, Said I. Rabie, Ahmed A. Ammar (all at Nuclear Materials Authority, P.O.Box 530 Maadi, Cairo, Egypt)

The main objective of the present study is to make use of the different geologic, topographic aeromagnatic and aeroradiospectrometric data in identifying the main directions of the interpreted structural lineaments prevailing in the area of Wadi Um-Had, Central Eastern Desert, Egypt. This objective was quantitatively achieved through the application of combined statistical analysis of trends using the autocovariance function and the successive overlap techniques for all the available data. Such analyses were devoted mainly to try visualize the relationship that might exist between the various interpreted trends and the tectonic pattern. Moreover, they may help reveal the tectonic forces that affected the basement rocks as well as any significant relations reflecting mineralization control.The results attained in this study seem to indicate eight main orientations that take the following particular sequences: N-S,NNW,NW,WNW,E-W,ENE,NE and NNE directions. Three trends (NNW, NW and WNW) out of the recorded eight were found to represent ancient (deep seated) as well as recent (near surface) structures. The E-W trend is interpreted as ancient trend. Besides, the study revealed the insignificant existence of two main trends: N-S and NNE as far as the area under study is considered. It is recommended that the NNW, NW and importance from the point of view of radiospectromic exploration.The investigated area has been subjected to a maximum principal stress that is nearly oriented in the ENE to NE trend which is perpendicular to the dominant NNW and NW trends. Furthermore, the degree of remobilization of uranium within the different rock units is reflected on the trends of the variations of uranium and thorium with their ratios. It was evident that a strong remobilization of uranium is indicated in the granitic rocks, Nubian sandstones, phosphate formation, gneisses and migmatites as well as the hammamat sediments.

JSA27/P/01-B1 1050

INTEGRATED GEOLOGICAL AND HIGH-RESOLUTION GEOPHYSICAL STUDIES ON THE COPPER-BEARING PRECAMBRIAN ROCKS AT SOUTH WADI HAMMAD AREA, NORTH EASTERN DESERT OF EGYPT

Aboulhoda M. ELSIRAFY, Mahmoud H. Shalaby (Nuclear Materials Authority of Egypt, P.0 Box 530 Elmaadi, Cairo, Egypt)

Field geological studies showed that the copper mineralization at south Wadi Hammad area, located in the northern part of the Egyptian Eastern Desert, is litho-tectonically controlled, and that the composition of the Precambrian metagabbro-diorite rocks, hosting this mineralization is rather complex. These rocks range from diorites, quartz diorites to granodiorites. In case of strong granitization they could approach the granitic composition and are intensly jointed and sheared. This is mainly attributed to their tectonic setting where they lie at the intersection of two regional fault zones. Petrographic investigations, on the other hand, indicated that these rocks are essentially composed of hornblende and plagioclase feldspars with a minor amount of biotite, quartz and orthoclase. The common accessory minerals are zircon, garnet, apatite, beside abundant iron oxides.
Electrical self-potential measurements confirmed the subsurface extensions of the structural zones controlling the copper mineralization down to depth level of 125 m. Further deeper extensions are highly expected. High resolution spectral gamma-ray scanning, carried out within some pre-existing deep exploratory and worked trenches, indicated that uranium enrichement is a phenomenon accompanying the copper mineralizing process. Potassium was also enriched but on a much smaller scale. So, spectral gamma-ray surveye is recommended as an efficient geophysical exploration tool for locating further copper-mineralized zones in the same geologic environment. In that regard radioelement ratio measurements will be of higher significance than the absolute abundance.

JSA27/E/09-B1 1110

3-D SEISMIC IMAGING OF A DEEP MASSIVE SULPHIDE DEPOSIT

Bernd MILKEREIT (Geosciences, Kiel University, 24118 Kiel, Germany,
email: bmilkereit@geophysik.uni-kiel.de); Brian Roberts (Geological Survey of Canada, Ottawa, Booth Street, K1A 0Y3, email: roberts@cg.nrcan.gc.ca)

The Sudbury Basin in Canada was selected for conducting one the world's first 3-D seismic survey for deep base-metal exploration. Over the past 5 years, an extensive database of geological mapping information, geophysical logs of existing deep drill holes, and core samples for physical rock property studies has been assembled to support the interpretation of seismic data across the Sudbury Structure. In terms of seismic exploration, the contact between the "transparent" SIC Norite and the "reflective" footwall complex represents a clear regional marker horizon, making it possible to map the bottom of the SIC and topography at the impact crater floor (the principle location for Ni-Cu deposits). In addition, the velocity-density field for sulfides (including the phyrrhotite and chalcopyrite assemblages typical for ores in Sudbury) is distinctly different from that for common silicate rocks (such as norite in the hanging wall and gneiss in the footwall), suggesting that massive sulfide bodies should generate prominent seismic reflections. Various stages of the ambitious 3-D seismic exploration study will illustrated: from survey design to helicopter assisted data acquisition and from special processing considerations to final interpretation and groundtruthing of the 3-D seismic data volume. The 3-D seismic experiment confirms that in a geological setting such as the Sudbury North Range, deep massive sulphide bodies cause a characteristic seismic scattering response. This provides an excellent basis for the direct detection of deep massive sulphides in the crystalline crust by seismic methods.

JSA27/E/06-B1 1130

APPLICATION OF SYNTHETIC APERTURE RADAR (SAR) FOR EXPLORATION OF MINERALIZED ZONES

Wooil M. MOON (Earth System Science, Seoul National University, Seoul 151-742, Korea, email: wmoon@eos1.snu.ac.kr or wmoon@cc.umanitoba.ca); W.W. Jiang (Institute of Geophysics, Academica Sinica, Beijing, China); S.G. Choi, S.W. Choi (Earth and Environmental Science, Korea University, Seoul, Korea)

Synthetic Aperture Radar (SAR) is an active sensor which has many advantages over optical sensors for its all-weather capability without solar illumination. For geological applications,

SAR systems can utilize X-, C-, and L-band microwave signals for imaging of the Earth's surface features. Furthermore, multiple polarization capabilities of the SAR antenna have greatly increased the applicability of SAR systems with respect to both surface and volume scattering over geologically anomalous zones such as specific mineralization. Although integrated approach in mineral exploration has become more cost effective and are well accepted, there are many technical and scientific issues to be further investigated and researched. In this study we have reprocessed several sets of previously surveyed exploration data and experimented with fuzzy logic digital fusion of the preprocessed data. The exploration target hypothesis was that there is a W-Mo-F mineralization in the study area. Among the numerous fuzzy logic operators, currently available for data driven integrated exploration strategy, we have used varying combination of fuzzy MIN, fuzzy MAX, and fuzzy SUM operators along with Gamma operator for digital fusion of geochemical, geophysical, and geological information, including the contact metamorphic zone information. In this study, we have also investigated and evaluated the JERS-1 SAR and SIR-C multiple frequency SAR data for differential backscattering effects of microwave with the surface geological material over skarn type ore mineralization. The fuzzy logic derived mineral potential anomaly has almost exactly matched the differential backscattering anomalies on the SIR-C C-band and L-band data overlaid on each other. Although the high degree of correlation is remarkable, the differential backscattering anomaly over the skarn type W-Mo-F ore mineralization in the study area requires further investigation.

HIGH RESOLUTION MAGNETIC AND ELECTROMAGNETIC IMAGES OF A CANADIAN MASSIVE SULPHIDE MINING CAMP

Michael THOMAS, Pierre Keating, John Katsube, Neil Rogers, Cees van Staal (all at Geological Survey of Canada, 615 Booth St., Ottawa, Ontario K1A 0E9, Canada, email: mthomas@gsc.nrcan.gc.ca)

A helicopter-borne geophysical survey over the entire Bathurst mining camp in the Canadian Appalachians collected magnetic, electromagnetic and radiometric data at mean terrain clearances of 45 m, 30 m and 60 m, respectively, along flight lines spaced 200 m apart. Resultant high resolution images of measured and derived parameters, particularly those for the magnetic and electromagnetic data sets, provide a unique perspective on the lithological and structural fabric of the bedrock geology, which is largely obscured by a glacial veneer. Calibration of magnetic anomaly and apparent conductivity maps (derived from the 4433 Hz co-planar electromagnetic data) with exposed bedrock indicates various close correlations between magnetic features and mafic volcanics, mafic dykes, gabbroic intrusions and iron formations, and between distinct conductivity features and sedimentary horizons containing black shale and argillite. Geophysical detection of poorly mapped or unmapped iron formations has particular relevance to massive sulphide exploration, given their genetic/spatial association with sulphide deposits. The high resolution maps have been used to enhance geological mapping in the dominantly felsic volcanic, northwest part of the camp. Thin sedimentary and mafic units have been traced geophysically, imparting a tectono-stratigraphic framework to the region. Truncation of units has provided evidence of several thrusts, whose presence must be considered in exploration strategies. Perhaps most importantly for exploration, the new geophysical maps reveal many direct targets for investigation, in the form of roughly circular to elliptical magnetic and conductivity highs. Many correlate with known massive sulphide occurrences, others remain to be examined. One set of co-spatial magnetic and conductivity anomalies that was investigated shortly after completion of the airborne survey resulted in discovery of a small sulphide body.

JSA27/P/04-B1 **1210**

HIGH PRECISION AIRBORNE MAGNETIC AND GAMMA SPECTROMETRIC SURVEY FOR MINERAL EXPLORATION IN THE EASTERN DESERT OF EGYPT

Kadry M. FOUAD (Prof. of Geophysics, Nuclear Materials Authority, P.O. Box 530 Maadi, Cairo, Egypt)

Airborne geophysical exploration activities in Egypt date back to the late fifties. A new king Air Beechcraft C90B aircraft was purchased lately equipped with state-of-the-art magnetic and spectrometric survey systems, as well as navigation and other ancillary equipment. The magnetometer inflight sensitivity is 0.001 nT, with ten measurements every 1.0 sec. The multichannel airborne gamma-ray spectrometer accepts signals from 50 1 of Na I (Tl) detectors. This system allows the quantitative interpretation of the geochemical parameters indicated by U, Th and K contents in rocks. An airborne differential GPS navigation system receives signals from 12 satellites to provide aircraft positioning in 3-D, accurate to 5 m or better. An IBM compatible data acquisition system accepts and corrects data from the whole system. An advanced software package is utilised for processing the data. The generated contour maps represent the total magnetic field, the total radiometric count, ar well as the U, Th and K contents. Powerful techniques are available to help interpret the maps. The power spectrum analysis transfers the magnetic data to the pole, separates the residual and regional fields, delineates the depths to the magnetic interfaces and bodies. The interpreted tectonic framework of the survey area is invaluable in delimiting locations of potential mineralization. Interpretation of the spectrometric data and their ratio maps (U/ Th, U/K and Th/K) results in the delineation of the surface distribution of the radioelements. Spots most favorable for U concentration are identified and the direction and degree of its remobilization from the mother rock is indicated. Surface-subsurface configuration of the geological-tectonic setting could be figured out. In addition digital image processing techniques applied to the non-image survey data provided extremely valuable information. Examples of case histories from the Eastern Desert of Egypt are presented.

TELEMETRED MULTICHANNEL SYSTEM FOR GEOPHYSICAL CABLE

Florin IONICA (National Institute for Earth Physics, P.O. Box MG-2, Bucharest, Romania presently at University of the West Indies, Earthquake Unit, Mona, Kingston 7, Jamaica W.I., email: fionica@uwimona.edu.jm)

A new telemetred multichannel system for geophysical cable is presented. The investigation of the boreholes is very important to be done using as many measuring channels as possible in order to have fast and effective results. Multiwire cable which are now used in multichannel systems are very problematic due the connectors, durability and wear. Water tightness must be very high degree because of high pressure which exist in boreholes over 1000 meters. Also noises and disturbances generated by external electromagnetic fields are big problems especially in VSP or HSP measuring where all the signals, also the weakest reflections must be recorded at sufficient resolution. Taking in account these requirements it was designed one modular system which is constructed to function on one coaxial cable where all the channels are located in parallel in frequency domain. This kind of system is called telemetry system and is used mostly in airplane and space equipment. This telemetry system consist of transducer units (every one with three geophones), circuits to transfer signals to cable, electronic controls and power supply components. These units are connected on a strong main coaxial cable as many as needed. Physically are in series with cable but electricaly are in parallel as on a bus line.

UTILIZATION OF AERORADIOSPECTROMETRIC SURVEY DATA IN DEFINING RADIOELEMENT ANOMALOUS ZONES IN ELGALALA ELBAHARIYA - ELGALALA ELQIBLIYA, NORTHERN EASTERN DESERT, EGYPT

Ahmed A. AMMAR, Mohamed A. Elsadek (both at Exploration Division, Nuclear Materials Authority, P.O. Box 530 Maadi, Cairo, Egypt); Ahmed M. Sabri (Geophysics Dept., Faculty of Science, Ain Shams Univ., Abbasiya, Cairo, Egypt)

Elgalala Elbahariya - Elgalala Elqibliya area is situated in the Northern Eastern Desert of Egypt. Its surface area, reached about 3000 km2. Variuos rock units are exposed in the study area and are represented by different lithological groups ranging in age from Late Paleozoic to Quaternary. The present work is dedicated to identify the significant aeroradiospectrometric zones of anomalously high "U" and/or "Th" concentrations. Their delineation is based on the techniques of construction of standard deviation (anomaly) contour maps as well as computation of uranium favourability index (U2) and the three-elemental effective parameters (F).
This study revealed the presence of 76 individual aeroradiospectrometric anomalies which could be assembled into three main groups. These anomalies could be related to either the prevailing faulting system and/or some specific lithologic units and formations. Their aerial eU and eTh values range from 0.50 ppm to 3.60 ppm for eU and between 0.60 ppm to 6.20 ppm for eTh. The eU/eTh, eU/K and eTh/K ratio values differ generally from 0.10, 1.0, and 5.50 to 2.50, 15.0, and 16.0 respectively. The U2 index and F-parameter oscillate from 0.10 to 1.85 for U2 and from 0.08 to 0.42 for F. From the economic potential point of view the most promising anomalies are three correlated with El-Galala, Duwi and Mokattam formations as well as Quaternary Sediments and also with the NW- and NE- ternding structures.

MATHEMATICAL REGIONALIZATION OF THE ORGANIC RESOURCE IN THE EARTH'S CRUST

Tarzadin ULAANBAATAR (Department of Earth Sciences, National University of Mongolia, email: numelect@magicnet.mn)

Reliable regionalization of the mineral resource of planet is one of the main bases of successful geophysical exploration. The organic resource in planetary-scale must determine by the reconstruction of the paleotropic and paleosubtropic zones and interglacial epochs when happened agreeable natural conditions for accumulation of the gigantic fauna and flora. In this paper a new mathematical geologic method for regionalization of geographical, climatic zones in accordance with geochronology is shown. The method is based on a 3D model of thermal regime on and near the Earth's surface which includes three simple parameters: number of day from winter solstice, measuring time, geographical latitude. Fortunately, the model parameters have determined geochronologically by studies of paleogeography,paleobotany, paleontology and paleogeocryology. In this paper the paleotemperature regime, insolation regime of geological past time, duration of the daylight, altitude of sun, total insolation in different time interval along interested latitude (zonal), geographical,climatic zones are described. For this reason, based on the mathematical model the organic mineral resources in the earth's crust are shown to be regionalized.

PROBLEMS OF HIGH RESOLUTION COMPLEX OF METHODS OF DYNAMIC GEO-ELECTRICITY CREATION FOR INVESTIGATION OF ZONE OF MINERALISATION

Gidroingeo R.TURSUNMETOV (64, Khodjibayev str., Tashkent, Uzbekistan)

Increase of exploration depth in complex geo-structural situation requires more reliable and effective methods of exploration. One of these methods is the method of dynamic geo-electricity which is being now under development. In this method along with rocks' statical properties, connected with linear processes, rocks' dynamic properties, connected with non-linear processes, are studied. Rocks' dynamic properties are bounded mostly with energetically active zones of mineralisation, where electro-chemical and elctro-cynetic processes, which, in turn, create intensive natural electric fields. Under electro- magnetic stimulation of these zones results are affected by external phenomena along with phenomena of polarisation that makes difficult their right interpretation. In this connection special investigations were carried out to create high resolution complex of dynamic geo-electric diagnostic methods for zone of mineralisation study, including the following tasks:
1.study of electro-magnetic properties of rocks dispersion in time and frequency domain and bringing results to the common level, because rocks' electro- magnetic properties differently response to electro-magnetic fields influence, created by different methods of stimulation.
2.Dynamic electro-magnetic properties of rocks are represented by non-linear parameters of resistance and polarization and by coefficient of heterogenity of electro-magnetic field. That is why electro-magnetic field distribution under different kinds of stimulation is desirable to use.
3.While studying electro-magnetic field behavior over zone of mineralisation it is necessary to take into account not only processes, connected with polarization under artificial electric current flow, but also the phenomena taking place before the environment stimulation. This question clarification will permit to study natural electric field with a depth. In order to solve above problems, managed installations are suggested, which allow to create definite current density on the definite depthand obtain information about environment's dynamic properties. Special installations are suggested also to study coefficient of heterogenity of electro-magnetic field and non-linear parameters of electric resistance.

THE PIEZOELECTRIC MODEL FORMATION NATURAL ELECTRIC FIELD IN THE EARTH

D.Kh. RASULOV (Lange Institute of Hydrogeology and Engineering Geology, Tashkent, Uzbekistan, e-mail: root@ariel.tashkent.su)

In the last 50 years the large volume of information stored about natural electric fields in the Earth. Despite of that the question of origin of some of theirs still remained open. The piezoelectric model formation natural electric fields of the Earth is considered in work: formulated the conditions of formation natural piezoelectric fields (NPF) and carried out detailed analysis their fulfilment on the concrete experimental material in natural environment. The principal condition of formation NPF is existence of piezoelectric textures in rocks. By works of previous researchers were ascertained that this condition often to fulfil. Another necessary condition of NPF formation is sufficiently high values of specific electric resistors of reserch rocks: over 1000 Ohm. The additional conditions of NPF formation are existence of the differentiation on rock's tense state and uneveness screening fluence of the cover beds. The piezoelectric model explains well all peculiarities of manifestation of such natural electric fields as "Changeable in time fields","Intensive negative anomalies", "Positive anomalies over the pegmatitic veins". The proposed model also explains many unique cases of observations of selfpotential over the sulphide and polymetallic deposits. The piezoelectric model shows how such physical parameters of rocks as temperature, pressure, dampness and selfpotential are correlated.

RADIOWAVE GEOINTROSCOPY OF THE ROCKS IN THE INTERWELL AREA (RWGI IWA)

V. A. ISTRATOV, M. G. Lisov (both at Radionda Ltd. C, 121614, Moscow, Krilatskie Holmi, G- 614, Box 44, email: radionda@glasnet.ru)

Presented technology for the detailed 3D-mapping non-homogeneouse geological strata, having internal peculiarities in electrical properties. The method is based on the relationship of radiowave dissipation in the rock massif strata, depending on electric resistance and dielectric permeability of the rocks situated on the way of radiowave beam. Method is realized by multiple high-frequency raying of the rock massif with dipole source and the following processing of the "radiowave picture" with tomographic, iterative, and other special technique. Applying of the RWGI IWA has resulted in significant reduction of prospecting and exploration drilling amounts, of the time consumption for geological surveys, searches, prospecting and exploration of ores, oil and gas deposits and for means of hydrogeology and engineering geology as well. This method has the most effective application in prospecting and evaluation serveys of deep ore deposits, when high drilling spending are accompanied with the highest business risk. The method can be used with high efficiency in express estimations of the geological researches quality during purchasing of licence for mineral mining. Presently this method can be applied for the interwell distance from 5 meters up to 1.5 kilometers. The biggest for the present time in the word distance is obtained by use relatively low frequency in observation (frequency range: 0.01 - 36 Mhz). RWGI IWA method is applied for prospecting and 3D mapping diamond pipes; in oil geology for determination and evaluation transport properties of fracture-porous collectors, mapping oil pools and studying their internal features; in engineering geology during construction and exploitation tunnels (in Moscow Underground), hydropower stations (in permafrost area) and environment high-risk big industrial objects. The method RWGI IWA was applied on different objects in Russia, Spain and South Africa.

DETAILED MAGNETIC INVESTIGATION FOR SEARCHING SHALLOW CHROME OREBODIES

Arben LULO, Alma Renja (Geophysical and Geochemical Center, L 9, Blloku "Vasil Shanto", Tirana, Albania)

Located in the southern part of Bulqiza Ultrabasic Massif, Albania, the area selected for investigation had rugged topography, delluvial thickness well developed and geological conditions favorable to chrome deposits. The detailed ground magnetic survey was conducted as part of the geological-geophysical study for searching shallow depth chrome orebodies associated with the harzburgite rocks section. Using a proton procession Scintrex magnetometer of 1 nT accuracy the survey net of 40m x 5m was carried out in an area of 4 km2. After the data were smoothed, resampled and gridded at a 10m interval the total field magnetic anomaly map was compiled.
In general there is not a good agreement in between the surface geology and the magnetic anomalies in this area. An interpretation of the total field magnetic anomaly map was made transforming it to the magnetization anomaly (susceptibility) map. With a strike filter the results are improved. Zones of the anomal magnetization (transitory from the negative to the positive magnetic susceptibility intensity) are obtained in this map, interpreted as in agreement with the modeling from the laboratory measurement in chromite samples. It was felt that the shallow orebodies which should influence the surface magnetic data could be more apparently defined in this transformed map. One of the susceptibility anomaly has revealed a shallow chromite deposit about 350m in length in a zone totally covered by overburden.

GPS ESTIMATION OF ATMOSPHERIC WATER VAPOUR FROM A MOVING PLATFORM

Alan DODSON, Wu Chen, Nigel Penna and Helen Baker (IESSG, University of Nottingham, Nottingham, NG7 2RD, UK, Email: alan.dodson@nottingham.ac.uk)

Estimates of atmospheric water vapour are of vital importance to meteorological and climatological modelling, contributing to a wide variety of processes from small scale weather systems to global climate change. In recent years there has been considerable international interest into the use of ground-based GPS for water vapour estimation and it has been demonstrated that the water vapour can be routinely obtained by GPS with an accuracy of 1 kg per square metre. A reliable method for accurately measuring atmospheric water vapour from a moving platform would be of great benefit to both meteorological and climatological disciplines, and as calibration for satellite-based estimates at coastal locations. It is common knowledge that the sea/air interface is a major contributor to worldwide weather fronts. The measurements of water vapour at strategic locations would provide an important data set for input into climatological models, as well as for meteorological purposes in coastal and near shore regions. In this presentation, a new algorithm is developed to separate the tropospheric delay from the motion of the GPS antenna, especially the height component. The initial test results will also presented.

GROUND BASED GPS METEOROLOGY: AN EVALUATION OF DIFFERENT SOFTWARE PACKAGES USING TWO YEARS OF DATA FROM THE SWEDISH NETWORK

J.M. JOHANSSON, G. Elgered, L.P. Gradinarsky, B.G. Stoew (all at Chalmers, Onsala Space Observatory, SE-439 92 Onsala, Sweden, e-mail: jmj@oso.chalmers.se)

A continuously operating network of ground-based GPS receivers in Sweden has produced data since the summer of 1993. We will here discuss the measurement uncertainty of the derived Integrated Precipitable Water Vapour (IPWV). The quality of the GPS estimates can be assessed through comparisons with independent techniques. We use microwave radiometry and radiosonde observations in order to study the different types of error sources involved.

JSG28/W/08-B1 **1030**

A CLOSE RELATIONSHIP BETWEEN TEMPORAL ANOMALIES IN SITE COORDINATE AND ZENITH TROPOSPHERIC DELAY IN GPS ARRAY OVER THE JAPANESE ISLANDS IN SUMMER

Tetsuya IWABUCHI (The Graduate University for Advanced Studies, Mizusawa, 023-0861, Japan, email: iwabuchi@miz.nao.ac.jp); Isao Naito (National Astronomical Observatory, Mizusawa, 023-0861, Japan, email: naito@miz.nao.ac.jp)

Under a simple assumption of azimuthally homogeneous distribution of water vapor in Global Positioning System (GPS) analysis, a close relationship between horizontal coordinate variation and zenith tropospheric delay (ZTD) is found in the operational analysis of nationwide GPS array of Geographical Survey Institute (GSI) over the Japanese Islands, in particular, during weather conditions that systematic horizontal gradient of water vapor exists in cases of front passages and tropical cyclone. The ZTD gradient of 50 mm per horizontal distance of 100 km is found to cause apparent horizontal coordinate variation of about 10 mm. These relationships become useful information to diagnose if unusually large horizontal coordinate variations retrieved by the GPS analysis reflect net crustal movements or noise due to water vapor distributions.

COMPARISON AND ACCURACY OF INTEGRATED WATER VAPOR FROM GROUND BASED GPS

H. Klein Baltink, A.C.A.P. van Lammeren, H. Derks (KNMI, De Bilt) B.A.C. Ambrosius, A.G.A. van der Hoeven, F. Kleijer, H. VAN DER MAREL (Delft University of Technology); A.J.M. Kosters (Survey Department of Rijkswaterstaat, Delft)

Integrated water vapor (IWV) is computed on a routine basis from a ground based GPS network in The Netherlands. The data is stored in a database together with IWV computed from radiosondes and IWV computed from KNMI's regional RACMO model. The standard deviation of the difference of the GPS derived IWV estimates for Kootwijk and radiosonde derived IWV in De Bilt, about 45 km from Kootwijk, is about 1.4 kg/m^2, with a bias of -0.1 kg/m^2.
Comparison with KNMI's RACMO model showed a good agreement as well. The results of the operational processing are displayed on the internet with a delay of 2 days.
The accuracy of the GPS IWV estimates has been confirmed by four experimental campaigns, where the GPS receiver in Delft was co-located with a microwave radiometer and/or radiosonde launches. Further experiments, using predicted IGS orbit in combination with orbit relaxation, showed that also for less accurate predicted orbit information, which is available in real-time, the same accuracy can be obtained as with rapid orbits.
Therefore, near real-time estimation of GPS IWV data for weather forecasting is in principle possible.

JSG28/E/11-B1 **1120**

FIRST EXPERIENCE WITH NEAR-REAL TIME WATER VAPOR ESTIMATION IN A GERMAN GROUND-BASED GPS NETWORK

Christoph Reigber, Galina DICK and Gerd Gendt (GeoForschungsZentrum Potsdam, Telegrafenberg A17, D-14473 Potsdam, Germany, email: dick@gfz-potsdam.de)

Water vapor plays a fundamental role in the transfer of moisture and latent heat in the atmosphere. Its observation remains one of the most complicated subjects and the knowledge of its distribution is yet insufficient. Therefore, continuous and well-distributed measurements of water vapor are of crucial importance for numerical weather predictions and climate research. The GPS technology is likely to become a very effective observing system for this key atmospheric parameter.
The European Union COST Action 716 is aiming at studying the usefulness of GPS-derived integrated water vapor in numerical weather prediction modeling. As a contribution to this study a joint project between GFZ and the German Meteorological Service (DWD) has been initiated in Germany. This project comprises all necessary components - data links and handling, path delay estimation, met data interpolation to GPS location, conversion to water vapor. Ten GPS receivers were installed at DWD synoptic sites in December 1998. The GPS and meteorological data are transmitted in hourly batches to the GFZ and processed with GFZ EPOS software, using predicted GPS orbits estimated at GFZ IGS Analysis Center. First experiences with near-real-time analysis have been obtained and the operational precision determination of water vapor within local GPS networks has been demonstrated. This initial project will be followed by a pilot project in a much denser German DGPS network. The presentation will give insight into all components of the system under development. It will demonstrate the capabilities of the methods used by GFZ for near-real-time processing and will show the strategy to develop from scientific processing to an operational day-to-day service. First results and comparisons will be presented.

IMPACT OF PRECIPITABLE WATER DERIVED FROM THE GPS NETWORK BY GEOGRAPHICAL SURVEY INSTITUE OF JAPAN ON NUMERICAL WEATHER PREDICTION

Nobutaka MANNOJI (Numerical Prediction Division, Japan Meteorological Agency, 1-3-4 Oote-machi, Chiyoda-ku, Tokyo 100-8122, JAPAN, email: nmannoji@npd.kishou.go.jp)

It is important to make accurate prediction of mesoscale phoenomina, which often bring torrential rain. In order to achieve the goal with numerical weather prediction (NWP), both the improvement of NWP models and accurate initial condition are needed. Although observation is necessary to make accurate initial condition, operational observation by radiosonde is too coarse in time and space resolution to capture the structure of such phenomena. Precipitable water (PW) retrieved from the zenith total delay of the GPS is revealed to be accurate.
Geographical Survey Institute (GSI) of Japan runs a nationwide GPS array composed of 949 observational points as of April 1998 separated typically by 15-30km from one another. Although this array is established to monitoring the crustal deformation, we can derive PW observation over Japan from this dense array with high resoloutin in time and space. PW retrieved from the GPS array are made use of in initial condition of water vapour in NWP, and the result of NWP with and without GPS PW are compared each other.

JSG28/E/09–B1 **1200**

EVALUATION OF WATER VAPOR OBSERVATIONS USING SAR, GPS, AND METEOSAT.

Ramon HANSSEN (Delft University of Technology, Thijsseweg 11, 2629 JA, Delft, the Netherlands, Email: hanssen@geo.tudelft.nl); Arnout Feijt (Royal Netherlands Meteorological Institute, P.O.Box 201, 3730 AE, De Bilt, the Netherlands, Email: feijt@knmi.nl); and Roland KLEES (Delft University of Technology, Thijsseweg 11, 2629 JA, Delft, the Netherlands, Email: klees@geo.tudelft.nl).

Water vapor is a key environmental parameter that is not currently measured with sufficient spatial density and accuracy for mesoscale meteorology and forecasting. Spaceborne radiometer observations, such as Meteosat, are available on spatial scales which are currently too coarse for, e.g., quantitative precipitation forecasting or cloud formation studies. Spaceborne geodetic observations such as GPS and radar (SAR) interferometry provide an independent source of meteorological information by analyzing the propagation delay of the electromagnetic signals. Availability of these data on a routine basis will improve numerical forecasting and mesoscale meteorology.
Here we evaluated observations obtained from the Meteosat water vapor channel, GPS stationary zenith delay time series, and SAR interferometry during a cold front passage over the Netherlands in March 1996. Repeat pass SAR interferometry combines two high resolution (20 m) radar images to measure lateral path length differences between the radar and the surface, with an accuracy of a few mm. These delay observations are then transformed to zenith integrated precipitable water (IPW) differences. Meteosat brightness temperature observations are transformed to IPW using a novel algorithm which also applies GPS observations. The GPS IPW measurements are obtained over a stationary site in the center of the cold front area.
An evaluation of the spatial correspondence between Meteosat and ERS SAR observations shows a sudden increase of 6 mm in integrated precipitable water (IPW), corresponding with the location of the cold front. Goodness of fit testing provided modest scaling factors for the dispersion of the difference between the two observations, achieving a standard deviation of 1.2 mm for the IPW observations. Currently, for localized applications of the technique, this is primarily attributed to the Meteosat observations. This spatial water…

REAL-TIME ESTIMATION OF PRECIPITABLE WATER USING NEW ZEALAND'S CONTINUOUS GPS NETWORK

Mark FALVEY (School of Earth Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand, Email: mfalvey@gamma.gns.cri.nz); John Beavan (Institute of Geological and Nuclear Sciences, PO Box 30368, Lower Hutt, Wellington, New Zealand, Email: J.Beavan@gns.cri.nz)

A network of five GPS receivers is currently in continuous operation in the New Zealand region, with much expansion expected in upcoming years. The primary purpose of the network is to monitor deformation occurring along the Australian-Pacific plate boundary. However the network is also being used to provide estimates of precipitable water (PW). For these to be most useful a real-time capability is required. Because data from all but one of the stations are acquired hourly this will be possible once a successful processing strategy is implemented.
To investigate the potential of real-time PW estimation from our network we have performed simulations of real-time processing. We identify two key factors which degrade the quality of the real-time estimates: (a) inaccuracies in the predicted orbit data used in the processing; and (b) end effects resulting from real-time estimates being made at the end of the data stream.
We examine the impact of each of the above. We also discuss techniques we have been using to remove poorly predicted satellite orbits from the estimation procedure. The method analyses the residuals of a first-guess estimation to identify those satellites that are most likely to cause problems. We find this results in a considerable improvement in the quality results.

ON GPS-DERIVED INTEGRATED WATER VAPOUR DURING FINNISH WINTER

Paavo J. AIRAKSINEN, Jussi Johansson, Hannu Koivula and Martin Vermeer (Finnish Geodetic Institute, P.O.Box 15, FIN-02431 MASALA, Finland; email: pja@fgi.fi, hko@fgi.fi and mv@fgi.fi)

A winter GPS-IWV field campaign was carried out in South-Western Finland in early 1998. The campaign included 6 temporal GPS-receiver sites around Jokioinen meteorological observatory where radiosondes were launched 2-3 times a day. An Ashtech Z12 GPS-receiver was coupled with a meteorological Vaisala PTU200 -transmitter at each site.
The data analysis was done using Bernese GPS-software and it shows that GPS-derived-IWV follows quite well the values of radiosonde-derived-IWV.
However during some days there exists systematical differences in the IWV within the mesoscale campaign area. These differences can be explained with horizontal inhomogenity of IWV during these days. During such days one should put special attention to the selection of the GPS-site against which comparisons of radiosonde-based-IWV are made. The effect of horisontally unhomogenious atmosphere to IWV comparisons is good to keep in mind also a larger spatial scale (i.e. comparing data from permanent GPS-sites).
The Finnish Permanent GPS-network (FinnRef with 12 sites) and a cooperative station in Xian (China) is now equipped with surface meteorological transmitters. Preliminary calculations of data from these stations in under way. However there are still some challenges to meet before ground based GPS-measurements can be used as an operational year-around source of data for meteorology in subarctic countries like Finland. During winter snow is temporally gathered on antenna radomes which causes an extra delay that sometimes can be of an order of the IWV or more.

GPS AND WVR DERIVED TROPOSPHERIC WATER VAPOUR IN THE GERMAN PERMANENT GPS NETWORK AND ITS USE FOR METEOROLOGY

Matthias BECKER, Georg Weber, Peter Franke and Wolfgang Schlueter (all at Bundesamt für Kartographie und Geodäsie, Richard Strauss Allee 11, D-60598 Frankfurt a. Main, Germany, email: becker@ifag.de).Christina Koepken (German Weather Service, Kaiserleistr. 42, D-63067 Offenbach, Germany, email: ckoepken@dwd.d400.de)

Since middle of 1996 the Federal Agency of Cartography and Geodesy (BKG) computes daily solutions for a set of German and European permanent GPS stations using the Bernese GPS Software. The EUREF-Per-manent network is densified by a set of twenty stations within Germany. The BKG processing is used to produce sets of tropospheric zenith path delay parameters in one or two hourly intervals. They are combined and compared with BKG Water Vapour Radiometer data (WVR), observed at the Fundamental Station Wettzell since October 1997. In a joint research project with the German Weather Service the potential use of the vertical integrated water vapour (IWV) content as derived from the tropospheric zenith path delay for the improvement of numerical weather forecast is studied. As a first step, the derived GPS-IWV is compared to IWV derived from weather forecast models. The influence of ancillary numerical model data used in the derivation of GPS IWV is studied. This paper presents re-sults of a test phase selected for a feasibility study and the ontinuous comparison of the WVR in Wettzell and the GPS estimates.

GROUND-BASED GPS METEOROLOGY AND CLIMATE RESEARCH

Michael BEVIS, James Foster and Steven Businger (SOEST, University of Hawaii, Honolulu, HI 96822, USA. Email: bevis@soest.hawaii.edu); Yoaz Bar-Sever, Bruce Haines and Jean Dickey (Jet Propulsion Laboratory, Los Angeles, CA 91109, USA); Peng Fang and Yehuda Bock (Scripps Institute of Oceanography, La Jolla, CA 92093, USA)

Ground-based GPS meteorology is now a fairly well established measurement technique. Most researchers engaged in the research and development of 'GPS met' are focusing mainly on its potential use in operational weather analysis and prediction. This is probably the most demanding of all applications identified to date by virtue of its requirement for nearly real-time measurements. Water vapor climatology is a less demanding application since solution latency is not an important consideration.
Nevertheless, using GPS networks for water vapor climatology involves a number of challenging technical problems, some of which are not very prominent in other applications. Our major emphasis to date is on water vapor and delay climatology in oceanic environments. We shall describe the scientific agendas, past experiences, preliminary results and future plans associated with our research programs in the Pacific Ocean and elswhere.

MONITORING THE ATMOSPHERE BY GPS AT MATERA SPACE GEODESY CENTRE

Ferraro C. (1), Nardi A. (1), Pacione R. (1), Sciarretta C. (1), Vespe F. (2) (1) Telespazio s.p.a. - Centro di Geodesia Spaziale Italiana - 75100 Matera (2) Agenzia Spaziale Italiana - Centro di Geodesia Spaziale Italiana - 75100 Matera

The Matera Space Geodesy Centre (CGS) has been providing geodetic (positions, baselines) GPS products relevant to the Mediterranean area to the international scientific users, by contributing to the IGS/EUREF project. In addition CGS supports, by its on-line data bank GeoDAF, the needs of the Italian operational and scientific users (e.g. land-surveyors, universities, cadastre,...). Beside the classical geodetic products, are now under testing other GPS by-products relevant to the monitoring of the charged and neutral atmosphere, such as TEC maps and Integrated Precipitable Water Vapour measurements. At present the procedures and the analysis strategy to recover reliably water vapour from tropospheric delays are under testing, mainly to contribute to the MAGIC project, a European joint project aiming to the use of permanent GPS receivers for weather forecast. In this work we want to present extensively a comparison of tropospheric zenith path delays obtained with different SW (GIPSY and MicroCosm) and strategies, using data of the Italian GPS Fiducial Network. Moreover the total tropospheric zenith path delay will be divided into dry and wet components using, when available, surface pressure and temperature. As far as the ionosphere is concerned, regional maps (for the Mediterranean latitudes) of Total Electron Content are produced, modelling a single-layered, 450 km high ionosphere by LS estimating the coefficients of the development of TEC as function of latitude and sun-fixed longitude, assuming as osservable the 'geometry-free' combination of L1 and L2. Examples of these products are shown and discussed as well as the procedure to obtain them.

GPS WATER VAPOR OBSERVATIONS OF A LANDFALLING HURRICANE

Seth GUTMAN (NOAA Forecast Systems Laboratory, 325 Broadway R/E/FS3, Boulder, Colorado 80303 USA, Email: gutman@fsl.noaa.gov)

High temporal resolution measurements of total column (integrated) precipitable water vapor during a landfalling Hurricane were successfully carried out this year by NOAA's Forecast Systems Laboratory using ground-based GPS meteorological techniques. GPS-IPW observations were made at NOAA Ground-Based GPS Water Vapor Demonstration Network sites located west and east of the eye of Hurricane Georges as it came ashore along the Gulf Coast of Mississippi on September 28, 1998. Several features of interest, such as the passage of cloud bands and the correlation of IPW maxima with pressure minima, are observed.

GPS DERIVED WATER VAPOR DISTRIBUTIONS COMPARED WITH SSM AND WVR: THE KILAUEA FIELD EXPERIMENT

Lars Peter KRUSE, Bernd Sierk, Beat Buerki, H.-G.Kahle (all at Geodesy and Geodynamics Laboratory,ETH Zurich,CH, email: kruse@geod.ethz.ch); Mike Lisowsky (US Geological Survey, HawaiianVolcano Obs., Hawaii, USA); Mike Bevis (University of Hawaii, Hawaii Instituteof Geophysics and Planetology, Hawaii, USA); Alan Dodson and Helen Baker (Institute ofEngineering Surveying and Space Geodesy,Universityof Nottingham, UK); Stefan V. Florek (Institute of Spechtrochemistryand Applied SpectroscopyRudower Chaussee 5, 12489 Berlin, Germany)

The estimation of total water vapor contents by ground based GPS meteorology is now a well established technique. However, the potential of the method for resolving 4-dimensional distributions of tropspheric water vapor still needs further investigation. In order to validatethis capability of GPS, we carried out a field experiment on Hawaii, USA. The ultra dense CGPS network operated at the Mt. Kialuea volcano provides an excellent basis for studies of new processing schemes such as GPS tomography. For comparison of GPS water vapor retrievals we as lodeployed radiosondes, 3 microwave radiometers and a newly developed Solar Atmospheric Monitoring Spectrometer (SAMOS). The poster presents a comparison of all the complementary techniques, focussing on vertical profiles of water vapor.

AN EXPERIMENTAL CAMPAIGN FOR EVALUATION OF WET DELAY VARIATIONS USING WVRS IN THE KANTO DISTRICT, CENTRAL JAPAN

ICHIKAWA Ryuichi (Kashima Space Research Center, Communications Research Laboratory, 893-1 Hirai, Kashima, Ibaraki 314-0012, Japan, e-mail: richi@crl.go.jp); ;Hiroshi Hanado (Communications Research Laboratory, 4-2-1 Nukui-kita, Koganei, Tokyo 184-8795, Japan); Kazumasa Aonashi (Meteorological Research Institute, Japan Meteorological Agency, 1-1 Nagamine, Tsukuba, Ibaraki 305-0052, Japan); Seiichi Shimada (National Research Institute for Earth Science and Disaster Prevention, 3-1 Tennoudai, Tsukuba, Ibaraki 305-0006, Japan); Yuki Hatanaka (Geographical Survey Institute, 1-Kitasato, Tsukuba, Ibaraki 305-0811, JAPAN); Joeta Yamamoto and Tamio Takamura (Center for Environmental Remote Sensing (CEReS), Chiba University, 1-33, Yayoi-cho, Inage-ku, Chiba-shi, Chiba 263-8522 Japan)

Understanding the space-time variability of the atmospheric delay is indispensable for accurate corrections of GPS and VLBI measurements. Recently, several anisotropic mapping functions in which atmospheric gradients are assumed to have a simple linear form have been proposed. On the other hand, meso and local scale phenomena such as passage of cold front, severe storms and land-sea breezes frequently occur in Japan. Thus, we have to evaluate the space-time variability of water vapor quantitatively under these meteorological conditions. For this purpose we carry on an experimental campaign for detecting and characterizing water vapor variations, using water vapor radiometers (WVRs) in the Kanto district of central Japan. WVR observations were started on June 24, 1998 and are still in progress. Our main concerns are (1) What is a dominant scale of disturbances causing significant positioning errors?, (2) Is it enough to use anisotropic mapping functions to remove effects caused by meso and local scale disturbances?, (3) Is it possible and useful to develop a new method for the correction using a Numerical Weather Prediction (NWP) Model? Observed results will be compared with precipitable water fields obtained by the permanent GPS array of the Geographical Survey Institute (GSI) and by the NWP model produced by the Japan Meteorological Agency. Atmospheric gradients estimated using GPS one-way phase residuals will be also compared with these water vapor fields. These analyzed results will be useful to develop an optimum method to handle the anisotropy of the atmosphere.

BEHAVIORS OF GPS RETRIEVED PRECIPITABLE WATER VAPORS OVER THE JAPANESE ISLANDS

Tetsuya IWABUCHI (The Graduate University for Advanced Studies, Mizusawa, 023-0861, Japan, email: iwabuchi@miz.nao.ac.jp); Isao Naito (National Astronomical Observatory, Mizusawa, 023-0861, Japan, email: naito@miz.nao.ac.jp)

Behaviors of precipitable water vapor (PWV) routinely retrieved from the nationwide array of Global Positioning System (GPS) in Geographical Survey Institute (GSI) of Japan for monitoring of crustal deformation are visualized and compared with the Japan area objective analysis data for numerical weather prediction (NWP) in Japan Meteorological Agency (JMA). While a front accompanying with heavy rainfalls moved eastward across the Islands during 9(LST) Sep. 1 - 9(LST) Sep. 3, 1996, the temporal anomalies in GPS PWVs moving along with the front are clearly detected with almost the same space resolution as in the array (50 km) all over the Islands. Comparisons of GPS retrieved PWVs with NWP PWVs show that GPS PWVs have negative biases amounting to 2 - 4 mm not due to the difference in the topographic heights are found all over the islands. The GPS array also retrieve behaviors of the diurnal variation of water vapor induced by thermally excited local circulation in summer over the Islands. Composites ZTD show characteristic tempo-spatial variations of water vapor losely related to topography of the Islands. In the principal component analysis of composite ZTDs, the first mode with contribution rate is about 75% having sudden increase of ZTD from dawn till dusk and gentle decrease from evening to night is dominant over the Islands especially in mountain area. These are consistent with results of model simulation on thermally excited local water vapor circulation.

REMOTE SENSING WATER VAPOR CONTENT THROUGH GROUND-BASED GPS DATA IN HONG KONG

Y. LIU, H.B.Iz and Y. Chen (Dept. of LSGI, The Hong Kong Polytechnic University, Hong Kong, email: 96980619r@polyu.edu.hk)

Spatial and temporal resolution of water vapor content is useful in improving the accuracy of short-term weather prediction. Dense and continuously tracking regional GPS arrays will play an important role in remote sensing atmospheric water vapor content. Establishment of a dense GPS array in the coming years in Hong Kong is under consideration for multi purpose applications including GPS Meteorology. In this study, we examined the problem of extracting water vapor content information from GPS data. A piecewise linear solution method was used to estimate the Precipitable Water Vapor (PWV) content from GPS observations in Hong Kong. To evaluate the solution accuracy of the water vapor content sensed by GPS, the upper air sounding data (Radiosonde) that are collected locally was used to calculate the precipitable water vapor during the same period. One-month results of PWV from both ground-based GPS sensing technique and Radiosonde method are in agreement within 1-2 mm.

WATER VAPOR DISTRIBUTION IN MIYAKE ISLAND, CENTRAL JAPAN DETECTED BY DENSE GPS MEASUREMENTS)

Atsushi MIWA (Division of Earth and Planetary Science, Graduate School of Science, Nagoya University, Furo, Chikusa, Nagoya, 464-8602, JAPAN, email: miwa@eps.nagoya-u.ac.jp); Fumiaki Kimata (Division of Science, G, Nagoya University, email: kimata@seis.nagoya-u.ac.jp)

Miyake Island, one of Izu Islands in Central Japan, is an active volcano and the eruptions have been repeated with intervals of about 20 years. The last eruption is in 1983. So GPS measurements in the island have been occupied continuously at ten stations and repeatedly in the dense network to discuss the crustal movement. Although Miyake Island is a small island such as 8 x 8 km, the top of the volcanic is 800m above the sea level. As local water vapor does not distribute uniformly over the island, GPS measurement errors show large. In the GPS measurements in 1998, we also made the meteorological observation at the GPS sites, it was raining locally and cap clouds were observed above the top. We would discuss the space-time distribution of water vapor with a_B&C_(J- mesoscale analyzing the GPS measurements.

TIME AND SPACE VARIATIONS OF WATER VAPOR DETECTED BY GPS PHASE RESIDUALS

Seiichi SHIMADA (Nat. Res. Inst. for Earth Sc. Disaster Prevention (NIED), 3-1 Ten-nodai, Tsukuba, Ibaraki 305-0006 JAPAN, email: shimada@geo.bosai.go.jp) Kazumasa Aonashi (Meteor. Res. Inst., 1-1 Nagamine, Tsukuba, Ibaraki 305-0052 JAPAN, email: aonashi@mri-jma.go.jp); Thomas A. Herring and Robert W. King (both at Dept. of Earth, Atmospheric and Planetary Sc., Massachusetts Inst. Tech., 77 Massachusetts Av., Cambridge, Massachusetts 02139 USA, email: tah@mtglas.mit.edu)

In usual GPS meteorological analysis, zenith delays of each GPS site are obtained and applied to discuss the water vapor variations. However from the nature of tropospheric phenomena, sometimes local scale inhomogeneity become dominant, and zenith delay, which represents 20 - 30km water vapor around GPS site averaging around 15 - 30 minute, is not suitable to discuss the water vapor time and space variations. Also in the mountainous and humid area like the Japanese Islands, local scale inhomogeneity is very usual. To detect the rapid and local scale water vapor behavior, we propose the GPS phase residual sky mapping obtained after the least-square parameter fitting. Because the traces of the GPS orbits at the short period are very limited, phase residuals in the isolated site may reduce poor water vapor sky distributions. Dense GPS network and/or slow local event like that caused by the tropospheric effect are very useful to apply the phase residual mapping.
We also demonstrate the examples of the horizontal mapping of the local scale inhomogeneity of water vapor caused by the local foehn event and the water vapor peak moving associated with the low-elevation clouds both observed in the Japanese GPS network (GEONET).

USE OF GPS FOR SENSING THE PRECIPITABLE WATER VAPOR IN EGYPT: A PROPOSAL

Ashraf MOUSA (National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt, email: ashrafkm@frcu.eun.eg)

Water vapor plays a crucial role in a variety of atmospheric processes that act over a wide range of spatial and temporal scale. It is widely appreciated that improved monitoring of atmospheric water vapor will lead to more accurate forecasts of precipitation and serve numerical weather modeling. However, the traditional tools for water vapor measurements or estimation is not adequate because, water vapor is the most variable of the major constituents of the atmosphere.
Emerging GPS networks invite a new and powerful approach to the remote sensing of the atmospheric water vapor. A GPS-based system for water vapor determination offers the benefits of better resolution of both spatial and temporal variation of the water vapor. This paper reviews the basics behind the use of GPS for water vapor prediction as will as its merits over traditional water vapor measuring tools. Then, the requirements of an operational GPS prediction system in near real time are summarized.

DETECTION OF TROPOSPHERIC DUCTS USING A GROUND-BASED GPS RECEIVER

Kenneth D. ANDERSON (Propagation Division, Space and Naval Warfare Systems Center San Diego D883, 49170 Propagation Path, San Diego CA, 92152-7385, email: kenn@spawar.navy.mil)

Terrestrial propagation of radio waves at frequencies somewhere above 30 MHz is often significantly affected by the composition of the troposphere, especially when both terminals are near a coastline. A famous example of anomalous propagation effects occurred in India during World War II when a 200 MHz radar (with an expected detection range of several hundred miles) detected the coast of Arabia some 2700 km away. Similar effects have been observed along the southern California coast by cell phone users in Los Angeles and San Diego who, instead of connecting with their local cell, are sometimes connected with a remote cell, perhaps 200 km away. Such anomalous effects are usually measured indirectly by sensing atmospheric properties with an instrumented weather balloon, a process that is both time-consuming and expensive. However, recent work with the Global Positioning System (GPS) demonstrates that ground-based measurement of GPS satellite signals can detect these anomalous propagation conditions. Therefore, by capitalizing on the existing technology of GPS, an affordable, all-weather, anomalous effects measurement capability is readily available.

GROUND-BASED GPS WATER VAPOUR ESTIMATION: POTENTIAL FOR METEOROLOGICAL FORECASTING

Helen BAKER, Alan Dodson and Nigel Penna (IESSG, University of Nottingham, University Park, Nottingham, NG7 2RD, UK, Email: helen.baker@nottingham.ac.uk); David Offiler and Mark Higgins (UK Meteorological Office, NWP Satellite Applications, London Road, Bracknell, Berks, RG12 2SZ, UK, Email: doffiler@meto.govt.uk)

In order to assess the impact of ground-based GPS Integrated Water Vapour (IWV) estimates in meteorological forecasting applications, estimates must be available within near real-time and must be of comparable accuracy to existing meteorological measurement techniques. As a prerequisite to assessing the potential benefit of GPS IWV estimates in Numerical Weather Prediction (NWP) models, extensive tests have been performed to examine the effect of various process error models, a-priori constraints and estimation techniques involved within GPS processing procedures, in order to devise a recommended processing strategy. One year of GPS data from a selection of stations, which are co-located with radiosonde launch sites, within the UK permanent GPS network, has been processed to validate these findings. Near real-time estimation issues have subsequently been examined, primarily using a sliding window processing approach to demonstrate the feasibility of producing accurate GPS IWV estimates within the required time frame. Additionally, preliminary work has been performed to assimilate GPS IWV into UK Meteorological Office Numerical Weather Prediction models (post-date), in preparation for impact assessments on the quality of mesoscale weather forecasts.

ATMOSPHERE PROBING BY GPS FOR SAR INTERFEROMETRY

Alessandro Bonforte and Giuseppe Puglisi (both at Istituto Internazionale di Vulcanologia - CNR, Piazza Roma, 2, I-95123, Catania, Italy; e-mail: bonforte@iiv.ct.cnr.it, geo@iiv.ct.cnr.it)

GPS measurements were carried out by the Istituto Internazionale di Vulcanologia in Catania (Italy) to evaluate the atmospheric effects on GPS signals. The aim of this work, performed in the framework of an EC project called Monitoring Active Deformation on Volcanoes by Interferometry as an Early Warning System (MADVIEWS), was to give an independent evaluation of the atmospheric artefacts that could affect the SAR interferometric images. The main effort of the IIV team in the project was to estimate the TEC (Total Electron Content) in the ionosphere and the ZPD (Zenith Path Delay) due to the troposphere. To this aim, GPS measurements have been carried out during the ERS-2 passes over Mt. Etna volcano. The knowledge of these parameters can be useful to model the SAR signal propagation respectively in ionosphere and troposphere. Since September 1996 to December 1997 these measurement sessions were carried out monthly, during both ascending and descending passes of the SAR sensor over the investigated area. About the ionosphere, local models were estimated for each ERS pass and TEC variations in the order of 10 TECU were found. Such variations are able to produce a difference in the SAR signal delay up to 20 cm. However, the variation of the TEC in the ionosphere may be considered almost uniform above the area covered by SAR images (about 100 Km X 100 Km). Thus, the result of the measured delay may be a vertical translation of the whole image or eventually a tilt, due to a different gradient in the TEC above the area during the two passes. About the troposphere, the ZPD was estimated for each station at each ERS pass; variation of the ZPD difference between the GPS stations up to 5-6 cm were measured, able to produce up to two fringes on the lower flanks of Etna in the interferograms in the worst conditions, simulating large scale inflations and deflations of the volcanic edifice.

4D TROPOSPHERIC TOMOGRAPHY USING GPS ESTIMATED SLANT DELAYS

A. FLORES, G. Ruffini, A. Rius, (Institut d'Estudis Espacials de Catalunya Edif. Nexus 204, C/ Gran Capita 2-4, 08034 Barcelona, Spain)

Retrieval of 4D fields of the tropospheric distribution of water vapor using GPS measurements is an additional and attractive use of the global positioning system. Stochastic GPS tomography has successfully been used in ionospheric studies and a we describe here a similar approach for tropospheric studies. We present here initial results on the tropospheric tomography, comparisons with other sources of data, an error analysis and a study of its resolution capabilities based on simulations. GPS data was tracked at the localpermanent network in Kilauea, Hawaii during one day in February 1997. It was then processed using the GIPSY-OASIS II software to extract the slant extra delays due to the wet troposphere. The inverse problem is then solved using our in-house software LOTTOS, which has been developed to yield the 4D refractivity field and the solution compared with ECMWF maps. This technique can potentially be used to monitor in a Near Real Time basis the status of the troposphere using a dense local network of receivers.

AN INTEGRATION OF GPS AND RADISONDE-DERIVED WATER VAPOUR CONTENT USING ARTIFICIAL INTELLIGENT FOR VALIDITY CHECKING

MANURUNG, Parluhutan (Bakosurtanal National Coordination Agency for Survey and Mapping, Jl. Raya Jakarta Bogor Km 46, PO Box 46/CBI, Cibinong 16911 Indonesia, E-mail: parlman@cbn.net.id Telephone No: +62-21-8764612 Fax No: +62 21 875 2064)

The paper demonstrates a combination of water vapor content (WVC) derived from GPS permanent tracking and radiosonde stations in the Indonesian region. Since the existing radiosonde network consists of 10 stations only, this is still inadequate to represent that of high varying WVC condition of the tropical country, with length and width of about 5000 and 2000 kilometres, respectively. Some efforts to increase the station number are limited due to a radiosonde is disposable resulting in expensive operational cost.
Validity checking of GPS-derived WPC were performed using artificial intelligent. The results show that the two types of observations are in close agreement.
Since the existing GPS permanent tracking stations in the country are of currently three stations only, the research is limited to provide a model for densification of WPC network. The model should be capable of integrating a number of additional stations as in the future the demand for that of GPS station is growing high, so that an integration of GPS with Radiosonde for determining representative WVC of the region could be achieved.

SPATIO-TEMPORAL VARIATION OF ATMOSPHERIC DELAY GRADIENT RETRIEVED BY A DENSE GPS ARRAY AND ITS RELATIONSHIP WITH SITE COORDINATE VARIATIONS

Shin-ichi Miyazaki (Geographical Survey Institute, Tsukuba, 305-0811, Japan, email: miyazaki@gsi-mc.go.jp); Tetsuya Iwabuchi (The Graduate University for Advanced Studies, Mizusawa, 023-0861, Japan, email: iwabuchi@miz.nao.ac.jp); Kosuke Heki (National Astronomical Observatory, Mizusawa, 023-0861, Japan, email: heki@miz.nao.ac.jp) Isao Naito (National Astronomical Observatory, Mizusawa, 023-0861, Japan, email: naito@miz.nao.ac.jp)

We performed a series of GPS analysis with estimating atmospheric delay gradient for the nationwide GPS array of Geographical Survey Institute (GSI) over the Japanese Islands in cases of front passages and tropical cyclone. Clear inverse correlation was found between the wet component of the gradient and the horizontal coordinate variation, and this result agreed with the result of a theoretical study and a simulation study. Furthermore, a large amount of the horizontal coordinate variation found by Iwabuchi and Naito (1999) disappeared when the atmospheric gradient was estimated. Therefore, we can conclude that the estimated gradient reflects the real spatial distribution of water vapor, and estimating the atmospheric gradient significantly improves the repeatability of horizontal coordinate when a systematic horizontal gradient of water vapor exist.

MEASURING REGIONAL PRECIPITABLE WATER VAPOR VARIATIONS USING THE JAPANESE DENSE GPS NETWORK

Ryu OHTANI (Univ. Tokyo, Department of Earth and Planetary Physics, 7-3-1 Hongo Bunkyo-ku, Tokyo 113-0033 Japan. E-mail: ryu@gpsun01.geoph.s.u-tokyo.ac.); Isao Naito (National Astronomical Observatory)

We investigate the applicapability of GPS for sensing water vapor using Japanese nationwide geodetic GPS network (GEONET) established by Geographical Survey Institute (GSI). We made a case study of summer days to see whether the 2 dimensional GPS derived precipitable water vapor (PWV) distribution field could detect the variations of water vapor over a regional scale. We used GPS data collected at about 200 GSI's stations deployed over the central part of Japan with the mean separation of about 25 km. We estimated zenith tropospheric delay every 5 minutes using GIPSY software and converted into PWV using surface pressure and temperature measurements. Then, we made contour maps of PWV every 1 hours plotted with the surface meteorological measurements (wind speed and direction, etc.) obtained by Automated Meteorological Data Acquisition System (AMeDAS) stations deployed by Japan Meteorological Agency all over the Japan islands. We found diurnal variations of PWV field associated with thermally- induced local circulation that drove water vapor from coastal regions to inland mountainous regions, that demonstrate the usefulness of GPS network to study the motions of water vapor with a spatial scale of a few tens of kilometers.

HIGH TIME RESOLUTION MEASUREMENTS OF PRECIPITABLE WATER VAPOR FROM PROPAGATION DELAY OF GPS SATELLITE SIGNALS

Takayuki YOSHIHARA, Toshitaka Tsuda (both at Radio Atmospheric Science Center, Kyoto University, Uji, Kyoto, 611-0011, Japan, email: yosihara@kurasc.kyoto-u.ac.jp) and Kazuro Hirahara (Department of Earth and Planetary Sciences, Graduate School of Science, Nagoya University, Nagoya, 464-8602, Japan, email: hirahara@eps.nagoya-u.ac.jp)

Aiming to apply Global Positioning System (GPS) measurements to an observation of meso-scale phenomena in the atmosphere, we estimated precipitable water vapor (PWV) with a good time resolution from GPS data. To verify such PWVs, we mainly used three meteorological instruments, which were radiosonde, radiometer and ceilometer. We analyzed two GPS campaign data sets, which were observed in Shigaraki, Shiga, Japan in 1995 and in Yamagawa, Kagoshima, Japan in 1996.
From comparison between the GPS and radiosonde results, we found that the GPS result with a high time resolution correctly provides the absolute values of PWV. In the comparison between the GPS and radiometer results (in the zenith direction), general tendency of the GPS results with a time resolution of 6 min. agreed well with the radiometer. Finally, we compared GPS results with the zenith delay caused by water vapor which were contained the lowest cloud layer, whose bottom height and thickness were obtained from a ceilometer measurement. As a result, we obtained good agreement of relative zenith delay perturbations between the results of GPS (estimated every 1 min.) and a ceilometer, especially, in the case of the cloud bottom height was as low as 100 m.

CALIBRATING SPACEBORNE MICROWAVE RADIOMETERS WITH GPS

Bruce HAINES, Yoaz Bar-Sever and Shailen Desai (all at Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109: e-mail: Bruce.J.Haines@jpl.nasa.gov)

Data from terrestrial GPS receivers are being used in growing numbers of applications requiring precise tropospheric sensing. One emerging application is the calibration of water vapor measurements from spaceborne microwave radiometers. An excellent candidate mission for developing this technology is Topex/Poseidon (T/P). A joint U.S./France mission launched in 1992 to measure global ocean circulation and sea level, T/P carries a microwave radiometer to provide measurements of wet path delay with cm-level accuracy. The nadir-looking Topex microwave radiometer (TMR) was included to provide a columnar water vapor delay correction for the altimeter range measurements used in forming the sea-surface height measurements. As such, any spurious drift in the TMR measurements can map significantly into the estimated rate of change in global mean sea level from T/P.
By virtue of their proximity to open-ocean T/P repeat tracks, many stations in the rapidly growing GPS global network are well suited for monitoring the TMR. For these locations, we are constructing time series based on the differences of the instantaneous vertical wet path delay derived independently from the TMR and GPS data at T/P overflight times.
Using data from four GPS stations with the longest and most consistent tracking histories, we concluded that the TMR measurements of wet path delay drifted lower by 1 mm/yr from 1992_97. We discuss the challenges encountered in using these long-term GPS time series as a calibration tool. We also present new TMR drift and scale error estimates from an extended analysis incorporating additional GPS stations. Finally, we discuss plans and prospects for calibrating the radiometer on the T/P follow-on mission (Jason-1), scheduled for launch in May, 2000.

EVALUATIONS OF THE ACCURACY OF PRECIPITABLE WATER VAPOR ESTIMATED FROM GPS OBSERVATIONS WITH RADIOSONDE MEASUREMENTS IN JAPAN

Ryu OHTANI (Univ. Tokyo, Department of Earth and Planetary Physics, 7-3-1 Hongo Bunkyo-ku, Tokyo 113-0033 Japan. E-mail: ryu@gpsun01.geoph.s.u-tokyo.ac.); Isao Naito (National Astronomical Observatory)

We compared precipitable water vapor (PWV) estimated from routine geodetic analyses of Japanese nationwide GPS network (GEONET) with nearby radiosonde observations. It is found that the accuracy of GPS PWVs estimated using GAMIT in 1995 and using Bernese in 1996 are 3.2 mm and 3.6 mm in r.m.s. sense, respectively. However, we found systematic deviation of the biases in both cases; there were significant differences in mean biases between radiosonde launching times (00UT, 12UT) and the PWV differences tend to become large in accordance with the increase of the total PWV. We investigated the causes of the above systematic deviation by analyzing GPS data collected at Tsukuba (IGS station) using different software with different analysis strategy. Comparisons with nearby radiosonde measurements for two years showed the agreement of 2.0 mm in r.m.s. sense though GPS PWV exhibited similar systematic deviation. It was found that incorporating GPS station displacement due to ocean tide loading in the analysis reduced the bias depending on radiosonde launching time. It was also found that adjusting mapping function by incorporating

the tropopause height and the surface temperature measurements reduced the systematic deviation that depended on total amount of PWV. These results suggest that the ocean tide loading effect and seasonal variation of the mapping function are important for precise determination of PWV in Japan.

JSG28/E/05–B2 0950

MITIGATING THE EFFECTS OF SPACE WEATHER ON THE CANADIAN WAAS

R.B. LANGLEY and P.J. Stewart (Geodetic Research Laboratory, Dept. of Geodesy and Geomatics Engineering, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3. E-mail: lang@unb.ca, pstewart@unb.ca)

GPS receivers typically used in aviation are single-frequency units. They are incapable, therefore, of using the dual-frequency technique of removing the ionospheric propagation delay from their pseudorange measurements. Furthermore, neither the measured pseudorange - carrier-phase divergence nor the predicted corrections provided in the navigation message are sufficiently reliable to provide the required vertical position accuracy for Category I precision approaches. The Wide Area Augmentation System (WAAS), currently being developed under the sponsorship of the U.S. Federal Aviation Administration in concert with Nav Canada, will provide real-time gridded values of vertical ionospheric delay from which user line of-sight delays can be computed. The vertical delays, together with error-bounding values, will be determined from the measurements by a network of continuously-operating dual-frequency reference receivers and delivered to users via satellite transmission.
Canada's northerly latitude makes mitigation of ionospheric effects a far from trivial task as the ionosphere can be markedly more active in the auroral and polar cap zones and hence more difficult to model. In this paper, we report on an evaluation of the proposed WAAS ionospheric modelling scheme as it would be used in Canadian airspace. Several recommendations concerning reference station location, ionosphere grid spacing, and the effect of ionospheric scintillations will be made.

JSG28/E/24–B2 1010

MAPPING AND PREDICTING THE EARTH'S IONOSPHERE BASED ON IGS DATA

Stefan SCHAER and Markus Rothacher and Gerhard Beutler (all at Astronomical Institute, University of Berne, Sidlerstrasse 5, CH-3012 Berne, Switzerland, email: stefan.schaer@aiub.unibe.ch)

CODE, the Center for Orbit Determination in Europe, has been routinely deriving global ionosphere maps (GIMs) from IGS (International GPS Service) data for long time. The current GIMs are represented by a spherical harmonic expansion of degree 12 and order 8 referring to a solar-geomagnetic frame. They describe the total electron content (TEC) with a 2-hour resolution and are made available since June 1998 in the IONEX (IONosphere Map EXchange) format adopted by the IGS.
In mid 1999, the time series of CODE GIMs cover 4.5 years without gaps. The associated time series of global TEC parameters document the evolution of the ionosphere during a period of low solar activity. We discuss series of particular TEC parameters, like the mean and maximum TEC. The series of spherical harmonic coefficients allow to study, for example, autocovariance functions, which may be used in turn to extrapolate signals related to individual coefficients or to predict GIMs. CODE is therefore in a position to generate 1-day as well as 2-day predicted GIMs on a daily basis. Finally, we give time series of differential code biases (DCBs) for GPS - and possibly GLONASS - satellites and for receivers obtained as a by-product of the TEC determination. Other IGS analysis centers also supply TEC/DCB products in the IONEX format. This allows to compare and validate results.

JSG28/W/12-B2 1030

STATUS REPORT ON THE OERSTED AND SUNSAT GPS OCCULTATION EXPERIMENTS

E. Robert KURSINSKI and George Hajj (Both at Jet Propulsion Laboratory, California Institute of Technology, Pasadena CA 91109 USA, Email: Rob.Kursinski@jpl.nasa.gov); Per Hoeg (Danish Meteorological Institute, Atmosphere Ionosphere Research Division, Lyngbyvej 100, DK-2100 Copenhagen, DENMARK, E-mail: hoeg@dmi.dk)

With their launch in January 1999, the Oersted and SUNSAT satellites are the first two in a series of orbiting GPS receivers which will acquire occultation data from low Earth orbit over the next several years. Oersted and SUNSAT provide a test bed for evaluating and developing the occultation capability and begin the dramatic increase in sampling density and continuity over that of the prototype GPS/MET experiment. The upcoming group of orbiting receivers will provide sampling comparable to and gradually surpassing that of the present global radiosonde network reaching densities needed to address significant scientific issues in weather, climate and the behavior of the coupled atmosphere-ocean system in general. In this presentation, we will provide a status report on the first 6 months of the occultation experiments on the Oersted and SUNSAT missions including the status of flight instruments and ground network used for clock calibration, and a summary of the data acquired thus far including spatial and temporal sampling and the processing status and availability of archived data. Early validation and analysis results will be presented. Plans for continued data acquisition and the configuration of the instruments will be discussed including data acquisition strategies under the constraint of limited power as necessary.

JSG28/W/27–B2 1110

APPLICATIONS OF COSMIC TO METEOROLOGY AND CLIMATE

Richard A. ANTHES, Christian Rocken, and Ying-Hwa Kuo (all at University Corporation for Atmsopheric Research, P.O. Box 3000, Boulder CO 80307, USA; email: anthes@ucar.edu)

Based on the success and scientific results of the GPS/MET experiment, Taiwan and the U.S are working together to develop COSMIC (Constellation Observing System for Meteorology, Ionosphere and Climate), a follow-on project for weather and climate research, climate monitoring, space weather, and geodetic science. COSMIC plans to launch eight LEO satellites in 2002. Each COSMIC satellite will retrieve about 500 daily profiles of key ionospheric and atmospheric properties from the tracked GPS radio-signals as they are occulted behind the Earth limb. The constellation will provide frequent global snapshots of the atmosphere and ionosphere with about 4,000 daily soundings. In meteorology COSMIC will provide high vertical resolution temperature, pressure and water vapor information for a variety of atmospheric process studies and to improve the forecast accuracy of numerical weather prediction (NWP) models. For climate research and monitoring COSMIC will provide an accurate global thermometer that will monitor Earth's atmosphere in all weather with unprecedented long-term stability, resolution, coverage, and accuracy. This paper discusses some of the applications of COSMIC data for meteorology, including NWP, and climate.

JSG28/W/23–B2 1130

FIRST RESULTS OF GPS ATMOSPHERE PROFILING FROM THE OERSTED MISSION

P. HOEG (Atmosphere Ionosphere Research Division, Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark, email: hoeg@dmi.dk), H.-H. Benzon (DMI, email: hhb@dmi.dk), J. Grove-Rasmussen (DMI, email: jgr@dmi.dk), C.O. Jensen (DMI, email: coj@dmi.dk), G.B. Larsen (DMI, email: gbl@dmi.dk), M.D. Mortensen (DMI, email: mdm@dmi.dk), M.B. Sorensen (DMI, email: mbs@dmi.dk), S. Syndergaard (DMI, email: ssy@dmi.dk)

The launch of GPS/MET in 1995 started a range of activities to establish the foundation for GPS atmosphere profiling of the Earth based on observations of GPS signals from a low Earth orbiting satellite. The next satellites able to perform the high-precision atmosphere limb soundings after the GPS/MET proof-of-concept mission are the Danish OERSTED satellite and the South-African SUNSAT satellite (here named the OERSTED mission). The launch of both satellites will take place in January 1999.
The first results from the OERSTED mission of limb soundings will be presented and evaluated in view of the results from the GPS/MET mission. Various effects of the error sources on the final retrieved profiles of refractivity and atmosphere parameters (temperature, pressure and humidity) will be discussed and related to global numerical weather prediction (NWP) model estimates. Additionally will the accuracy of the technique, when applying alternative inversion theories, be addressed.
Preliminary results of the directly integrated limb sounding measurements into NWP models will be laid out along with discussions on the influence of dynamical effects on the retrieved data.

JSG28/W/10–B2 1140

GLOBAL IONOSPHERIC MODELS FROM GPS MEASUREMENTS

C. Brunini, A. Meza: (Facultad de Sciencias Astronomicas y Geofisicas, La Plata, Argentina), Kleusberg, D. DETTMERING: (Institute of Navigation, University of Stuttgart, Germany, E-mail: dettmering@nav.uni-stuttgart.de Telephone No: +49 711 121 4137, Fax No: +49 711 121 2755)

GPS signals passing through the earth's atmosphere are affected by refraction in the ionosphere and the lower neutral atmosphere. For many applications these effects are seen as nuisance, but on the other hand refraction effects in GPS measurements contain useful information about the structure of the atmosphere.
In this contribution we focus on the upper part of the atmosphere: the ionosphere. The dispersive nature of this layer gives the opportunity to use two frequency GPS measurements to recover information about the electron density distribution.
Ground-based GPS measurements allow the determination of two dimensional global maps of the Total Electron Content (TEC). To obtain three dimensional models it is necessary to include data collected by one or more space-borne receivers on Low Earth Obiters (LEOs).We present two-dimensional ionospheric maps calculated from data provided by globally distributed IGS stations. In a second part, we discuss the extension of the model into the third dimension and show the possibilities of this approach as well as its limitations. Especially the requirements of the model on the number of LEO satellites and on their orbit parameters are analyzed.

VERIFICATION OF GPS/MET TEMPERATURE PROFILES WITH RADIOSONDE AND LIDAR MEASUREMENTS

Masahiro Nishida and Toshitaka TSUDA (Radio Atmospheric Science Center, Kyoto University Uji, Kyoto 611-0011, Japan, Email: nishida@kurasc.kyoto-u.ac.jp, tsuda@kurasc.kyoto-u.ac.jp); Christian Rocken and Randolph H. Ware (GPS/MET Project, GPS Science and Technology (GST) Program, UCAR, Boulder, CO 80307-3000, Email: rocken@unavco.ucar.edu, ware@unavco.ucar.edu); Hideaki Nakane, Nobuo Sugimoto, and Parameswaran S. Namboothiri (National Institute of Environmental Studies (NIES), Tsukuba 305-0053, Japan,Email: nakane@nies.go.jp, sugimoto@nies.go.jp)

This paper is concerned with a comparison of the GPS/MET temperature retrievals with the profiles collected with a balloon-borne radiosonde and a Rayleigh lidar in Indonesia and Japan. We have obtained 33 cases when the GPS/MET profile was determined within several hundred kilometers of two balloon launch sites in Indonesia; Bandung (6.9S, 107.6E) and Pontianak (0.03N, 109.3E). The rms deviation between GPS/MET and radiosonde results was approximately 1 K in the upper troposphere when effects of humidity are small, and about 2 K in the lower stratosphere below about 35 km. We have also compared 18 GPS/MET profiles with Rayleigh lidar measurements in Tsukuba, Japan (36.1N, 140.1E), and found the mean rms difference of 6.0 K and 10.2 K at 30-40 km and 40-60 km altitudes, respectively. These validation studies suggest that the GPS/MET profiles resolve detailed temperature structure, including sharp inversions and the step-wise increase of the temperature gradient near the tropical tropopause.

CODE DEVELOPMENT AND ASSESSMENT OF METEOROLOGICAL PARAMETERS DERIVED FROM GPS/MET DATA

Ting-To YU (Satellite Geoinformatics Research Center, National Cheng Kung University, Tainan, Taiwan, email: yutt@mail.ncku.edu.tw); Ming Yang(Dept. Survey Engineering, National Cheng Kung University, Tainan, Taiwan, email: myang@mail.ncku.edu.tw)

The major mission of ROCSAT III/COSMIC is to retrieve profiles of water vapor, temperature, electron density, and atmospheric refractivity from gathered data globally. Through out the mean of obtaining radio occultation observations from 24 GPS satellites to a constellation of 8 low Earth orbit (LEO) satellites, the variation of electron density within ionosphere, and so is the temporal/spatial change of global meteorological parameters can be estimated. The raw data acquired from GPS/MET satellites handled by certain process can produce the information regarding to the electronic density of ionosphere, and profile of atmospheric refractivity (N). Such processes including the excess delay of GPS signal, bending angle, impact parameter (a) and radius at tangent points. These data thus integrated by the Abel transform to compute the three dimensional distribution of electronic density of ionosphere, and also the global coverage for the profile of atmospheric refractivity (N). From this, one can estimate the meteorological parameters; such is water vapor, pressure, temperature etc. The data processing begin from data set of Level 0, that is the raw science data and satellite attitude and ephemeris. Afterward is the double difference handling to the GPS signal to remove both the clock bias between satellite and receiver, and the selective availability (SA) which deployed by the Department of Defense of United States. With different applied process, the Level 0 to Level 4 data can finally be sorted with developed codes, and the content of Level 4 data mainly is the meteorological parameters, which is the goal of this COSMIC mission. However, the inverting process from atmospheric reflectivity to the meteorological parameters is non-linear. It is an interactive and multi-parameters schema, which is difficult to achieve by traditional linear inversion or controlling factors method.

SPATIAL CORRELATION OF IONOSPHERE DURING DISTURBANCES DERIVED FROM GPS MEASUREMENTS

Lubomir W. BARAN (Institute of Geodesy, Olsztyn University of Agriculture and Technology, 10-957 Olsztyn, Poland, email: baran@moskit.art.olsztyn.pl); Ivan I. Ephishov and Irk I. Shagimuratov (both at West Department of the Institute of Geomagnetism, Ionosphere and Radiowave Propagation of the Russian Academy of Sciences)

The magnetospheric storms create severe ionospheric conditions for precision of geodetic measurements. Storm effect (in value of TEC) depends on latitude and local time. As a result, the spatial correlation of ionosphere at far stations in storm time spoils. We analysed the spatial correlation of ionosphere for storm on 22 November 1997 using the GPS measurements of European IGS stations: Jozefoslaw, Lamkowko, Matera, Mendeleevo, Metsahovi. To exclude the influence of biases the ionospheric Doppler data were used. For quiet day – 21 November 1997 the correlation at distance about 2000 km was 0.9 – 0.8. During storm the correlation decreased. It strongly varied in time. For individual GPS satellite passes the correlation is dropped to become lower than 0.5, at distance 300 km. The analysis of the behaviour of the TEC shows the essential increase of the TID during the storm. It concerns the large as well as medium-scale TID. The correlation of the ionospheric Doppler effect at presence of the TID is lowered down to 0.5, at distances less than 100 km. In the paper we also discuss the behaviour of single-differences between stations during the storm.

SOME ASPECTS OF APPLICATION OF IONO- AND TROPOSPHERIC MODELS TO PROCESSING OF PERMANENT GPS OBSERVATIONS.

Janusz BOGUSZ and Mariusz Figurski (Institute of Geodesy and Geodetic Astronomy, Warsaw University of Technology, 00-661 Warszawa, POLAND, e-mail: jb@gik.pw.edu.pl)

The GPS permanent services in the whole world become more and more important in monitoring of the global geophysical fluids. The accuracy of such measurements is influenced by atmospheric effects, ambiguities of the phase measured, corrections for the rate of satellite clock and the ground reception systems GPS, as well as a number of instrumental errors. With good approximation, these effects may be modelled by using algorithms included in professional software designed to develop high accuracy GPS systems. Of many possible errors to be encountered, we should take into account either the problem of ionospheric refraction or the effect of the tropospheric zenith delay. This paper deals with these two problems occurring in GPS measurements, especially in permanent sites and presents the methods of their solving tested in the Warsaw University of Technology IGS Associate Analysis Centre.

GPS-OBSERVED IONOSPHERIC DISTURBANCES AROUND AUSTRALIAN REGION DURING THE 4 MAY 1998 MAGNETIC STORM

Yue-Jin WANG (IPS Radio and Space Services, Sydney, Australia, email: yuejin@ips.gov.au)

On 4 May 1998, a major magnetic storm was observed at IPS Learmonth Observatory in Western Australia. The storm is explained as being due to the coronal mass ejection associated with an X1 solar flare observed on 2 May 1998. Using data from the Australian Regional GPS Network (ARGN), we have detected some significant ionospheric disturbances during the storm period. In this paper we present the GPS-observed results of ionospheric irregularities by analysing the large gradients of the ionospheric total electron content (TEC) due to the magnetic storm activity. The temporal and spatial variations of TEC are analysed and the potential ionospheric limitations to Wide Area Differential GPS are discussed.

GPS REMOTE SENSING FOR TEMPERATURE, PRESSURE AND TROPOSPHERIC WATER VAPOR IN THE ATMOSPHERE USING ADDITIONAL WATER VAPOR FREQUENCIES

Dasheng FENG, Benjamin Herman and David Flittner (Institute of Atmospheric Physics, University of Arizona, Tucson, 85721 U.S.A., email: feng@atmo.arizona.edu); E. Robert Kursinski and Thomas P. Yunck (Jet Propulsion Laboratory, MS 238-600, Pasadena, CA 91109 U.S.A.)

The GPS/MET project has successfully shown that the space-borne radio occultation technique using the GPS L1 and L2 channels can be utilized for remotely sensing pressure and temperature of the Earth's atmosphere from near ground to ~40 km height with unprecedented accuracies. The major observables in GPS/MET are the Doppler-shifted frequencies (phases) of the L1 and L2 signals due in part to the bending of the rays caused by gradients in atmospheric index of refraction. Atmospheric temperature and pressure profiles can then be derived using the bending angles as determined from the measured Doppler shifts. The major disadvantage of this method is the inability to separate water vapor contributions from the dry air contributions to the total atmospheric bending angles with just the L1 and L2 frequencies. Consequently, the retrieved temperatures are considerably different from the real temperatures in the lower part of the troposphere where water vapor is usually plentiful. In addition, water vapor cannot be retrieved from the GPS sounding without additional information and assumptions.
By adding water vapor absorption frequencies around 22 GHz in addition to the standard GPS L1 and L2 frequencies, tropospheric water vapor profile may also be retrieved. Three independent equations are needed for the three variables: temperature, pressure, and water vapor. The first equation comes from the measured atmospheric index of refraction obtained from the GPS L1 and L2 phase measurements; the second equation consists of the measured transmission in the water vapor absorption band; and the third equation is the hydrostatic equation. Solving this closed set of equations, temperature, pressure and tropospheric water vapor can all be retrieved accurately, simultaneously, and independently.
Results of our simulation studies, along with a discussion of the results, will be presented.

ATMOSPHERE WATER VAPOUR DETECTION APPLYING GPS LIMB SOUNDING

J. GROVE-RASMUSSEN (Atmosphere Ionosphere Research Division, Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark, email: jgr@dmi.dk), P. Hoeg (DMI, email: hoeg@dmi.dk); M.B. Sorensen (DMI, email: mbs@dmi.dk) and S. Syndergaard (DMI, email: ssy@dmi.dk)

GPS atmosphere limb soundings on a low Earth orbiter (LEO) have demonstrated the potential of obtaining vertical temperature profiles of the atmosphere. The water vapour profile of the troposphere can be detected by a similar technique. From information on the received phase of the two GPS radio frequencies, precise position and velocity of the involved GPS satellites and LEO, the bending angle of the radio signals, caused by the refraction in the atmosphere, can be determined. Through a relation between the refractivity, temperature, air pressure and water vapour, the dry air temperature can be determined at altitudes above the bulk water vapour content of the troposphere. The water vapour pressure profile is established by comparing the obtained dry temperature profile with an externally determined temperature profile.
The presented initial results from the Danish OERSTED satellite consist of comparisons of derived water vapour profiles with numerical weather prediction analyses and co-located radiosonde observations. Quality testing and error analysis of the retrievals are performed as function of geographical position, enabling tests of moist (tropical) and dry (high latitude) occultation results. The inversion method applied is examined for its ability to measure physical phenomena in the atmosphere and the dependency upon the assumptions throughout the analysis.
Initial results from the OERSTED satellite and the general ability to measure water vapour in the atmosphere by the GPS occultation technique will be presented.

ANALYSIS OF RADIO OCCULTATION DATA BY MEANS OF THE RADIOHOLOGRAPHIC METHOD

K. HOCKE, A. Pavelyev, O. Yakovlev, N. Jakowski (DLR-DFD, Kalkhorstweg 53, 17235 Neustrelitz, Germany, e-mail: hocke@nz.dlr.de, IRE RAS, Fryazino, Vvedenskogo sq. 1, 141120 Moscow region, Russia, e-mail: agp117@ire216.msk.su)

The radioholographic method was developed by IRE RAS using radio occultation data of "MIR"-GEO satellites. Recently this method was applied to GPS/MET occultation data by joint efforts of IRE RAS and DLR-DFD. The radio signals received at the LEO satellite are analysed by using a reference beam. From the continuous phase and amplitude measurements at the LEO satellite it is possible to derive high resolution angular spectra as function of time during the occultation event. Subsequently, profiles of bending angle, refractivity and temperature can be retrieved from these angular spectra. This new method is briefly described in the present paper. Angular spectra obtained by various spectral analysis methods are compared, and the corresponding profiles of bending angle and temperature are presented. The potential of the radioholographic method will be discussed in view of enhanced height resolution and detection/removal of multibeam effects.

COSTELLATION OBSERVING SYSTEM FOR METEOROLOGY, IONOSPHERE, AND CLIMATE---COSMIC: AN OVERVIEW

Ying-Hwa KUO (UCAR, P.O. Box 3000, Boulder, CO 80307, USA, Email: kuo@ucar.edu); Chris Rocken (UCAR, P.O. Box 3000, Boulder, CO 80307, USA, Email: rocken@ucar.edu); Gerald Liu (NSPO, 8F, 9 Prosperity 1st Road, SBIP, Hsing-Chu, Taiwan, Email: di13@nspo.gov.tw); Lou Lee (NSPO, 8F, 9 Prosperity 1st Road, SBIP, Hsing-Chu, Taiwan, Email: loulee@nspo.gov.tw)

Constellation Observing System for Meteorology, Ionosphere and Climate---COSMIC is a collaborative science project between the United States and Taiwan. The goal is to launch a constellation of eight small satellites in late 2002. The primary science payload is the latest version of the GPS flight receiver developed by the Jet Propulsion Laboratory. Two secondary payloads are a Tiny Ionospheric Photometer (TIP), developed by the Naval Research Laboratory (NRL) and a Tri-Band Beacon (TBB) transmitter, jointly developed by NRL and Applied Research Laboratory at the University of Texas. COSMIC will produce approximately 4,000 radio occultation sounding every day, in all weather and uniformly distributed around the globe. The TIP and TBB will provide ionospheric measurements that are highly complementary to the GPS occultation soundings. Recent scientific studies have indicated that these soundings and ionospheric measurements will be useful for a variety of weather, climate and ionosphere research and operational applications. COSMIC is a research and operational demonstration program designed to provide atmospheric and ionospheric data in near real time. These data will be provided openly and at the minimum cost of communication and reproduction. In this presentation, we will discuss the preliminary design of the COSMIC system and the program schedule.

VERTICAL RESOLUTION OF GPS OCCULTATION DATA FROM OERSTED/SUNSAT

M. D. MORTENSEN, (Atmosphere Ionosphere Research Division, Danish Meteorological Institute, Copenhagen, Denmark, email: mdm@dmi.dk.)

Vertical resolution is an important aspect of all atmospheric remote sensing techniques. In the troposphere there are features with small scale variations - such as the planetary boundary layer and the water vapor concentrations - which requires better vertical resolution than most remote sensing techniques can achieve at the moment. Occultations using the Global Positioning System (GPS) gives vertical profiles of the atmosphere when inverted. These profiles have inherently high vertical resolution but still, the vertical resolution is limited by diffraction effects. Recently developed inversion methods takes diffraction effects into account and thereby improves the resolution. Initial tests indicates that the diffraction methods improves the resolution by a factor of several, down to ~100m. In this talk a brief explanation of the different inversion methods will be given but the main aim is to present high resolution tropo-spheric profiles from real occultation measurements. Hopefully, it will be possible to use Oersted and/or Sunsat data. The results from the different inversion methods will be compared and further-more, comparisons with radiosonde data and ECMWF-data will be presented. Noise and small scale horizontal variations are likely to influence the results. On the other hand the diffraction methods shows great robustness towards noise in the simulations. The focus will be on determining whether the theoretically derived vertical resolution seems likely to be achievable in practise.

ON THE USE OF GPS MEASUREMENTS ON BOARD OF POSAT - 1 FOR TEC EVALUATION

Isabel OSORIO and J. Pereira Osorio (both at Faculty of Sciences, University of Porto, Monte da Virgem, 4430 Vila Nova de Gaia, Portugal, email: iposorio@oa.fc.up.pt, posorio@oa.fc.up.pt); J. M. Rebordo (INETI / LAER - Aerospace Laboratory, Estrada do Pao do Lumiar, 1699 Lisboa Codex, Portugal, email: jmr@laer.ineti.pt)

On board of the LEO Portuguese micro-satellite PoSAT - 1, codephases and Doppler GPS measurements are available, from a TRIMBLE TANS II receiver.Codephases measurements are ambiguous to the entire number of milliseconds of the signal propagation time, according to the receiver specifications. However, Doppler measurements are good enough to be used

on a process of pseudo-ranges smoothing. With this method a new signal of good quality is generated.Sets of fifteen minutes of those measurements, at a cadency of 0.5s, were used, in order to calculate the satellite orbit and the receiver clock error. This can be accomplished with reduced dynamics in a seven states Kalman filter.
Once the Kalman filter convergence is reached, the measurements from thelowest GPS satellite, in the PoSAT - 1 horizon, are used in an inverse process for Total Electron Content (TEC) evaluation, along the signal path, in the upper layers of the ionosphere. So, a contribution is given for the ionosphere knowledge, in directions impossible to be defined from the Earth's surface. The tomography of those zones is, then, possible since TEC values are known in many contiguous directions.In this paper the methods used and the results obtained will be presented.

SAGE III TEMPERATURE MEASUREMENTS

Michael C. PITTS (Science Applications International Corporation, 1 Enterprise Parkway, Hampton, Virginia 23666, USA, email: m.c.pitts@larc.nasa.gov); Larry W. Thomason (Atmospheric Sciences Division, NASA Langley Research Center, Hampton, Virginia 23681, USA,
email: l.w.thomason@larc.nasa.gov)

The Stratospheric Aerosol and Gas Experiment (SAGE) III is the fourth generation of solar occultation instruments designed by NASA to measure vertical profiles of aerosols and important trace gases in the atmosphere. As part of NASA's Earth Science Enterprise (ESE), Earth Observing System (EOS) program, SAGE III instruments are currently scheduled to fly onboard the polar-orbiting Meteor-3M satellite in Fall 1999, the International Space Station in 2002, and a future flight of opportunity between 2000 and 2005.Unlike its predecessors, SAGE III has the capability to retrieve profiles of atmospheric temperature and pressure utilizing multi-spectral measurements of the oxygen A-band transmission in the 760-nm spectral region. The profiles will extend from the surface (or cloud top) up to 85 km and their vertical resolution will be approximately one kilometer. Given the inherent insensitivity of solar occultation experiments to long-term instrument egradation and the expected lifetime of the instruments (6+years), the SAGE III suite of instruments should provide a long-term record of self-calibrated, high vertical resolution temperature and pressure measurements. These measurements will be valuable for monitoring temperature trends in the stratosphere and mesosphere and for comparison studies with other temperature data sets. An overview of the SAGE III temperature and pressure retrieval algorithm and results from simulated retrievals using realistic measurement noise will be presented. The expected uncertainties in the retrieved profiles will also be discussed.

SPACEBORNE ATMSOPHERIC PROFILING: RESULTS FROM GPS/MET AND ANALYSIS PLANS FOR COSMIC

Christian ROCKEN, Sergey Sokolovskiy, Bill Schreiner, Doug Hunt, Richard Anthes, Ying-Hwa Kuo, and Randolph Ware (all at University Corporation for Atmospheric Research (UCAR), PO Box 3000, Boulder CO, 80307, USA; email: rocken@ucar.edu)

Data from over 62,000 atmospheric soundings from the GPS/MET experiment have been archived between April 1995 and June 1997. About 11,000 of these soundings have been processed at UCAR to Level 3: atmospheric temperature, pressure and humidity as a function of geometric height. In addition a large number of ionospheric soundings has been analyzed to compute electron density profiles. Based on the GPS/MET experience and results we are now developing the COSMIC Data Analysis and Archive Center (CDAAC). COSMIC will be described in other presentations at this session. CDAAC will process all sounding observations from the eight COSMIC satellites within less than three hours of data collection, for an operational demonstration of the impact of the data on weather forecasting and space weather monitoring and forecasting. Issues that will require special development for the CDAAC analysis system include lower troposphere data analysis, ionospheric correction and profiling, water vapor profiling, multipath in the atmosphere and at the ground fiducial sites, and low Earth satellite orbit prediction. We will summarize the most important results from the GPS/MET mission and outline the planned development and data analysis improvements for the CDAAC.

NEAR REAL-TIME ORBIT DETERMINATION FOR THE COSMIC SATELLITES: METHODOLOGY AND EXPERIMENTAL RESULTS

Ming YANG (Department of Surveying Engineering, National Cheng Kung University, Tainan 701, Taiwan, Email: myang@mail.ncku.edu.tw)

The joint Taiwan-US space program of COSMIC (Constellation of Observing System for Meteorology, Ionosphere and Climate), also known as ROCSAT-3 in Taiwan, will consist of 8 low- earth orbiting micro-satellites to be launched by the year 2001. The major objective of the project is to conduct atmospheric limb sounding using the GPS/MET radio occultation technique. The GPS/MET soundings will be analyzed within 1 hour of data collection to provide precise, global coverage, and near real-time weather information. Prior to the recovery of atmospheric refractivity in GPS/MET data analysis, precise knowledge of the geometry between the GPS satellites, the COSMIC satellites, and the ground fiducial sites must be resolved first. Therefore, near real-time orbit determination for the COSMIC satellites is needed for the success of the mission. This paper proposes a triple differencing GPS data handling methodology for near real-time orbit estimation. Orbital results obtained from the experimental MicroLab-1 satellite are presented.

ON THE ASSIMILATION OF GPS/MET REFRACTION ANGLE MEASUREMENTS USING THE NCEP'S SSI ANALYSIS SYSTEM

X. ZOU, B. Wang, H. Liu, R. A. Anthes, T. Matsumura and Y.-J. Zhu (Florida State University, Department of Meteorology, 404 Love Building, Tallehassee, FL 32306 4520 USA,
E-mail: zou@met.fsu.edu Telephone No: (850) 644-6025 Fax No: (850) 644 9642

In recent work we developed and validated a GPS forward raytracing operator, completed the development of the tangent linear and adjoint of the raytracing operator, and tested the correctness and the characteristics of these operators in several least-square-fit problems. We describe here the implementation of the GPS software and GPS/MET data into the National Centers for Environmental Prediction (NCEP) operational data assimilation system to examine the analysis increment due to the inclusion of GPS/MET refraction angles in the presence of a complete background term.
Additional issues to be addressed are related to the development of a model describing the measurement errors of GPS/MET data, the computational requirements for the forward raytracing and its adjoint operators, and the feasibility of the operational use of GPS data.

JSG28/E/21–B2 Poster **1400-14**

AN EVALUATION OF ANISOTROPIC MAPPING FUNCTION BY USING JMA 10KM SPECTRAL MODEL

ICHIKAWA Ryuichi (Kashima Space Research Center, Communications Research Laboratory, 893-1 Hirai, Kashima, Ibaraki 314-0012, Japan, e-mail: richi@crl.go.jp); Michael Bevis and James Foster (Hawaii Institute of Geophysics and Planetology, University of Hawaii, 2525 Correa Road Honolulu, HI, USA 96822); Nobutaka Mannoji (Numerical Prediction Division, Japan Meteorological Agency, 1-3-4 Ohte-machi Chiyoda-ku, Tokyo 100-8122, Japan)

Several anisotropic mapping functions are available for the analysis of GPS and VLBI measurements (MacMillan, 1995; Chen and Herring, 1997). Chen and Herring (1997) have demonstrated good agreement between horizontal gradient parameters estimated using their mapping function and the NCEP (National Center for Environmental Prediction) analysis field that is given on a 2.5degree grid. However, the utility of this anisotropic mapping function has not been evaluated with respect to mesoscale phenomena such as the passing of cold front, heavy rain fall, and severe storms because the NCEP analysis field has insufficient horizontal resolution for this purpose. Accordingly, we evaluate the Chen and Herring mapping function by ray tracing through the 10km spectral model of the Japan Meteorological Agency (JMA).Preliminary results indicate that gradient vectors can be incorrectly estimated in the presence of intense mesoscale disturbances, but that these conditions occur only infrequently.

A STUDY OF SPATIAL WATER VAPOR DISTRIBUTIONS BY USING ONE-WAY RESIDUALS OF GPS PHASE MEASUREMENTS

Takayuki YOSHIHARA, Toshitaka Tsuda (both at Radio Atmospheric Science Center, Kyoto University, Uji, Kyoto, 611-0011, Japan, email: yosihara@kurasc.kyoto-u.ac.jp); and Kazuro Hirahara (Department of Earth and Planetary Sciences, Graduate School of Science, Nagoya University, Nagoya, 464-8602, Japan, email: hirahara@eps.nagoya-u.ac.jp)

It is very important to investigate characteristics of water vapor distribution in the troposphere, especially in the small scale variations of time and space, for researches on meso-scale phenomena. We aim to find out water vapor distributions by using propagation delays along each signal path from a GPS Satellite to a receiver. We took notice of a potential for pulling out water vapor informations from residuals, which were obtained as by-products of GPS phase data analysis. We analyzed a campaign data set, which was carried out over 12 days in Yamagawa, Kagoshima, Japan on June in 1996. For the analysis of the GPS data, we used GIPSY-OASIS II software. In the observation period, weather condition greatly changed 4 times with the motions of a cold front and a Baiu front, which passed toward north and south above Yamagawa. Time series of "original residuals" (i.e. outputs obtained directly from GPS data analysis) shown rather characteristics of dependences on elevation angles of GPS Satellites than spatial ones of vapors. We calculated "mean residuals" of entire observation period for dependences on elevation angles (for each GPS satellite), and subtracted them from "original residuals". As results, the residuals which calculated by such a method shown differences in spatial distributions as relative values, however, only in several cases of changes of weather condition with the passages of a cold and a Baiu fronts above mentioned.

SUOMINET: A NATIONAL REAL-TIME GPS NETWORK FOR ATMOSPHERIC RESEARCH

Randolph WARE (GST); Dave Fulker (Unidata); Seth Stein (Northwestern U.); David Anderson (U. Colorado); Richard Clark (Millersville U.); Kelvin Droegemeier (U. Oklahoma); Soroosh Sorooshian (U. Arizona)

The 24 Global Positioning System (GPS) satellites flood the Earth atmosphere with microwave radio signals. Phase delays induced in these signals by the lower and upper atmosphere can be converted into integrated water vapor and total electron content (TEC) along each of the dozen or so ray paths to GPS satellites in view. We have proposed to develop "SuomiNet", a university-based GPS network to provide real time GPS data for atmospheric research and education. Named to honor meteorological satellite pioneer Verner Suomi, the network will make thousands of accurate tropospheric moisture and ionospheric TEC measurements per day during all weather conditions. SuomiNet will demonstrate the concept of a university-based national geophysical instrument providing real time atmospheric data to universities. We describe the proposed network and its potential for research in mesoscale and ionospheric modeling and data assimilation, severe terrestrial and space weather effects, precipitation, cloud dynamics, regional climate, and hydrology. Other potential research applications for SuomiNet data include detection and forecasting of low latitude ionospheric scintillation activity, geomagnetic storm effects at ionospheric mid latitudes, coastal meteorology, atmospheric chemistry, calibration of satellite radiometry, and correction of synthetic aperture radar for crustal deformation applications. The impact of these new data and observation methods on the atmospheric and related sciences may be dramatic, comparable to the impact GPS data have had in a few short years on the solid-Earth sciences.

A NUMERICAL INVESTIGATION OF SEISMIC WAVES AND MAGMA DYNAMICS ASSOCIATED WITH A VOLCANIC ERUPTION

Takeshi NISHIMURA (Dept. of Geophysics, Graduate School of Science, Tohoku University, Sendai 980- 8578, Japan, email: nishi@zisin.geophys.tohoku.ac.jp); Bernard Chouet (U. S. Geological Survey, 345 Middlefield Road, Menlo Park, CA, USA, email: CHOUET@chouet.wr.usgs.gov).

We apply the finite difference method to calculate the magma dynamics and seismic waves associated with a volcanic eruption. Our model consists of a cylindrical reservoir and a narrow cylindrical conduit which are vertically oriented and embedded in a homogeneous half space. A lid caps the vent at the free surface and the magma is overpressurized prior to the eruption.

The eruption is triggered by the instantaneous removal of the lid, at which point the exit pressure becomes equal to the atmospheric pressure. Magma dynamics is expressed by the equations of mass and momentum conservation in a compressible fluid, in which the vesiculation process associated with depressurization is accounted for by a constitutive law between pressure and density (Ida, 1990). Radial velocities and normal stresses are continuous across the conduit and reservoir boundaries. Free slip is allowed at the fluid-solid boundary. Results from our calculations indicate that magma migrates gradually upward in response to the pressure gradient established between the atmosphere and reservoir, which is detected as long-period seismic signals. Superimposed on the long-duration signal associated with mass transport are short-period oscillations of the magma resulting from resonance of the reservoir, which are detected as short period seismic waves. The volume of the reservoir, vent size, and magma properties control the duration of long-period waves and the dominant periods of short-period oscillations.

JSV29/E/05-B1 1420

A MODEL OF MAGMA ACCUMULATION AND RELEASE TO DESCRIBE THE RHYTHMS AND STYLES OF VOLCANIC ERUPTIONS

Yoshiaki IDA (Earthquake Research Institute, University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113-0032, Japan, email: ida@newsida.eri.u-tokyo.ac.jp)

A simple model of the magmatic process leading to volcanic eruptions is proposed with an elastic magma chamber connected to a shallower cylindrical conduit that opens or closes following inelastic response of the surrounding country rock to the magma pressure. It is further assumed in this model that the magma viscosity depends on the ascending magma flux, reflecting the cooling effect. According to the analysis, suitable coupling of the mechanical and thermal effects allows cyclic flow and episodic effusion of magma for the supply from below at a constant rate. Slow magma accumulation followed by quick release at an eruption is explained by some nonlinear effects included in the model.
Magma migration in a growing fissure from the elastic magma chamber is also modeled. In this case, growth of the magmatic fissure is controlled by the crustal stress as well as the magma pressure. When the initial magma pressure is high enough to suppress the crustal stress, the fissure elongates unlimitedly even to the ground surface while the width finally decreases. When the crustal stress is of sufficiently strong extension, the growth finally stops with the finite length and width of the fissure stabilized in the crustal interior. So the magma migration is either "extrusive" or "intrusive", depending on the crustal stress condition.

MAGMA CHAMBERS DYNAMICS OF CRYSTALLISATION AND ERUPTION

C.C. MOURTADA-BONNEFOI (Univ. Blaise Pascal et C.N.R.S., U.M.R. 6524, 5 rue Kessler 63038 Clermont-Ferrand cedex, France; now at University of Bristol, Wills Memorial Building, BS8 1RJ, United Kingdom, email: c.mourtada-bonnefoi@bris.ac.uk); A. Provost (Univ. Blaise Pascal et C.N.R.S., U.M.R. 6524, 5 rue Kessler 63038 Clermont-Ferrand cedex, France, email: provost@opgc.univ-bpclermont.fr); F. Albarede (E.N.S. de Lyon, 46 Allee d'Italie, 69364 Lyon cedex 7, France, email: albarede@geologie.ens-lyon.fr)

On the time scale of their lifetime, most volcanic systems may be modelled as open reservoirs, forced by the input flux of magma and heat loss rate through the wall-rocks, where the magma mixes with input magma, cools, undergoes fractional crystallisation and differentiates.
In a simplified model of a chemically and thermally homogeneous reservoir, the mass, the chemical and the heat balance equations were derived; and their steady state solutions were determined graphically (Mourtada-Bonnefoi et al., 1999). Because of crystallisation kinetics (existence of a maximum crystallisation rate at some undercooling), for some forcing conditions, two stable steady states are possible. The initial conditions determine which of these steady state is realised.
During the lifetime of a volcano, the long term drift of the forcing of the chamber may lead the system to an unstable steady state when the number of stable steady states bifurcates from two to one; it ensues a magmatic catastrophe that implies a brutal increase (or, a decrease) of crystallisation rate, magma differentiation (reverse differentiation), the decrease (increase) of magma undercooling and the decrease (increase) of discharge rate of erupted lava. The model predicts that the magma is maintained at an undercooling of only a few tens of oC in the chamber and that during a magmatic catastrophe, the composition jumps by a few per cent of SiO2 while the temperature jumps by a few tens of degrees. We suggest that composition gaps in the lava series may be the consequence of magmatic catastrophes. The wide range of lacking compositions, the widths of the gaps, the involvement of fractional crystallisation in lava differentiation and the discontinuity of mineralogy throughout the gap seem compatible with both the qualitative and the quantitative predictions of the model.

MAGMA MIXING MODEL IN THE 1991-1995 ERUPTION AT UNZEN VOLCANO

Setsuya NAKADA (Earthquake Res. Inst., Univ. Tokyo, Japan, Email: nakada@eri.u-tokyo.ac.jp), and Chang-Hwa Chen (Inst. Earth Sci., Acad. Sinica, Taipei, Email: china@earth.sinica.edu.tw)

Disequilibrium texture of phenocrysts and the occurrence of enclaves are common in dacite lavas of the latest eruption at Unzen. Glomerophyric aggregation of phenocrysts implies their coexistence either in a crystal mush of the reservoir or in intrusive rocks before eruption. Sr and Nd isotopic ratios of phenocryst species and the groundmass are different from each other. The groundmass is less evolved isotopically than the coexisting hornblende. These facts require that coexisting phenocrysts had spent time as long as 10^5 yr. in a closed system, and that they met a new melt during eruption. A plausible model is either that (1) crystals of old plutonic rocks were incorporated accidentally, or that (2) these phenocrysts had spent a significant time in a stagnate marginal layers of the reservoir. Enclaves are micro-gabbroic in texture with glass in the matrix, isotopically similar to or a little less evolved than the host dacite, having the composition much away from the evolution trend for the Unzen lavas (e.g., in 87Sr/86Sr-FeO*/MgO plot). The enclaves may represent a sort of cumulate derived from a crystal-mush layer in a cooling magma reservoir, or from a partial-melting zone in the wall rock. Similarly, disequilibrium in texture and chemistry of phenocrysts can be produced either by incorporation of crystals from partial melting zone or by recycling of crystals from a long-lived margin of the reservoir. Thus, disequilibrium can occur as a self-generating process in a cooling magma reservoir rather than as injection of new magma.

RECENT MAGMA DISCHARGE RATE AT COLIMA VOLCANO, MEXICO: IMPLICATIONS ON ITS INTERNAL STATE

Juan Manuel ESPÍNDOLA (Instituto de Geofísica, Universidad Nacional Autónoma de México, Ciudad Universitaria, México 04510 D.F., e-mail: jme@tonatiuh.igeofcu.unam.mx)

The last strong explosive eruption at Colima volcano took place in 1913. That activity produced a crater 350m deep and a jagged rim 400m in diameter. The morphology of the crater varied little during about 18 years. In 1931 the floor of the crater flattened due to a renewed ascent of magma which continued until 1961. At that time the blocky lava accumulating inside the crater reached the northern and lowest part of the rim outpouring and forming a small lava flow. By 1962 the crater had been completely filled and was building up a protruding dome above the level of the former crater rim. We have estimated the volume of material filling the crater in about 44 million cubic meters (mcm), and the volume of the 1961 lava flow in 1.5 mcm. The volume of magma discharged between 1962 and 1984 was estimated through photographs taken in those years from about the same point, some 8 km NE from the crater. From those pictures and topographic maps of the area (scale 1:50,000) we estimated the volume of the dome in 8 mcm. The volcano had other merapian-type eruptions in 1975 and 1982, producing lava flows for which we have estimated a volume of 11 mcm. Thus, we estimate the average annual discharge rate during that period in 0.86 mcm/yr. This estimate and gravity data published previously allow us to formulate a thermal model of the plumbing of Colima volcano, based on a simple conduction model of flow with heat generation due to shearing. We also analyze all the registered seismicity related to the volcano in terms of the model.

MAGMA TO SEISMOGRAMS SEISMIC OBSERVATIONS FROM SOUFRIERE HILLS VOLCANO IN MONTSERRAT

Dr Jurgen NEUBERG, (School of Earth Sciences, Leeds, email: locko@earth.leeds.ac.uk)

From Magma to Seismograms Seismic observations from Soufriere Hills volcano in Montserrat reveal a wide variety of low-frequency seismic signals which are considered to play an indicative role in assessing the state of volcanic activity. These events occur usually in swarms, they are associated with tilt, and occationally merge into tremor, an observation that has shed further light on the generation and composition of harmonic tremor. We use a finite difference method to model several features of low-frequency seismic signatures and compare them with observations. Depth-dependent velocity models for a fluid-filled conduit/dyke are derived by solving the differential equations governing the fluid flow and the resulting pressure fluctuations in the magma. We account for the degasing of the magma and the possible feed-back mechanism exerted by the seismic signals. Episodes of tremor which show shifting spectral lines and model those in terms of changes in the gas content of the magma as well as in terms of a time-dependent triggering mechanism of low-frequency resonances. Several models for repetitive triggering mechanisms in a two-phase flow regime are discussed.

EXPERIMENTAL STUDIES OF ROCK FAILURE AT NEAR-SOLIDUS TEMPERATURES

P.Sammonds, (Email: p.sammonds@ucl.ac.uk); P.Meredith, (Email: p.meredith@ucl.ac.uk); V.ROCCHI, (Email: ucfbvro@ucl.ac.uk); (all at University College London, Dept. of Gelogical Sciences, Rock and Ice Physics Laboratory, Gower St, London WC1E 6BT, UK); C.Kilburn, ((University College London, Benfield Greig Hazard Research Centre, Gower St, London WC1E 6BT, UK Email: c.kilburn@ucl.ac.uk)

Seismicity is a key precursor to volcanic eruptions. As magma approaches the surface, seismicity may be induced by fracturing of country rock and cooled magma (as new conduits form or as existing pathways change shape), and by degassing or dynamic processes within the magma itself. Much of the fracture-induced seismicity is expected to occur in heated rock and solidifying magma at the margins of the feeding dyke or conduit, at nominal temperatures of 500-1000C. A new rock mechanics cell has been designed to operate at these temperatures and at pressures from atmospheric to 70 MPa (corresponding to depths of 6 Km or less), in order to investigate variations in (1) the compressive and tensile strength of magma, (2) Young's Modulus, and (3) rates of microseismic emission during fracture. The results will provide a coherent database for analysing seismic sequences at volcanoes and for identifying patterns (such as spatial clustering of hypocentres or time increases in seismic rate) that may be diagnostic of an imminent eruption.

JSV29/W/08-B1 1640

NUMERICAL SIMULATIONS OF MULTIPHASE NON-EQUILIBRIUM MAGMA ASCENT DYNAMICS WITH COMPOSITIONAL AND PHASE DISTRIBUTION DEPENDENT MAGMA PROPERTIES, STRAIN-INDUCED MAGMA FRAGMENTATION, PUMICE FORMATION, AND CHOKING

Paolo PAPALE (Istituto Nazionale di Geofisica, via S. Maria 53, I-56126 Pisa, Italy,
email: papale@dst.unipi.it)

Steady-state magma ascent along a one-dimensional volcanic conduit is numerically simulated by accounting for the separated flow of homogeneous liquid magma plus crystals, and gas exsolving from the liquid. Relevant properties (density, viscosity, H20 or H2O+CO2 saturation) are calculated on the basis of magma composition in terms of 10 major oxides plus two dissolved volatile species, by using most recent and accurate models. Magma viscosity is corrected for the presence of crystals and gas bubbles, and also depends on the stress field with possible pseudoplastic (or shear thinning) and dilatant (or shear thickening) rheology of the magmatic mixture. Magma fragmentation is assumed to occur at either a critical gas volume fraction, or at a critical strain-rate exceeding the inverse of the structural relaxation time of magma and producing strain-induced brittle failure of the liquid continuum. Above fragmentation, the gas phase is transported partly as a continuum, and partly as gas bubbles in liquid+crystal+gas fragments (or droplets) corresponding to pumice; glass shards (or liquid droplets) and free crystals also form at fragmentation. The multiphase magmatic mixture is assumed to chok at the conduit exit, where correspondingly the magmatic pressure can be larger than the atmospheric pressure by several factors. Several simulations have been performed by varying the eruptive conditions in terms of conduit size, mass flow-rate, magma composition, volatile abundance and composition, crystal content and distribution, and assumed amount of pumice formed at fragmentation. The present modeling and the information it supplies can form a basis for a future coupling of magma ascent fluid dynamics with other geophysical disciplines such as volcano seismics and acoustics; such coupling would allow better capability of interpreting signals during eruptions, deriving constraints for the subsurface fluid dynamics, and at the end understanding and predicting volcanic eruptions.

FALL VS FLOW ACTIVITY DURING THE 1991 CLIMACTIC ERUPTION OF MT. PINATUBO (PHILIPPINES)

Mauro ROSI, Andrea Di Muro and Riccardo Leoni (Universita' degli Studi di Pisa, Pisa I-56126, Italy, E-mail: rosi@dst.unipi.it, dimuro@dst.unipi.it, rleoni@dst.unipi.it); Ma. Lynn o. Paladio-Melosantos and Terecito Bacolcol (Philippine institute of Volcanology and Seismology)

Six years after the 1991 Mt. Pinatubo eruption the deep erosion have superbly exposed pyroclastic deposits enabling us to assess the stratigraphic relationships between climactic fall, flow and surge deposits in the Marella Valley and contiguous ridges on the SW, downwind side of the volcano. In addition maximum clast size measurements of lithics and pumices were carried out on the plinian fall deposit all around the volcano. The maximum height of the convective column obtained using the Carey and Sparks (1986) model is in good agreement with satellite measurements. Field data indicate that the fall bed is normally graded with most of the surge beds intercalated to its upper finer grained portion. The intra-plinian pyroclastic surges propagated up to 10 km from the crater both on valley bottom and contiguous ridges, while post-plinian pyroclastic flows have greater runout and are not associated to ash cloud surges. We believe that during climactic event a progressive shift from an early convective column, to a transitional column feeding both plinian convective plume and radially distributed dilute currents, to a fully collapsing fountain producing only pyroclastic flows without associated plinian fall activity occurred. We believe that the transition from plinian to a large coignimbritic convective column accounts well for the lowering of the plume as measured by the satellites.

PYROCLAST MASS PARTITION OF COLLAPSING AND TRANSITIONAL COLUMNS BY USING NUMERICAL SIMULATIONS

Andrea di Muro and Mauro Rosi (Universita' degli Studi di Pisa, Pisa I-56126, Italy,
Email: dimuro@dst.unipi.it, rosi@dst.unipi.it)
Augusto NERI (Consiglio Nazionale delle Ricerche, Pisa I-56126, Italy, Email: neri@dst.unipi.it)

Pyroclast distribution and mass partition between convective and collapsing regions represents a major issue in the understanding of the dynamics of explosive eruptions. The spatial and temporal distribution of pyroclasts during full-collapsing and transitional columns were investigated by using a transient, two-dimensional, and three-phase - one gas phase and two solid phases representative of pyroclasts of different size and density - flow model. Several simulations were carried out by using different water contents of the eruptive mixture and assuming both pressure-balanced and overpressured conditions at the vent region. For full-collapsing columns, simulation results allowed the quantification of the mass of different pyroclasts forming the pyroclastic flow, the co-ignimbrite column, and the thermal plumes rising from the fountain and the deflation zone. The total mass transported in the whole convective system ranges from about 10 up to about 30% of the total mass erupted. With an increase in water content the collapsing character of the column moves towards more transitional behavior. Such a regime is characterized by a greater collapse height, the generation of a more dilute density current, a shorter flow runout, and by a more transient behavior of the column and flow. In these cases, the total mass forming the convective portions can reach values of up to 50% of the erupted pyroclasts with a significant amount of coarse particles. At higher water contents the column becomes Plinian with 100% of the erupted mass feeding the plume.

WHAT IS HAPPENING AT THE DEPTH OF 70 M AT STROMBOLI?

Sylvie VERGNIOLLE (Laboratoire de Dynamique des Systemes Geologiques, Institut de Physique du Globe- 4 place Jussieu - 75252 Paris Cedex 05 FRANCE, email: vergniolle@ipgp.jussieu.fr)

Activity of Stromboli is characterised by a series of explosions, whose origin lies in the breaking of a metric (radius of 0.9 m and length of 15 m), over pressurised bubble (0.031 MPa) at the surface of the magma column. Overpressure at the surface strongly suggests overpressure at depth, when the "slugs" are formed. Here we study the motion of a slug initially over pressurised in a vertical tube of length 70 m and diameter 2 m. The acoustic pressure radiated from the bubble rise at the vent is calculated and compared with acoustic measurements. Because bubbles are formed with an initial overpressure and rise in a tube, they grow mainly by increasing their length (slug flow), overshoot their equilibrium position and the gas compressibility provides the restoring force for their oscillations. The change in the volume of the rising bubble pushes the liquid column up and down, vigourously enough to produce sound waves of low frequency (0.5 Hz). Because the bubbles are relatively long (15 m) compared to their radius (0.9 m), their shape is assumed to be a cylinder whose length oscillates until it stops by viscous dissipation in the magma. Sound is expected at bubble formation around 0.5 Hz and dies quickly after. The strong expansion of the "slug" when it is formed at depth is also able to excite "sloshing waves" at the top of the magma column, whose frequency is between 1 and 3 Hz. The model of acoustic pressure predicts that a peak in acoustic pressure should appear in the frequency range 0-1 Hz (volume mode) simultaneously with a peak in the range 1-3 Hz (sloshing mode), which is what is observed at Stromboli volcano. The amplitude of the precursory signal shows that the "slug" is formed with an overpressure of 14 MPa, an initial length of 0.2 m and at the depth of 70 m. Because "slugs" are formed by the coalescence of a foam layer at the top of the magma chamber, 70 m is its depth.

SUBSURFACE GEOMETRY OF CALDERA IN RELATION TO DEPTH OF MAGMA CHAMBER, MIOCENE KUMANO CALDERA, SW JAPAN

Daisuke MIURA (Geology Department, Abiko Research Laboratory, Central Research Institute of Electric Power Industry, 1646 Abiko, Chiba 270-1194, Japan, email: dmiura@criepi.denken.or.jp)

Scaling law of fragmentation and population of fault data with respect to caldera formation produce to evaluate quantitatively subsurface structure of caldera and genetic relationship to the underlying magma chamber. Miocene Kumano caldera, 41 by 23 km in diameter as a whole, southwest Honshu, Japan, is an example to field application based on this idea. Nested piston-cylinder structure is suitable to overall geometry of the caldera.
To select the caldera-related faults, characters of faults, veins, and intrusions in and around the caldera behaved to classify a measured fault data by use of paleo-stress analysis. Comparison of the respective paleo-stress results implies that both tumescence and collapse of country rocks occurred during the caldera formation. Property of the obtained fault set thus represents the subjective caldera geometry. The exponent of 0.41 on cumulative fault throw distribution produces exponent of 0.6-0.7 on cumulative fragment mass distribution, which reveals a mode of fragmentation of two-dimensional object by vertical stress input. This finding explains well a thin-plaster geometric relation to underlying magma chamber of piston-cylinder caldera, and it suggests that the exponent is useful to chase variation of caldera geometry.

JSV29/W/05-B1 Poster **1400-02**

EVALUATION OF SUBSURFACE STRUCTURE AND LONG-TERM STRAIN RATE OF MIOCENE KUMANO CALDERA, JAPAN, BY USE OF FAULT POPULATION DATA

Daisuke MIURA (Geology Department, Abiko Research Laboratory, Central Research Institute of Electric Power Industry, 1646 Abiko, Chiba 270-1194, Japan, email: dmiura@criepi.denken.or.jp)

Scaling law of fragmentation and population of fault data with respect to caldera formation produce to evaluate quantitatively subsurface structure of caldera. Miocene Kumano caldera, 41 by 23 km in diameter as a whole, southwest Honshu, Japan, is an example to field application based on this idea. Nested piston-cylinder structure is suitable to overall geometry of the caldera.
To select the caldera-related faults, characters of faults, veins, and intrusions in and around the caldera behaved to classify a measured fault data by use of paleo-stress analysis. Comparison of the respective paleo-stress results implies that both tumescence and collapse of country rocks occurred during the caldera formation. Property of the obtained fault set thus represents the subjective caldera geometry. Extrapolation of an exponent of 0.41 on cumulative throw distribution to maximum data and K-Ar ages indicate a long-term strain rate of the caldera development, ca. several cm/year. This value roughly coincides with present short-term rate of caldera and/or of volcano-tectonic depression, as estimated elsewhere.
The exponent of 0.41 produces exponent of 0.6-0.7 on cumulative fragment mass distribution, which reveals a mode of fragmentation of two-dimensional object by vertical stress input. This finding explains well a thin-plaster geometric relation of caldera and underlying magma chamber as proposed to piston-cylinder model, and it suggests that such exponent is an intense variable to chase.

THE INTENSITY AND DEPTH OF THE PRIME HEAT SUPPLY, THE ISOTOPIC CHEMISTRY OF THE OCEAN FLOOR BASALT, BATHYMETRY, AND EQUATION-OF-STATE: A UNIQUE PHENOMENON

Giovanni P. GREGORI (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy; e-mail: gregori@atmos.ifa.rm.cnr.it); and Gino M. Crisci (UNICAL, 87036 Arcavacata di Rende, Cosenza, Italy; e-mail: crisci@fis.unical.it)

The isotopic chemistry of ocean floor basalts is usually interpreted in terms of a mixture of different primitive end-members with reservoirs at different depths ("reservoir rationale"). We show how it can rather be explained in terms of a different melt i ng-depth of every basalt, from a combination of the total prime endogenous heating and of the temporal evolution of its upward propagation. Up to some extent, the equation-of-state relates with each other the prime heat supply, the melting depth, the lav a fluidity, and the bathymetry or topography of the outpoured magma. Therefore, geomagnetic phenomena, the axial bathymetry of mid-ocean ridges and their variation vs. latitude, and the isotopic chemistry of basalts, are correlated with each other. Observations can be interpreted in terms of a chemically spherically isotropic Earth, differentiated vs. geocentric radial distance, and of a spatial variation of the prime endogenous heat supply. Ocean basalts can be distinguished into 5 main categories ("clus t ers"), every one being speculated to correspond to a typical range of prime heat supply ("energy hierarchy"). A wealthier database of isotopic measurements should allow for investigating the temporal evolution of the magmatic history at every site. The g e ographical distribution of the isotopic signature is also proposed. Such mere observational evidences can be interpreted in terms of basically three competing viewpoints: (i) the reservoir rationale; (ii) the trailing continental edge hypothesis; and (ii i) the energy hierarchy. A tentative model for global volcanism ought to distinguish (i) mid-ocean ridge; (ii) Dupal's; (iii) hot spot and DAVI; and (iv) island arc and Cordilleran volcanoes.

THE ROLE OF HYDRAULIC FRACTURES AND INTERMEDIATE DEPTH EARTHQUAKES IN GENERATING SUBDUCTION ZONE MAGMATISM (SZM)

J. Huw DAVIES (Dept. of Earth Sci., Univ. of Liverpool, L69 3BX, UK, email: davies@liv.ac.uk)

Hydrous fluxing can unequivocally be shown to be important for generating most present day SZM. Given our present, incomplete, understanding of the connectivity of a hydrous fluid in cold oceanic crust and mantle; it seems that water cannot interconnect and hence percolate out to the hot mantle. So how does the water (released by dehydration of hydrous minerals produced by hydrothermal circulation at the ridge) enter the mantle to generate melting?

Intermediate depth earthquakes are also a puzzle, since the frictional stress preventing slip on a fault plane is greater than the strength of rocks at these depths. One solution is that the pressure of the trapped pore water, which cannot percolate, reduces the effective normal stress (and hence frictional stress). Following the earthquake, the pore water will be temporarily interconnected on the fault plane by the coseismic slip. If this film is sufficiently inter-connected, and exceeds a critical vertical height (>15m-1.5km - range due to uncertainty in fracture properties of rocks at high pressures), then it can spawn a hydrofracture that will propagate out into the mantle wedge. The volume of water contained will largely control how far they get. The biggest hydrofractures could reach the hottest part of the mantle wedge leading to rapid melting and magma fracturing, while the smallest might stop in the subducted sediments. This process therefore has the potential to explain the wide range of time scales interpreted from short half-life isotopes. A quantitative model for the source region of SZM was developed based on this hypothesis and the recent wet melting experiments of Hirose and Kawamoto. It predicts sensible major element compositions; and a close relationship between water and magma flux.

JSV30/W/11-B1 0900

HIGH MG# ANDESITES IN THE ALEUTIAN-KAMCHATKA JUNCTION: IMPLICATIONS FOR CONTINENTAL CRUST FORMATION BY SUBDUCTION MAGMATISM

Gene M. YOGODZINSKI (Dept. of Geology, Dickinson College, Carlisle, PA, U.S.A.); Jonathan M. Lees (Dept. of Geology & Geophysics, Yale University, New Haven, CT, U.S.A.); T. G. Churikova, A. A. Koloskov (both at Inst. of Volcanic Geology and Geochemistry, Petropavlovsk, Kamchatsky, 683006 Russia)

The Aleutian-Kamchatka junction is characterized by unusually high heat flow in the western most Bering Sea, and a shallowing of seismicity northward along the subduction zone from southern Kamchatka (600 km) to the Kamchatka-Bering Fault intersection (100-200 km). If the Pacific plate is torn below the Bering fault, a slab window will be present through which mantle material can flow around the exposed northern edge of the Pacific Plate. In this model slab rollback beneath Kamchatka has induced asthenospheric flow around the northern edge of the subducting plate, and is the cause of the anomalously high magma production from beneath the Kamchatka Central Depression. The northern group volcanoes (Sheveluch, Kharchinsky, Zarechny), which lie in the Aleutian Kamchatka junction immediately above the proposed Pacific Plate edge, are chemically distinct from the adjacent Klyuchevskoi group volcanoes in a way that implies the presence of an anomalously large slab melt contribution to the northern group rocks. Relatively high Mg/Mg+Fe (Mg#) in andesitic rocks of the northern group (55-63% SiO2) results in a major element trend that is more strongly calc-alkaline (higher Mg# relative to SiO2) than that defined by rocks of the Klyuchevskoi group to the south. The high Mg# andesitic rocks of the northern group also have anomalously low Y and high Sr/Y compared to the Klyuchevskoy rocks, and compared to common arc volcanic rocks world-wide. These features are interpreted to imply the presence of primitive (mantle-derived) andesitic magmas produced by slab melting and melt-peridotite interaction in the mantle wedge beneath the northern group volcanoes (Kay, 1978; J. Volc. & Geoth. Res, v4., p117). The anomalous slab melt contribution is interpreted to result from strong heating of the Pacific Plate by asthenospheric flow around its northern edge. Geochemically, high Mg# andesitic rocks of the Aleutian-Kamchatka junction are broadly like many Archean-age calc-alkaline rocks which were produced at a time when the average age of the subducting lithosphere was relatively young and when melting of the subducting slab may have been more common.

JSV30/E/06-B1 0920

MID-CRUSTAL ARC LITHOSPHERE AND DEVELOPMENT OF CONTINENTAL CRUST

PATRICIA FRYER (Hawaii Institute of Geosciences and Planetology, 2525 Correa Rd Honolulu, HI 96822, USA, email: pfryer@soest.hawaii.edu)

A major problem in trying to develop constraints on models for the relationship between evolution of arc and continental crust is understanding the "fundamental paradox" of development of andesitic bulk composition of continental crust despite the basaltic additions that characterize magmatic growth in arcs. Understanding the architecture of the arc crust and aspects of geochemical mass flux into and out of the arc lithosphere in convergent margins are critical to developing models for the evolving composition of continental crust.
Recent geophysical studies of the Izu arc have produced a more detailed model for arc velocity structure than ever before. The interpretation that the arc is underlain at mid-crustal levels by a tonalitic layer of considerable thickness is germane to the questions of arc lithosphere composition and evolution. Seismic refraction studies of the Mariana system suggest a similar layer may be present at 18°N, although the data are sparse. The suggested tonalitic layer is too deep beneath the Izu arc to be sampled, but tectonic processes may have exposed a portion of it in the southeastern Mariana forearc. Tonalitic intrusive rocks were dredged from the inner slope of the southeastern Mariana Trench at depths greater than 7000 m. Tectonic erosion has reduced the width of the forearc to approximately 100 km, half that elsewhere (200 km). The region over which these rock types have been recovered is extensive. Nowhere else in an active convergent margin setting are such rocks exposed in close proximity to the active volcanic arc and in an interoceanic setting where influences of continental contamination are minimal. Analyses of these rocks are underway and it will be important to compare the results of these studies with the work that has already been done on the Izu peninsula sequences. A comparison would permit us to test the possibility that mid-crustal arc lithosphere development in these two localities could serve as a model for general interpretation of evolution of arc crust and ultimately of a fundamental process of development of continental crust.

JSV30/E/05-B1 0940

LONG AND SHORT TERM PETROLOGICAL PROCESSES IN ARC VOLCANOES: IMPLICATIONS FOR CRUSTAL GROWTH FROM MOUNT RUAPEHU, NEW ZEALAND

John GAMBLE (School of Earth Sciences, Victoria University of Wellington, Wellington, New Zealand, email: John.Gamble@vuw.ac.nz); Richard Price (School of Science & Technology, University of Waikato); Ian Smith (Department of Geology, University of Auckland); Peter Wood (Institute of Geological & Nuclear Sciences); Robert Stewart (Department of Soil Science, Massey University); William McIntosh, Nelia Dunbar (both at Geochronological Laboratory, New Mexico Bureau of Mines)

Mount Ruapehu (2797 m and 110 km3) is the largest active andesite – dacite volcano in the Taupo Volcanic Zone. The volcano has been continually active for the past two millennia with small volume (< 0.1 km3) eruptions modulated through a vent system beneath a summit crater lake. Since the well documented events of 1945, eruptions of juvenile lava bombs in 1966, 1969, 1971, 1975, 1977, 1995 and 1996, together with reports of activity around 1925, 1895 - 1905 and 1860, have indicated a periodicity of 20 – 30 years for historic times. Because this type of activity was (a) largely phreatomagmatic and (b) minor in volume, little evidence for its existence can be detected on the active edifice, where the dynamic processes of erosion are extreme. However, a complete record of activity is preserved in the tephra sequences on the ring plain and the record can be further constrained by well dated and interbedded rhyolite tephras from the caldera centres to the north. Based upon the tephra records and new 40Ar/39Ar dating studies, we conclude that late Quaternary – Holocene activity on Ruapehu has been pulsatory, with periods of high magma production (~130 ka; 22 ka and 10 ka) bracketed by periods of lower, but more or less continuous activity, which is representative of the situation at present. During periods of high magma production, effusive activity built up thick lava flow sequences, commonly in small time windows. These comprise the bulk of the eroded edifice and eruptive volumes are an order of magnitude larger than the small events. Petrographic and geochemical study of the modern (1945 - 1996) lavas shows that these are generally similar to prehistoric lavas. Conventional geochemical variation diagrams show compositional overlap between modern and prehistoric lavas which satisfy general models of evolution by AFC. Detailed study of the modern and prehistoric samples, based on stratigraphy, reveals complexities requiring the interplay of complex mixing and mingling processes as melts make their way through the crust and into the shallow plumbing system of the volcano.

THE PETROLOGY OF THE SOUTHERN LONGWOODS COMPLEX, SOUTH ISLAND, NEW ZEALAND: IMPLICATIONS FOR CRUSTAL GROWTH IN SUBDUCTION RELATED MAGMATIC SYSTEMS

Richard PRICE (School of Science & Technology, University of Waikato, Hamilton, New Zealand, Email: rprice@waikato.ac.nz); Anthony Reay (Department of Geology, University of Otago, Dunedin, New Zealand); Richard Arculus (Department of Geology, Australian National University, Canberra, ACT, Australia)

Intrusive rocks of the Longwood Complex in New Zealand's South Island provide an opportunity to gain insights into the petrological processes operating beneath a subduction related volcanic arc. The complex is of Permian-Triassic age and contains rocks ranging in composition from ultramafic cumulates and gabbros through quartz diorites to granites. All analysed samples show trace element characteristics typical of subduction-related magmas (Cs, Rb, Ba, and K are relatively enriched, Nb is depleted relative to K, U, and La, and Pb is enriched relative to Ce) and quartz diorites are compositionally similar to low to medium K andesites. Gabbroic rocks have some of the features of arc tholeiites [eg. low K and depleted REE -(La/Yb)n = 2.15; (La/Ce)n ~ 0.8] Overall , the geochemical variation in the complex is consistent with a model whereby dioritic rocks were derived by crystal fractionation from mafic precursors represented by the gabbros.
Dykes are abundant within the complex and many are composite with compositions ranging from dolerite through andesite to dacite. Geochemically, the components of composite dykes cannot be related in a simple way to the rocks of the major intrusive units of the complex and they may represent the feeder conduits for andesitic volcanoes that once overlay the intrusive complex. Felsic material in some dykes could be either a residual evolved magma left from earlier recharge events or melt derived by anatexis of the host quartz diorite. Abundant mafic enclaves in quartz dioritic rocks derived by crystal fractionation from magmas represented by the gabbroic rocks of the complex and were incorporated when quartz diorite magmas were intruded into and disrupted evolving basaltic magma chambers. If the quartz diorites are mixed magmas, then the enclaves cannot represent the mafic component of this mixing trajectory.

PETROLOGY AND PETROGENESIS OF VICO VOLCANO, CENTRAL ITALY

Giulia PERINI, Jon P. Davidson (both at Department of Earth and Space Sciences, University of California, Los Angeles); Sandro Conticelli (Centro di Geodinamica, Università della Basilicata, Potenza, Italy); Lorella Francalanci (Dipartimento di Scienze della Terra, Universitá di Firenze, Italy)

Plio-Pleistocene alkaline ultrapotassic magmatism produced several different rock series in Italy. In the same area contemporaneous subalkaline magmas of calcalkaline affinity were also erupetd. At Vico volcano and the adjacent area products having distinct petrochemical affinities were erupted in a short period of time. The petrology and petrogenesis of Vico magmas is of importance for unravelling the genetic relationship between the different ultrapotassic rocks series, and also between ultrapotassic and subalkaline magmas. Vico volcano has erupted mainly ultrapotassic silica-undersaturated magmas with minor volumes of silica-saturated and -oversaturated magmas. Stratigraphy indicates that the eruptions sampled evolved oversaturated magma at the beginning of Vico's activity and silica-undersaturated magmas toward the end. However, contemporaneous eruptions of primitive silica-saturated and -undersaturated compositions took place during the youngest activity. LILE/HFSE, LREE/HFSE ratios as well as isotope composition (Sr, Nd and Pb isotopes) of the most primitive samples indicate that three non-cogenetic parental magmas having different petrochemical affinities were present in the Vico system. Geochemical and isotope variations indicate that these parental magmas evolved by polybaric fractional crystallization, mixing and crustal assimilation. The oldest silica-oversaturated magmas are the result of mixing between a high potassium calcalkaline magma and an ultrapotassic silica-undersaturated magma. Ultrapotassic primitive silica-saturated magma erupted during the last stage of activity was present in the system earlier than the time of its first eruption.

FOR A HIGHLY HETEROGENEOUS SUBDUCTION-MODIFIED MANTLEDAWNIKA

L. BLATTER, Ian S. E. Carmichael (both at Dept. of Geology and Geophysics, University of California, Berkeley, CA. 94720, USA, Email: dblatter@uclink4.berkeley.edu)

Volcanism in the western part of the Mexican Volcanic Belt (MVB) is related to the subduction of the Rivera plate beneath the Jalisco block. Highly potassic absarokites and minettes, along with calc-alkaline basaltic andesites and andesites have erupted within conspicuous grabens at the front of the western MVB. This unusual suite has high oxygen fugacities ranging from NNO +1 to 5, and is thought to be generated by partial fusion of subduction modified mantle wedge material that is extremely oxidized and marbled with veins rich in phlogopite and apatite (Carmichael et al, 1996). Under this hypothesis, the extremely potassic lavas are produced from the phlogopite and apatite-rich material, and the calc-alkaline basaltic andesites and andesites are partial melts of a more typical spinel lherzolite assemblage. Evidently, the ascent and eruption of the entire suite was facilitated by the localized extension of the overriding plate. In central Mexico, MVB-related volcanism overlies the subducted Cocos plate. Like western Mexico, there are prominent extensional fault systems at the front of the MVB in central Mexico, near Valle de Bravo. Although the tectonic setting here is similar to that of the arc-front grabens in western Mexico, highly oxidized minettes and absarokites are not found. Instead, we find Quaternary, fault-associated, high-K andesites and shoshonites, as well as calc-alkaline basaltic andesites, andesites and dacites, all of which have lower Al2O3 concentrations and oxygen fugacities (~NNO _1.0 to NNO +2.7) than their western Mexican equivalents. Small, upper mantle derived, spinel lherzolite xenoliths are hosted in one of these calc-alkaline andesite flows. The xenoliths have oxygen fugacities ranging from NNO +0.7 to 1.6, and many contain abundant hornblende, but no phlogopite or apatite (Blatter and Carmichael, 1998). Based on these observations, we conclude that the mantle beneath the front of the MVB in central Mexico is more refractory and less oxidized than that beneath western Mexico.

HORNBLENDE CRYSTALLISATION AS A BARRIER TO ERUPTION IN HYDROUS BASALTS: AN EXAMPLE FROM THE VOLCANIC FRONT OF WESTERN MEXICO

J. BARCLAY (1), Ise Carmichael (Dept of Geology and Geophysics, UC Berkeley,USA; (1) Dept de Mineralogie, Universite de Geneve, Switzerland.)

The hydrous phase relations of a Quaternary ne-normative trachybasalt from the volcanic front of Western Mexico have been determined experimentally (from 0.1 to 700MPa) in order to elucidate the conditions of ascent and storage of the unusual phenocryst assemblage which includes hornblende as well as apatite, olivine and augite. At fO2's equivalent to NNO+2 hornblende crystallisation occurs at the expense of ol and aug and is found at T < 1040oC and PH2O> 130MPa with a positive dP/dT slope of gradient of ~1 from 40 to 100MPa. Coexisting liquids evolve from ne-normative basaltic andesite to qtz-normative dacite in the most crystalline experiments, following a shoshonitic 'liquid line of descent'. With the onset of hornblende crystallisation, experimental crystallinities increase dramatically (from ~15-20vol% to >40vol%) with only small degrees of undercooling. This is equivalent to an increase in magma viscosity from ~10Pas to >106Pas, close to the limit of eruptibility of most magmas. Similar increases in sample crystallinity are found in other experimental studies and it is proposed that many hydrous mafic magmas do not erupt in subduction zones as a consequence of this enhanced crystallisation. The subsequent remelting of 'frozen' underplated basalt will produce magmas similar in composition to those of the coexisting experimental liquids. Such magmas are found in subduction zones with low volumes of eruption in regions also usually associated with extensional tectonics.

THE GUERRERO TERRANE IN WESTERN MEXICO; A MEOZOSOIC EXAMPLE OF TRANSITION FROM ARC TO CONTINENTAL CRUST

Joaquin RUIZ (Dept. of Geosciences, University of Arizona, Tucson, Arizona 85721, USA, email: jruiz@geo.arizona.edu)

The Guerrero Terrane in western Mexico constitutes about half of Mexico's surface and is a superb example of the transition between accretion of oceanic material, arc magmatism, to formation of continental crust. The basement of the Guerrero terrane, known as the Arteaga Schist, consists of mid-ocean ridge basalts with pillow structures in places and deformed and metamorphosed sediments with Proterozoic isotopic values. The age of the basement is probably Triassic based on paleontological evidence. Unconformably overlying the Arteaga Schist is an arc complex with interbedded andesitic flows and pyroclastics and fossiliferous limestone. The accretion of the arc complex to nuclear Mexico was probably in Neocomian times. The whole complex is intruded by Cretaceous calc alkalic and peraluminous granites and then overlain by large Tertiary silicic flows and pyroclastics that are part of the Sierra Madre Occidental volcanic province. Thus the evolution of the region has been from an island arc to a continental arc. This change includes the appropriate change in the chemistry of the igneous rocks from intermediate and mafic to silicic. Although the chemistry of the Guerrero terrane crust is continental-like, the thickness is not always so. In some places the lithosphere is thought to be no more than 12 km. Towards the east, the lithosphere reaches a more reasonable thickness for continental crust. The change in chemistry from island-arc to continental-like crust seems to have been aided by magmatic assimilation of the thick sequence of sediments that were deposited in the ocean floor before accretion by the arc magmatism, and by the loss of deeper parts of the crust after accretion.

MANTLE AND CRUSTAL CONTRIBUTIONS TO PRIMITIVE AND EVOLVED ARC MAGMAS AT THE TATARA-SAN PEDRO COMPLEX (TSPC: 36° S, CHILEAN ANDES): IMPLICATIONS FOR REGIONAL CHEMICAL TRENDS IN THE FRONTAL ARC OF THE SOUTHERN VOLCANIC ZONE (SVZ: 33-41° S)

Michael DUNGAN (Département de Minéralogie, Université de Genève, 13 rue des Maraîchers, 1211 Genève 4, Switzerland, email: dungan@terre.unige.ch)

The long-lived Tatara-San Pedro complex (930 ka - Holocene) is located within the transitional region between thin crust of the southern SVZ (< 40 km; 41-36° S) and thicker, older crust to the north (50-60 km; 33-35° S). For many geochemical parameters the TSPC is intermediate between extremes recorded by centers to the north and south, but previous generalizations concerning systematic along-arc variations among frontal-arc centers as a function of crustal or lithospheric thickness are to some degree confounded by the exceptional diversity of this center (650 analyses). Compositions of primitive, uncontaminated basaltic compositions at the TSPC overlap for most elements with those from the southern SVZ, suggesting less systematic along-arc variability in parent magma composition than previously inferred. However, the major and trace element systematics of evolved mafic magmas (51-53 % SiO2) indicate that basalts with 5-6 % MgO are unreliable carriers of source characteristics, as many are either crustally contaminated or mixed with evolved magmas. A range of differentiation trends, some derived dominantly by closed system fractionation of diverse parent magmas and others generated by open system evolution, manifest variable suppression of Y-HREE in evolved magmas relative to enrichments for closed system fractionation. This probably reflects variable incorporation of silicic crustal components with compositions shaped by residual garnet in their source, although other factors may also be involved. Differentiation of variable parent magma compositions by multiple processes, at multiple levels in the crust, and long-term modification of the crustal column beneath the volcano, have contributed to the geochemical diversity of Tatara-San Pedro magmas.

CONSTRUCTION THROUGH ARC MAGMATISM

Richard J. ARCULUS (Dept. of Geology, Australian National University, Canberra, ACT 0200, Australia, email: richard.arculus@anu.edu.au)

Genesis of continental crust (CC) is a first-order problem. The granodioritic composition can be produced through: fractional crystallisation of basalt; direct melting of subducted/underplated mafic lithosphere; fractionation of high-Mg andesites generated by wet melting of peridotite. Trace element and isotopic systematics require (at some stage) in CC genesis, low % mantle partial melting; garnet-bearing protolith involvement; fluid/solid elemental fractionation. Temporal changes in CC genesis through Earth history have been important. Post-Proterozoic constraints are: 1. Without recycling of H2O, neither melting of subducted slab nor overlying mantle wedge occurs; order of crystalline phase appearance in cooling basalt magmas containing a few % H2O is: olivine, pyroxene, plagioclase _ delay in plagioclase appearance in the "wet basalt case" enhances concentration of Si, Al, Na, K in residual magmas (key elements characteristic of granites); presence of hydrated minerals (amphibole/biotite) in crystallisation products of wet magmas is also important in generation of granitic magmas during ultra-metamorphism of CC. 2. a key requirement for fractional crystallisation is for the system to "be left alone" (ie allowed to cool and crystallise) with minimal accompanying magma chamber tapping or replenishment. Neglect is a function of local magma flux, and in arcs, this is ~0.1 of the ridge flux. 3. disposal of ultramafic/mafic crystalline cumulates from basalt fractionation processes is crucial for production of granodioritic crust. Cumulates may be underplated (sub-Moho) as part of the continental lithosphere or dynamically removed. Melts escaping from a supra-subduction zone system are not coupled to crystal cumulates and residual mantle; the latter are advectively dragged by the subducted lithosphere and recycled deep into the mantle.

THE PHILIPPINE ISLAND ARC CRUST: THICKNESS, MAGMATIC CONTRIBUTION AND ISSUES

Eddie L. LISTANCO (National Institute of Geological Sciences, University of the Philippines, Diliman, Quezon City, 1101 Philippines, email: edlist@hotmail.com)

On the basis of the global variations of crustal thickness with Na2O6.0 and CaO6.0 of island arc volcanic rocks, the thickness of the Philippine arc crust has been estimated to range from 30 to 40 km. Current geochemical database on Philippine volcanoes suggests spatial variations in crustal thickness. The thinnest crust occurs in northern Philippines where xenoliths believed to be of mantle origin are quite common. Incompatible element ratios of volcanic rocks also suggest occasional tapping of non-cogenetic magmas by some volcanic edifices. Variations in the crustal thickness may be partly attributed to age of the crust and to the space-time production rates and emplacement of magmas. Although contributions to volumetric crustal growth can be estimated since the Quatenary, inputs from previous magmatism evident in the underlying volcanogenic sediments and pre-Quaternary volcanics and intrusives remain unresolved.

LATE CRETACEOUS MAGMATISM AND MULTIPLE POST-OROGENIC DENUDATION EVENTS IN THE COASTAL REGION OF SOUTHEAST CHINA

Cheng-Hong CHEN, Wayne Lin, Chi-Yu Lee (All at: Department of Geology, National Taiwan University, Taipei 106, Taiwan, ROC; e-mail: chench@ccms.ntu.edu.tw)

Late Cretaceous I- and A-type granites in the coastal region of SE China were generated in a post-orogenic extensional setting. Voluminous I-type calc-alkaline granites, intruded the late Jurassic/early Cretaceous volcanics at shallow crustal levels during 107-99 Ma., whereas A-type granites emplaced into these preceding plutonic/volcanic suites at 93-90 Ma. Coeval mafic dykes (94-76 Ma) of basic to intermediate composition are also found in this coastal region. They exhibit high-K calc-alkaline trend and lower HFSE abundances similar to I-type granitic suites, but present distinctive Ta and Nb depletions in the spidergram. The geochemical features of A-type granites, such as high silica, alkalis, Ga/Al, Nb, and low Sr, P, Ba contents, are distinguished from those I-type Granites, inferring that A-type magmas in SE China were derived from a separate source other than those of mafic dykes as well as the I-type ones. Lower temperature thermochronological results of these granitic intrusives suggest two distinct episodes of rock mass uplift and denudation during the late Cretaceous. The first episode (~97-84 Ma), deciphered mainly by K-Ar/Ar-Ar biotite and feldspar thermochronology, is possibly controlled by block faulting under the post-orogenic extensional regime, which is accompanied with the development of batholiths subsidence. Syn-extentional mafic dikes emplaced into the faults and joints have been dated coincidently with this time span. The second episode (84-50 Ma), as indicated by apatite fission-track thermochronology, is possibly a reflection denudation. The amount of rock mass uplift and denudation has been estimated to be about 3 km as indicated by the Al-amphibole geobarometers.

THE MAGMATOLOGY OF BEZYMIANNY VOLCANO: A POSSIBLE MODEL FOR KAMCHATKA ARC VOLCANISM

G.E. BOGOYAVLENSKAYA (Institute of Volcanology, Petropavlovsk-Kamchatskii, 683006 Russia, email: volcan@svyaz.kamchatka.ru); M.L. Tolstykh and V.B. Naumov (both at Vernadsky Institute, Moscow, 117975 Russia); M.P. Semet (Institut de Physique du Globe, 75252 Paris, email: semet@ipgp.jussieu.fr)

The chemical composition of products emitted throughout the history of Bezymianni volcano is rather typical of those found at a number of Kamchatka active and extinct volcanoes. Lavas are dominantly of andesitic composition and, usually, highly porphyritic. We have investigated the petrogenetic processes responsible for this rather restricted petrographic and chemical variability by a study of a number of samples representative of the evolution of the volcano including a study of the chemistry of glass inclusions in phenocrysts. Plagioclase (on average An60) is the most abundant phenocryst in the lavas and is accompanied by modest amounts of both clino- and orthopyroxene. A few modal percent of hornblende and olivine are sometimes present whereas oxydes form a constant minor constituent. Glass inclusions were mostly observed in plagioclase crystals and show a range of composition from basic andesitic to rhyolitic. However, the latter composition is the most frequently observed. A conclusion of this is that the andesitic bulk-rock composition results from the presence in about equal proportions of dacitic to rhyolitic liquid and the observed crystals in the magmas feeding the eruptions. The parageneses of the lavas and the volatile contents of the glass inclusions point out to pre-eruptive evolution of the magmas in crustal reservoirs. Because the ultimate source of magmas is from the mantle and of basaltic composition, the above observations require that substantial amounts of material is added to deeper parts of the crust in the form of gabbroic to dioritic complexes as is observed in eroded parts of the peninsula.

40AR/39AR GEOCHRONOLOGY OF THE LAST ERUPTIVE PHASE OF CIOMADUL (CSOMÁD) VOLCANO, EAST CARPATHIANS, ROMANIA

D. KARÁTSON (Eötvös University, Department of Physical Geography, 1083 Budapest, Ludovika tér 2, Hungary. Email: dkarat@ludens.elte.hu); L. W. Snee (US Geological Survey, Box 25046, MS913, Federal Center, Denver, CO 80225, USA)

For more than a century it has been well-known that the last volcanic eruptions of the Carpathians occurred at the end of the Pleistocene in the Harghita Mts, at twin-cratered Mt. Ciomadul. In the past years, 14C and K/Ar methods have been employed in attempts to date the youngest units of the volcano. The 14C method has produced contoversial dates in the 10- to 40-ka range. K/Ar results have been inadequate because of the very small radiogenic 40Ar

abundances in these samples. Recently we found a new exposure of the products of the last phase of the two craters. These dacitic pumices and lithics are base surge deposits from the eastern crater and the overlying pyroclastic flow and fall deposits mostly from the western crater. At the top of the exposure are the products of the youngest eruption. Biotites from pumices in five distinct units have been separated and will be dated by the 40Ar/39Ar method at U.S. Geological Survey laboratory in Denver, CO, USA, using high-sensitivity mass spectrometer with ultra-low blank laser and furnace argon-extraction systems. Argon extraction will be done both by step-heating in the low-blank furnace and by laser-fusion. It is anticipated that our results will clearly define the age of the last eruptive phase of the Carpathians. Here we used data from 1997 and 1998 to assess the influence of the analysis strategy, elevation cut-off angle, and software packages. In all cases IGS orbits and earth orientation products were utilized. The SWEPOS GPS-data are analysed using the GIPSY software package both with traditional network strategies as well as with the precise point positioning method and for different elevation cut-off angles. The tropospheric water vapour content is estimated at each station as a random-walk process with 5 minutes between parameter updates in the Kalman filter. The same data set is also analysed using the Bernese software and the GAMIT software. In this analysis we estimate the water vapour content in a piecewise constant least-squares process.

GENESIS AND GEODYNAMIC IMPLICATIONS OF GARNETS AND GARNET-BEARING MIOCENE CALC-ALKALINE VOLCANIC ROCKS IN THE NORTHERN PANNONIAN BASIN, CENTRAL-EASTERN EUROPE

Szabolcs HARANGI (Department of Petrology & Geochemistry, Eotvos University, H-1088 Budapest, Muzeum krt 4/A, Hungary, e-mail: harangi@iris.geobio.elte.hu); Hilary Downes (Dept of Geological Sciences, Birkbeck College, Malet St., London, WC1E 7HX, UK); Laszlo Kosa, Csaba Szabo (both at Dept of Petrology & Geochemistry, Eotvos University, H-1088 Budapest, Muzeum krt 4/A, Hungary)

Almandine-rich garnets are rare phenocrysts in calc-alkaline volcanic rocks and indicate high-pressure crystallisation and relatively rapid ascent of magma. Thus, occurrences of primary garnet-bearing volcanic rocks appear to indicate a special geodynamic environment. In the Carpathian-Pannonian Region, Miocene to Quaternary calc-alkaline volcanic rocks were formed in a retreating subduction zone. Although a direct relationship has been suggested between volcanism and subduction events in the eastern segment of the Carpathian arc, genesis of the calc-alkaline volcanic rocks of the western segment of the Carpathian arc is more controversial. Volcanism in the western segment of the Carpathian arc started with eruption of garnet-bearing volcanic rocks which in turn are very rare in the eastern part of the arc. Primary garnet phenocrysts occur both in diopside-normative andesites (Type 1 garnets) and corundum-normative dacites and rhyodacites (Type 2 garnets) in the Inner Western Carpathians Volcanic Field, Northern Pannonian Basin. Grossular content of Type 1 garnets is between 8 and 20 mol% and have low d18O (6.2-6.5). Type 2 garnets in general show higher grossular content (Gro=8-12 mol%) than majority of garnets from corundum-normative volcanic rocks world-wide and have d18O=6.9-7.2. Garnet xenocrysts from these rocks show lower grossular content (Gro=1-8 mol%), typically higher spessartine content (Spes10 mol%) and higher d18O (8-10.5) than the primary ones. Sr-Nd isotope ratios of the host rocks indicate that crustal contamination had a major role in the petrogenesis of these rocks. However, the relatively low d18O values of the garnets may suggest that they could have been formed from mantle-derived magmas prior the contamination processes. Eruption of garnet-bearing volcanic rocks may indicate a change in the tectonic regime of the area, i.e. transition from compressive to extensional phase

FLUID-CONTROLLED ELEMENTAL TRANSFER FROM SLAB TO CRUST IN THE CENTRAL IZU ARC (NW PACIFIC)

S.M. STRAUB (Geomar Research Center, Wischhofstr.1-3; 24148 Kiel, FRG: e-mail: sstraub@geomar.de); GD Layne (Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA); A Schmidt, KA Hoernle (Geomar Research Center, Wischhofstr.1-3; 24148 Kiel, FRG)

We investigated fluid-dominated arc front volcanism in the intraoceanic Izu arc (NW Pacific) by approximated arc melts by glasses (matrix shards, melt inclusions) in distal fallout tephra (ODP Site 782A) that ranges from mid-Miocene to Quaternary in age. The glasses show a large range in silica (50-75 wt% SiO2) that corresponds with a small range in MgO (=6-1 wt%). High-MgO glasses are offset from N-MORBs with similiar MgO: TiO2 (0.5-1 wt%), P2O5 (= 0.1 wt%), Na2O (1.5-2 wt%), Be (0.4-0.5 ppm) and F (80-100 ppm) are lower, but Al2O3 (14-15 wt%) and the incompatible elements B (10-20 ppm), K2O (0.2-0.4 wt%), Cl (800-1600 ppm) and H2O (up to 4 wt%) are higher. The linear trends of incompatible elements and the only minor Be enrichment from =0.4 to =0.6 ppm with increasing silica suggest that the compositional range of the glasses has been produced be melt mixing. A simple genetic model is that a HFSE- depleted mantle wedge is fluxed by a Be-poor component from the slab, that is differently enriched in Si, B, K, Li, Cl, F, H (and possibly Na and Al). Unidirectional temporal trends are not apparent in abundances and ratios of incompatible elements. The tephras are nearly homogenous in initial radiogenic isotope ratios (87Sr/86Sr = 0.70339 - 0.70364, 143Nd/144Nd = 0.51305 - 0.51311, 206Pb/ 204Pb = 18.36 - 18.46; 207Pb/204Pb = 15.50-15.55; 208Pb/204Pb= 38.16-38.34). This suggests that fractionation processes are superimposed on the elemental fluxes. The extent of fractionation can vary considerably as indicated by the range in ratios of LLE/Be (e.g. B/Be=20-100) which nearly reaches the global arc range (e.g. B/Be= 5-120). Thus, the glasses provide insights into fluid- controlled fractionation processes that are believed to play an important role in creating the typical elemental signatures of subduction-related magmas.

JSV30/W/04-B1 Poster **1400-07**

COMPARATIVE EVOLUTION OF THE CENTRAL IZU AND MARIANA VOLCANIC ARCS DURING THE PAST 15 MILLION YEARS

A. SCHMIDT, S.M. Straub, K.A. Hoernle (Geomar Research Center, Wischhofstr.1-3; 24148 Kiel, FRG: e-mail: aschmidt@geomar.de); A.G. Hochstaedter (Earth Sciences Dept. UC Santa Cruz; CA 95064; USA); C.H. Langmuir (Lamont Doherty Earth Observatory, Palisades, NY 10964, USA); J. Gill (Earth Sciences Dept. UC Santa Cruz; CA 95064; USA)

The intraoceanic Izu and Mariana volcanic arcs (IBM) in the NW Pacific have a similar evolution and many common subduction parameters. However, the chemical signature of arc front volcanic rocks is different, with the Izu arc being less enriched in LILE (e.g. K2O: Izu=0.3 wt%; Mariana=0.7 wt%) and radiogenic Pb (e.g. 206Pb/204Pb: Izu=18.42; Mariana=18.84) and more depleted in HFSE (e.g. Nb: Izu=0.57 ppm; Mariana=1.07 ppm). Distal tephra layers show that the compositional differences between the Izu and Mariana arcs have persisted for 15 million years. Low K65 = 0.5 wt% (K2O at 65 wt% SiO2) and a clear separation in low-K and high-K series prevail in the Izu arc in contrast to the Marianas that have a higher K65 = 1 wt% and display a continuum from low-K to high-K series. It is an open question whether compositions of the various crustal and mantle sources - all else being equal - can account for all differences in isotope and elemental signatures observed. A striking difference between the Izu and the Mariana arcs are the different angles of the subducting slab (Izu=45°; Mariana=80-90°) beneath the volcanic front and the width of the active volcanic zones (Izu=170 kilometer, Mariana =30 kilometer). Assuming that recycling occurs across a finite p- T-range, the different angles of subduction could result in different horizontal widths across which recycling occurs. If so, the wider volcanic zone in the Izu arc could mirror the larger horizontal vector of the subducting slab. A first order consequence is a better spatial resolution of slab components which are strongly fluid-controlled at the Izu arc front (e.g. high Sr/Nd, high Pb) and but become melt-dominated with increasing depth. In contrast, the steeper angle in the Marianas would result in an "integrated" signal, because fluid- and melt-dominated slab components ascend along a narrower vertical path. Sr-Nd-Pb isotope systematics are consistent with this model but modelling of the elemental budget is needed to further test this hypothesis.

JSV30/W/10-B1 Poster **1400-08**

GEOLOGICAL AND PETROGRAPHICAL CHARACTERISTICS OF THE SOFUGAN TECTONIC LINE, IZU-OGASAWARA ARC

Izumi SAKAMOTO, Toshiya Fujiwara (Deep Sea Res. Dept., Japan Marine Science & Technology Center, e-mail: izumis@jamstec.go.jp)

Sofugan Tectonic Line (STL) which is located in the central part of Izu-Ogasawara Arc shows NNE - SSW trending, and cross cutting the whole island arc body. The STL has a 200km-lomg steep slope (more than 70_‹and 1000m in height) in this study area. The steep slope observed along the S-E cliff, while the back slope is relatively gentle. Some sea mount with recent volcanic front activity cut the STL in topographically. Lithology of the typical cross section of the STL is divided into the following four units in ascending order: 1) massive volcanic rocks (K-Ar age=3.8 to 2.9 Ma), 2) hyaloclastites, 3) volcanigenic sediment, and 4) mud stone. Alternation with hyaloclasite and mudstone was observed in the upper part of this section. Lithologic changes from pyroclastic fragments to volcaniclastic sediments shows decreasing of volcanic activity. Mudstone includes late Pliocene nanno fossils (CN11B-13b). Altered basalt were sampled from the lower part of unit 1 from the STL, and fresh olivine basalts were collected from middle to upper part of the STL. All of these volcanic rocks are island arc type tholeiite series from the geochemical data (low-K2O, low-TiO2, and Nb anomaly is observed in MORB normalized spider diagram).

SIMULTANEOUS CRYSTALLIZATION AND MELTING AT BOTH THE ROOF AND FLOOR OF CRUSTAL MAGMA CHAMBERS

Katsuya KANEKO (Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-city, 270-1194 Chiba, JAPAN, email: katsuya@criepi.denken.or.jp); Takehiro Koyaguchi (Earthquake Research Institute, University of Tokyo, Tokyo 113-0032, JAPAN, email: tak@eri.u-tokyo.ac.jp)

Thermal and compositional evolution of magmas after a basalt emplacement into continental crust has been investigated by means of fluid dynamics experiments using a cold solid mixture with eutectic composition and a hot liquid with higher salinity in the NH4Cl-H2O binary eutectic system. The experiments were designed to simulate the cases where melting occurs at both the roof and floor of crustal magma chambers. The results show that thermal and compositional convection occur simultaneously in the solution; the thermal convection is driven by cooling at the roof and the compositional convection is driven by melting and crystallization at the floor. The roof was rapidly melted by convective heat flux, which resulted in the formation of a separate eutectic melt layer with negligible mixing of the underlying liquid. On the other hand, a mushy cumulate layer formed at the floor. The compositional convection at the floor carried a low heat flux, so that the heat transfer at the floor was basically explained by simple heat conduction. The compositional convection resulted in stabilizing compositional gradient and formation of double-diffusive convecting layers in the solution, which decreased the upward heat flux. These experimental results imply that, when a basalt magma is emplaced in continental crust, floor melting does not always enhance the cooling of the magma, but it may even decrease the total heat loss from the magma to the crusts due to the formation of double-diffusive convecting layers.

TEMPORAL EVOLUTION OF K2O CONTENT IN ARC-TYPE VOLCANOES: EXAMPLES FROM NEW ZEALAND AND INDONESIA

Ian E.M. SMITH, Supriyati Andreastuti (Department of Geology, University of Auckland, N.Z., email: ie.smith@auckland.ac.nz); Richard C Price (School of Science and Technology, University of Waikato, N.Z.); Bob Stewart (Department of Soil Science, Massey University, N.Z.)

The correlation of the K2O content of magmas erupted from volcanic arcs with depth to the underlying seismic zone (the K-h relationship) has laid the basis for petrogenetic models in which subduction of oceanic lithosphere plays a major role in their petrogenesis. However, detailed studies of individual volcanoes shows that K2O contents (and that of geochemically similar elements) show systematic increases with time for equivalent SiO2 content.This indicates that interpretation of the K-h relationship in terms of tectonic setting is too simplistic Ruapehu and Taranaki Volcanos in northern New Zealand occupy frontal and back- arc positions respectively. Merapi Volcano in central Java lies on the arc front. In all three volcanoes the erupted magmas exhibit relatively short time scale (100-1000a) compositional variations which are interpreted as the results of relatively shallow crustal processes probably dominated by fractionation. Longer time scale (1000-10,000a) compositional trends are toward higher K2O (and commonly more mafic) compositions and are often correlated with petrographic evidence for recharge of the magmatic system from deeper levels. This trend appears to be independent of tectonic setting and is thought to reflect a process of assimilation of early arc precursors at or near the base of the crust. Our explanation of the observed trends invokes thermal evolution of the arc basement to a stage where reaction between anhydrous mafic cumulates and wall rocks in the amphibole stability field produce progressively more potassic parental magmas as the arc evolves.

CRUSTAL ANATEXIS BENEATH THE TONGA-KERMADEC ARC

Tim J. WORTHINGTON, Ian E.M. Smith (Dept of Geology, University of Auckland, Auckland, New Zealand, e-mail: tj.worthington@auckland.ac.nz / ie.smith@auckland.ac.nz)

Voluminous eruptions of sparsely phyric felsic magma (>10 km3) have alternated with eruptions of crystal-rich basaltic-andesitic magma at nine Tonga-Kermadec arc volcanoes since 10 ka. Along-arc variations in felsic and mafic magma composition are dissimilar, and suggest each magma type is derived from a different source. Furthermore, each eruption of felsic magma at Raoul Volcano is geochemically distinct, and these magma batches cannot be related to each other or to a common mafic precursor by simple fractionation processes. The geochemistry of Raoul dacite is modelled by 20-35 % dehydration and 0.6 GPa. Thermal

models invoke crustal heating from an ambient 600 oC by underplating and convective cooling of primitive high-Mg magma from 1250 to 1100 oC. Budget calculations based on erupted volumes of dacite and basalt-andesite show that ample heat exists to drive this process (>2.5 times that required). Sub-arc crust is thus transformed to anhydrous granulite + dacitic magma, whereas primitive high-Mg magma evolves to crystal-rich low-Mg magma + cumulates.Crustal anatexis and felsic magmatism are restricted to an adolescent arc window 1-3 m.y. after arc inception if the crust is the sole source of H2O. Conversely, anatexis may persist throughout the life of the arc if H2O exsolved by primitive magma hydrates the crust. The pulse of felsic magmatism presently sweeping the <3 m.y. Tonga-Kermadec arc, the <2 m.y. Taupo Volcanic Zone, and peaking at 3 Ma in the 5 m.y.-old Mariana arc highlights the role of crustal H2O.

ARC MAGMAS PRODUCE CONTINENTAL LITHOSPHERE? (NOT JUST CRUST)

Jon DAVIDSON (Dept. of Earth and Space Sciences, UCLA, Los Angeles, CA 90095, USA, email: davidson@ess.ucla.edu)

Magmatism at convergent plate margins is thought to be the principle mechanism for long-term addition of material from the mantle to the crust. The Andean arc offers an opportunity to test simple models of crust generation. Here, volcanic rocks and their plutonic equivalents are compositionally similar to estimates of "average crust", notwithstanding the chemical differences found in Archean crust. An analysis of magmatic differentiation processes, however, suggests that the similarity is a reflection of large-scale cannibalization – Andean magmatic rocks look like "crust" because they contain a significant component of recycled crust. There is little compelling evidence that the magmas derived from the mantle are different from those encountered at oceanic subduction zones. Here, again accounting for differentiation effects, it is clear that the mass flux from the mantle is fundamentally basaltic. Thus, the composition of material added to the crust instantaneously at subduction zones is very different from the bulk composition of the crust. This observation may suggest that a large fraction of crust formed early in Earth history, by a mechanism different from today's subduction-related magmagenesis. A more reasonable alternative is that the crust is simply a differentiate of the added material, requiring the existence of an ultramafic complement. The complement may be recycled into the convecting mantle (during arc magmagenesis or at some later time in an unrelated plate tectonic environment) or may reside in the mantle lithosphere. The issue of crustal growth may therefore seem overly complicated because of our definition of the Moho, which may simply separate feldspar-rich differentiates from ultramafic cumulate.

ORIGINS OF SANIDINE MEGACRYSTS IN ITALIAN ALKALINE ROCKS

Giulia PERINI, Frank J. Tepley III, Jon P. Davidson, (all at Department of Earth and Space Sciences, University of California, Los Angeles, USA); Sandro Conticelli (Centro di Geodinamica, Università della Basilicata, Potenza, Italy)

Sr-isotope compositions were used to determine the origin of sanidine megacrysts found in primitive ultrapotassic and trachytic rocks from the Italian Plio-Pleistocene Volcanic Region. At Cimino volcano, primitive megacryst-bearing rocks are associated with the evolved rocks. The primitive magmas are high-silica lamproite- to- transitional-ultrapotassic rocks characterised by high Mg# and high compatible element contents. The evolved rocks are trachytes, which were erupted before the primitive magmas at Cimino. 87Sr/86Sr ratios in the primitive rocks from Cimino volcano vary from 0.713 and 0.716 whereas the more evolved trachytes have ratios between 0.713 and 0.714. Sanidine megacrysts have variable morphologies that range from euhedral in the trachytes to subhedral in the primitive rocks, but in either case they are not fragmented. Core-rim Sr-isotope analyses were performed by the microdrilling technique. 87Sr/86Sr values of sanidine crystals from primitive rocks are between 0.71370 and 0.71398 but cores and rim 87Sr/86Sr ratios are indistinguishable. However, the megacrysts are not in isotopic equilibrium with the host rocks, which are less radiogenic (0.71384-0.71582). Sanidine crystals from a trachyte have similar Sr-isotope compositions to those in the primitive rocks, but the 87Sr/86Sr ratios vary significantly from core (0.71387) to rim (0.71356). Whole-rock Sr-isotope compositions of the trachyte (0.71333) reveal that the sanidine crystals are also not in isotopic equilibrium with their host. We postulate that all of the sanidine megacrysts grew in a relatively low 87Sr/86Sr trachytic magma. Mixing between trachyte and ultrapotassic magmas distributed the megacrysts among all magmas. Sanidine megacrysts hosted in the primitive rocks did not grow in that melt, but were inherited from the trachytic melts, resulting in dissolution of the megacryst rims and the observed subhedral shapes

VOLCANISM IN THE SAN PEDRO-CEBORUCO GRABEN (NAYARIT, EXICO): COEXISTENCE OF MAGMAS WITH DIFFERENT PETROLOGICAL AFFINITY

C.M. Petrone (1), L. Francalanci (1), S. CONTICELLI (2), L. Ferrari (3) (1: Dipartimento di Scienze della Terra, Università di Firenze; 2: Centro di Geodinamica, Università della Basilicata; 3: Unidad de Ciencias de la Tierra, UNAM, Juriquilla, Mexico)

The San Pedro-Ceboruco graben is a complex asymmetric basin in which calc-alkaline and Na-alkaline magmas coexist in a tectonic setting characterized by active subduction and extension. At least four different volcanic systems, belonging to the Trans-Mexican Volcanic Belt, are set in the San Pedro-Ceboruco graben: 1) allignments of cinder cones and domes arranged parallel to the border of the graben; 2) a volcanic system formed by several domes and a shield volcano, San Pedro-Cerro Grande Volcanic Complex; two polygenetic stratovolcanoes, 3) Tepetiltic and 4) Ceboruco. Calc-alkaline and mildly Na-alkaline rocks coexist in the allignments of cinder cones and domes and in the San Pedro-Cerro Grande Volcanic Complex.
In particular, the shield volcano of the latter has a Na-alkaline composition. Ceboruco and Tepetiltic stratovolcanoes are both calc-alkaline. Mineralogical, chemical and isotopic data have pointed out the existence of at least five different parental magmas whose characteristics encompass the entire compositional range between calc-alkaline and Na-alkaline magmas. They have been interpreted as deriving from a heterogeneous mantle wedge in which MORB-type and OIB-type components mights coexist.

MAGMATISM IN THE SOUTH SANDWICH ISLANDS AND EAST SCOTIA RIDGE, SOUTH ATLANTIC

P.T. LEAT, J.L. Smellie, R.D. Larter, R.A. Livermore, T.R. Riley, I.L. Millar (British Antarctic Survey, High Cross, Madingley Road, Cambridge CB3 0ET, UK, email: p.leat@bas.ac.uk)

The South Sandwich Islands are a 350 km long, intraoceanic island arc built on the Sandwich plate above west-subducting South American plate. The Sandwich plate is separating from the Scotia plate at a rate of 6.5-7 cm/yr at the back-arc East Scotia Ridge. This oceanic arc to back-arc system is one of the smallest and tectonically simplest subduction systemson Earth. As such, it is an important location for studies of island arc structure and growth, primitive arc composition, and the timing and composition of slab-derived fluxes in the mantle source. It is also an analogue for suprasubduction ophiolites. The islands comprise tholeiitic and rare calc-alkaline basalt to dacite. They are typically ca. 5 km across and represent the subaerial expressions of seven large volcanoes built on the oceanic crust of the Sandwich plate. Marine magnetic anomaly interpretation indicates that the ocean crust beneath the volcanoes was formed at the East Scotia Ridge between anomalies 4 and 5 (ca. 7.5-10 Ma), and that fore-arc erosion of the overriding plate is taking place at the trench. The implication is that earlier volcanic edifices have collapsed into the trench and have been subducted.
Trace element variations indicate that two distinct slab-derived chemical components are present in the arc, a high LREE, high Th/Nb component, probably subducted sediment (end-member: Visokoi Island), and a high Ba,U,Cs/Th, high Sr/Nd component, probably slab-derived fluids (end-member: Vindication Island). Both occur as minor components in back-arc magmas, whose main variations are related to plume mantle (possible migrating westward from Bouvet) entering the back-arc around the edges of the subducting slab and interacting with depleted (MORB-source) mantle.

PHANEROZOIC SUBDUCTION AND THE TTG-MAMGMATIC CONSTRUCTION OF ARCHAEAN CONTINENTAL CRUST

Miles OSMASTON (The White Cottage, Sendmarsh, Ripley, Woking, Surrey, GU23 6JT, UK, email: miles@osmaston.demon.co.uk)

My studies of the evolution of Phanerozoic subduction zones (e.g. IGC1992, IUGG1995), noting their impact upon the geology above them, clearly indicate the presence of two major non-arc processes. (1) Subduction tectonic erosion (STE). In STE the young-plate (<70Ma) downbend mechanism is able to nibble away the hanging wall at the downbend, shallowly and rapidly advancing the downbend position beneath the upper plate by hundreds of kilometers, rendering the margin susceptible to imbrication. STE implies young-plate buoyancy, achievable if a substantial thickness of LVZ material forms an integral part of the plate. This, in turn, provides the heat for (2), post-subduction magmatism (PSM). Here the cessation of subduction gives time for the LVZ heat to soak through the former slab and induce wholesale melting of its subduction interface crustal material, resulting in a several-100km-wide belt of silicic/granitoid magmatism (examples given). The granitoid (TTG) intrusion of Archaean greenstone belts appears consistent with PSM into an extensively STE-undercut margin, as subducted plates would certainly have been young and hot. Key to the much-debated tectonic location and magmatic origin of greenstone belts seems to be my recognition (IGC1992) that Phanerozoic subduction has commonly started in the oceanic domain, reaching continental margins by repeated STE and imbrication. Thus at least the initial forearc is oceanic-crusted, having formed a passive margin made by the MOR process before subduction began. In the same way, Archaean greenstone belts may indeed have originated as oceanic crust.

THE ADAKITE-LIKE AND HIGH-CA BONINITE-LIKE VOLCANIC ROCKS IN CENTRAL AND SOUTHERN TIBET: INPLICATION FOR TIBETAN TECTONIC RECONSTRUCTION

Chang-Hwa CHEN (Inst. of Earth Science, Academia Sinica., Taiwan, email: china@earth.sinica.edu.tw); Kenneth J. Hsu (Tarim Associates AG, Frohburgstrasse 96, Zurich, Switzerland); Jason Jiun-San Shen (Inst. Earth Sci., Academia Sinica, Taipei, Taiwan); Charles T. Wu (Dept. Geol., Univ. Western Ontario, Canada)

The geochemistry of volcanic rocks in orogenic belts places new constraints on tectonic interpretations of orogenically deformed plate. The adakite-like rocks from Qiangtang Terrane in central Tibet suggested that the magmas were derived from the partial melting of the subducted slab of a young and hot oceanic plate of back-arc basin, not of the Paleotethys ocean plate. The adakite-like rock from Lhasa Terrane in southern Tibet indicated that the magma was derived from the subducted hot ocean crust of a back-arc basin, the Zhangbo Back-arc Basin (Hsu et al., 1995, Inter. Geol. Rev., 37, 473-508), not of the Neotethys Ocean plate. Moreover, the High-Ca boninite-like from Amdo along the Banggon-Lujiang suture (BNS) may have been generated from a suboceanic lithosphere by contact melting adjacent to rising MORB source diapirs. Tectonic reconstruction indicates that the Lhasa and Qiangtang Terranes were archipelagos of island-arcs and back-arc basins on the margin of the Gondwana and Cathaysian plates. The Banggon-Lujiang suture (BNS) marks the position of the collision of the two plates.

PERIODICITY OF MONOGENETIC BASALTIC VOLCANISM AND ITS RELATIONSHIP WITH TECTONIC ACTIVITY AT THE BASIN OF AVACHA RIVER, KAMCHATKA, RUSSIA

Oleg V. DIRKSEN, Ivan V. Melekestsev, Lilia I. Bazanova (Institute of Volcanic Geology and Geochemistry, Piipa blvd. 9, Petropavlovsk-Kamchatsky, 683006, Russia, email: ivgg@svyaz.kamchatka.su)

The research region is situated at 70 km NW of Petropavlovsk-Kamchatsky at a zone of intensive uplifting of the earth surface. We studied 22 Holocene monogenetic centers: 2 maars and 20 scoria cones. Chemically all the eruptive products (except for 1 center) represent basalts (SiO2 46.20-53.07 wt %) and usually have high MgO concentration. Maximum MgO concentration is in rocks of Zavaritsky volcano (up to 13 wt %). Using tephrochronological and radiocarbon dating we determined that during the Holocene we can fairly distinguish three outbursts of monogenetic volcanism: I-7700-11000 14C BP (8 centers), II-2500-3000 14C BP (9 centers, 6 of them form volcano Zavaritskogo) and III-600-1600 14C BP (5 centers). The volume of erupted tephra and lava is 0.11 and 0.02 cub km; 0.77 and 0.06 cub km: 0.04 and 0.1 cub km respectively. The studied region is also characterized with a strong tectonic uplifting during the Holocene. This activity is reflected with many river terraces developed over Levaya Avacha river. Our tephrochronological scale allowed us to determine the age of about 30 terraces of different ages. It was clearly identified that in terms of age most of terraces clustered in four time interval:1) 10000-7700 14C BP, 2) around 4000-3500 14C BP, 3) 2200-1700 14C BP, and about 600 14C BP.
These time intervals correlate well with the periods of volcanic activity. We consider the volcanic outbursts occurred simultaneously with or were preceded by the beginnings of strong tectonic uplifting in studied area. This assumption testifies to close relationship of both volcanic and tectonic processes in this region. In future we plan to continue our investigation to identify the relationship of these phenomena in other parts of Kamchatka.

EOCENE-NEOGENE CONTINENTAL MAGMATISM IN NECHAKO RIVER AREA, CENTRAL BRITISH COLUMBIA, CANADA

Robert G. ANDERSON (Geol. Survey of Canada, 101 – 605 Robson St., Vancouver, B.C., Canada, V6B 5J3)

Eocene and Neogene magmatism in the Nechako River area was widespread, post-accretionary, and well inboard of the Tertiary Canadian Cordilleran continental margin. Several collaborative studies have established the extent, age, structural setting, composition, and isotopic character of the Eocene felsic Ootsa Lake (OLG) and mafic Endako (EG) groups rocks, and Neogene mafic rocks. A fault-bounded, Eocene (53-45 Ma) bimodal, volcano-plutonic complex developed coeval with terminal cooling of a nearby, extensional metamorphic complex and contemporaneous with trans-tensional tectonics. Rhyolitic and dacitic, biotite-quartz-alkali feldspar phyric tuff, pyroclastic rocks, breccia, flows, and siliceous and glassy domes and minor, basal basalt and andesite (OLG) are overlain by amygdaloidal, hypersthene-augite-plagioclase phyric andesite to basaltic andesite flows and hyaloclastite (EG). OLG rocks are silicic, calc-alkaline, very high-K and large ion lithophile-enriched, peraluminous, and have a moderate to marked Eu anomaly. EG mafic flow rocks are mildly alkaline, transitional to calc-alkaline, high-K, and have within-plate and continental affinities. Both units are isotopically primitive (Sri: 0.70401-42; ENd: +1.3 to +3.2). Associated coeval, bimodal and miarolitic leucocratic granite and porphyry plutons are silicic, calc-alkaline, high-K, met- to peraluminous, and are partly of within-plate granite affinity.
Neogene (locally Middle Miocene) basanite and hawaiite flows were erupted from compositionally similar volcanic and diabasic centres which were localized along re-activated? Eocene block faults and characterized by spinel lherzolite and crustal xenoliths. Olivine, pyroxene, plagioclase, and magnetite occur as xenocrysts, megacrysts, and/or phenocrysts. The rocks are typically alkaline (ne-normative), high-K, and encompass within-plate and continental affinities.

GEOCHEMISTRY OF MESOZOIC-CENOZOIC IGNEOUS ROCKS IN THE SOUTH SHETLAND ISLANDS, ANTARCTICA

Guang-Fu XING, Qing-Min Jin (both at the Antarctic Research Center, Chinese Academy of Geological Sciences, 534 East Zhongshan Rd., Nanjing, P.R.China, email: nigmr@public1.ptt.js.cn); De-Zi Wang and Wei-Zhou Shen (both at Department of Earth Sciences, Nanjing University, 22 Hankou Rd., Nanjing,P.R.China.)

The South Shetland Islands (SSI) in West Antarctica outcrops extentively Mesozoic-Cenozoic arc volcanic-plutonic rocks (high-alumina basaltic-dacitic). King George Island rocks are 77-14Ma in age but mostly in Tertiary, their (87Sr/86Sr)i, =CE=B5Nd(t), 206Pb/204Pb, 207Pb/204Pb and 208Pb/204Pb are 0.70260-0.70387,2.77-7.28(mostly >5),17.776-18.768,15.506-15.736 and 37.726-38.961, respectively. Rocks from Greenwich and Half Moon islands have (87Sr/86Sr)i of 0.70404-0.70475,=CE=B5Nd(t) of 1.14-3.56, 206Pb/204Pb of 17.831-18.487, 207Pb/204Pb of 15.505-15.611, 208Pb/204Pb of 37.829-38.426. Combined with reported Mesozoic igneous rocks from adjoining Livingston, Robert and Nelson islands, arc igneous rocks become younger and younger, i.e., on the whole from late Cretaceous to late Tertiary, and contain more and more radiogenic isotopes along the SSI from SW (Livingston Island) to NE(King George Island). Based on their isotopic compositions, enriched LREE, high LILE/HFSE ratios, negative Ce and Nb anomalies, etc., the authors advance that arc igneous rocks from King George, Greenwich and Half Moon islands derived from upper mantle wedge enriched by metasomatism of CO2-rich fluids from subducted carbonate-rich pelagic sediments, and that their evident isotopic variations are ascribed to different degrees of fluid metasomatism rather than crustal contamination.

ISOTOPIC GEOCHEMISTRY OF MESOZOIC VOLCANO-INTRUSIVE ROCKS FROM NORTHERN MARGIN OF THE DABIESHAN OROGENE, CHINA

Zhu-Liang YANG, Kui-Yuan Tao, Fang-Gui Xie and Jia-Lin Shen (all at Nanjing Institute of Geology and Mineral Resources, 534 East Zhongshan Rd., Nanjing, P. R. China, email: nigmr@public1.ptt.js.cn); Wei-Zhou Shen (Department of Earth Sciences, Nanjing University, 22 Hankou Rd., Nanjing, P. R. China)

Mesozoic volcanic rocks from northern margin of the Dabieshan orogene can be divided into two episodes, I and II. Episode I (140-126Ma) are mainly andesitic and belong to high-K calc-alkaline series. Episode II (126-117Ma) rocks have two different evolution trends, one the acidic belonging to calc-alkaline series, the other alkaline to shoshonitic series. All of the volcano-intrusive rocks out-cropped in northern margin of the Dabieshan orogene have the following isotopic characteristics: (87Sr/86Sr)i>0.708, =EF=81=A5Nd(t)=3D-14.7--21.7, 204Pb=3D1.371-1.439, 206Pb/204Pb=3D15.975-17.363, 207Pb/204Pb=3D15.305-15.537, 208Pb/204Pb=3D36.856-38.816. These indicate that the basement metamorphic rocks play important roles in the petrogeneses of the volcano-intrusive rocks. But two facts must have attention, one is that the direct basement rocks in the area have =EF=81=A5Nd(t) larger than -21.7 (i.e. cannot reach so negative value), the other is that the basement rocks have TDM values (two-stage Nd isotopic depleted mantle model age) less than those of Mesozoic rocks. Recently, we have found the episode I volcanic rocks inside the orogene. All of these show that the Mesozoic rocks were formed in the post-orogeny stage and the basement of the whole orogene and its northern margin is to a great extent akin to the North China Block.

ACROSS-ARC MANTLE HETEROGENEITY IN THE SOUTHERN MARIANA

Teruaki ISHII, Hiroshi Sato, Satoru Haraguchi, Shinji Kaneyama (Ocean Res. Inst., Univ. Tokyo, Nakano-ku, Tokyo 164-8639, Japan; email: ishii@ori.u-tokyo.ac.jp); Hidetsugu Taniguchi (Komazawa Univ. High School, Tokyo, Japan), and Yasuhiko Ohara (Hydrographic Dep. Japan, Tokyo)

Where the ophiolites came from is one of the most interesting problems in the earth science. For these ophiolite problem, we have been investigating on the in situ ophiolite (= proto-ophiolite) in the sea floor, i.e., modern analogue of on-land ophiolites. Trench inner wall of the Southern Mariana shows very steep slope with about 400 km wide having an EWE strike and with about 5000 m high having a southward dip of about 12-15d due to the highly oblique subduction of the Pacific plate beneath the Philippine Sea Plate. The escarpment can be assumed as a huge fault plane. Along the escarpment, several geological cross sections including from crust down to upper mantle successions of the island-arc system with back-arc spreading can be observed, i.e., including the West Mariana Ridge (remnant arc), Mariana Trough (back-arc basin), Mariana Arc (active arc and remnant arc), and Mariana Forearc from west to east. Dredged mantle peridotites can be divided into three groups on the basis of the mineralogical & petrological characteristics and estimated degree of depletion for magmatic components, i.e., Cr-spinel bearing harzburgite (group A), Cr-spinel bearing meta-peridotite (B), and plagioclase bearing spinel lherzolite (C) were collected from diapiric serpentine seamounts in forearc, back-arc area and forearc area, respectively. Petrological evidences of peridotites and associated effusive rocks suggest that very depleted (=A), moderately depleted (=B) and relatively fertile (=C) peridotites may be refractory residual peridotites after segregation of boninitic magma, arc-tholeiitic magma and back-arc-basin basaltic magma, respectively.

GEOCHEMISTRY OF MG-RICH VOLCANIC ROCK SERIES IN ALTAY MT., NORTHWEST CHINA AND ITS GEOLOGIC SIGNIFICANCE

Yu XUEYUAN, Niu Hecai, Xu Jifong, Chen fanrong, Zheng Zuoping (Guangzhou Institute Of Geochemistry, Chinese Academy of Sciences, Guangzhou, 510640,
email: yuxueyua@public.guangzhou.gd.cn)

A sequence of rare Mg-rich volcanic rocks has been found in western Altay Mt., Northwest China. It mainly consists of dacite and basalt. They are part of a marine volcanic strata of Middle Devonian epoch. The volcanic rocks are characterized by MgO-rich (2.69-5.24% in the dacites and 9.78-12.19% in the basalts), TiO2-poor (0.26-0.31% and 0.55-0.65%), high-SiO2 (61.93-66.91% and 47.26-53.54%) and strong depletion of HFSE (Zr=29-35ppm and 24-27ppm, Hf=0.39-0.67ppm and 0.27-0.31ppm, Y=10-13ppm and 10-13ppm, P205=0.05-0.07% and 0.10- 0.14%). The ratios of 143Nd/144Nd of the Mg-rich rocks are lower (0.512644-0.512712) with ŒNd=+1.l - +1.3. Although these geochemical features of the Mg-rich volcanic rocks are similar to boninite, the lack of Mg-rich andesite and associated ophiolite in this area suggests they are more likely to be a Mg-rich volcanic rock series. The high-Mg and strong depletion of HFSE as well as lower ratios of 143Nd/144Nd of the Mg-rich rocks show that they are derived from a depleted source peridotite. Their parent magma might have been formed from the partial melting of residual refractory peridotite of the upper mantle. Two-component mixing modeling (143Nd/144Nd and 87Sr/86Sr) indicated that the parent magma might have been contaminated by subducted continental crust or oceanic sediment (about 30%). The patterns of incompatible elements for dacites and basalts in this area are similar to those for the primitive plagiogranite of the island arc tholeiitic series and oceanic island arc basalts respectively, suggesting that they may have been formed in the intra-oceanic island arc setting (or fore-arc such as Izu-Bonin arc)…

WIDESPREAD OIB-TYPE VOLCANISM IN THE MEXICAN VOLCANIC BELT: AN UNUSUAL CONTINENTAL ARC

Surendra P. VERMA (Centro de Investigación en Energía, UNAM, Priv. Xochicalco S/No., Apartado Postal 34, Temixco, Mor. 62580, Mexico, email: spv@mazatl.cie.unam.mx)

Mexican Volcanic Belt (MVB) is a presumably continental arc of Miocene to Recent age, and is probably related to the subduction of Rivera and Cocos plates. It extends approximately 1000 km from the Pacific coast to the coast of Gulf of Mexico in an E-W direction. Although calc-alkaline volcanism dominates, there is also a widespread distribution of Ocean-Island basalt (OIB) type rocks throughout the belt. Furthermore, both types of volcanism seem to be closely related in both space and time. To mention just some of the areas with OIB type volcanism (mainly based on my published and unpublished data) one may state: Tepic-Zacoalco rift in the north-western part of the MVB, Michoacan-Guanajuato and Sierra de Chichinautzin monogenetic volcanic fields in the central MVB, and Los Humeros-Las Derrumbadas and Palma-Sola areas in the eastern MVB.
It seems that the MVB does not share these unusual chemical characteristics with other arcs, including those in the Circum-Pacific area. It is interesting to note that the MVB is probably the only arc in the world that is not parallel to the subduction but makes an angle of about 20° with respect to the Middle-America trench. Although different explanations have been put forth for these unusual characteristics, the most recent one by Márquez et al. (Geology, 1999, in press) is that both plume and subduction-related phenomena coexist in the MVB and therefore it represents a hybrid case with volcanism originating both from the migration of North American plate over a plume and the subduction of Cocos and Rivera plates. The following questions may well be worth addressing. If such a hybrid model is true, what implications does it have for crustal growth? Is there any modern or ancient analog for such an arc?

METASOMATIC MANTLE COLUMN BENEATH BARTOY VOLCANOES

ASHCHEPKOV, I.V. (United Institute of Geology Geophysics and Mineralogy, SD RASc, e- mail: garnet@uiggm.nsc.ru)

Xenoliths from the Quaternary volcanoes SW Trans Baikal represent rare mantle column with the regular changes in metasomatic assemblages from dry sheared Fe- lherzolites to Phl porphy ric, Amph-Phl microveined, Dry protogranular, Amph fine equigranular Lherzolites. Amount of Cpx megacrystalline (from Ga to Pl bearing) groups (4) coincides. Two first lherzolite groups compile thermally excited branch of geotherm while other are close to SEA. Megacryst further evolve to the Kaers g Kaers-Phl g Kaers- AnClaseg AnClase-Ti Biotite association. Rarely they reveal direct contacts with lherzolites. Three other evolving magmatic branches: 1) black layered Cpx-Gar-Pl cumulates; 2) large hydrous basalt veins Phl-MegaCpxg Ga-Pl-Kaersg Ga-Ilm-Cpx,; 3) filtration of hydrous melts through lherzolites Ol-Cpx-Kaers g Ol-Amph-Phl-Opx-Cpx-Sp; 4) green low Cr-MegaCpx (+Pargasite)g TwoPx-Ga-Sp hybrid picrite melt fractionation. Temperature groups of cumulate and lherzolite xenoliths represent different level of capturing and interaction of evolving hydrous plume magma with lherzolites. Each of close located volcanoes and portion of lava contain individual set of inclusions increasing in hydrous phases to last stage of mantle activity (1,5-0.8 Ma). (Grant RBRF 93-05-17103) 20

EVOLUTION OF THERMAL CONDITIONS IN MANTLE BENEATH VOLCANIC REGIONS IN BAIKAL RIFT ZONE (OPX THERMOBAROMETRY)

ASHCHEPKOV I.V. (United Institute of Geology Geophysics and Mineralogy, SD RASc, 630090, Novosibirsk, academician V.Koptyug avenue 3, e-mail: garnet@uiggm.nsc.ru)

Thermal conditions beneath volcanic Vitim and Trans Khamar-Daban regions determined on fertile mantle xenoliths for three magmatic stages reveal distinct PT paths and varying mantle layering. Garnet facie part at pre-rifting (1ststage) represented melted and partly solidified mantle diapir with more hot melt percolation zone and plume heat impact zone near 30 kbar. After the lava plateau creation (2nd stage) it consists from steep diapiric and more hot melt percolation branches. Layered mantle column suggests polybaric intrusion of melts with the creation of several local melt filtration zones. The more continuos zones of filtration are pronounced at the 3rd Quaternary stage. Upper cold high gradient lithospheric Spl facie part was thermally excited from basement mainly in last two stages. The depth of melt percolation is close to magma generation level. In Khamar Daban early stage show cold fertile lherzolite

with the incompartible element enrichment upward (15-10 kbar) and thermal excitation at about 18 kbar. Later stages are characterized by the deepening of the xenoliths capture and small heating with gradients close to SEA. Pressure estimates are correct for the garnet and fertile spinel lherzolites and less for pyroxenites and depleted peridotites. (Grant RBRF 93-05-17103)

GEOCHRONOLOGICAL AND VOLCANOLOGICAL STUDY OF NEOGENE CALC-ALKALINE VOLCANIC ROCKS FROM TRANSCARPATHIA, SW UKRAINE

Zoltan PECSKAY (Institute of Nuclear Research of the HAS, H-4001 Debrecen, P.O.Box 51, Hungary, e-mail: balogh@cseles.atomki.hu Ioan Seghedi (Romanian Instit of Geology , Caransebes str. 1., RO-78344 Bucharest 32, Romania. e-mail: seghedi@ns.igr.ro) Hilary Downes (Dept. of Geology, Birkbeck College, Malet St., London, WC1E 7HX,. e-mail: hdownes@ucl.ac.uk) Michail Prychodko and Bogdan Mackiv (ZGRE, Geologov 10., UR-295510 Beregovo, Ukraine)

The Neogene Carpathian arc is a complex subduction-related magmatic arc, extending from Slovakia into Romania via Hungary and Ukraine. The Transcarpathian region in SW Ukraine comprises the central part of this arc. The volcanic structures of the Transcarpathian region can be divided into three major areas: a. Outer Arc Area; b.Intermediate Area; c. Inner Arc Area. This division reflects the basic geotectonic features of the Ukrainian Carpathians, but differs from other parts of the Carpathian arc. Lavas, tuffs and ash deposits of dacitic, rhyodacitic, rhyolitic, andesitic and basaltic-andesitic composition are observed. Lava flows, domes, dykes/sills, volcanic necks, ignimbrites and lahars are characteristic elements of the Middle-Late Miocene volcanic activity. Radiometric dating has yielded K-Ar ages 13.4-9.1 Ma. This time interval (almost 4.5 million years) is identical to that of the neighbouring Carpathian volcanic regions to the west (Tokaj, Hungary) and to the east (Calimani, Romania). Thus there is no evidence in this area for any along-arc migration of volcanism. Volcanic activity started simultaneously in both Outer Arc and Inner Arc volcanic areas (~13.4 Ma). Different peak of volcanic activity was observed, between 12.3-11.6 in the Inner Arc area, interpreted as the major period of generation of the complex of resurgent domes related to a caldera formation and between 11-10.4 Ma in Outer Arc area, representing the main period of volcanoes generation, resulting in a lateral symmetry of the volcanic range. The end of the volcanic activity (9.5-9.1 Ma) is sparse and less voluminous.

GEODETIC CONSTRAINTS ON TECTONIC MODELS

JSS31/W/03-B2 **0930**

GLOBAL VELOCITIES FROM VLBI

Chopo MA (Space Geodesy Branch, Goddard Space Flight Center, Greenbelt, MD 20771, USA, email: cma@virgo.gsfc.nasa.gov); David Gordon (RITSS, Goddard Space Flight Center, Greenbelt, MD 20771, USA, email: dgg@leo.gsfc.nasa.gov); Daniel MacMillan (NVI, Inc., Goddard Space Flight Center, Greenbelt, MD 20771, USA, email: dsm@aleph.gsfc.nasa.gov)

Precise geodetic VLBI measurements have been made since 1979 at ~130 points on all major tectonic plates, including stable interiors and deformation zones. From the data set of ~2900 observing sessions and ~2.3 million observations, useful three-dimensional velocities can be derived for ~80 sites using an incremental least-squares adjustment of terrestrial, celestial, Earth rotation and site/session-specific parameters. The long history and high precision of the data yield formal errors for horizontal velocity as low as 0.1 mm/yr, but the limitation on the interpretaion of individual site velocities is the tie to the terrestrial reference frame. Our studies indicate that the effect of converting precise relative VLBI velocities to individual site velocities is an error floor of ~0.4 mm/yr. Most VLBI horizontal velocities in stable plate interiors agree with the NUVEL-1A model, but there are significant departures in Africa and the Pacific. Vertical precision is worse by a factor of 2-3, and there are significant non-zero values that can be interpreted as post-glacial rebound, regional effects, and local disturbances.

PRESENT-DAY PATTERN OF CORDILLERAN DEFORMATION IN THE WESTERN UNITED STATES

Richard A. BENNETT, James L. Davis, and James E. Normandeau (Harvard-Smithsonian Center for Astrophysics, 60 Garden Street, Cambridge, Massachusetts 02138, USA, email: rbennett@cfa.harvard.edu); Brian P. Wernicke (California Institute of Technology, 1200 E. California Blvd., Pasadena, California 91125, USA)

We are combining campaign and continuous Global Positioning System (GPS) and very long baseline interferometry (VLBI) observations to infer the pattern of Western United States Cordillera (WUSC) deformation west of longitude 110W, south of latitude 42N, and north of latitude 31N. Preliminary results are consistent with a number of features previously observed through local geodetic studies and very sparse space geodetic studies, including a dominant pattern of right-lateral shear associated with the San Andreas fault, rates of sites along the California coast of 46-48 mm/yr relative to a North America reference frame, and some 11-13 mm/yr of deformation accommodated east of the Sierra Nevada in the Basin and Range province north of latitude 36N. In addition, our results reveal that south of latitude 36N the southernmost San Andreas fault system accommodates effectively all Pacific-North America interplate motion and that the southern Basin and Range is not deforming significantly. At latitude 37N, the eastern California shear zone appears to exhibit simple shear oriented between N20W and N40W relative to North America, with a fairly well defined transition zone from localized shear to diffuse spreading in the Basin and Range. Enigmatically, this transition involves a significant component of contraction normal to the overall shear zone trend, with sites in the Great Basin moving southwestward at up to 5 mm/yr relative to sites within the eastern California shear zone. This apparent shortening may be indicative of "competition" between northwest-southeast plate-boundary shear and eastward buoyancy-driven collapse in the vicinity of latitude 37N. To the north of latitude 37N, in contrast, there appears to be a relatively smooth transition from east-west spreading within the eastern Great Basin to northwest-southeast shear across the westernmost Basin and Range. Our deformation results are available to the community either via the WUSC World-Wide-Web site (URL: http://cfa-www.harvard.edu/~rbennett/WUSC) or via anonymous FTP (ftp://cfa-ftp.harvard.edu/pub/rbennett/WUSC). The WUSC web-site is presently being redesigned and we will demonstrate the new features of the redesigned web-site.

PRESENT-DAY DEFORMATION ACROSS THE BASIN AND RANGE PROVINCE, WESTERN UNITED STATES AND ITS DYNAMICAL IMPLICATIONS

THATCHER, Wayne, (email: thatcher@usgs.gov); Julian, B. R., Svarc, J., E. Quilty, E., Bawden, G (U. S. Geological Survey, MS/977, Menlo Park, CA 94025); Foulger, G. (R.Department of Geological Sciences, University of Durham, Science Laboratories, South Road, Durham DH1 3LE, U. K.)

The distribution of internal deformation across the Basin and Range has been determined from 1992, 1996 and 1998 surveys of an 800-km aperture 63-station GPS network. Internal deformation follows the pattern of Holocene fault distribution and is concentrated in narrow zones near the eastern and western extremities of the province. 2.8 ± 0.5 mm/yr of relative motion occurs across the Wasatch and related faults in central Utah. Little net deformation occurs across the central ~450 km of the network in western Utah and eastern Nevada. Velocities jump abruptly by 3.7 ± 0.8 mm/yr across the central Nevada seismic zone and increase an additional 6.0 ± 1.6 mm/yr towards the Sierra Nevada, indicating partitioning of eastern California shear zone motion between these two zones. Concentration of deformation adjacent to the rigid Sierra Nevada (SN) and Colorado Plateau (CP) blocks indicates plate boundary tractions play a dominant role in driving Basin and Range deformation. There is evidence for local modulation of these forces by extensional stresses generated by internal buoyancy forces due to lateral density gradients and topography near the SN and CP boundaries.

SOUTHERN CALIFORNIA CRUSTAL DEFORMATION AND ITS TECTONIC IMPLICATIONS

Zheng-Kang SHEN and David D. Jackson (both at Department of Earth & Space Sciences, UCLA, Los Angeles, CA 90095-1567, USA; email: zshen@ess.ucla.edu)

The Crustal Deformation Working Group of the Southern California Earthquake Center has recently released its Southern California Crustal Deformation Velocity Map 2.0 (http://www.scecdc.scec.org/group_e/ release.v2. We analyzed the geodetic data used in the release and derived station velocities before and after the 1992 Landers earthquake. Significant velocity changes were found for sites located within about 60 km of the earthquake epicenter. The average strain rate in the region increased from ~0.10 to ~0.30 micro-radian/yr. We also estimated fault slip rates in southern California using the pre-Landers geodetic velocities and elastic dislocation theory. We used a modified fault model, defined by the California Department of Mine and Geology (USGS Open-file Report 96-706) and derived mainly from geological information, to lay out the fault geometry. We adopted the CDMG fault slip rates and uncertainties as a priori data to constrain the least-squares inversion of geodetic data for fault slip rates. Generally the geodetic and geologic estimates are quite consistent, except for a few places. For example, the geodetic rates are significantly lower than the geologic rates along the Mojave, San Bernardino, and Coachella Valley sections of the San Andreas, but the other way round at the Brawley seismic zone and the Imperial fault. These discrepancies suggest that the current fault slip rate beneath the locking depth along the San Andreas is lower than its long-term average. This may reflect the fact that the San Andreas has experienced no large earthquake since 1857, and the fault has passed the time period of rapid post-seismic deformation and entered one of slow deformation. On the other hand, the Landers and Imperial faults are still being affected by post-seismic deformation caused by the 1992 Landers and the 1940 and 1971 Imperial Valley earthquakes respectively. A second inversion of the geodetic velocities derived from the post-Landers data reveals a substantial reduction of the fault slip rate along the Mojave section of the San Andreas and a significant increase of the fault slip rate along the San Bernardino section of the San Andreas respectively.

JSS31/W/16-B2 **1110**

FEM MODELING OF SUBDUCTION DEFORMATION IN THE NANKAI TROUGH

Phil R. CUMMINS, Yoshiyuki Kaneda, and Satoshi Hirano (Frontier Research Program for Subduction Dynamics, Japan Marine Science and Technology Center, 2-15 Natsushima-cho, Yokosuka 237-0061 Japan, email: cummins@jamstec.go.jp)

The Nankai Trough in southwest Japan is the scene of large, destructive earthquakes which have repeatedly caused substantial loss of life and property in the region. For this reason, measurements of crustal deformation were already being made prior to the last major earthquakes in 1944 and 1946. These measurements continue to the present day, so that the Nankai Trough is said to have the world's most complete record of deformation during the "earthquake cycle". Substantial deformation has been inferred using leveling and tide gauge data, as well as a modern GPS network. However, these observations are typically interpreted using very simple structural models, such as an elastic halfspace or an elastic layer over a viscoelastic halfspace. Such models incorporate none of the structural complexity typical of a subduction zone. We consider whether such complex structure has an important influence on the deformation by performing FEM modeling using a realistic model of subduction zone structure. Our model for the Nankai Trough region is based on a combined OBS/MCS seismic survey performed by JAMSTEC in 1997. Features of this model which may influence the regional deformation include: a plate boundary with very shallow dip, a thin oceanic crust and subducting slab, and a well-developed accretionary prism near the trench. Our results indicate that the influence of complex structure can be important. In particular, the presence of the subducting slab gives rise to a dramatic difference in the coupling of surface deformation to viscoelastic relaxation in the asthenosphere.

JSS31/W/09-B2 **1130**

NUMERICAL MODELS OF THE SOUTHERN HIKURANGI TROUGH SUBDUCTION ZONE, NORTH ISLAND, NEW ZEALAND

Steven COHEN (Goddard Space Flight Center, Greenbelt, MD, 20771, USA, email: scohen@car- noustie.gsfc.nasa.govo); Desmond Darby (Institute of Geological and Nuclear Sciences, Lower Hutt, New Zealand, email: D.Darby@gns.cri.nz)

The southern portion of the Hikurangi subduction zone is characterized by oblique convergence with nearly equal components of trench parallel and trench normal motion. Walcott (1978) proposed a slip-partition model in which the motion is accommodated by strike-slip faulting in the North Island Dextral Fault Belt (DFB) and low angle reverse faulting on more trenchward features. We are developing two and three dimensional viscoelastic finite element and elastic dislocation implementations of this model. Constraints come from geological estimates of the fault slip rates, seismicity, and historical and contemporary geodetic data. Of the several strike-slip faults within the DFB the two most important are the Wairarapa fault,

which slipped during an M=8 event in 1855 and the Wellington fault, which has been geologically active and historically quiescent.Shear strain release on the DSZ faults can accommodate most of the right lateral strain accumulating on the locked megathrust provided the slip surface extends to the depth to the locked megathrust. Darby and Beanland (1993) proposed that the slip surface in the 1855 event was listric, with the slip depth extending to at least 20-25 km. If so, the locking depth is greater than that of most strike-slip faults in transform environments. The trench normal strain is accommodated by strain release either along the megathrust or a hypothesized low angle reverse fault lying between the DSZ and theaccretionary wedge. The shallowest portions of the plate interface may not be locked or the motion may be accommodated within the accretionary complex.

JSS31/L/01-B2 1150

ON THE USE OF SIMPLE ELASTIC DISLOCATION MODELS IN MODELLING STRAIN ACCUMULATION

John BEAVAN and Desmond J Darby (Institute of Geological and Nuclear Sciences, Lower Hutt, New Zealand, email: j.beavan@gns.cri.nz)

We report two examples of the use of dislocation calculations for interpreting GPS-derived horizontal surface deformation resulting from interseismic strain accumulation. In the oblique Hikurangi subduction zone of the southern North Island, New Zealand, we model the state of locking on the subduction interface, and the state of partitioning between thrusting on the interface and strike-slip in the over-riding plate. In the oblique continental convergence zone of the central South Island, we model the ongoing slip rate on a deep extension of the Alpine fault, and the substantial fraction of the plate motion that occurs as distributed deformation well east of the Alpine fault.
We utilise formal inversion techniques using non-linear least-squares methods, and we advance on previous work by propagating the full covariance information from the GPS data analysis through the inversion. We argue that both these features are necessary for optimal application of dislocation methods. The fact that simple dislocation models can usually be found to fit horizontal surface deformation data with high accuracy emphasises one theme of this symposium: that additional information must be included in support of such inversions.

JSS31/E/07-B2 1210

NUMERICAL MODELLING OF CRUSTAL DEFORMATION IN THE TIEN SHAN: COMPARISON WITH GPS-MEASUREMENTS

Holger SCHELLE, Christoph Reigber, Detlef Angermann, Jürgen Klotz, and Gero Michel (GeoForschungZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany, email: schell@gfz-potsdam.de)

Numerical simulations were carried out in order to relate crustal deformation processes to the surface motions constrained within different GPS-campaigns between 1992 and 1998. In order to simulate the crustal deformation processes, the 3d - distinct element code 3DEC was used. The main part of the presentation deals with the Ms: 7.3, Aug 19, 1992 Suusamyr earthquake and its induced co-seismic surface motions. Aims of the modelling include to check different focal models that explain the earthquake rupture process derived from seismological investigations, and to test different focal parameters. Using information from the measured surface deformations, the model of the earthquake rupture process with the best fit to the GPS-based displacement vectors was selected. The resolving parameters that describe the main shock are: mean stress drop 7 MPa, peak stress drop 11.9 MPa, mean dislocation 1.39 m, and peak dislocation 2.37 m. In addition to the above described models, further numerical simulation has been conducted in order to explain the crustal deformation measured using GPS within the N-Pamirs, Tien Shan and Tarim. The presentation gives an overview of some first and important results.

THE CENTRAL ANDES GPS PROJECT : GEODETIC MEASUREMENTS OF CRUSTAL MOTION AND DEFORMATION IN THE CENTRAL AND SOUTHERN ANDES

Eric Kendrick and Michael BEVIS (HIGP, University of Hawaii, HI 96822, USA. Email: bevis@soest.hawaii.edu); Robert Smalley (CERI, University of Memphis, Memphis, TN 38152, USA); Oscar Cifuentes (Instituto Geográfico Militar, Santiago, Chile); Fernando Galban (Instituto Geográfico Militar, Buenos Aires, Argentina); Thomas Herring (Dept. Earth, Atmospheric & Planetary Sciences, MIT, Cambridge, MA 02139, USA); Rick O'Connell (Dept. Earth & Planetary Science, Harvard University, Cambridge, MA 02138, USA)

We will present velocity fields for the plate boundary zone associated with subduction of the Nazca plate beneath the South American plate. These solutions, which are based on roving and continuous GPS measurements that began in 1993, are presented in a frame that nominally fixes the rigid core of the South American continent. These motions manifest a mixture of interseismic, coseismic and postseismic deformations. Seperation of the elastic and anaelastic contributions to the deformation field will be a major challenge. The observations allow us to address along-strike segmentation of tectonic style within the Andes, as well as cross-strike partitioning of elastic and anelastic deformation. There are several other major GPS projects working in this region. The GFZ (Potsdam, Germany) network strongly overlaps our own. We have long coordinated the designs of our networks in the sense of minimizing useless spatial redundancy, and we are starting to work on the problem of combining our velocity fields. We also need to combine these results with those obtained further north by project SNAPP, which operates in Bolivia and Peru.

JSS31/W/12-B2 1420

SPATIAL AND TEMPORAL VARIATION OF GPS-DERIVED DEFORMATION IN THE CENTRAL AND SOUTHERN ANDES

KLOTZ, J., Angermann, D., Michel, G.W., Reigber, (GeoForschungs Zentrum Potsdam, Telegrafenberg A17, 14473 Potsdam, Germany, e-mail: klotz@gfz-potsdam.de); Cifuentes, O., (Instituto Geografico Militar de Chile, Santiago, Chile); Barriga, R., (Academia Militar Politecnica, Santiago, Chile Barrientos, S., Univ. de Chile, Santiago, Chile); Perdomo, R., (Univ. Nac. La Plata, Argentina Viramonte, J., Univ. Nac. de Salta, Argentina); Rios, V., (Univ. Nac. Tucuman, Argentina)

In the framework of SAGA (South American Geodynamic Activities) we conducted GPS-measurements at 215 sites covering Chile and parts of Argentina in order to study the surface deformation related to the subduction of the Nazca plate beneath South America. The spatial and temporal distribution of surface deformation related to the 30 July 1995, Mw = 8.0 Antofagasta, Chile, earthquake was studied using 4 datasets of GPS campaigns (70 sites). Re-observations between Arica and Pto. Montt (18°S to 42°S) indicate strong inter-seismic strain accumulation that slightly varies along strike. Post-seismic displacements of the Antofagasta earthquake area are significantly different from those derived in parts of the net dominated by inter-seismic deformation. We observed a similar post-seismic deformation pattern south of 37°S, in the area of the great Chilean earthquake rupture zone of May 22, 1960.

JSS31/W/14-B2 1440

TECTONICS OF INTERIOR ALASKA: A STUDY USING GPS MEASUREMENTS

Hilary J. FLETCHER and Jeffrey T. Freymueller (both at Geophysical Institute, University of Alaska, Fairbanks, AK 99775, email: hilary@giseis.alaska.edu)

To assess the seismic hazard in interior Alaska, it is necessary to understand the tectonics of the area in greater detail. Interior Alaska has produced three earthquakes with magnitudes greater than seven in this century and yet this area has received little study. The Denali fault is an obvious geomorphic feature, extending in a broad arc for more than 2000 km, with up to 400 km of offset over the last 60 million years. Slip rates of 8-12 mm/yr are estimated for the Denali fault based on offset Pleistocene glacial features to the east of Mt. McKinley. Previous geodetic measurements of slip rate along the Denali fault have produced results at odds with this geologic evidence, with two trilateration networks across the Denali fault giving results consistent with a much smaller rate of right lateral shear on the Denali fault than expected based on the Holocene slip rate. Another major tectonic feature in Alaska is the Tintina fault, a large dextral fault system 250km to the north of the Denali fault. The pattern of seismicity in the region between these two fault systems shows NE-SW lineations, which have been interpreted as edges of elongate crustal blocks.
We established a network of GPS sites in interior Alaska between the Denali fault and the Tintina fault in 1995. Velocities st these sites show a low rate of strain accumulation. In 1997 a dense profile of 17 GPS bench marks was installed across the Denali fault. Initial results from surveys of this profile show that some sites in the profile have motion consistent with right lateral shear along the fault. We use an elastic screw dislocation model to invert the estimated site velocities for a slip rate of the Denali fault. We discuss possible tectonic models for interior Alaska in light of our new results

JSS31/E/06-B2 1500

GPS GEODETIC CONSTRAINTS ON RIGID CARIBBEAN PLATE MOTION AND PLATE BOUNDARY DEFORMATION

Pamela JANSMA (Dept. of Geology, University of Puerto Rico, Mayaguez, PR 00681 USA, Email: pam@geology.uprm.edu); Roger Bilham, (Dept. of Geological Sciences, University of Colorado, Boulder, CO 80309 USA, Email: bilham@stripe.colorado.edu); Chuck Demets (Dept. of Geology and Geophysics, University of Wisconsin, Madison, WI 53706 USA, Email: chuck@geology.wisc.edu), and Glen Mattioli (Dept. of Geology, University of Puerto Rico, Mayaguez, PR 00681 USA, Email: glen@geology.uprm.edu)

The velocity of the Caribbean plate relative to North America has been estimated at 1-2 cm/yr from traditional sources such as summing seismic moments of earthquakes, deriving velocities from poorly expressed magnetic lineations in the Cayman trough, or calculating closure from global plate circuits. The motion of the Caribbean plate relative to its neighbors remains controversial, however, with proposed intraplate deformation significant enough to produce distinct eastern and western Caribbean plates. Although GPS methods provide instantaneous relative velocities, it has been difficult to obtain measurements from islands outside the zone of active plate boundary deformation defined by diffuse seismicity, and few islands are found in the interior of the plate. We report here measurements obtained in 1994 and 1998 from Aves Island (15.667N, 63.618W) in the eastern interior of the Caribbean plate, which imply motion relative to North America at 19-20 ± 2 mm/yr to the ENE. The similarity within error to GPS-derived velocities at San Andres Island and Cabo Rojo, southern Dominican Republic in the western interior and northern Caribbean, respectively, supports a single, rigid Caribbean plate and allows determination of a stable Caribbean reference frame with which to interpret geodetic results and to quantify deformation in the North and South American plate boundary zones and the Lesser Antilles island arc. Implications for constraints on plate boundary processes will be discussed.

JSS31/L/02-B2 1520

TECTONICS OF PAPUA NEW GUINEA FROM GPS OBSERVATIONS

Paul Tregoning, Kurt LAMBECK, Herbert McQueen (all at Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia, email: Kurt.Lambeck@anu.edu.au); R. Jackson, R. Little (both at Department of Surveying and Land Studies, The Papua New Guinea University of Technology, Lae, Papua New Guinea); Robert Rosa (National Mapping Bureau, PO Box 5665, Boroko, Papua New Guinea); Eli Silver (Earth Sciences Department, University of California, Santa Cruz, CA 95064, USA)

Plate tectonic motions have been estimated in Papua New Guinea from several years of GPS observations on a network of sites spanning most of the country. A tectonic model has been developed comprising three microplates trapped between the colliding Australian and Pacific Plates. This simple model is consistent with the major tectonic features of the region; subduction along the New Britain Trench, spreading on the Woodlark Basin Spreading Centre, convergence along the Ramu-Markham Fault, both strike-slip motion and spreading along different sections of the Bismarck Sea Seismic Lineation. The model predict relative strike-slip motion of ~130 mm/yr between the South Bismarck and Pacific Plates in the southern part of New Ireland. Preliminary GPS results indicate that not all the relative motion occurs on the Weitin Fault; rather, a significant proportion of the convergence is accommodated to the west of the Gazelle Peninsula. A general overview of the tectonics of Papua New Guinea and new results in the East New Britain/New Ireland region will be presented.

JSS31/L/05-B2 1600

CRUSTAL MOTION AROUND THE WESTERN SEGMENT OF THE NORTH ANATOLIAN FAULT ZONE : GEODETIC MEASUREMENTS AND GEOPHYSICAL INTERPRETATION

Mehmet Emin AYHAN, Coskun Demir, Ali Kilicoglu, Ilhan Sanli (General Command of Mapping, TR-06100, Ankara, Turkey); S. Mete Nakiboglu (Middle East Technical University, Ankara, Turkey.

Contemporary horizontal crustal motion in the western part of the North Anatolian Fault Zone (NAFZ) is investigated utilizing 25 common points of a triangulation network established in 1940s and a GPS network observed in 1995. The common network, extending about 25 x 103 km2, covers the boundary zone of the Anatolian and Eurasian tectonic plates. The GPS network is adjusted on the ITRF94 reference frame using precise orbital information and simultaneous observations to 7 precisely known IGS stations in Europe and Asia within the fiducial network strategy. The repeatibilities of the horizontal coordinates are below about 15

mm. The triangulation observations are also adjusted on the same datum by holding the GPS coordinates of two stations as fixed. A comparison of triangulation and GPS coordinates yields the relative displacements in the area ranging from 3.0 m to a few cm with uncertainties of about 25 cm emanating predominately from the triangulation errors. The estimates reveal a westward drift of the Anatolian plate which deviates significantly from a rigid body motion. The relative displacements may be viewed as a combination of rigid body motion and plate boundary deformations which may incorporate co-seismic and/or aseismic components. A cooperative international GPS network covering the same area with 40 different stations observed annually from 1992 to 1998 is re-processed using the precise positioning techniques outlined above. The resulting velocity field reveals the combined effects of rigid body motion and aseismic deformation but no co-seismic deformation as there were no major earthquakes, resulting in fault rupture in the region during this period.
The resulting velocity field is modeled using a least squares Inversion assuming screw dislocations in an elastic half-space. The best estimate of the velocity of Anatolia relative to Eurasia is found to 25 mm/yr. Armutlu Block in the west of the area appears to be moving together with Anatolia, but Almacik Block in the center of the region exhibits a rigid translation of about 15 mm/yr superimposed onto a slow clockwise rotation. The fault segments Ismetpasa- Bolu and Iznik-Sapanca exhibit significant aseismic creep with rates of 7.5 and 14 mm/yr respectively. The Mudurnu Valley and Mekece...

SOME ASPECTS OF AEGEAN CONTINENTAL DYNAMICS INFERRED FROM A DECADE OF GPS MEASUREMENTS AND A CENTURY OF TRIANGULATION

PETER CLARKE (Dept. of Geomatics, University of Newcastle, Newcastle NE1 7RU, UK, Email: Peter.Clarke@ncl.ac.uk); Philip England, Barry Parsons (Dept. of Earth Sciences, University of Oxford, UK); Robert Davies (Research School of Earth Sciences, Victoria University, Wellington, NZ); Haris Billiris, Jordan Galanis, Demitris Paradissis, George Veis (Higher Geodesy Laboratory, National Technical University, Athens, Greece); Paul Cross, Paul Cruddace (Dept. of Geomatic Engineering, University College London, UK); Pierre Briole, Helene Lyon-Caen (Insitut de Physique du Globe, Paris, France); Hans-Gert Kahle (Institut fur Geodasie und Photogrammetrie, ETH Honggerberg, Zurich, Switzerland); Boudewijn Ambrosius (Faculty of Aerospace Engineering, Delft University of Technology, Netherlands)

We have obtained the velocities at more than 200 sites in Greece using GPS data from over 30 epoch campaigns spanning up to 10 years , under the assumption that short-term inter-seismic velocities are steady and therefore reference frame biases can be estimated. Over 20 of these sites are coincident with or close to pillars in 20- and 100-year-old triangulation networks. By extrapolating a minimal subset of the GPS pillar velocities, we estimate the scale and orientation of the triangulation networks.
We find that the coordinate fit of the triangulation networks fits our model of steady- state velocities well within 95% confidence limits, and observe that the velocity field is generally smooth spatially as well as temporally. From our interpolated velocity field we calculate the strain tensor field and associated derived
quantities. We note that the current and recent orientations of faults are consistent with those predicted from the velocity field but oblique to earlier crustal trends. This observation, coupled with the temporal and spatial smoothness of the crustal velocity field, is suggestive of a dynamic model in which brittle-elastic crustal deformation is driven by the ductile lower lithosphere. Further densification and expansion of the GPS network is currently in progress (Cruddace et al., this volume).

GPS MEASUREMENT OF CRUSTAL MOTION IN BULGARIA

Valentin KOTZEV (Central Laboratory of Geodesy, Bulgarian Academy of Sciences, ul. 15 noemvri 1, 1040 Sofia, Bulgaria, email: kotzev@bgcict.acad.bg); Clark Burchfiel and Rob Reilinger (Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, 77 Massachusetts Avenue, 54-1010 Cambridge, Massachusetts 02139, USA, email: bcburch@mit.edu)

Active and young deformation in central and southern Bulgaria represents the northernmost extent of the Aegean extensional domain and thus represents an active example of back arc type extension adjacent to a zone of coeval subduction and convergence along the Hellenic subduction boundary. To determine the present day kinematics of the major tectonic elements in Bulgaria, a regional GPS network was established and surveyed in 1996, 1997 and 1998. We present here a solution for the horizontal velocities of 18 sites based on observations performed over the two-year period. We use Kalman filter to estimate a consistent set of coordinates and velocities by combining our loosely constrained solutions with the solutions derived at SOPAC from the analysis of a global tracking network. The reference frame of the computed velocity field is defined through minimizing the departure of the estimated horizontal velocities for 39 core ITRF96 stations from their nominal values. The post-fit of the velocity transformation is 2.6 mm/yr. The relative to Eurasia velocities we estimate are less than 5mm/yr. We obtain one-sigma uncertainties of (0.7 mm/yr for the east components and of (0.4 mm/y for the north components. Most of the stations indicate N to NE oriented motion at a rate of 3-5 mm/yr. Stations west of the seismically active Struma fault zone show NE motions of 3 mm/yr and those east of the faults show no motions at the 95% confidence level. The two sites located in the west central part indicate NW oriented motion at a rate 3 mm/yr.

MODELLING OF VERTICAL MOVEMENTS IN CAUCASUS REGION USING GPS DATA

Mikhail PRILEPIN (United Institute of Physics of the Earth, B.Gruzinskaya Str., 10, 123810 Moscow, Russia, email: prilepin@uipe-ras.scgis.ru) Robert E. Reilinger Earth Resources Laboratory, Massachusetts Institute of Technology, 42 Carleton St. Cambrige, Massachusetts 02148

We began GPS-geodinamic measurements in the Caucasus region in 1991 as a part of a cooperative American-Russian-Georgian-Armenian initiative [Reilinger et al., 1997; Prilepin et al., 1997]. Repeat surveys were completed in 1994, 1996 and 1998. The analysis of these observations show that the the one-sigma uncertainties for vertical rates for regional sites relative to a reference station on the Skifs platform (100-500 km distance) are about 2-3 mm/year, quite comparable with errors for levelling in mountainous terrains.Inspite of short time interval covered (5 yrs), GPS derived vertical motions support some earlier inferences made from repeated leveling surveys, particularly that movements vary substantially between different parts of the Caucasus: the Greater Caucasus experience uplift but the Lesser Caucasus do not reveal any significant vertical movements. Also GPS sites in the Greater Caucasus show larger variations in rates compared to sites in the Lesser Caucasus. The average rates in the Greater Caucasus are about 6-8 mm/year, reaching are maximum of 22 mm/year, while sites in the Lesser Caucasus are characterized by average rates of 3-5 mm/year and a maximum of 8 mm/year. Sites in the easten and western parts of the GPS network suggest that vertical motions in Caucasus can discribe by stepped model, dicussed in the report.Four out of five GPS sites in a local network situated in the epicentral area of the 1991, M=7.3, Racha earthquake indicate postseismic (from 3 months after the earthquake to 1996) relative uplift at rates of 2-11 mm/year and only one , most distant from the epicenter, shows subsidence at a rate of 2 mm/year. New 1998 repeat GPS measurements, which are currently being analyzed, will be presented and should help constrain better the model of vertical motions in the Caucasus region.

GEODETIC DETECTION OF ACTIVE FAULTS IN SOUTHERN CALIFORNIA

Shimon WDOWINSKI and Yonadav Sudman (both at Department of Geophysics and Planetary Sciences, Tel Aviv University, Ramat Aviv 69978, Israel, email: shimon@geo1.tau.ac.il); Yehuda Bock (Institute for Geophysics and Planetary Physics, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA 92093-0225, USA, email: ybock@ucsd.edu)

The steady tectonic motion between the Pacific and North American plates in western North America deforms a broad plate boundary zone, accumulating elastic strain in the lithosphere and creating seismic hazards. Geodetic measurements of the San Andreas fault system have shown a pattern of inhomogeneous strain accumulation, in which strain is localized along active faults where most major (M>6) earthquakes occur. We systematically analyze geodetic determinations of horizontal site velocity fields recently available in southern California to identify and quantify strain localization patterns and active faulting. We find that strain is localized along nine shear belts, which coincide with geologically mapped major strike-slip fault segments and a compressional belt along the northern extent of the Transverse Ranges. Within the highly populated Los Angeles basin, we detect strain localization related to the Newport-Inglewood and Santa Monica faults. We surmise that the steady accumulation of strain pushes the local stress field closer to its yield envelope and hence increases the likelihood of a major earthquake occurring along the geodetically detected active fault segments. Furthermore, the observation that other fault segments, which are known to have significant permanent deformation from geologic and paleoseismic records, are not presently active provides evidence that intraplate strain rates may vary temporally as well as spatially.

ABOUT THE ISOSTATIC COMPENSATION OF THE EARTHS CRUST

Nadejda A. CHUJKOVA , Tatiana G. Maximova (Sternberg State Astronomical Institute, Universitetskij pr.13, Moscow, e-mail: chujkova@sai.msu.ru)

The comparative analysis of the harmonic expansions for the heights of the equivalent rock topography for the depth of the Moho discontinuity and for the Earth' gravity field have shown: 1) the Earth's global topography up to expansion of 10 degree is bassically isostatically compensated on the Moho surface; 2) the total shift about 20 degrees of the Moho surface relative to the theoretical surface of compensation is observated in direction NE; 3) the surplus geoid flattening is caused by the large surplus flattening of Moho surface relative to theoretical surface of compensation; 4 the estimation of the Moho depth by means of the correlation with the Bouguer anomalies is not confirmed; 5) the correlation of the crust boundaries with the geoid is nonsignificant for expansion up to 10 degree; 6) the correlation of the noncompensated topography with the geoid and the core boundary is partly noticeable

INVERSION OF STRESS DISTRIBUTION IN JAPAN USING GPS DATA

M. HORI, T. Kameda, and T. Kato, (Earthquake Research Institute, University of Tokyo, Yayoi 1- 1-1, Bunkyo, Tokyo 113-0032, JAPAN)

A new inversion method which computes spatial stress distribution from measured displacement distribution is developed. The charm point of this inversion is that it does not have to assume particular constitutive relations. Indeed, the inversion results in solving a well-posed boundary-value problem for unknown stress distribution. Numerical simulation verifies the basic validity of the proposed method, as it succeeds in computing stress distributions of a body with unknown elasto-plastic properties. The method is applied to the GPS data which have been densely measured in Japan. Presented are the current results of the inversion, regarding to the stress distribution and the local constitutive relations of Japan.

JSS31/W/05-B3 Poster 0830-05

THE KMS99 GLOBAL ALTIMETRIC MARINE GRAVITY FIELD

O. ANDERSEN, P. Knudsen, (both at National Survey and Cadastre, Copenhagen NV, Denmark, email: oa@kms.dk, pk@kms.dk)

The KMS99 altimetric derived global marine gravity field is the latest version of gravity fields derived from ERS-1 and GEOSAT geodetic mission. This presentations describes the new gravity field and the improvements over the older KMS global marine gravity fields as described by Andersen and Knudsen (JGR, 97, ERS special issue) .The present resolution of the KMS gravity field is 1/30 degree corresponding to 2 minutes or 4 km at the Equator. In order to improve the capability of the gravity field to map short spatial wavelength in the gravity field, it has been necessary to investigate if data with a higher along track sampling than the present 1Hz data can be used. For the KMS99 gravity field the possibility of using reinterpolated 2 Hz along track observations have been carried out. Some of the other improvements that have been introduced in the new version of the gravity field is the use of repeat track altimetry to improve the spatial resolution at high latitude. Similarly, investigation of a better screening of the raw data have been carried out to improved the gravity field in especially coastal regions.

INVARIANT GEODYNAMICAL INFORMATION IN GEOMETRIC GEODETIC MEASUREMENTS

Peiliang XU and Torao Tanaka (both at Res. Centre for Earthquake Prediction, Kyoto University at Uji, Uji, Kyoto 611-0011, Japan, email: pxu@rcep.dpri.kyoto-u.ac.jp); Seiichi Shimada (Natl Res. Inst. for Earth Sc. and Disaster Prevention, Tennodai 3-1, Tsukuba, Ibaraki 305-0006, Japan); Yoichiro Fujii (Nippo Co. Ltd., 1-8-7, Kodai, Miyamae-ku, Kawasaki 216, Japan)

Repeated geodetic measurements have been used to extract geodynamical quantities such as displacements, velocities of movement and crustal strains. For the geodetic network without tie to an external reference frame, free network adjustment methods have been widely applied to derive geodynamical quantities. Currently, it has been understood that relative displacements can be found uniquely if the geodetic network is geometrically redundant. Strain tensors are then reported to be uniquely determined. We have carried out a theoretical analysis of invariant geodynamical information in geometric geodetic observations and concluded: (1) that relative displacements are not invariant quantities and thus cannot uniquely be determined from free geodetic networks; and (2) all the components of the strain tensors are not invariant and thus cannot individually be determined uniquely from the networks. However, certain combinations of strain components are indeed invariant and can uniquely be determined from geometric geodetic measurements. The theory of invariant information is then applied to analyzing the Tokai first order triangulation/trilateration network spanning over an interval of more than 100 years. The results have shown that the normal strains and the principal strains are significantly affected by the unknown scaling biases and orientation differences; thus any attempt of geophysical interpretation of these quantities must be exercised with great care. If the scaling bias and the orientation difference are small, the shear strain is shown to be practically invariant. The invariant analysis of the Tokai network has also shown that a belt near Shizuoka has been significantly deformed in the past 100 years, which has never been seen in any previous analysis of displacements and/or strains, and may be attributed mainly to the 1923 Kanto Earthquake M7.9, Japan.

GEODETIC DATUM CONSTRAINTS ON PLATE TECTONIC AND CRUSTAL DEFORMATION MODELS (APKIM9.0)

Hermann DREWES (Deutsches Geodaetisches Forschungsinstitut, Marstallplatz 8, D-80539 Muenchen, Germany, email: drewes@dgfi.badw-muenchen.de)

Various space geodetic techniques (e.g., GPS, SLR, VLBI) contribute to the modelling of Actual Plate KInematic and crustal deformation Models (APKIM) by providing observed station velocities. A problem in combining these velocities is to homologize the different datum realizations. Each of the technique dependent solutions refers by definition in general to the NNR NUVEL-1A no net rotation plate kinematic model. The realization, however, is quite different by fixing or constraining arbitrarily individual station velocities in each solution. As a consequence we have datum differences resulting in systematic discrepancies between the technique dependent station velocities exceeding by far the observation accuracies.
An actual global no net rotation datum is realized by an integrating procedure of all geodetic observations over the entire surface of the Earth. The Earth's surface is divided into 1 _1 - blocks attributed to either rigid plates or continuous deformation zones, respectively. The plate motion and crustal deformation parameters are estimated by a least squares adjustment or finite element model, respectively. The sum of actual plate motions and crustal deformations is constrained to be zero. The kinemantic datums of the individual techniques are simultaneously estimated in the adjustment procedure.

GEODETIC AND GEOLOGICAL APPROACHES TO DESCRIBE THE GEODYNAMICS OF THE CENTRAL MEDITERRANEAN AREA: A COMBINED INTERPRETATION.

R. Devoti, C. FERRARO , R. Lanotte, V. Luceri, A. Nardi, R. Pacione, P. Rutigliano, C. Sciarretta, F. Vespe (Centro di Geodesia Spaziale -75100 Matera – Italy- Email: vespe@asi.it), E.Gueguen (ITIS/CNR, Centro di Geodesia Spaziale - 75100 Matera - Italy)

Numerous active tectonic zones are present in the Central Mediterranean area. Africa is slowly moving towards Eurasia; southward, the Ionian subduction zone is still active and retreats roughly eastward; during the last 5 My, the Apenninic system has been splitted in two sub-arcs separated by the Tremiti line: in the southern segment of the chain the migration of the subduction hinge slowed down, due to the presence of thicker continental crust of the Apulian Platform, whereas in the central and northern part the presence of thin Adriatic lithosphere allowed faster subduction. Nowadays, these movements can be detected not only with a geological approach, based on million years of history impressed in the rocks, but also with geodetic techniques, which give the present movements of the tectonic plates based on few years of data. A dense network of geodetic GPS, SLR and VLBI stations in the Central Mediterranean has been established and long time series of their coordinates and velocities are currently available. This network is a tool to estimates the tectonic velocities and compare them with those derived from geological data in this area, where a high tectonic plates fragmentation is present. We will determine the field of relative velocities in the area and compare the different results in the ITRF96 reference frame. The main stations involved in this work are: Matera (GPS, SLR and VLBI), Medicina (GPS and VLBI), Noto (GPS and VLBI), Cagliari (GPS and SLR), Wettzell (GPS, SLR and VLBI) and Madrid (GPS, SLR and VLBI). Moreover, a particular attention will be given to the interpretation of the vertical movements, which could be the signal of fenomena different from tectonic movements (eg. seasonal effects or subsidence).

CRUSTAL STRESS IN AUSTRALIA: A MODEL BASED ON GPS VELOCITIES

Y. Zhang (CSIRO Exploration & Mining, PO Box 437, Nedlands, WA 6009, Australia; ph. +61-8-9284-8447; email: zhang@ned.dem.csiro.au); E. Scheibner (CSIRO Exploration & Mining, North Ryde, NSW 2113, Australia; email: erwin.scheibner@dem.csiro.au); P. Morgan (Information Scicences Faculty, Uni. of Canberra, ACT 2601, Australia; email: pjm@mawson.canberra.edu.au); B. E. Hobbs; A. Ord; S. J. D. Cox (all at: CSIRO Exploration & Mining, PO Box 437, Nedlands, WA 6009, Australia; email: b.hobbs@per.dem.csiro.au, a.ord@ned.dem.csiro.au, s.cox@ned.dem.csiro.au)

Regional stress data indicate that the contemporary stress field in SE Australia is dominated by high horizontal compressive stresses in an E-W direction. This is in contrast with the N-S direction of absolute plate motion in Australia over the period Miocene-present, from which one might expect high horizontal stresses oriented N-S. Therefore, the stress pattern of SE Australia cannot be explained simply by considering plate motion-related boundary forces. In this study we aim to model the stress field of the Australian continent using GPS velocities as constraints. The conventional way to model the stress of the Australian plate is to use plate boundary forces as constraints. However, such models do not predict the dominantly E-W oriented stresses in eastern Australia. The E-W compression can be predicted if compressive forces along the eastern boundary of the plate is introduced, but there is no evidence supporting the existence of such forces. An alternative approach is to use GPS velocities to constrain the model. The idea is that if the true material movements are known, we can use such movements (velocities) as constraints in a mechanical model to simulate the deformation and stress fields.
Based on the scope of the existing GPS velocity data which is mostly located on the Australian continent, we have constructed two types of models, including a traditional triangulation model using all the GPS data and a fully mechanical model using the GPS velocity data near the coast. In contrast to the models involving plate boundary forces, the stress results of the present model reproduce the E-W to NEE high compressive regional stress pattern for eastern Australia. The orientation of major horizontal compression seems to vary further inland so that N-S to NE compression dominates. The normalised GPS velocities of Australia show that the eastern seaboard is moving towards the west, that is, there seems to be a contraction between east and west Australia. This probably explains why E-W compression occurs in east Australia. We will continue to refine the data, aiming to build more rigorous models.

GENETIC ALGORITHM - FINITE ELEMENT INVERSION OF INTRAPLATE STRESS FIELD IN BRAZIL

Yaolin SHI (Graduate School, University of Science and Technology of China, Academia Sinica, Beijing 100039, China, email: shiyl@sun.ihep.ac.cn); Marcelo Assumpcao (Institute of Astronomy and Geophysics University of San Paulo, Brazil, email: marcelo@)iag.usp.br)

Genetic Algorithm - Finite Element Method (GA-FEM) provides a way to solve inverse problem of partial differential equations. If stresses or displacements are observed, boundary conditions and material properties can be calculated. Inversion of the effective (or apparent) mechanical property is very important to analyze geodetic observations of faulted blocks.
In this study, we apply GA-FEM to carry out inversion of boundary displacements and nodal forces from observed crustal stress field in Brazil and adjacent areas. Normal, thrust and strike slip types of faulting from earthquake mechanism and geologic observation are also used for additional constraints on the relative magnitude of vertical and horizontal stresses. Our inversion confirms previous studies showing that plate boundary actions are the main controlling factors of regional stress field, and spreading forces at the Andes Mountains and continent-ocean boundaries are important factors. Furthermore, we show that plate bending under vertical load of sedimentation or magma intrusion can affect significantly the local stress field. Our inversion also indicates that, in addition to the well recognized E-W compression in South America, a differential N-S deformation at the northern boundary may exist and play its own role in the regional stress field of northern Brazil. This suggestion is in agreement with recent GPS analysis of relative motion between North
and South American plates.

DETERMINATION BY GPS OF THE DISPLACEMENTS CAUSED BY THE FAIAL SEISM OF 9 JULY 1998

Virgilio B. MENDES (Faculty of Sciences of the Lisbon Classical University, Rua Ernesto de Vasconcelos, Bloco C1, A, 1700 Lisboa, Portugal, email: vmendes@lmc.fc.ul.pt); Jorge Pinto and Helena Ribeiro (both of the Geodetic Department of Portuguese Institute of Cartography and Cadastre, Rua Artilharia 1, 107, 1070 Lisboa, Portugal, email: jtpinto@ipcc.pt and lenarib@ipcc.pt); Joaquim Pagarete (Faculty of Sciences of the Lisbon Classical University, Rua Ernesto de Vasconcelos, Bloco C1, A, 1700 Lisboa, Portugal, email: pagarete@fc.ul.pt)

The authors have already studied the geodynamical behavior of the Central Group from Acores in former presentations, comparing mostly classical geodetic observations from the thirties with GPS observations. Those studies pointed out, especially in Faial case, for a concordance between the displacements deduced from these geodetic observations and the geodynamical model proposed by Madeira y Ribeiro. In July-August 1997, a new GPS campaign was performed by the portuguese geodetic authority (IPCC), covering systematically all the Faial island network. In 9 july of 1998 a strong earthquake took place in Faial, withan epicenter some kilometres on the sea between Faial and S. Jorge islands. A month after the seism, IPCC reobserved with GPS, the most affected area of the Island, as well as the connection to Pico an S.Jorge Islands. In the present work the authors analyze the results of this pos-seismic observations against the former campaigns. This results have a capital importance to help in a correct interpretation of the data recovered by the Geologists and the seismologists during and after the seism. Particularly, this results are an important contribution towards a comprehension about which faults have worked during the main seism and their replicas. The 1998 GPS campaign, which covered almost 60% of the Faial network, allows a rigorous quantification of the displacements inside the island, by comparing it with the 1997 campaign, done a year before the earthquake. Some of these displacements are clearly identifiable by physical evidence in the terrain which could only be caused by the seism. The short interval between the two campaigns, about an year, allows no other cause for the deduced displacements than the seism of 9 July.

PROGRAM FOR MONITORING CRUSTAL DEFORMATION AND SEISMIC HAZARD ASSESSMENT IN EGYPT USING GEODETIC TECHNIQUES

Ali TEALEB (National Research Institute Of Astronomy And Geophysics, NRIAG, Helwan, Cairo, Egypt, email: salahmm@frcu.eun.eg)

The geodetic methods, terrestrial and space techniques, are considered as one of the most accurate tools for monitoring the vertical and horizontal components of the crustal deformations. Different programs wre early intiated since 1983 for recent crustal movement studies in Egypt. The Egyptian programs for monitoring crustal deformations and for seismic hazard assessment include the applications of both the terrestrial and space(GPS) geodetic techniques. The precise terrestrial geodetic techniques(horizontal and vertical methods) as wee as the precise gravity measurements were applied since 1983 for monitoring recent crustal movements associated with the earthquake activirty in different seismoactive areas in Egypt. Now-a-days the space geodetic techniques, especially the Global Positioning System (GPS) , are widely used for monitoring the relative crustal movements between the continental margins and the Lithospheric plates as well as in regional and stuy the relative movements between African plates as well as Sinai region. Different applications of the GPS techniques were also carried out to measure regional and local geodetic networks in Egypt. In order to develop and integrate the present programs, the installation of a series of tide gauages and fiducial GPS stations in several locations along the Egyptian shorelines are essential. The collected geodetic data enable the comparison between the sea level changes and the vertical crustal movements. These data may contribute to the seismic hazard assessment in Egypt.

TECTONIC IMPLICATION OF STRAIN RATES DEDUCED FROM REPEATED GPS MEASUREMENTS AROUND GREATER CAIRO, EGYPT

Ali Tealeb, Salah Mahmoud, Ali Rayan(All at National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt, email: salahmm@frcu.eun.eg) Yoichiro FUJII and Yao Tanaka(both at Nippo,Co.Ltd.,1-8-7,Kodai,Miyama-ku,Kawasaki 2160007,Japan,email: nipposys@bremen.or.jp)

A GPS network consisting of eleven geodetic points near greater Cairo were initially measured during the period from April 27 to May 5,1996 and measurements were repeated in December, 1996;October,1997;July,1998 using Trimble receivers 4000 SSE and SSI. Four dimensional network adjustment has been applied in order to determine strain rates within the network. The resules of strain analysis indicate that almost north-south extension is prevailing within the south-eastern part of the GPS network,and the highest rate of maximun shear strain is found to be 0.215_$B!^_(J0.202microstrain/a. The Red Sea is an opening boundary between the Arabian plate and the African plate.The fault system of the Gulf of Elat(Aquaba)-Dead Sea is the transform fault between the Arabian plate and Africa plate.The Gulf of Suez is also a divergent plate broundary between the Sinai peninsula and the African continent. We may assume the Sinai subplate.The tectonic extension of the northern part of the Gulf of Suez is not yet definitely known, while Ben-Menahem,Nur,Vered(1976) assume that north-west extension is across the southern Nile Delta.The geodetic strain deduced from repeated GPS measurements supports an idea of this north-west extension of the western boundary of the Sinai subplate.

THE AMIGO PROJECT: PRESENT-DAY CRUSTAL DEFORMATION OF THE WESTERN SECTION OF THE ALPINE-MEDITERRANEAN PLATE BOUNDARY ZONE

P. ELOSEGUI(1,2), D. Ben Sari(3), J. M. Davila(4), J. Garate(4), V. Mendes(5), D. Ouazar(3), J. Pagarete(5), R. Relinger(6), A. Rius(2), J. Talaya(7), R. Bennett(1), and J. L. Davis(1)
(1) Harvard-Smithsonian Center for Astrophysics, Cambridge, MA, USA; (2) Institut d'Estudis Espacials de Catalunya, Barcelona, Spain; (3) Ecole Mohammadia d'Ingenieurs, Universite Mohamed V, Rabat, Morocco; (4) Royal Naval Observatory, San Fernando, Cadiz, Spain; (5) Faculdade de Ciencias da Universidade de Lisboa, Portugal; (6) Massachusetts Institute of Technology, Cambridge, MA, USA; (7) Institut Cartografic de Catalunya, Barcelona, Spain;

The AMIGO (Atlantic and Mediterranean Interdisciplinary Geophysical Observations) Project is a scientific collaboration among researchers involved in GPS (Global Positioning System) activities along the western section of the Alpine-Mediterranean plate boundary zone. This boundary is made up of a broad transition region between the Eurasia and Africa plates. Its western section extends west-east from the Azores triple junction on the Mid-Atlantic Ridge to Tunisia and Sicily, and is home to a large variety of tectonic processes. Global plate models for this region indicate that the Africa plate is moving northwest relative to Eurasia at a rate of 4-6~mm~yr^{-1}. In our presentation, we will describe the objectives of the AMIGO Project, present our most recent GPS measurements of present-day crustal deformation from approximately a year of permanent and campaign data at several sites in this region, and discuss the implications of these, and future measurements for kinematic and dynamic models of this plate boundary zone.

INVESTIGATION OF NAHANNI (CANADA) EARTHQUAKE AREA USING SPACE-BORNE

Sar Johannes P. RISTAU (Geophysics The University of Manitoba, Winnipeg, Canada R3T 2N2 (email: jristau@cc.umanitoba.ca WOOIL M. MOON (Earth System Science, Seoul National University, (email: wmoon@eos1.snu.ac.kr and also with Geophysics, University of Manitoba, Winnipeg, Canada, R3T 2N2 (email: wmoon@cc.umanitoba.ca); Joong-sun Won (Dept. of Earth System Science, Yonsei University, (email: jswon@bubble.yonsei.ac.kr)

The Nahanni River earthquake area in the northeast Cordillera, Northwest Territories, Canada is an intra-plate earthquake area and located in the north-central region of the North American plate and several large earthquakes have recently occurred, including the ones on 5 October 1985 (Ms 6.6), 23 December 1985 (Ms 6.9) and 25 March 1988 (Ms 6.2). The earthquakes occur within a relatively small undeformed plateau, west of the Mackenzie Plain, in the Foreland Fold Belt created along the northeastern Cordillera during the Columbia or Laramide Orogeny. One of the difficulties of studying the geological and tectonic setting of the Nahanni region has been lack of comprehensive geological and geophysical data, perhaps due to remote isolation and logistic difficulties in accessing the study area. In this study an attempt was made to utilize various remote sensing techniques, including the data sets such as CCRS's airborne C- and X-band SAR data and available satellite (Landsat, SPOT, ERS-1, JERS-1, ERS-2, RADARSAT) data for investigation and imaging of the tectonic features. Detailed investigation of the surface structural features of each individual and the final integrated composite images over the epicentral area indicates that there are several new structural features intersecting the major northwest trending Iverson thrust fault and accompanying structures in the vicinity of the earthquake epicentral region. The NW-SE trending structural thrust faults and associated features have been mapped previously but the new N-S trending faults and several NEE-SWW (approximate strike) trending structures (faults) have not been identified before. The single event P-nodal solution plots for the aftershocks M 5.0 and larger (Horner et al., 1989) also confirm the new structures as well as the previously mapped regional features in the Nahanni area. Strikes of the primary and auxiliary fault planes estimated from these large main and aftershocks convincingly outline the structural trends parallel to the Iverson thrust fault. Similarly a newly mapped E-W trending fault intersects the Iverson thrust fault and appears to interact each other. Present results require further detailed ground truthing.

INVESTIGATION OF TECTONIC DEFORMATION ALONG CYPREAN ARC

Coskun Demir, Ali Turkezer, General Command of Mapping, Cebeci, 06100 Ankara, Turkey, email: cdemir@hgk.mil.tr

Crustal deformation in the eastern Mediterranean is mainly caused by the northerly motion of the African and Arabian plates relative to Eurasia plate. One of the most important tectonic features in the region is the subduction of the African plate beneath the Eurasia and Anatolian plates along Hellenic and Cyprean arc. Although the tectonic deformation along Hellenic arc is well understood, we have yet no much detailed information about Cyprean arc. In this paper, we have analyzed terrestrial and GPS observations to resolve tectonic deformation along Cyprean arc. The first order network of Turkish Republic of Northern Cyprus of 21 points extending 35 km in N-S direction and 135 km in the E-W direction is situated along the eastern part of the Cyprean arc. A triangulation-trilateration survey was performed in the network in 1987. All the network points, except destroyed one in the nortwest, were re-occupied with GPS in 1998. GPS coordinates are determined in the ITRF94 using high precision IGS products following fiducial network strategy. The triangulation-trilateration network is re-adjusted independently in the various datums defined by holding coordinates of two points fixed in the ITRF94. The adjustment of the terrestrial network results in the precision varying from 2 cm to 4 cm in the investigated area. Then, the comparison of both terrestrial and GPS results spaning 11 years is performed to estimate the horizontal velocity field. Our findings reveals no significant relative motion of the southern part of the network with respect to the northern part.

PLATE MOTIONS AND INTRA-PLATE DEFORMATIONS IN TURKEY FROM 1992-1998 FROM GPS MEASUREMENTS

MEHMET EMIN AYHAN, Coskun Demir, Muzaffer Kahveci, Ali Kilicoglu, Mustafa Kurt, Onur Lenk, Mustafa Ocak and Ali T (General Command of Mapping (GCM), TR-06100, Ankara, Turkey) Aykut Barka (Istanbul Technical University (ITU), Istanbul, Turkey) Robert Reilinger and Nafi Toksoz (Massachusetts Institute of Technology (MIT), ERL, USA) Hermann Seeger and Y Altiner (Bundesamt f_r Kartographie und Geodaesie (BKG), Frankfurt am Main, Germany.

Turkey is located in the Alpine-Himalayan collision zone, and is characterized by active and complex tectonic deformation. As a result of northward motion of the African and Arabian plates relative to the Eurasian plate, the Anatolian block (bounded by the North Anatolian Fault Zone (NAFZ) on the north, the African plate on the south, the Aegean region on the west, and the East Anatolian Fault Zone (EAFZ) on the east), moves westward. Simultaneously, the Aegean region is being extended in a north-south direction. Hence, Turkey is caught in a complex zone of interaction between various tectonic regimes, including collision, extension, lateral plate extrusion, and other intra-plate and plate boundary deformations. In order to quantify the present-day deformation field, we began GPS measurements for geodynamic studies in Turkey in 1988.
However, satellite orbits and earth rotation parameters accurate enough for determining plate motions have been computed and released to the research community only since 1992. Currently we have 17 GPS campaigns performed from 1992 to 1998. The GPS campaigns included in this study are;1992, 1994, 1996, 1998 surveys performed throughout Turkey jointly by MIT/GCM/ITU, 1992, 1994, 1996 campaigns conducted as a joint project by the Federal Institute of Technology Zurich(ETHZ)/GCM/ITU in the Marmara Sea region, 1992, 1993,1995, 1997 surveys along the west end of the NAFZ, and 1992, 1993,1994, 1997 observations in the Aegean region of western Turkey carried out in collaboration with BKG. We also include in our analysis GPS measurements at tide gauge stations on the Turkish coast and in the European Unified GPS Vertical Network(EUVN) Turkey sub-network performed by GCM in 1995 and 1997 respectively, as well as observations from the 1998 GPS surveys of the Turkish National Fundamental GPS Network. All GPS data were reprocessed by GCM using IGS products and BERNESE V4.0 software following the same processing strategy. The results of all GPS campaigns are combined individually using both BERNESE V4.0/ADDNEQ and GAMIT/GLOBK software to obtain the velocity field in Turkey. We compute site velocities in the ITRF96 reference frame by fixing the velocities of Onsala, Matera, and Wettzell located on the western part of Eurasia, and also estimate velocities relative to Eurasia. The velocity field relative to Eurasia reveals...

REVIEW OF NLC MEASUREMENTS BY LIDAR

Jeffrey P. THAYER (SRI International, 333 Ravenswood Avenue, Menlo Park, CA, 94025, USA, Email: thayer@sri.com); Ulf von Zahn and Goertz von Cossart (both at Leibniz-Institute of Atmospheric Physics, D-18225 Kuehlungsborn, Germany, email: vonzahn@iap-kborn.de, vcossart@iap-kborn.de)

Over the past decade high latitude lidar systems have contributed to the study of noctilucent clouds (NLCs) by providing direct measurements of basic cloud properties and their temporal evolution. Since the first definitive lidar detection of a noctilucent cloud by Hansen and von Zahn in 1989, new lidar systems with enhanced capabilities for NLC measurements have been deployed in the arctic. The enhancements made by most of these lidar systems have come in the form of simply increased laser power and increased telescope aperture. These improvements have enabled measurements of NLC characteristics (i.e. height, thickness and backscatter strength) at high temporal and spatial resolution (10's of meters within 10's of seconds) over a range of local times. The Sondrestrom lidar facility in Greenland has, for example, made NLC measurements of this type for the past four summer periods. One facility, the ALOMAR facility in northern Norway, has made the most significant advancements by providing a high power and large aperture lidar system while detecting NLCs at all local times and at three different wavelengths. The multiwavelength measurements allow for the NLC particle size distributions to be derived. The daytime capability permit studies concerned with local time variations in the NLC characteristics. Presently, the ALOMAR facility, followed by the Sondrestrom lidar facility in Greenland, has the most extensive database of NLC detections by lidar systems. Interestingly, these two stations show statistically very different behavior in NLC characteristics. In this presentation, we will review the contributions made by lidar to NLC studies as well as highlight new results and future plans.

CURRENT STATUS OF PMC/PMSE OBSERVATIONS

W. SINGER (Leibniz-Institut fuer Atmosphaerenphysik an der Universitaet Rostock, D-18225 Kuehlungsborn, Germany)

Intensive studies in recent years have shown that the occurrence and morphology of layered structures, such as polar mesosphere summer echoes (PMSE) observed by radars and noctilucent clouds (NLC) observed by optical instruments, are tightly coupled to the thermal and dynamical structure of the mesopause region. PMSE appear in the high latitude summer mesopause region with a large occurrence rate and have been studied at an increasing number of locations. We will briefly address the various radar experiments with special emphasis on new methods. We will review the development of knowledge on PMSE (e.g. connection of PMSE occurrence with seasonal temperature changes and with tidal wind components, correlation between PMSE and NLC).

JSM32/W/12-B2 Invited **1100**

ROCKET BORNE MEASUREMENTS OF SMALL SCALE FLUCTUATIONS OF PLASMA, NEUTRAL, AND AEROSOL DENSITIES

Dr. Tom Arild BLIX

The paper will review in situ measurements of plasma, neutral and aerosol densities in the upper mesosphere during Noctilucent Cloud (NLC) and Polar Mesosphere Summer Echoes (PMSE) conditions. Both small-scale (1-10 m) fluctuations and larger scale (100 m - 1 km) variations will be treated. Of special interest is the small-scale variations observed when passing through the PMSE layers. We will discuss possible mechanisms responsible for the observed fluctuations, such as neutral air turbulence and plasma instabilities. We will also discuss the importance of aerosols (1 nm) for the charge balance in the region of NLC and PMSE, and possible size distributions of these particles depending upon the actual temperature and water vapour content at these heights.

JSM32/W/06-B2 Invited **1135**

TURBULENCE AND MIXING DUE TO KELVIN-HELMHOLTZ INSTABILITY: IMPLICATIONS FOR LAYERING AND ATMOSPHERIC STRUCTURE

David C. FRITTS, Joseph A. Werne (Colorado Research Associates, 3380 Mitchell Lane, Boulder, CO 80301, USA)

Numerical simulations of Kelvin-Helmholtz (KH) instabilities have recently described, for the first time, both the transition to turbulence and the dynamics and mixing occurring within the turbulent flow. The morphology of KH billows includes the initial 2D billow roll-up, transition to 3D through the formation of isolated, streamwise-aligned convective rolls, expansion of 3Dstructures and turbulence throughout the billow cores, homogenization of turbulence horizontally, and restratification of the shear flow as turbulence energy decays. This talk will provide an overview of the dynamics of KH breakdown and turbulence generation, with emphasis on the implications for mixing, formation of layered structures, observations, and inferred dynamics.

ELECTRIC FIELD STRUCTURE IN THE VICINITY OF NOCTILUCENT CLOUDS AND PMSE

Alexander M. ZADOROZHNY (Novosibirsk State University, Pirogova 2, Novosibirsk 630090, Russia, email: zadorozh@phys.nsu.ru)

During NLC-91 campaign, disturbances of rocket electric field mill signal of more than 1 V/m were detected at 82.5-84.5 km. The region of the large fields was clearly limited by the noctilucent clouds on the bottom and by the PMSE layer on the top. Both rocket data and laboratory results of a post-flight examination of the field mill probe showed that the perturbations in the field mill signal are caused not only by atmospheric electric fields but also by the impact of solid particles. Simultaneous analysis of the rocket and laboratory data allowed us to estimate sizes of the particles in the PMSE layer to be 13-40 nm and the vertical electric fields at 84 km to be ~0.9 V/m. The height correlation of the observed electric field disturbance with the NLC and PMSE positions indicates the importance of the aerosol particles in the generation of the vertical electric fields. A simple gravitational falling of charged aerosol particles could not explain the V/m fields. The main obstacle for the forming of the large fields is a high conductivity of the atmosphere. To explain the V/m fields, we assume he simultaneous existence in the mesosphere both the negative and positive multiply charged aerosol particles. Cho et al. (1992) showed that a presence of charged aerosol in the mesospheric plasma leads to a drastic decrease of effective electron diffusivity when somewhat more than half of the charge is tied up in aerosols. The effective ion diffusivity will be obviously decreased under the same conditions, too. As a result, a large enough charge carried by the particles can reduce effective conductivity of the atmosphere significantly and make it possible of existence of V/m electric fields. The proposed model can explain the existence of the vertical fields observed in the NLC/PMSE vicinity if particles with radius of about 20-25 nm carry 2-4 unit charges.

THE RELATIONSHIP OF ICE SATURATION AND POLAR MESOSPHERIC CLOUDS

Gary E. THOMAS (Laboratory for Atmospheric and Space Physics, University of Colorado, CB 392, Boulder, CO 80309, USA, Email: thomas@alcor.colorado.edu)

Polar Mesospheric Clouds (PMC) are thought to be ice crystals which form in the saturated environment of the polar summertime mesopause. The climatology of PMC should therefore be governed by the seasonal cycles of mesospheric temperature and water vapor. This paper examines the latitudinal, seasonal and height dependence of the ice existence region (IER), as determined by satellite measurements of temperature and water vapor, and relates this region to the occurrence statistics of PMC, as observed by UV scattering measurements from the Solar Mesospheric Explorer satellite. In a similar way, the seasonal dependence of a related phenomenon, Polar Mesospheric Summertime Echoes (PMSE) is also related to the IER. PMSE are layers of high radar reflectance observed near the mesopause from fixed ground locations. In general both PMC and PMSE are confined within the IER, but there is a seasonal asymmetry in terms of the beginning and ending dates. There is a curious difference between the beginning of saturation and the onset of PMC and PMSE, and between the end of saturation and the disappearance of PMC/PMSE. Local time dependence of the IER, and its seasonal changes, may be a key factor in the explanation of the asymmetry. Falling-sphere measurements of density (and inferred temperature) at fixed local times, and satellite measurements made at various local times, may be combined to yield information on local time variability of the IER. These empirical relationships will be used in testing the "standard" growth-sedimentation model of PMC.

PLANETARY WAVE MODULATION OF PMSE AND NLC

S. KIRKWOOD, A. Réchou, K. Stebel (Swedish Institute of Space Physics, MIR Atmospheric Research Program, Box 812, Kiruna, S-981 28 SWEDEN, e-mail: sheila.kirkwood@irf.se)

PMSE occurrence measured by the ESRAD radar during 3 summer seasons are show significant variation with 4-6 day periodicities. Planetary waves in the same frequency band are extracted from UKMO assimilated analyses (up to 60 km altitude) and compared with the PMSE variations. Good correlation is found for the upper PMSE altitudes, and it is suggested that the temperature modulation associated with the planetary waves is sufficient to modify the nucleation of aerosols. The possible correlation between noctilucent cloud occurrence and planetary wave activity is also studied, using the observations from the Scottish network and UKMO global meteorological analyses from 1979 - 1999.

JSM32/E/02-B2 **1500**

ON THE DIURNAL VARIATION OF POLAR MESOSPHERE SUMMER ECHOES

J. KLOSTERMEYER (Max-Planck-Institut fuer Aeronomie, 37191 Katlenburg-Lindau, Germany, email: jkloste@gwdg.de)

Observations of polar mesosphere summer echoes yield diurnal variations of the occurrence frequency and the signal-to-noise ratio (SNR) that are characterized by a pronounced maximum and a pronounced minimum near 14 and 20 LT, respectively. A weaker maximum and a weaker minimum may occur between 00 and 10 LT. Several authors suggested a dominant influence of diurnal and semidiurnal tidal wind or temperature variations but excluded any significant effects of the sun's zenith distance and of energetic particle precipitation. A partial regression analysis of published SNR data measured by the ALOMAR-SOUSY radar during July and August 1994 shows on the contrary that SNR is strongly correlated with both the cosine of the sun's zenith distance and the square of the cosmic noise absorption. These results indicate that SNR varies with the square of the electron concentration, in agreement with theoretical predictions. In addition, a negative correlation between SNR and tidal temperature variations is found confirming earlier suggestions and theoretical considerations. After elimination of these effects, the residual time series has an almost white spectrum indicating that other mechanisms had no significant influence on the observed diurnal variation.

JSM32/W/01-B2 **1600**

MODELLING OF PARTICLE CHARGING: FINGERPRINTS OF NLC AND PMSE PARTICLES IN THE AMBIENT PLASMA

M. Rapp, F.-J. LUEBKEN (Physikalisches Institut der Universitaet Bonn, Nussallee 12, D-53115 Bonn, Germany, email: luebken@physik.uni-bonn.de)

Aerosol particles in the polar summer mesosphere which are believed to cause noctilucent clouds (NLC) and polar mesosphere summer echoes (PMSE) lead to a characteristic fingerprint in the height profiles of the ambient electron and positive ion densities mainly as a result of plasma diffusion. Microphysical modelling of aerosol charging shows that specific signatures are expected in the plasma which have indeed been observed in various rocket borne measurements of electron and ion density profiles in the polar summer mesopause region since the late 1960's. We will discuss different scenarios leading to these signatures in terms of the aerosol abundance and composition, as well as the ionization rate and the recombination coefficient. In addition to the frequently observed 'bite-out' in the plasma profiles we found that an enhancement of both positive ions and electrons can occur, in agreement with observations. We find a nice agreement of measured and modelled Schmidt numbers in the electron bite-out situation. Special attention will be given to the case of an electron density enhancement which, according to our current understanding, can be caused only by photoemission on the aerosol particles.

THE ROLE OF METALLIC SPECIES IN THE NUCLEATION OF NOCTILUCENT CLOUDS

John PLANE (School of Environmenal Sciences, University of East Anglia, Norwich NR4 7TJ, UK, email: j.plane@uea.ac.uk)

Two theories have been proposed to provide the source of condensation nuclei for the formation of noctilucent clouds in the high latitude summer mesosphere: ions (either metallic or proton hydrate) and meteoric "smoke". There are difficulties with both theories, such as the presence of sufficient densities of ions below 90 km, and the precise nature and mechanism for the formation of the smoke. This paper will present an alternative theory that combines some elements of the previous two. Meteoric ablation gives rise to the atomic Na layer at 90 km, and we know from a combination of work in our laboratory and atmospheric modelling that the major reservoir for the metal between 80 and 87 km is sodium bicarbonate (NaHCO3), with a density in excess of 1e4 cm-3. We have recently carried out new high level quantum calculations on this molecule. These show that the molecule is ionised with a substantial dipole moment, and that NaHCO3 forms very stable complexes with a sequence of H2O molecules. Under mesospheric conditions, formation of these clusters will be activated in a narrow temperature range below about 150 K. This feature, together with the estimated number density of NaHCO3, makes the molecule (and possibly other metallic compounds with very large dipole moments such as MgCO3) attractive candidates as condensation nuclei for NLC.

POLAR MESOPHERIC CLOUDS SEEN FROM GEOSTATIONARY ORBIT

M. GADSEN

When the sun is at a declination greater than 9 degrees North or less than 9 degrees South, a geostationary meterological satellite is in full sunshine at midnight but the Sun is outside the field of view of the radiometer. (The corresponding dates are 13 April-28 August and 19 October-24 February). At this time, forward- scattered sunlight is seen iln the atmosphere at high latitudes.
These satellite images allow PMC's to be detected. There are, implicitly, some 20 years of these data available in the geostationary satellite archives, data which refer alternately to the northern and the southern mesospheres . Results of a first-look at this data resource are presented and disscused.

ON THE INTERHEMISPHERIC DIFFERENCES OF PMSE

Ben B. BALSLEY (CIRES, Campus Box 216, University of Colorado, Boulder, CO 80309, USA, email: balsley@terra.colorado.edu); Ronald Woodman (Instituto Geofisico del Peru, Apartado 13-0207, Lima 13, Peru, email: ron@geo.igp.gob.pe); Mercedes Huaman (372 Rhodes Hall, Cornell University, Ithica, NY 14853, email: huaman@ee.cornell.edu)

IA

VHF radar observations of PMSE made at Peru's Machu Picchu Radar Facility on King George Island, Antarctica show a marked difference to similar observations made at comparable latitudes in the Northern hemisphere. Basically, PMSE in the Southern hemisphere are between 33-40 dB (i.e. a factor of 2000-10000) weaker than their northern counterparts. This observation is based on some three years of data at Machu Picchu and even more extensive measurements in the Northern hemisphere. The most likely reason for the difference is that summertime high-latitude mesospheric temperatures are somewhat warmer in the southern hemisphere, a possibility that is borne out by a variety of satellite observations and models. The rationale for these warmer temperatures begins with weaker gravity wave activity in the Southern hemisphere that results in reduced mesospheric meridional and vertical winds and a concomitant reduction in near-mesospause cooling. A warmer southern-hemispheric mesosphere is less hospitable to the production of ice particles and the associated phenomena of Polar Mesospheric Clouds (PMC) and PMSE. We will outline a series of recent studies obtained from a variety of observing platforms (satellites, VHF radars, MF radars) that support these ideas.

JSM32/W/08-B3 Invited **1005**

SMALL SCALE LAYERS AND TRENDS IN THE MESOSPHERE

F.-J. Luebken (Physikalisches Institut der Universitaet Bonn, Nussallee 12, D-53115 Bonn, Germany)

The occurrence of small scale layered phenomena such as noctilucent clouds (NLC) and polar mesosphere summer echoes (PMSE) in the high latitude summer mesosphere is related to various geophysical parameters, such as temperature, water vapour, and condensation nuclei. The question which one of these parameters is of prime importance is investigated by studying the variations of these phenomena on seasonal and decadal time scales. Recent results from ground based, insitu, and satellite observations suggest that temperature is the prime parameter controlling the morphology of these layers, whereas e.g. water vapour and condensation nuclei are of secondary importance. The experimental evidence for a temperature trend in the mesosphere and its potential impact on the occurrence frequency of NLCs and PMSEs will be critically reviewed in this paper. New experimental results from various techniques will be presented.

JSM32/W/07-B3 **1100**

DISTRIBUTIONS OF POLAR MESOSPHERIC CLOUDS OBSERVED BY A MIDDLE ULTRAVIOLET IMAGER

D. MORRISON, J. F. Carbary, G. J. Romick, L. J. Paxton, C.-I. Meng (Johns Hopkins University, Applied Physics Laboratory, 11100 Johns Hopkins Rd., Laurel, MD 20723, USA, email: daniel.morrison@jhuapl.edu)

We report on analysis of images of polar mesospheric clouds (PMC) observed in the middle ultraviolet (235-263 nm). The images were obtained from the UVISI (Ultraviolet and Visible Imaging and Spectrographic Imaging) instrument on the MSX (Midcourse Space Experiment) satellite and cover both the northern and southern polar regions during the arctic summer of 1997 and austral summer of 1997-1998. The imager look-point made multiple trans-polar passes over the Arctic and Antarctic and obtained over 500 images of PMCs at latitudes poleward of 80°. The unprecedented accuracy and stability of the satellite platform (~10 µrad) conferred advantages for investigating both the large-scale (>100 km) and small scale (~1 km) spatial structures of PMCs. The UV imager clearly observed PMCs distinct from the atmospheric backgrounds. Poleward of 70°, the clouds existed in discrete, filamentary structures at altitudes between 80 and 85 km, although most of PMCs appeared at altitudes between 82.5 and 83.0 km. Within these ranges, cloud altitudes were essentially random on a trans-polar scale of ~1000 km. In some instances, the clouds did cluster at common altitudes for distance scales of ~100 km across the polar mesosphere. The PMC altitudes do not appear correlated with latitude or local time on the scale of the observations discussed here. A diffuse signal above the clouds was readily observed in many cases. For some cases comparisons with a co-aligned visible imager will be presented. Analysis of the two dimensional structure of the PMCs in latitude and longitude will be also be presented.

JSM32/L/01-B3 **1125**

OBSERVATION OF A NOCTILUCENT CLOUD AT DAVIS, ANTARCTICA IN FEBRUARY 1998

W.J.R. FRENCH (1), G.B. Burns (1), P.A. Greet (1), D.J. Murphy (1), K.J. Quinnell (2) (1: Australian Antarctic Division, Channel Highway, Kingston, Tas. 7050, Australia; 2: Bureau of Meteorology, G.P.O. Box 727G, Hobart Tas 7001, Australia)

This paper reports observation of a Noctilucent Cloud (NLC) from Davis Station, Antarctica (68 35'S; 77 58'E) on 18-FEB-1998, first observed at 1850UT and photographed until it dispersed at 2000UT. These photographs are analysed to determine the cloud's position and extent, and the wavelength, orientation and motion of the wave structures observed. The observation was accompanied by rotational temperature measurements of the OH(6-2) band using a Czerny Turner scanning spectrometer. The OH emission is centered at about 87km altitude, slightly above the typical height of cloud formation. Analysis of these results yields average temperatures considerably lower on the night of the cloud observation than the 7 days prior to and post the event. A dual channel Fabry-Perot spectrometer was also operating, measuring winds and temperatures from OH(6-2) Q1(1) and the Oxygen 558nm emission. Analysis and results of these temperature measurements is also discussed. In addition, data from a 2 MHz MFSA radar, co-located at Davis, is examined for evidence of PMSE's and the meteorological balloon flights surrounding the observation are examined for evidence of stratospheric warming.

THE VIRTUAL WORLD DATA CENTER SYSTEM.

Yu.TYUPKIN (Geophysical Center, Joint Institute of Physics of the Earth, Molodezhnaya 3, Moscow 117296, Russia, email: tyupkin@wdcb.rssi.ru)

The World Data Center system (WDC system) was established in 1957 to serve the International Geophysical Year (IGY) program. Two complex centers were established by USA (WDC A) and USSA (WDC B). These centers realized functions of data acquisition, storage and distribution of most IGY disciplines. In many disciplines there was a special centers known as WDC C1 if in Western Europe and WDC C2 if in Asia or Australia in addition to complex centers. Multiple centers were deemed advisable to guard against catastrophic loss of data, and for the convenience of data providers and users. Because of its success, the WDC system was made permanent and used for post IGY data. Today the WDC system is healthy and available. But new technology of data storage, data access and data processing require new approach to realization of main functions of the WDC system. The conception of Virtual World Data System (VWDCS) is discussed. VWDCS is a distributed automated system on the INTERNET basis. The VWDCS resource is built up by various systematized and reliable information on geosciences that can be reached through Internet and has the main WWW page with the fields filled according to the VWDCS standard. The VWDCS management system must realized functions: 1. The procedure of presentation of a new information resource by the author. 2. The access to Internet informational resources not included in VWDCS. 3. Automatic revision of the informational resources of the VWDCS network. 4. The specific features of work in countries with limited access to Internet. The now existing WDCs should carry out at least three functions in the frame of the VWDC System: - Long-term storage of information. - Provision of means for maintaining control over the quality of information available in VWDCS. - 3. Maintenance and co-ordination of connections with new informational resources on national (WDC A, WDC B, WDC D) and regional (WDC C) levels.

JWS33/W/10-B2 **0945**

WEB EFFECTS: FRONTIERS IN INFORMATION DELIVERY

Allen M. HITTELMAN and Susan J. McLean (NOAA's National Geophysical Data Center, World Data Center for Solid Earth Geophysics, 325 Broadway, Boulder, CO 80303, U. S. A., email: ahittelman@ngdc.noaa.gov)

Without question, one of the most profound impacts on information technology is the advent of the Web. In just a few years, this media has drastically altered our perceptions of information services and created new paradigms for data dissemination. To cope with this unprecedented explosion of change, many of us in the information service business had to re-evaluate organizational goals and objectives. Where once we felt comfortable with our awareness of user needs, now we fell distant due to the impersonal nature of our Web sites (which seem to serve 99% of our scientific clientele's needs).
The National Geophysical Data Center, and its several supported World Data Centers, has pioneered many new innovative methods that enrich data and information delivery on the Web. Examples of these techniques include: the interactive creation of graphical spreadsheets (see http://swat.ngdc.noaa.gov/cgi-bin/wist/wist.pl), the satellite browse, display and download features of the Space Physics Interactive Data Resource (SPIDR, see http://julius.ngdc.noaa.gov:8080/) and access to gridded relief models (see http://www.ngdc.noaa.gov/seg/topo/globe.shtml). Newer techniques are empowering users with the ability to access data and meta-data through GIS-enabled Web servers. We have also explored data mining tools to provide improved understandings of the needs of our Web users -- from where do they come and for what do they search?

JWS33/W/11-B2 **1000**

NEW DIRECTIONS IN NASA EARTH SCIENCE ENTERPRISE DATA MANAGEMENT: PLANS FOR A NEW DATA INFORMATION SYSTEMS AND SERVICES APPROACH (NEW DISS)

Ronald L. S. WEAVER, (National Snow and Ice Data Center, CIRES, Campus Box 449, University of Colorado Boulder, Colorado, 80309)

The NEW DISS effort of the NASA Earth Sciences Enterprise (ESE) has now completed its preliminary report on how to implement data management within the agency in the coming 5-7 year timeframe. The key elements of this plan include more investigator involvement in data management and emphasis on more de-centralized data management services. Design concepts include a modular approach to data system functional elements. The report recognizes the need for distributed, flexible, yet responsive systems and ESE's need to have smaller, more manageable components.
The purpose of this paper is to provide an update on the NEW DISS study team's progress, and to report on the probable course of NASA ESE data management. The author will provide a perspective on these activities based on his involvement as a member of the NEW DISS study Core Team and as an EOSDIS Distributed Active Archive Center (DAAC) Manager.

JWS33/W/15-B2 **1015**

OPEN DISTRIBUTION OF LIVE SEISMIC DATA VIA THE INTERNET

Robert WOODWARD (United States Geological Survey, Albuquerque Seismological Laboratory, Bldg. 10002, Kirtland AFB-E, Albuquerque, NM 87115-5000, USA, e-mail: woodward@asl.cr.usgs.gov)

We have developed a mechanism for the open distribution of digital seismic data, in near-real-time, via the Internet. The seismic data are collected by stations of the Global Seismographic Network at sites on every continent. Data from these seismographic stations are used for a variety of purposes, such as earthquake reporting, tsunami warning, and nuclear monitoring.

The data distribution mechanism, which we call the Live Internet Seismic Server (LISS), is modeled on the concept of a webserver. The LISS accepts a virtually unlimited number of simultaneous client connections via the Internet. Each client simply stays connected to the LISS and receives copies of the digital seismic waveform data which the server is receiving from the seismographic stations. Thus, clients are connecting to the LISS to receive seismic data much like clients connect to a webserver to receive text or images. Latency of data obtained from the LISS is typically less than 30 seconds.
LISS's can be run in a chain, such that one LISS is a client to another LISS. In this way LISS's can be placed at different locations on the Internet to provide redundant paths for accessing the data. At present, auxiliary LISS's are running in Moscow and Beijing and these are forwarding data to the primary LISS at United States Geological Survey's Albuquerque Seismological Laboratory. Data from 30 stations around the world are presently available via theLISS. In addition to distributing these data, the most recent 24 hours of data from each station are plotted in a manner resembling the popular drum style (helicorder) recording mechanism which is widely familiar to the public. These plots are updated every thirty minutes and are accessible via the WWW. These data plots, as well as more information on the LISS, can be obtained via the WWW at the URL: http://aslwww.cr.usgs.gov/Seismic_Data/liss.htm.

JWS33/W/06-B2 1045

BASIC PACIFIC TSUNAMI CATALOG AND DATABASE, 47 B.C. - 1998 A.D

V.K.GUSIAKOV (Institute of Computational Mathematics and Mathematical Geophysics, Siberian Division, Russian Academy of Sciences, Novosibirsk 630090, Russia, Email: gvk@omzg.sscc.ru)

A compilation of parametric tsunami data for tsunamigenic events occurred in the Pacific from 47 B.C. to 1998 has been made within the joint IUGG Tsunami Commission and ICG/ITSU Project "Basic Pacific Tsunami Catalog and Database". The project is directed to improve the situation with catalogization of historical tsunamis in the Pacific by means of organising them in the form of the database containing all the meaningful historical tsunami data along with additional reference information related to the tsunami problem. Its final goal is the development of the multimedia CDROM "Tsunamis in the Pacific, 47 B.B.- 2000 A.D.". The initial data collection has been made within the relational DBMS dBASE that has been established and being maintained at the Tsunami Laboratory of the Institute of Computational Mathematics and Mathematical Geophysics of SD RAS. A special graphic shell (the GIS-type mapping subsystem) has been developed for easy data manipulation, visualisation and handling. The condensed version of the database (the catalog of the Pacific tsunamigenic events) has been created on the basis of the MS SQL Server 6.5 and available on the following Web site: http://tsun.sscc.ru/htdbpac/. This site contains the most comprehensive and constantly updated list of historical tsunamigenic events in the Pacific with their basic source parameters. A set of parameters includes date, time, coordinates of the epicenter, source depth, surface-wave and moment-magnitudes, Abe's tsunami magnitude, tsunami intensity on the SolovievImamura scale, the maximum tsunami run-up height, the number of available run-up observations, cause of the tsunami, validity of the event, coded name of the source region and the main reference to the event. The full version of the database (including the catalog of historical run-up observations with geographical co-ordinates of sites) provided with the Windows-based graphic shell and geographic mapping subsystem is distributed on a CD-ROM. The example of the CD-ROM content can be found at the following URL: http://omzg.sscc.ru/tsulab/htdb_f.html).

JWS33/W/13-B2 Invited 1100

DATA COLLECTION, DATA PROCESSING AND DATA DISSEMINATION IN THE RUSSIAN VIRTUAL GEONETWORK

Pavel PLETCHOV (Geological department, Moscow State University, Moscow, Russia E-mail: lym@ccas.ru); Eugene Kozlov (Computational Mathematics and Cybernetics department, Moscow State University, Moscow, Russia E-mail: james@geo.web.ru)

RVGN - (Russian Virtual GeoNetwork) is distributed automated system, which ensure systematization, examination and periodic checks of an information on geosciences in a Russian part of Internet. The main server of the RVGN is available by URL: http://geo.web.ru/. RVGN is oriented to WWW (HTTP) access to each resource. The RVGN provides automatic checking of the current state of information resources of the net and a system of automatic distribution of information communications. A special robot regularly analyses the content of all informational RVGN resources, and if any changes are revealed made by the authors of the resource, or if a new information resource appears, the robot updates the corresponding information in the central RVGN database. The system automatically formulates communications about the detected changes, from key words draws the distribution list of information to interested users of the net, and transmits communications by the E-mail. RVGN includes a Link Manager program, which support dynamic lists of links. It's like thematic bookmarks or Internet directories, but all RVGN lists of links are constantly updated and automatically checked. Each RVGN expert can support own classification system and edit his classification via ClassEditor. ClassEditor allows create, delete classes and change class attributes. This system support enclosed sections of classification by parent class attribute. If a parent class is HTML file, content of this class will be written to this file. Otherwise, this class is a subsection of a parent class. As a result, dynamic lists of RVGN virtual layer are created daily. RVGN consists of a lot of the connected among themselves programs and user interfaces, which will be discussed in the presentation.

JWS33/E/09-B2 Invited 1115

AN APPROACH TO ON-LINE INTELLIGENT GEODATA ANALYSIS

V. GITIS, B. Osher, A. Dovgyallo (Institute for Information Transmission Problems, RAS, Moscow, Russia, email: gitis@ippi.ras.ru); T. Gergely (Applied Logic Laboratory, Budapest, Hungary, email: gergely@all.hu)

An approach to creation of information technology for on-line intelligent geo-information modelling and complex analysis of space-time properties of geological environment is suggested. The technology supports two types of users' queries: (a) Getting knowledge about geological properties of a region; (b) Investigation of properties and solving practical problems of geological and geophysical forecasting. The client part of the system prototype is realised in Java 1.1 and is accessible on address http://www.iitp.ru/projects/geo and http://ta-www.jrc.it/gitis/geoprocessor.html. Applet supports the following functions of space-time data processing and analysis: (i) Cartographic data representation (map composition, sizes and scale changing, reading a map values, visualisation of crossections, compiling the maps of similarity with precedents); (ii) Data transformation: (shadow modelling, algebraic and logical raster operations, filtration, learning and testing sample sets formation); (iii) Plausible reasoning of forecast maps: (method of similarity, method of membership function, method of nonparametric regression). The work is partially supported by the project ASPELEA granted by EU Inco-Copernicus Project contract # ERBIC 15CT970200 and by Russian Foundation on Scientific Research, project # 97-07-90326.

JWS33/W/16-B2 1130

HIGH LEVEL SEARCH TOOLS FOR SPACE PHYSICS DATABASES

Mike HAPGOOD (CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire, OX11 0QX, UK, Email: M.Hapgood@rl.ac.uk); Chris Harvey (Centre d'Etude Spatiale des Rayonnements, 9 avenue du Colonel Roche, BP 4346, 31028 Toulouse Cedex 4, FRANCE, Email: Christopher.Harvey@cesr.fr); Jim Thieman (National Space Science Data Center, Code 633, NASA/Goddard Space Flight Center, Greenbelt, MD 20771, USA, Email: thieman@nssdc.gsfc.nasa.gov)

As the number of space physics data-sets increases internationally it becomes increasingly important to have a method to find and retrieve data of interest wherever they are located on the network. One important method is the use existing web search engines such as AltaVista. This method is suitable for finding data made available by individual scientists and small groups. It requires only that the data are made available via a web page that is well-indexed using search keywords that are intuitive to the user. This method is likely, however, to give a large number of extraneous results as well. Another method, more suited for searching the larger data centres, is the use of a specialised search protocol limited to searching pre-selected sites. This protocol should also support searching for particular types of data recorded at a particular location or during a given time period. A similar protocol is already in use in searches for astrophysics data and includes support for searches over multiple sites. This protocol can be extended to allow simultaneous for overlapping data in selected time intervals or for particular locations. In this paper we discuss and assess the different search methods and describe efforts now underway to implement these ideas in space physics.

JWS33/W/03-B2 1145

AN INTEGRATED SATELLITE ALTIMETRY, GRAVITY AND GEODESY DATA BASE: ARCHITECTURE, VERIFICATION, DATA PROCESSING, DATA BASE MANAGEMANT SYSTEM

P.P. MEDVEDEV, Yu.S. Tyupkin, S.A. Lebedev (Geophysical Center, Russian Academy of Sciences, Molodezhnaya 3, 117296, Moscow, Russia, email: pmedv@wdcb.rssi.ru)

The integrated database of satellite altimetry data and supplementary gravity and geodesy information which is necessary for geodesy, geophysics, geology and oceanography applications was created in Geophysical Center of RAS. The satellite altimetry data sets include data measured by the Russian GEOIK geodetic satellites and by GEOSAT, ERS-1, ERS-2 and TOPEX/POSEIDON during the period 1985-1998. Database management system includes problem-oriented modes in additional to the usual DBMS functions. Database consists of three levels: preliminary data, integrated data, results of special processing. The architecture of database, database management system and data processing, future plans and problems are discussed. The work was supported by Russian Basic Research Foundation.

JWS33/W/14-B2 1200

VIRTUAL DATABASE DEVELOPMENT FOR FLOOD MANAGEMENT IN THE RED RIVER BASIN

Slobodan P. SIMONOVIC (Natural Resources Institute, University of Manitoba, Winnipeg, Canada, R3T 2N2, e-mail: simon@ce.umanitoba.ca)

The interim report of the International Red River Basin Task Force (IJC, 1997) provides background on the 1997 flood and describes the development of virtual database as fundamental for success of the study. This paper describes issues involved in the development of a "virtual database" (Data catalog or library) in the form of an internet web site, in sufficient detail to provide the following services: (a) Quickly locate data required for flood reporting and flood fighting in the Red River Basin; and (b) Describe in detail the contents and limitations of the data. Virtual database is searchable by data type, data holder/owner, location, etc. It is proposed that a single link, such as a Web Page, be established that will be the door through which the overall Red River Database is accessed. During the Flood of 1997 numerous Internet "Flood Information" Web pages appeared that provided useful information to data consumers in the basin. However, these sites were not integrated in a way to allow access to all potential sites or sources of information. Based on the International Joint Commission (IJC) public meetings in the Red River Basin and user needs assessment, conducted in July 1998, there is a real need to integrate and make more readily accessible the distributed databases that currently exist and those to be developed in the future. The Red River Basin Virtual Database (RRBVD) has no single data repository thus eliminating the requirement to provide regular updates of data to a data clearinghouse. Some data sets, however, may need to be centralized depending on the preferences of the data set providers. The Red River Basin Virtual Database will be used in three modes: (a) planning and design for flood protection; (b) real time flood emergency; and (c) flood recovery.

JWS33/E/04-B2 1215

A NEW APPROACH TO GEOPHYSICAL DATA PROCESSING FOR DETECTING EARTHQUAKE PRECURSOR ANOMALY

Yueqing ZHU (Center for Analysis and Prediction, China Seismological Bureau, P. O. Box 166 Beijing, 100036, email: zhuyq@sun.ihep.ac.cn)

Audio-visual and comfortable detection to the earthquake precursor anomalies from geophysical observations is one of the very important aspects for earthquake prediction researches.
The Author and his research group have recently developed a strategy and a related intelligent software system for doing geophysical data processing and also detecting earthquake precursor anomalies from geophysical observations of different disciplines on single station and/or station networks. The results can be also automatically disseminated to a series of expert systems for doing medium-term, short-term and urgent earthquake prediction, which are developed by the author and his other research groups.
The system is consisted of a method-library, synthetic databases, GIS application sub-system, report and table auto-generation sub-system and anomaly feature auto-recognition and recording sub-system. The spatial and temporal variation features of the anomalies detected will be displayed in screen, listed in suitable tables and plotted in maps formed by GIS within suitable text reports in national language or English. It can detect special features of precursors of earthquake generation process and possesses good audio-visual functions.

JWS33/E/06-B2 1230

HIGH-CAPACITY NETWORKING TECHNOLOGY FOR PROCESSING OF THE EARTH'S VIBRATIONAL SOUNDING DATA

M.S.KHAIRETDINOV, Yu.I.Rodionov, A.P.Grigoryuk, L.G.Dvoretskaya, G.F.Sedukhina. (Institute of Computational Mathematics and Mathematical Geophysics, Siberian Branch, Russian Academy of Sciences.); M.S.Sevastianov, R.V.Radygin. (Novosibirsk State Technical University. Russia, Novosibirsk.)

The method of deep vibro-seismic sounding of the Earth, because of its high resolution and high accuracy of measurement, has considerable promise for solution of a number of urgent seismological problems. In the first place, these are: problems of monitoring of seismic-prone zones, seismic tomography, precise calibration of traces of seismic wave propagation, etc. Solution of these problems is connected with recording and processing of a large bulk of data, whose capacity can be estimated as N=Fd*p*M*L*T, where Fd is the sampling rate of input signal values, p is word length of sampling values, M is the number of recording channels, L is the number of repeating sounding performances, T is duration of each performance. Selection of the parameters L and T determines the noise immunity of vibroseismograms. As applied to solution of the problems in question, for example, to vibromonitoring of seismic-prone zones, an area of 1000 kmx1000 km, the capacity of accumulated information can reach about 100Gb. In order to handle such a large amount of information, the authors have developed a network technology of data processing, which consists of two levels. The lower level of processing is connected to data gathering stations and contains the software for recording and accumulation of initial data with their simultaneous processing, in the first place, calculation vibroseismograms (correlograms) and evaluation of their primary parameters of each of M channels in the real-time mode in the course of experiment. Because of the latter, the information is M*T/Ts times compressed, where Ts is duration of a vibrocorrelogram. In particular, at M=500, T=3600sec, Ts=150sec, the compression makes about 1000 times, which allows us to essentially decrease the requirements on the channels rate of data transmission to the processing system of the upper level. At the upper level of the system, additional processing ….

Tuesday 27 July PM

Presiding Chair: Yu S Tyupkin (Geophysical Center, RAS, Russia)

JWS33/E/17-B2 1400

REAL-TIME INTEGRATION OF SEISMIC DATA USING THE ANTELOPE SYSTEM

Danny J. HARVEY (Boulder Real Time Technologies, Inc., 2045 Broadway Str., Suite 400, Boulder, CO 80302, USA, email: danny@brtt.com); Frank L. Vernon (Boulder Real Time Technologies, Inc., 2045 Broadway Str., Suite 400, Boulder, CO 80302, USA, email: vernon@palapa.ucsd.edu)

Within the last several years, a new and effective real-time system for transporting and processing seismic data has been developed. This system, known as Antelope, makes it possible to integrate near real-time geophysical data from many diverse and geographically distributed data sources, over the Internet, into a complete real-time processing system. We will show how Antelope has been developed and how it has been used to create global scale "virtual" seismic networks composed of many different individual regional networks and single stations from other more traditional global networks. This has been accomplished with a minimal impact upon the operations of the station owners. In order to integrate real-time geophysical data flows, we make extensive use of both public and private Internet facilities and the standard TCP/IP communications protocols. We will show how Antelope provides important capabilities for geophysical data integration and data sharing that are relevant to all of the earth sciences.

JWS33/W/25-B2 1415

NEW WINDOWS-BASED SOFTWARE FOR GEOMAGNETIC OBSERVATORY DATA PROCESSING

D.C.HERZOG (USGS Box 25046, MS 966, Denver Federal Centre, Denver, Colorado 80225-0046, USA. Email: herzog@ghtmail.cr.usgs.gov)

The U.S. Geological Survey (USGS) has contracted with a commercial vendor to develop a new Windows-based application software program for processing geomagnetic observatory data. This graphical user interface (GUI) program provides a means for loading data from a variety of input formats; displaying it on-screen; deleting values with the aid of "blowup" sections of the plotted values; displaying the calibration baseline values and applying that data directly to the imported data values; and outputing the resulting data in a variety of file types, including the INTERMAGNET CD-ROM and WDC-A formats. The software provides "one-stop" processing capability and greatly improves the efficiency and flexibility with which observatory data can be processed.

JWS33/W/37-B2 1430

ANALOGUE MAGNETOGRAM SERVICE THROUGH INTERNET

Toshihiko IYEMORI, Masahiko Takeda and Toyohisa Kamei (WDC-C2 for Geomagnetism, Graduate School of Science, Kyoto University, Kyoto 606-8512, Japan, email: iyemori@kugi.kyoto-u.ac.jp, takeda@kugi.kyoto-u.ac.jp, toyo@kugi.kyoto-u.ac.jp); Akinori Saito, Yoshifumi Futaana and Tohru Araki (Geophysical Institute, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan, E-mail: saitoua@kugi.kyoto-u.ac.jp, futaana@kugi.kyoto-u.ac.jp, araki@kugi.kyoto-u.ac.jp)

In recent years, most of geomagnetic data are provided in digital form through Internet etc.. However, there still exist many observatories, which use analogue magnetometers. At the World Data Centers, there exists a huge archive of analogue magnetograms recorded on microfilms or printed annual reports, which cover for more than 100 years. Although number of the users of these analogue data is decreasing, there still exist considerable amount of data requests. When we investigate the old events before 1980 or some historical events such as the geomagnetic effects of comet Halley's encounter in 1910, we need to look at the analogue magnetograms. To use the analogue data recorded on microfilm, the user have to visit the data center or the staff at the center have to make hard copy of them and send by mail. Users often give-up to use the analogue data because of such procedure which takes time. To improve such situation, we are constructing a system to serve the image files of magnetograms from WWW. We report the method and quality of analogue magnetogram service through Internet and discuss on the problems and future possibility.

JWS33/W/01-B2 1445

THE RUSSIAN MAGNETIC OBSERVATORIES DATA ON CD-ROM

Alexander ZAITZEV and Vladimir Odintsov (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation,Troitsk, Moscow Region,142092, RUSSIA, e-mail: zaitzev@izmiran.rssi.ru)

Despite the general problems of the Russian science, the network of the magnetic observatories of Russia and CIS are still operated. As a rule, all observatories have own hardware and software systems and store an original records on sites which are inaccessible to a wide range of users. We propose to convert the all variational data of magnetic observatories in 1-min binary format and to save it on an optical disk (CD-ROM). In addition of data base production we propose to create the information system for automated data processing. The final CD-ROM we plan to install on Web server to organise a data access via INTERNET . It will allow the broad usage of the magnetic observatories data in the scientific and applied research programs. At the first stage for accommodation on CD-ROM we collect the results of the Moscow observatory data in the form of standard tables of hourly values and 1-min. variational data for period 1991-1998. The variational data was received on experimental digital station CMVS-6. The current observations in the form of variational data are displayed on site: http://www.izmiran.rssi.ru/magnetism/mos_data.htm. Beside Moscow data we have a regular 1-min. variational data from expedition site Cape Kamenny (Yamal peninsula), for Jan. 1991 - Sep. 1998, and Cape Schmidt (Chukotka region) observatory for 1995-1997. We call of all our colleagues on Russian magnetic observatories to help us collect the digital data, which might be available for period 1991 and onwards. In the final stage of the project we plan to make enough CD-ROM copies to supply of all scientists interested in Russian magnetic observatories data for period of 1991-1998. The work is supported by Russian Fund of Fundamental Researches Grant 98-07-90278.

JWS33/E/13-B2 1500

PRESENTATION OF THE GEOMAGNETIC DATA BASE OF THE NIEMEGK OBSERVATORY VIA INTERNET AND ITS ACCESS

Hans-Joachim LINTHE (GFZ Potsdam, Adolf-Schmidt-Observatory, Lindenstr. 7, D-14823 Niemegk, Germany, email: linthe@gfz-potsdam.de)

The Adolf-Schmidt-Observatory Niemegk is in continuous operation since 1890. So the observatory today manages a data series of nearly 110 years. Hourly, monthly and annual mean values are available in a database for the whole period. Additional minute mean values, instantaneous minute values, instantaneous second values and activity indices for longer or shorter periods are also contained in the database. The database is handled by means of the local area network of the observatory, which consists of several PCs, a workstation and software routines. The structure of the data, the data handling and the methods of data access will be presented.

JWS33/W/30-B2 1515

DATA CREATION USING THE SCF SYSTEM

CARRIE A. GONZALEZ (Instrumentation and Space Research Division, Southwest Research Institute, San Antonio, Texas 78228, e-mail: carrie@pemrac.space.swri.edu)

Many times in the space physics world there arises the need to derive different quantities based upon data parameters that are returned by one or more spacecraft. In some cases, these derived products may be dependent upon values returned from a single instrument; in other cases, the derived products are dependent upon values taken from many instruments. In either case, there is a need to specify data parameters and the algorithms necessary to produce derived data products. To fill this need, a domain specific system has been developed that allows for the definition of the new space data products from an homogeneous, spacecraft/instrument independent primary data format. This system, referred to as the SCF (Science Computation Formulation) software, utilizes a GUI-based definition session in which the user defines the input variables, the temporary variables and the output variables in addition to the actual set of mathematical operations to be performed on the data to produce the derived data products. The input variables are symbolic names given to the data parameters returned by the spacecraft. Temporary variables are symbolic names given to hold constant values (such as pi) or to hold intermediate results during the evaluation of the algorithm (such as the angle between the spacecraft velocity vector and the vector to the sun). Output variables are symbolic names given to the derived data products that are returned by the software. For the algorithm definition, the SCF software recognizes the standard mathematical operations of addition, subtraction, multiplication, and division. These operations are designed to operate on vector-vector, scalar-scalar, or vector-scalar quantities. In the SCF context, a scalar quantity is a single value and a vector quantity is a multi-value entity (an array of values). For the vector-vector operations, the lengths of the vectors must be the same. In addition to the standard mathematical operators, the SCF software supports standard mathematical functions such as square root, sine, cosine, and polynomial expansions to name a few. The SCF software also supports tensor data products. To date, the SCF mathematical library for matrix operations include addition, subtraction, and multiplication. There are functions that return the lower and upper triangular of a given matrix or an identity matrix of a specified order. The trace of a matrix, the transpose of a matrix, the determinant of a matrix and the inverse of a matrix are also supported functions within the SCF mathematical library. The definition of the derived data products is made once and then that information is stored. Realization of the new data …

EARTHQUAKES AND THEIR SPECTRAL ESTIMATIONS USING EINSTEIN DECONVOLUTION

Dan LOEWENTHAL, Raymond & Beverly Sackler (Faculty of Exact Sciences Department of Geophysics and Planetary Sciences and Tel Aviv University (Ramat Aviv 69978, Israel. email: danlo@jupiterl.tau.ac.il)

In a recently patented idea, I have conjectured the validity of dual fields theory, which teaches us how seismic or electromagnetic phenomena can be analysed to a much higher precision in comparison to a single field analysis.
In its acoustic embodiment these dual fields are the pressure and the particle velocities fields, as registered by hydrophones and geophones, respectively. This can be effectively done in ocean bottom environment. According to this theory both these fields are initiated by the same source. They both solve the same classical wave equation in regions of homogeneous layers but they differ and are nonlinearly coupled through the boundary conditions, where they possess opposite sign reflection coefficients. Since the source is common, it convolves both fields. Thus, its Green's function is estimated by the ratio of these fields defined through its Z transform polynomials. Using transform ratio of these two fields, a rational polynomial presentation of the system is attained, where the source wavelet cancels out. This allows deterministic spectral estimation similar to the maximum entropy or bayesian estimators. But

while the bayesian and maximum entroy estimators are of trial and error statistical approach, our source de-convolution, which is the essence of Einstein-Lorentz velocities additions-subtractions formula, is deterministic in nature.

JWS33/W/21-B2 1605

SEARCH INFORMATION RESOURCE IN THE FIELD OF OCEANOGRAPHY USING INTERNET

Evgeny D. Vyazilov and Valentine I.Ibragimova (Russian Research Institute of Hydrometeorological Information - World Data Center 6, Korolyov St., Obninsk, Kaluga region, 249020, Russia, e-mail: vjaz@meteo.ru)

An abundance of WEB sites created in INTERNET on oceanography as well as their volume make search and browse of the necessary data very difficult. A lot of servers already are provided with pages containing the list of hat links that are considered useful for the potential users. These addresses are often poorly classified and are not accompanied with information. The most well classified server is IOC WEB site. From viewpoint of search of different organizations' pages, involved in the ocean exploration, this is the best server. Unfortunately, information resources are not presented there. In some research directions the special pages are already created of a general character. Those pages present summaries on information resources in this or that country (e.g. Russian information resources in INTERNET) or separate scientific directions.
That is why there is a strong demand for creation a page for organizing a search of information resources in the field of oceanography. The structure of such a page is as follows: general address (publish house, libraries, magazines, councils, education, hot links, search of work, conferences, funds, plays and other); metadata (platforms, experts, databases, formats, projects, inventories and other); information on organizations (address, functions, projects, in which participate organization); information technology (GIS, software, satellite, ftp).

JWS 33/E/14-B2 1620

ELECTRONIC PUBLISHING ENVIRONMENT IN GEOPHYSICS

Vitaly NECHITAILENKO (Geophysical Center, Russian Academy of Sciences, 3 Molodezhnaya Str, Moscow 117296, RUSSIA, email: vitaly@wdcb.rssi.ru)

The paper will discuss the state-of-the-art of electronic publishing in geophysics and its nearest perspectives with the emphasis on technical issues, especially on creating an integrated environment for collecting and managing both data and results of their analysis.
The discussed EP environment (http://eos.wdcb.rssi.ru/) developed at Geophysical Center RAS includes a full set of technologies and tools for preparation of papers from manuscript to print and online versions, including online submissions, peer-review process, updating and revising papers, back- and forward referring, markup language conversion, hyperlinking based on automatic syntax analysis, and interface to data bases and interactive components.
The current EP technologies and tools, and those which will appear in the nearest years, produce strong influence on authors' and publishers', as well as data producers' and data managers', roles and vice versa. In this respect an emphasis will be given to hot and cool technologies and tools, a problem of their harmonization. Main elements of the paper are supported by online presentation.

Presiding Chair: V Gitis (Institute for Information Transmission Problems, RAS, Moscow, Russia)

JWS33/W/22-B2 Poster 1635-01

NETDC: A SYSTEM TO NETWORK SEISMOLOGICAL DATA CENTERS

Tim AHERN and Rob Casey (IRIS Data Management Center, 1408 NE 45th Street, #201, Seattle, WA 98105, USA, Email: tim@iris.washington.edu); Doug Neuhauser and Stephane Zuzlewski (475 McCone Hall, UC Berkeley, Berkeley, CA 94720, USA Email: doug@perry.berkeley.edu); Bernard Dost (ORFEUS Data Center, PO Box 201, 3730 AE De Bilt, the Netherlands, Email: dost@knmi.nl); Genevieve Roult (Institute de Physique du globe de Paris, Dept. de Sismologie, Programme GEOSCOPE, 4, Place Jussieu, 75252 Paris cedex 05, France, Email: groult@ipgp.jussieu.fr)

The Federation of Digital Broadband Seismographic Networks (FDSN) has implemented a system that supports data request processing for distributed data centers. The NETDC system allows users to make requests for various types of information to any of the participating data centers, independent of where the data actually reside.
The NETDC system manages the coordination of information requesting and information distribution between the data centers in a manner that is transparent to the seismological data requester. At the present time requests can be made for station inventories, channel response information, and for seismic waveform data. The system is easily extensible to other data types. Currently data centers in Seattle, Washington, Berkeley, California, deBilt, the Netherlans and Paris, France have installed this system. This presentation will summarize how the NETDC system works, what the present status of the system is and hopefully encourage other disciplines to consider a similar method for standardizing methods of coordinating a globally distributed system of data centers.

JWS33/W/34-B2 Poster 1635-02

ADVANCES IN CRYOSPHERIC DATA MANGEMENT

Roger G. BARRY, Ronald L. S. Weaver, Matthew Cross, Gregory Scharfen (National Snow and Ice Data Center, CIRES, Campus Box 449, University of Colorado Boulder, Colorado, 80309)

Over the past 10-15 years the National Snow and Ice Data Center (NSIDC) has played a pro-active role in cryospheric data management. Three themes illustrate the advances that have been made. (1) In the areas of new integrative products, three major CD-ROMs were produced. These comprise: the first global assembly of data and information on frozen ground and permafrost; the CAPS CD-ROM which contains digital maps of permafrost, numerous soil temperature and borehole data sets, a 12-language glossary, a cumulative bibliography and an inventory of Russian permafrost maps. A second example is the Polar Pathfinder Sampler CD-ROM that provides combined fields of IR/VIS AVHRR, passive microwave SSM/I and TOVS atmospheric sounder data in a common (Equal Area Scalable Earth Grid) geo-referenced system. A third product is an educational CD (Into the Arctic), designed for schools, using Greenland ice core climate data. (2) NSIDC has provided leadership in data set collection and dissemination through active collaboration with scientific societies and organizations. These include the IPA, the WGMS for glacier inventory data, CONMAP SCAR for the US National Antarctic Data Center for Antarctic metadata, the WMO Commission on Maritime Meteorology for the Global Sea Ice Data Bank and the International Antarctic Buoy Program (IABP). (3) NSIDC's participation in the GCOS TOPC and the IPA Working Group on Data and Information has helped stimulate the organization of a global monitoring network for ground temperature regime (the Circumpolar Active Layer Monitoring Program network), involving data protocols, site selection etc. at the national level. NSIDC's role in the US NSF ARCSS Data Management and the Antarctic Master Directory contributed to the development of NSF guidelines for investigators to submit data to Data Centers in a timely fashion.

DATA COLLECTION AND PROCESSING AT THE ISTITUTO NAZIONALE DI GEOFISICA DATA CENTER

L. BADIALI, F. Mele, R. Di Giovambattista and A. Basili (Istituto Nazionale di Geofisica, Via di Vigna Murata, 605, I-00143 Roma, Italy. E-mail: BADIALI@ingrm.it)

With the advent of Internet, there was an arise of the request for real time access to seismic data. In an effort to advance the Italian Telemetered Seismic Network (ITSN) we developed a new system for acquiring and processing digital and analog signals that makes extensive use of both standard internet TCP/IP communication protocol and international standard for data exchange. We identify 5 different levels of available information: (1) triggered or continuous seismic signals, (2) automatic picking of seismic phases, (3) automatic determination of earthquake location and magnitude, (4) locations reviewed by a human analyst for prompt alarm and (5) parameters reviewed and analysed by humans after integration with all the available data. Each level of information has its own distribution link.
Data are disseminated in two different ways: (1) the system sends data to a predefined list of targets as soon as they are available or (2) stores them on a server for distribution on request.

INCREASED DEMAND FOR RAPID ACCESS TO UK MAGNETIC OBSERVATORY DATA : IMPLICATIONS FOR QUALITY CONTROL PROCEDURES

Ellen CLARKE and Pamela White (both at Global Seismology and Geomagnetism Group, British Geological Survey, West Mains Road, Edinburgh, EH9 3LA, Scotland. e-mail: e.clarke@bgs.ac.uk)

The scientific and commercial demand for rapid access to UK magnetic observatory data has steadily increased over recent years, prompting the continued development of the data processing procedures and quality control standards. The modern user requirements for accurate as well as timely data has triggered the need for refined automatic quality control procedures. This paper discusses these procedures, highlighting the different user requirements in terms of level of accuracy and speed of dissemination of the data products.

DATA PROCESSING IN THE ARCTIC OCEAN DIGITAL BATHYMETRY MODEL

Elena DANIEL (All-Russia Research Institute for Geology and Mineral Resources of the World Ocean, 1, Angliysky pr., St.-Peterburg, 190121, Russia, email: dani@vniio.nw.ru)

A new computer model of the Arctic Ocean is made under the activity IOC/IASC/IHO project (Macnab & Grikurov, 1997) for building of an international digital bathymetric data base of the Arctic High Seas. The digital model (bathymetry presented as 10 x 10 km grid) is a first relies of the compilation of the various Russian and western bathymetry data. These data include initial observations, digital contours from published bathymetric maps, global data sets. The compilation has started with the collection, digitisation, formatting, editing, and adjustment of bathymetric data. The next step included building a coherent digital data base, gridding and production of computer derived bathymetric maps. The data were processed using common technological procedure for digital compilation of potential fields and other geophysical data. However there are some special items in coherence and gridding of bathymetric data due to higher variability of depth field in comparison with that of magnetic and gravity anomalies. Methods that provide with grid values calculations according to specific features of bottom topography (the existence of linearly extended features, complex mosaic relief, offshore zone, etc.) were used for the constructing of correct digital model. They improved the bathymetry model especially under conditions sparse data distribution in the Arctic Basin. The digital relief model will be distributed on CD-ROM as an ASCII-file containing grid values and as a graphic file that displays bathymetry, and, in addition, as printed maps at a scale of 1:6,000,000.

JWS33/E/03-B2 Poster 1635-06

POST-PROCESSING OF SEISMIC EVENTS RECORDED BY THE ISTITUTO NAZIONALE DI GEOFISICA SEISMOGRAPH NETWORK: AN ANALYSIS OF THE ACCURACY OF THE MAIN DISSEMINATED SEISMIC PARAMETERS

R. DI GIOVAMBATTISTA, F. Mele, A. Marchetti, L. Badiali, S. Baccheschi,P.Battelli, L. Giovani, G. Modica, L. Piccolini, F. Pirro, M. Pirro, R.Tardini and A. Basili (Istituto Nazionale di Geofisica, Via di Vigna Murata, 605, I-00143 Roma, Italy. email: digiovam@marte.ingrm.it)

Some of the most significant advances in seismology have resulted from analysis performed on the seismic parameters reported in the Bulletins and disseminated by the seismological data centers. A large fraction of works on travel time residuals and tomography has relied upon arrival times published by the bulletins. A precise estimate of the onset time of seismic phases is needed to obtain accurate event locations necessary for seismological studies of spatial patterns of earthquake hypocenters. To obtain very precise onset times for all seismic signals, seismological data center mostly rely on the picks provided by their human analysts. However, the increase in the number of analysts and the quality of arrivals reported in bulletins has also been debated. We present the results of an analysis aimed to estimate the quality of phase arrivals. A comparison between the arrival times reported in the Istituto Nazionale di Geofisica (ING) bulletins and those retimed in an effort to obtain accurate pickings for a tomographic study is also presented.

GIS TOOLS TO STRUCTURE THE CENTRAL ANDES ON A REGIONAL SCALE

H.-J. GOETZE and S. Mohr (FU Berlin, Institut fuer Geologie, Geophysik und Geoinformatik, Malteserstr. 74-100, D-12249 Berlin, Germany, email: hajo@geophysik.fu-berlin.de)

For the last ten years the Central Andes fold belt is focus of scientific investigations conducted within the frame of the "Collaborative Research Center 267 -- Deformation Processes in the Andes". Over the years a wealth of data from various disciplines of geosciences has been compiled. To handle this information, and to support an interdisciplinary and international cooperation among involved scientists, the establishment, organization and maintenance of a diversified GIS was necessary, and a data catalogue was set up, which is available on the Web under URL: http://userpage.fu-berlin.de/~data.
Application of GIS methods allows structuring of the remote mountainous region of the Central Andes on a regional scale, which is generally marked by a lack of infrastructure and by topographic extremes. Numeric procedures, such as statistical methods, filter techniques or

algorithms of lineament recognition are applied. For example the evaluation and interpretation of geomorphometric data is suited to identify various morpho-structural units of the Andean topography. Investigations of the intensity and direction of inclination and characterization of vertical doming allow to outline the regional strike and identify predominant structural directions. Lineaments, derived from data of topography and gravity grids with objective methods such as algorithms of edge detection or horizontal gradient recognition, which are only in part suitable for correlation with geological data, can also be used for an identification of the structuring of areas under investigation. Investigations of the fractal geometry of contour lines in areal portions warrant a subdivision into morphologically weak and strong structured regions, and reflect the different climatic conditions at the western continental margin of South America.

EXPORTING IDFS-FORMATTED DATA TO CDF AND NETCDF FORMATS

Carrie A. GONZALEZ (Instrumentation and Space Research Division, Southwest Research Institute, San Antonio, Texas 78228, e-mail: carrie@pemrac.space.swri.edu)

Southwest Research Institute has developed a data storage format referred to as the Instrument Description File System (IDFS) format. The IDFS format is a data storage format that is designed to be general enough to handle the majority of spacecraft science and engineering data sets. These data sets include raw telemetry, processed data, simulation data and theoretical data. The IDFS paradigm performs a real-time conversion of telemetry data into physical units as the data is accessed. This approach allows for the refinement of calibration factors and processing algorithms without having to reprocess the original data set and avoids the storage of many different unit values. A small core of generic routines services the IDFS format. This covers access of the individual data files through a distributed database, positioning within the data file based on time, access of the data and the real-time conversion of the data to physical units.
Recognising the popularity of the CDF and netCDF file formats, Southwest Research Institute has developed software that extracts and exports data that has been stored in the IDFS format. Currently, IDFS data can be exported to one of three file formats:
(1) Common Data Format (CDF version 2.6)
(2) Unidata Network Common Data Form (netCDF version 2.4)
(3) IDFS - ASCII dump
When the CDF file format is selected, a CDF file is created which contains the requested data parameters and meta data. The meta data is comprised of global-scope attributes that provide information about the data set as an entity. Some of the required global attributes have been selected for potential modification by the user.

DATA PROCESSING AND PRODUCTS AT THE GERMAN SEISMOLOGICAL DATA CENTER

Gernot HARTMANN (Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany, Email: hart@sdac.hannover.bgr.de)

The German Seismological Data Center operates the seismic GERESS array of 25 stations and is responsible for the collection of data from the German Regional Seismic Network (GRSN). This network consists of 13 three-component broadband stations distributed throughout Germany. Real-time data from the GERESS array are recorded continuously at the Data Center. The data from the GRSN stations are automatically retrieved at the end of each day. A seismic alert system provides for rapid epicenter determination of strong events in Germany and adjacent areas. Triggered by a detection algorithm applied to the data of the GERESS array, time segments of the assumed event are retrieved from the GRSN stations for confirmation of the detection and improvement of the epicenter and magnitude determination. The continuously recorded data, as well as the data segments of strong events, are stored on a RAID system until they are archived on CDRs in two jukeboxes with 500 CDs each. This technique provides immediate access to all data, either interactively or by autoDRM via e-mail. This data forms the basis for routine analysis, which includes several newly developed automated procedures:
(1) event detection, location, and epicenter determination;
(2) testing of the reliability of the results by several consistency checks;
(3) screening out explosions from well known quarries and mines.
The interactive analysis of these predefined events ensures the high quality of the determined event parameters, stored in a database management system. The results of automatic and interactive data analysis are published on the homepage of the Data Center. A monthly catalogue of local and regional events is produced by including associated epicenter determinations and phase readings reported from a number of local networks in Germany. A compilation of this catalogue data is published annually as the German Earthquake Data Catalogue. The data processing schemes and their interaction are presented in the poster.

THE SOUTHERN CALIFORNIA EARTHQUAKE CENTER DATA CENTER (SCEC-DC)

K. HAFNER, R. W. Clayton (Seismological Laboratory, Caltech,California)

The SCEC-DC is the principal archive for seismological waveform and associated parametric data from the Southern California Seismic Network (SCSN). Established in the fall of 1991, the SCEC-DC is now entering a major period of transition. In addition to expanding its archive from a 0.6 Tbyte to a 5 Tbyte WORM mass storage system, the SCEC-DC is developing a new database/archiving system. This system will result in a more interdependent relationship between the SCEC-DC and the real-time data collection/data analysis systems of the SCSN. The system under development has three primary missions: 1) provide rapid access to real-time parametric and waveform earthquake data, 2) consolidate and maintain one oritative database available to the real-time data acquisition systems, the data analysts and the archive facility; and 3) facilitate a seamless exchange of seismological waveform and parametric data with other seismological data centers. In our system, the real-time data collection system populates a local database with parametric earthquake data. This data is "replicated" to a database on the SCEC-DC, where it is accessible within a few minutes of an event. Data analysts interact with and update the database via a java GUI interface, while other users of the data access the database via WWW interfaces on various internet and intranet sites. These interfaces will allow users to search and extract from the earthquake hypocenter and phase catalogs, view and request calibrated waveforms, and view such products as Shakemaps. Once this database comes on-line, it will provide "real-time access" for an average of 26,000 earthquakes/year, in addition to storing the ~400,000 events in the historical Southern California earthquake catalog.

WEB EFFECTS: FRONTIERS IN INFORMATION DELIVERY

Allen M. HITTELMAN and Susan J. McLean (NOAA's National Geophysical Data Center, World Data Center for Solid Earth Geophysics, 325 Broadway, Boulder, CO 80303, U. S. A., email: ahittelman@ngdc.noaa.gov)

Without question, one of the most profound impacts on information technology is the advent of the Web. In just a few years, this media has drastically altered our perceptions of information services and created new paradigms for data dissemination. To cope with this unprecedented explosion of change, many of us in the information service business had to re-evaluate organisational goals and objectives. Where once we felt comfortable with our awareness of user needs, now we fell distant due to the impersonal nature of our Web sites (which seem to serve 99% of our scientific clientele's needs).
The National Geophysical Data Center, and its several supported World Data Centers, has pioneered many new innovative methods that enrich data and information delivery on the Web. Examples of these techniques include: the interactive creation of graphical spreadsheets (see http://swat.ngdc.noaa.gov/cgi-bin/wist/wist.pl), the satellite browse, display and download features of the Space Physics Interactive Data Resource (SPIDR, see http://julius.ngdc.noaa.gov:8080/) and access to gridded relief models (see http://www.ngdc.noaa.gov/seg/topo/globe.shtml). Newer techniques are empowering users with the ability to access data and metadata through GIS-enabled Web servers. We have also explored data mining tools to provide improved understandings of the needs of our Web users -- from where do they come and for what do they search?

JWS33/E/06-B2 Poster **1635-12**

HIGH-CAPACITY NETWORKING TECHNOLOGY FOR PROCESSING OF THE EARTH'S VIBRATIONAL SOUNDING DATA

M.S.KHAIRETDINOV, Yu.I.Rodionov, A.P.Grigoryuk, L.G.Dvoretskaya, G.F.Sedukhina. (Institute of Computational Mathematics and Mathematical Geophysics, Siberian Branch, Russian Academy of Sciences.); M.S.Sevastianov, R.V.Radygin. (Novosibirsk State Technical University. Russia, Novosibirsk.)

The method of deep vibroseismic sounding of the Earth, because of its high resolution and high accuracy of measurement, has considerable promise for solution of a number of urgent seismological problems. In the first place, these are: problems of monitoring of seismic-prone zones, seismic tomography, precise calibration of traces of seismic wave propagation, etc. Solution of these problems is connected with recording and processing of a large bulk of data, whose capacity can be estimated as N=Fd*p*M*L*T, where Fd is the sampling rate of input signal values, p is word length of sampling values, M is the number of recording channels, L is the number of repeating sounding performances, T is duration of each performance. Selection of the parameters L and T determines the noise immunity of vibroseismograms. As applied to solution of the problems in question, for example, to vibromonitoring of seismic-prone zones, an area of 1000 kmx1000 km, the capacity of accumulated information can reach about 100Gb. In order to handle such a large amount of information, the authors have developed a network technology of data processing, which consists of two levels. The lower level of processing is connected to data gathering stations and contains the software for recording and accumulation of initial data with their simultaneous processing, in the first place, calculation vibroseismograms (correlograms) and evaluation of their primary parameters of each of M channels in the real-time mode in the course of experiment. Because of the latter, the information is M*T/Ts times compressed, where Ts is duration of a vibrocorrelogram. In particular, at M=500, T=3600sec, Ts=150sec, the compression makes about 1000 times, which allows us to essentially decrease the requirements on the channels rate of data transmission to the processing system of the upper level. At the upper level of the system, additional processing of seismograms is implemented…

THE METHOD OF THE ANALYTICAL AND NUMERAL DESCRIPTION OF THE GEOMAGNETIC FIELD'S GRADIENTS FOR ITS USING TO SOLVE THE GEOLOGICAL AND NAVIGATION PROBLEMS

Valentina I. KOLESOVA, Maria A. Effendieva and Sergey V. Hotin (St.-Petersburg filial, Institute of Terrestrial Magnetism, Ionosphere and Radiowave Propagation, Muchnoy per.2, box 188, 191023, St.-Petersburg, Russia, Email: kmp@telecom.lek.ru)

The gradients of the geomagnetic field can be successfully used to investigate the physical processes at the Earth and in the space, to solve scientific and applied problems in the geology and the navigation. Now in general case geomagnetic gradients can be received only by calculation. It was supposed to consider the value of the magnetic field in any point of the space to be the sum of the four components: the main field, the intermediate anomalies field, the regional field and the local field. The gradients of the main field are described the best of all by the Gaussian series. The construction of the fictitious dipole sources approximate the intermediate anomalies. The geometrical parameters of the construction are determined previously at the base of the space spectral analysis. The gradients of regional and local anomalies are calculated using the Poisson's integral. For the essential decreasing of the calculation time and increasing of the result accuracy it was offered to approximate the field by quadratic function at the range of the elementary grid. Then the integral can be calculated analytically in the quadratures using the formula of the highest algebraic accuracy. The method of the magnetic gradients calculation was realised in algorithms and programs, the last were included in the system, which guarantee the functioning of the database. The system gives the opportunity to digitise graphs, maps of graphs, maps of isolines; to include data in the database, to control data, to do the data processing, to create analytical and numeral geomagnetic field models, numeral and graphical charts, to visualise the information.

ABOUT EARTH'S FREE OSCILLATIONS IN THE FORM OF TILTS AND STRAINS

Ludmila LATYNINA, Aleksei Ljubushin, Denis Vvedensky (United Institute of Physics of the Earth, RAS, B.Gruzinskay,10 , Moscow Russia, 123186 email: lat@uipe-ras.scgis.ru, Fax (095) 2556040

Data of oscillations within the periods of 2 minutes to 2 hours have been obtained at Protvino observatory near Moscow with help of strainmeters and tiltmeters. The recording computer with16-bit ADC keeps records with resolution equal to 0.1E-09. We consider the Earth free oscillations of last strong Earthquakes and the results of spectral analysis of the observational data during several months. Continuous noticeable oscillations have been observed at the same frequencies (between 3 and 8 mHz) as in works by T.Tanimoto and others and by N.Suda and others (1998). The attempts of long-periodic wave forerunners discovering before strong Earthquakes have been made.

JWS33/W/17-B2 Poster **1635-17**

USAGE OF MODERN METHODS OF REFERENCE OCEANOGRAPHIC DATA ORGANISATION

Igor LEBEDEV, Ludmila Kuznetsova (All-Russian Research Institute of Hydrometeorological Information - World Data Center (RIHMI-WDC), department National Center Oceanographic Data of Russia, 6, Korolyova st., Obninsk, Kaluga region, 249020, Russian Federation; Tel: (7)(08439) 74676; Fax: (7)(095) 2552225; email: lebedev@meteo.ru)

In early 80s Oceanographic Data Centre of Russia pioneered the creation of reference information base on oceanographic data. Since then information base had been used on RV cruises, research projects (programmes), observing platforms, marine institutions and agencies, etc. At the moment reference information data are organised in dbf-tables and are applied under control of DBMS Microsoft FoxPro 2.0. These data are used for obtaining various kinds of reports and references as well as working with observation data.
But there are also a number of drawbacks. These are errors in organising some tables, which are not associated with each other; poor automatization in work with reference data. The need is now obvious for organising reference information into unified database under modern DBMS control that enables one to apply the architecture of client/server computing and the distributed data processing. Besides, a demand arose in publication of some certain reference data on Web. Similar work is already being performed in some data centres /abroad.
Some time ago realisation of such a database was started in Oceanographic Data Centre. Oracle8 is used as the DBMS, meeting all the requirements needed. The development of database and its pilot loading has been performed by the present moment. The work is currently underway on refinements of the database structure; working out additional requirements of the final loading of all data as well as development and creation of the client applications.

DISSEMINATING AEROMAGNETIC DATA ON THE WEB

Susan Mclean (World Data Centre, email: smclean@ngdc.noaa.gov)

The National Geophysical Data Center (NGDC) is undertaking a pilot study to make critical aeromagnetic data sets available via the WWW. The project's goal is to address problems of multiple grid formats, large file size and regionally distributed data. One significant problem when distributing data via the WWW is the potential separation of associated metadata. Proper recognition of the organization or institution that originally collected the data and any value added processes that contributed to the present version of the data set must be retained. A pilot system to access aeromagnetic data via the WWW will be demonstrated by NGDC. The ESRI Spatial Data Engine (SDE) and Oracle database are the heart of the web site. Using these tools, we enable a GIS expert system with dissemination via FTP on-line or CD-R and DVD-R for off-line delivery. In many cases, higher resolution data sets exist. In these circumstances, we provide the proper links and contact information to the original organization. If the large file size presents a data transfer problem, we offer an alternate off-line data distribution method using CD-R or DVD-R.

COMPUTER SYSTEM OF KEEPING, PROCESSING AND ANALYSIS OF GEOMAGNETIC DATA

Oleg MIKHEEV and Pyotr Djadkov (Institute of Geophysics, av. Acad. Koptyug, 3, Novosibirsk, 630090, Russia, E-mail: oamih@uiggm.nsc.ru)

Modern development of the geomagnetic instruments is characterized by high accuracy and possibility of digital registration of continuous observations carried out both geomagnetic observatories and stations on different geophysical polygons. Necessity of realisation of modern instrumental possibilities requires a special computer system which allow to operating and suitable performance of the data. Such a system is elaborated now under IDE "Delphi 3" onWindows95 platform. It has several basic aims: 1) maintenance of reliable keeping and initial processing of large data arrays; 2) getting high quality authentic information as result of using special algorithms for elimination of outliners and different artificial and natural geomagnetic noises; 3) opportunities and techniques for detailed special analysis of information. As core for the database access system is using the integrated system - Borland Database Engine. The basic data format is the native dBaseIV-format in which digital primary data are converted by original software. On a contemporary stage the system is interpreted as local database, but afterwards its way can be extended to Intranet/Internet data-access technology. The system is under evaluation on the Baikal geodynamic polygon, where at present time the high-precise observations (up to 0.05 nT) are carried out in a several stations and geomagnetic observatory "Enhaluk".

ESTIMATION OF POTENTIAL SEISMIC RISK AREAS BY GIS AND ITS ROLE IN CITY PLANNING - A CASE STUDY

Naside OZER, Demir Kolcak, Oguz Gundogdu, Yildiz Altinok (all at Department of Geophysical Engineering, Faculty of Engineering, University of Istanbul, Avcilar, 34850, Istanbul, Turkey, Email: naside@istanbul.edu.tr), Recep Cakir and S.Shelton Alexander (both at Department of Geosciences, The Pennsylvania State University, 308 Deike Building, University Park, PA 16802, USA, Email: recep@essc.psu.edu)

A Geographical Information System(GIS) is a data-based Information System that facilitates the integration and joint analysis and interpretation of almost any kinds of spatial data, including maps, aerial photographs, lines and points. It can be used for planning and design, decision making, research and archiving by the central and local governments or by individual groups.
GIS-based investigations are at a very early stage in Turkey and therefore it is necessary to carry out some pilot studies for testing purposes and to gain experince in the use of GIS methodology.
GIS applications explicitly depend on the collection of available spatial data that are relevant to the application. The initial focus for seismic risk applications should be ann important places where there exist sufficient data and information from geophysical, geological, and geodetic studies carried out through previous and ongoing national and international projects.
After conversion of the data collected to digital form, GIS utilities(ARC/INFO, ARCVIEW etc.) were used for integration and analysis of data sets to investigate different scenarios relating to hazard and risk for people and infrastructure in populated areas.
Integration of those data and preparing the scenario will offer a knowledge database for contemporary city planning and for central and local governments and private organisations to make informed decisions.

RESTORATION OF SPACE PARTICLE DATA COLLECTIONS

Nickolay N. PAVLOV, Nickolay N. Kontor and Elmar N. Sosnovets (Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119899, Russia, email: nnpavlov@taspd.npi.msu.su)

Since 1965, Theoretical and Applied Space Physics Division, Institute of Nuclear Physics, Moscow State University carries out monitoring of charged particles in space with use of Russian far spacecraft and satellites. Significant part of the data from old missions is stored only on paper, many data sets have been saved due to special issues published by the WDC-B. The data sets from both paper and old tapes needed to be restored and transferred to the modern computer media. This work has been supported by NASA, grant NAG5-4656. Useful collaboration with NSSDC has also made this project realisable.
Assuming that similar projects are being currently launched by many research groups for the sake of utilisation of the benefits of the new Internet era we would like to share our experience in typical problems, common approaches and software tools used in our work. The main goal is to make the collection living and publicly accessible via Internet. Such issues as data input, data formats, file structure, use of database system, IDL, Java are concerned here. Interactive graphic rectification of raw data sets and creation of the proper documentation are highlighted as the most important for the solving of a key problem of data quality. A simple method of improving the ability of navigation within a multi-spacecraft data collection based on a plain ftp is discussed as well as our approaches to the effective graphic access to the data. Attaching of some simple tools for remote data analysis to the user interface is also considered as a way to make the services more attractive and useful.

DATA COLLECTION, PROCESSING AND DISTRIBUTION FOR THE NASA TIMED MISSION'S GLOBAL ULTRAVIOLET IMAGER (GUVI)

Larry J. PAXTON (240 228 6871; email: larry.paxton@jhuapl.edu); Michele Weiss (240 228 4806; email: michele.weiss@jhuapl.edu); Rob Barnes (240 228 8134; robin.barnes@jhuapl.edu); Sanae Kubota (240 228 8404; email: sanae.kubota@jhuapl.edu); Rosalyn Pham (240 228 8587; email: rosalyn.pham@jhuapl.edu); Ching-I. Meng (240 228 5409; email: ching.meng@jhuapl.edu) At The Johns Hopkins University Applied Physics Laboratory 11100 Johns Hopkins Rd., Laurel, MD 20723, United States; Andrew Christensen (310 336 7084; email: Andrew.B.Christensen@aero.org) The Aerospace Corporation Space and Environment Technology Center P.O. Box 92957 Los Angeles, CA 90009

The Global Ultraviolet Imager (GUVI) is one of four instruments that on the NASA Thermosphere Ionosphere Mesosphere Energetics and Dynamics (TIMED) spacecraft, the first mission of the NASA Solar Connections program. TIMED, which is scheduled for a May 18, 2000 launch, will be used to study the energetics and dynamics of the mesosphere and lower thermosphere. The focus of the TIMED mission is the processes occurring between altitudes of 60 to 180 kilometers. The other instruments that are a part of the TIMED mission are the Solar EUV Experiment (SEE), the TIMED Doppler Interferometer (TIDI), and SABER (Sounding of the Atmosphere Using Broadband Emission Radiometry). GUVI is a far-ultraviolet (115 to 180 nm) scanning imaging spectrograph that provides horizon-to-horizon images in five selectable wavelength intervals or "colors." These colors (HI 121.6 nm, OI 130.4 nm, OI 135.6 nm, and N2 Lyman-Birge-Hopfield bands 140 to 150 nm and 165 to 180 nm) are chosen in order to produce the GUVI key parameters. These key parameters are produced on a routine basis and will be available via the internet. GUVI supports the TIMED science objectives and will:
1) Determine the spatial and temporal variations of constituent number densities and temperature in the thermosphere.
2) Determine the relative importance of auroral inputs, Joule heating, and solar EUV for the thermal structure of the lower thermosphere.
Each day GUVI produces 88 MB of raw data which must be processed, vetted, and available for distribution within a day of receipt. This requires the introduction of a rather large amount of software capable of automated processing (about 100,000 lines). In addition there is a graphical user interface, written in Java, that allows users to browse and manipulate the data products locallly or over the Internet. GUVI data products and graphical user interface are available at: http://sd-www.jhuapl.edu/TIMED/GUVI/ and http://www.aero.org/GUVI/ . These sites document the GUVI project and provide details of the instrument and are the means for accessing the data.
These activities will be demonstrated and discussed.

DESIGN AND OPERATION OF GEOSCIENTIFIC CLEARINGHOUSES AT THE GFZ POTSDAM

Bernd RITSCHEL (GFZ Potsdam, Data and Computing Center, 14473 Potsdam, Telegrafenberg A3, email: rit@gfz-potsdam.de)

IA

The usage of clearinghouse techniques are a state of the art way to disseminate the digital geoscientic data as well as the information or metadata about the data. A geoscientific clearinghouse consists of a relational database server, a web server and application software for retrieval, presentation and download of data. The client side only needs an internet browser to get access to the clearinghouse features. Metadata are necessary for the operation of clearinghouses. Often the relationships between data and belonging metadata are lost or the metadata itself don't exist. To create form the start a scientific product always as set of a data and a metadata file is an easy way to keep together both digital data and metadata. The product metadata existing as extended DIF documents will be extracted and pumped into a relational database as well as stored as text files together with the data files in a product archive. The extended DIF file contains all attributes are necessary for an aimed und successful geoscientific product retrieval. For the connection of different clearinghouses Z39.50 interfaces and servers are used.

DATABASE OF THE PACIFIC LITHOSPHERE DIGITAL MODELS FROM GEOTRAVERSES

A.G. RODNIKOV, N.A.Sergeeva, M.V.Rodkin, L.P.Zabarinskaya (Geophysical Center, Russian Academy of the Sciences, Molodezhnaya 3, 117296 Moscow, Russia, email: rodnikov@wdcb.rssi.ru); (P.A.Stroev Sternberg State Astronomical Institute, Moscow State University, 117296 Moscow, Russia); V.A.Rashidov(Institute of volcanic geology and geochemistry, Petropavlovsk-Kamchatski, Russia)

Within the framework of the Geotraverse Project, a geological/geophysical deep-cross sections of the lithosphere and asthenosphere in the transition zone from Asian continent to the Pacific Ocean has been constructed. A set of bathymetric, magnetic, gravity and geological maps of the area has been made also. The purpose of the research is to study the deep structure of the region having in mind it's connection with formation of sedimentary basins, seismic zones, and sea bottom minerageny. Primary geological and geophysical data were collected. The database includes now bathymetric data, gravimetric and magnetic surveys data, heat flow measurements, deep seismic sounding data, catalog of earthquakes, information about magnetic linear anomalies and faults, data on deep structure of the lithosphere and asthenosphere, geological and geophysical data from sea bottom boreholes, and data on sea bottom minerageny. AutoCAD-14 was used for digitizing of graphic images and Surfer32 was used for maps compiling from the primary data. Address of our homepage in Internet is http:/www.wdcb.rssi.ru/GCRAS/traverse.html. The database will include the Okhotsk Sea Geotraverse, the Japan Sea Geotraverse and the Philippine Sea Geotraverse. Now the data on the Philippine Sea Geotraverse and a few maps of the area are presented in Internet only. The Project is sponsored by Russian Foundation for Basic Researches, grant N 98-07-90201.

AN ON-LINE ACCESS SYSTEM FOR THE TRMM DATA

Hualan RUI (Distributed Active Archive Center, NASA/Goddard Space Flight Center, Greenbelt, MD 20770, email: rui@daac.gsfc.nasa.gov)

The Tropical Rainfall Measuring Mission (TRMM), jointly sponsored by the National Aeronautics and Space Administration (NASA) of United States and the National Space Development Agency (NASDA) of Japan, provides visible, infrared, and microwave observations of tropical and subtropical rain system. TRMM satellite was launched on November 27, 1997(EST). Data from TRMM are being archived, processed, and disseminated by Distributed Active Archive Center (DAAC) at the Goddard Space Flight Center (GSFC) of NASA. An online system or user interface is designed for easy, friendly, and quick display and access of the TRMM data. Components, features, and limitations of the system will be demonstrated. The TRMM standard products and variety of the subsets will be shown and their availability will be discussed.

INTERACTIVE POTENTIAL FIELD MODELLING AND INTEGRATION OF CONSTRAINING DATA BY IOGIS

S. SCHMIDT and H.-J. Goetze (FU Berlin, Institut fuer Geologie, Geophysik und Geoinformatik, Malteserstr. 74-100, D-12249 Berlin, Germany, email: sabine@geophysik.fu-berlin.de); R. Seidemann and A. Siehl (University Bonn, Geologisches Institut, Nussallee 8, D-53115 Bonn); A.B. Cremers, M. Breunig and S. Shumilov (University Bonn, Roemerstr. 164, D-53117 Bonn)

Three-dimensional (3-D) interactive modelling permits an integrated processing and interpretation of geoid, gravity and magnetic fields, yielding an improved geological interpretation. Generally these 3-D models are constructed by triangulated polyhedra with constant density and/or induced and remanent susceptibility. Interactive modifications of model parameters (model coordinates, rock density and susceptibility), access to the numerical modelling process and direct visualization of both, calculated and measured fields of gravity and magnetics, enable the interpreter to design the model as realistic as possible. An approach is described to integrate constraining data into the interactive modelling process by means of visualization and combination of independent data and information together with the density/susceptibility model. This visual combination of 2- and 3-D models (e.g. from seismic reflection or refraction surveys) enables a quantitative comparison and adjustment by the interpreter, and results in a model comprising as much independently derived information as possible. The definition of 'geo-objects', which link geoscientific vocabulary with geometrical elements of the model, provides a comfort environment for interpretations. The modelling method is embedded in an Interoperable Geoinformation System (IOGIS) which uses new object-oriented database management technique. As an example we show results from the southern Northwest German Basin.

DEKORP'S SEISMIC DATA IN THE INTERNET

Christian SEEGRAEF, (Lutz Lesch GeoForschungsZentrum Potsdam, email: seegraef@gfz-potsdam.)

At the GFZ Potsdam a working group was established in 1998 to prepare, archive, and protect seismic data sets, which were originally recorded on common _ inch magnetic tapes, on modern storage media and provide them to the public and scientific community. This is achieved by the establishment of an online-available database. Seismic data in different processing stages (from the field tape to the final line-drawing) will be available for all collected surveys in trace as well as in graphical format together with related information such as coordinate tables, maps, geological interpretations, etc. Final results, such as migrated, depth-converted sections or line-drawings, are kept on a FTP-server for interested users. In addition a possibility should be managed to command data records online and receive them in the form of a CD-ROM. The prime aim is to provide a catalogue-like structure with download-facility using the modern information technologies that are or will be available in the near future.

GIS-BASED ANALYSIS FOR GEOPHYSICAL EXPLORATIONS: IMPROVING POSITIONAL AND ATTRIBUTE DATA MANAGEMENT

SHYLLON E. A., Olaleye J. B and Olunloyo V. O. S (Geoinformatics Laboratory, Faculty of Engineering, University of Lagos, Lagos, Nigeria.)

In a geophysical exploration, the position and attribute of subsurface features are defined using Two-Way-Travel (TWT) time(s) which are interpreted from 3D & 4D reflection seismology or other techniques such as refraction seismology, magnetic, gravity, etc. As a consequence, data management becomes a major task. Then faster means of analyzing and integrating the data sets, and presenting the results are required. A GIS is the means of achieving this for all geospatial data.
The GIS database takes a great variety of explorations geophysical data. In this paper, they are categorized and of many types. The categories distinguish seismic lines and shot points, Magnetic (Geomagnetism and Aeromagnetism), gravity, well log, etc. The data types distinguish such as stratified points samples, interpolated surfaces, etc.
The exploration geophysical data require careful preparation before input into the GIS database. This paper will treat advance data structuring technique of such complex data with position and highly dynamic attributes.It will discuss georeferencing of exploration geophysical data to the Earth system of coordinates; which must be accurate particularly if the results of international and national geophysical observations are to be integrated.
This GIS-based-analysis is a faster means of analyzing these data sets from various sources, and presentation of results to international and national geophysical communities.

A SPACEBASED OCEAN SURFACE EXCHANGE DATA ANALYSIS SYSTEM

Wenqing TANG and W. Timothy Liu (Jet Propulsion Laboratory, Caltech,
email: wqt@pacific.jpl.nasa.gov)

Emerging technologies have provided unprecedented opportunities to transform information into knowledge and disseminate them in a much faster, cheaper, and user-friendly mode. We have set up a system to produce and disseminate high level (gridded) ocean surface wind data from the NASA Scatterometer and European Remote Sensing missions. The data system is being expanded to produce real-time gridded ocean surface winds from an improved sensor SeaWinds on the Quikscat Mission. The wind field will be combined with hydrologic parameters from the Tropical Rain Measuring Mission to monitor evolving weather systems and natural hazard in real time. It will form the basis for spacebased Ocean Surface Exchange Data Analysis System (SOSEDAS) which will include the production of ocean surface momentum, heat, and water fluxes needed for interdisciplinary studies of ocean-atmosphere interaction.
Various commercial or non-commercial software tools have been compared and selected in terms of their ability in database management, remote data accessing, graphical interface, data quality, storage needs and transfer speed, etc. Issues regarding system security and user authentication, distributed data archiving and accessing, strategy to compress large-volume geophysical and satellite data/image. and increasing transferring speed are being addressed. A simple and easy way to access information and derive knowledge from spacebased data of multiple missions is being provided. The evolving 'knowledge system' will provide relevant infrastructure to address Earth SystemScience, make inroads in educating an informed populace, and illuminate decision and policy making.

GEOPHYSICAL METADATA SYSTEM OF SLOVENIA

Bojan URAN (Geophysical Survey of Slovenia, Kersnikova 3, 1000 Ljubljana, Slovenia, email: bojan.uran@gov.si); Marjeta Car and Robert Stopar (Institute for Geology, Geotechnics and Geophysics, Dimi eva 14, 1000 Ljubljana, Slovenia, email: mcar@i-ggg.si, rstopar@i-ggg.si)

Geophysical investigations in Slovenia have a long tradition, but until recently we have not got a systematic overview on them. We started to collect data about geophysical investigations in Slovenia from different sources and organised them in a metadata system. The structure of the metadata follows European draft standard for georefered data, so it is easy to combine and correlate our data with geodetic and geologic data as separate layers inside the GIS system. The role of metadata is very important if we want to join data from different sources. It contains basic information of the dataset, its quality and availability. We added also data about geophysical methodology used, aim and scope of the investigations, investor(s), site location, keywords, accessibility of data, short abstract of the results etc. A lot of work and special attention has been paid to critical evaluation of the quality of the observed data and to the harmonised and consistent keyword system. The role of the latter is the possibility of quick and effective searching of data. Additionally, the gravity, geomagnetic, geothermal and geoelectrical resistivity maps have been added. The organisation of information system allows us to use for different purposes. On one hand, it as a metadata system with public access over the Internet. It uses three tier architecture, connecting user with web browser to WWW and database server. On the other hand, it is a full database system, including also raw data, for storage, processing and presentation of data with the GIS tools in an intranet inside the institution.

JWS33/W/24-B2 Poster **1635-31**

EVIDENCE FOR MULTIFRACTAL SCALING FROM GEOMAGNETIC DATA

Zoltan VOROS (Geophysical Institute SAS, Komarnanska, 947 01 Hurbanovo, Slovak Republik, email: geomag@geomag.sk); Peter Kovacs and Arpad Juhasz (Eotvos Lorand Geophysical Institute, Budapest, Columbus u. 17-23, Hungary, email: kovacs@elgi.hu)

The question of the higher order statistical analysis of geomagnetic data is propounded. Evidences for multifractal scaling laws describing scale-invariant statistical properties of "geomagnetic turbulence" are presented. The multifractal probability measure constructed from geomagnetic data proved to be singular and distributed on fractal support. The existence of multifractal structure in geomagnetic data is the signature of nonhomogeneous, intermittent energy transfer within the solar wind - magnetosphere - ionosphere system.

JWS33/W/33-B2 Poster **1635-32**

POLAR PATHFINDER DATA SAMPLER: NEW DATA FORMATS FOR INTEGRATIVE SCIENCE

Ronald L. S. WEAVER, L Cheshire, R Hauser, M Meshek, M Marquis, and A Varani, (National Snow and Ice Data Center [NSIDC], CIRES, Campus Box 449, University of Colorado Boulder, Colorado, 80309); Siri Jodha Singh Khalsa, (Steven Myers and Associates, Space Science and Engineering Division, 9315 Largo Drive West, Largo, MD, 20774)

Impediments to the cross-disciplinary use of remote sensing data are the complexities of data formats, lack of common geographic and temporal referencing systems, and consistent timeseries over the course of a sensor's lifetime. In order to break down some of these barriers specifically found in polar-related remote sensing data, the NOAA-NASA Polar Pathfinder research teams, in conjunction with NSIDC staff embarked on an effort to integrate selected polar remote sensing data. It is a unique effort to provide data sets, which lower the cross-sensor use barriers due to differing geo-referencing, sensor resolution, and temporal schemes.
These data have been packaged on a CD-ROM, which contains selected animations for previewing large-scale atmospheric and surface condition changes. NSIDC has also produced a data access and browse tool based on the commercial off the shelf (COTS) product IDL.

THE BRITISH ATMOSPHERIC DATA CENTRE: DATA FOR UK ATMOSPHERIC SCIENCE

Simon WILLIAMS and Lesley Gray (British Atmospheric Data Centre, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX, UK, email: s.r.williams@rl.ac.uk)

This poster describes data services provided by the British Atmospheric Data Centre (BADC) to the atmospheric science community. We use the example of the support given to atmospheric chemists working on the UK ACSOE (Atmospheric Chemistry Studies in the Oceanic Environment) programme to illustrate the BADC's work. The BADC is the main archive for atmospheric data produced by the UK academic community, but it also holds over 1Tb of 3rd party data sets, such as observational and model data from the Met Office and the European Centre for Medium Range Weather Forecasts (ECMWF). Researchers use our WWW site to find data and then simply copy them over the Internet to their own computers. ACSOE is a research programme of the Natural Environment Research Council, which is working to improve the understanding of the marine atmosphere. Measurements have been made from a remote research station on the west coast of Ireland and from ships and aircraft offshore. The BADC has been actively involved since the outset of the programme and the poster gives an outline of the automatic archive and catalogue system provided by the BADC, which allows the ACSOE researchers to deposit their data and share them efficiently with collaborating groups. It also describes the forecast air parcel trajectories provided to ACSOE through the BADC which researchers found an invaluable aid in planning their measurements. The BADC is funded by the Natural Environment Research Council.

SHORT CIRCUITING EARTH: A REVIEW OF GLOBAL SCALE GEOELECTRIC FIELD MEASUREMENTS USING SUBMARINE CABLES

H. SHIMIZU (ERI, University of Tokyo, Tokyo, Japan, email: shimizu@eri.u-tokyo.ac.jp); L. J. Lanzerotti (AT&T Bell Laboratories, Murray Hill, NJ, USA); H. Utada (ERI, Univ. of Tokyo, Tokyo, Japan); and A. Chave (WHOI, Woods Hole, MA, USA)

Over the past decade, more than ten Pacific and three Atlantic submarine telephone cables have been instrumented to monitor the induced geoelectric voltage after their removal from commercial service. These time series are now of significant length, and have been applied to the study of space physics, deep geomagnetic, and oceanographic problems. Both Pacific and Atlantic cables have been used for studies of ionospheric and magnetospheric current systems. In particular, the geoelectric field induced across the Pacific TPC-2 cable (Hawaii to Guam) has been used for studies of the magnetosphere equatorial ring current, and the relationship of the ring current and the induced geoelectric field to interplanetary conditions outside the magnetosphere - the solar wind velocity and the interplanetary magnetic field. An empirical relation has been derived between the induced geoelectric field across this route and the energy input to the magnetosphere from the solar wind. The toroidal geomagnetic field strength and its variation at the CMB have been constrained using both the DC and slowly varying geoelectric potential with an assumed global electrical conductivity structure in the mantle. The constraints are consistent with the results of MHD geodynamo calculations. Regional conductivity structures beneath the Pacific have been estimated using data taken on the HAW-1 and western branches of TPC-1. These inputs are essential to construct a 3D conductivity model of the mantle.

JWA34/W/01-B2 0930

A JAPANESE CONTRIBUTION TO GLOBAL DEPLOYMENT OF OCEAN BOTTOM GEOPHYSICAL OBSERVATORIES (OHP PROJECT)

Yoshio FUKAO (Earthquake Research Institute, University of Tokyo, Tokyo 113, Japan, email: fukao@eri.u-tokyo.ac.jp)

The Ocean Hemisphere network Project (OHP) is to establish geophysical observation networks centered on the western Pacific for seismology, geo-electromagnetism, and geodesy. Besides land stations now under construction the OHP network will have the ocean bottom observatories including three ODP borehole seismic stations. We have already established a network of seven retired submarine telephone cables for electrical potential measurement. Construction of ocean bottom observatories requires various types of system development. (a)Borehole observation system: for the 1999 drilling program we developed a composite sensor string hanging a ultra-sensitive volumetric strainmeter, broadband seismometers, backup seismometers and tiltmeters. (b)Broadband seismometer system: we developed a self-popup system acoustically controlling the tilt of sensors and separation of pressure vessels, with a data logger having a memory capacity of 72 Gbytes. (c)Electromagnetic observatory: we developed a system of eight component geo-electromagnetic sensors with which a long-term observation was conducted at a water depth of 5400m, including an acoustic communication experiment at a data transfer rate of 1200 bps. (d)Crustal movement observation system: our experiment on acoustic distance measurement showed an accuracy of better than 1cm over a 1.35km long baseline on the sea floor, and the experiment on ocean bottom gravity measurement showed a residual fluctuation of 10 microGal after removal of tidal and drift effects. (e)Long-life power supply and acoustic transmissin systems: we imtegrated a sea water battery and a pressure bessel submersible up to 6000m into a system for long-term observations, and completed a system of acoustic data transmission (4800 bps) and satellite communication via a buoy at the surface of relatively shallow ocean.

JWA34/W/10-B2 0950

GEOSTAR

Dr Guiseppe Smriglio (Instituto Nazionale di Geofisica, Roma Italy Email: geostar:ing750.ingrm.it)

(GEophysical and Oceanographic STation for Abyssal Research) is a project funded by European Commission in the 4th Framework Programme. Aim of the project is the development of the first prototype of a deep sea benthic observatory capable to carry out long-term (up to 1 year) scientific observations at abyssal depths (up to -6000 m). The project is splitted in two phases. The first phase (1995- 1998), was concluded with the demonstration mission in Adriatic Sea at 42m.w.d The second one (1999 - 2001), provides for the completion of the system to be able to operate in near real-time up to -6000 m and for the first long-term deep sea scientific mission scheduled during 2000 for 5-6 months at 3400 m in the Southern Tyrrhenian bathyal plain.. GEOSTAR is characterised by specific solutions enabling the execution of the deep sea mission. Among these solutions: a lightweight and modular frame, active devices for the deployment of specific packages, a dedicated data acquisition and control hardware, autonomous mission control capabilities, multiple possibilities of interfacement with external devices (satellite communication systems, deployment system) for continuous control of system status. The configuration of the Observatory, conceived to be a node of monitoring networks, is made up of two main subsystems: Bottom Station and Active Docker. The Bottom Station includes the acquisition and power systems, the communication system and hosts all the sensors. The Active Docker is a dedicated tool for surface-assisted deployment and recovery. The Bottom Station includes the acquisition and power systems, the communication system and hosts all the sensors, including geophysical, geochemical and oceanographic instruments. The scientific and technological solutions adopted in the first project phase and planned for ongoing second phase are presented and discussed.

JWA34/W/06-B2 1010

MOISE:A FIRST PROTOTYPE OF A MULTIPARAMETER OCEANBOTTOM OBSERVATORY

Amal SEBAI, El\'eonore Stutzmann, Wayne Crawford,Jean-Paul Montagner, Genevi\`eve Roult, Jean-Francois Karczewski (all at IPGP, Dept.Sismologie, UMR7580, 4 Place Jussieu, 75252 Paris05, France.),Jean-Louis Thirot, Pascal Tarits (both at Universit\'e de Bretagne Occidentale, UMR6538, BP809, Brest 29285, France.), Barbara Romanowicz (at UCB Seismologicallaboratory, Berkeley CA 94720, U.S.A.), Debra Stakes (MBARI, PO Box 628, Moss Landing, CA95039-0628, U.S.A.).

During the international co-operative pilot experiment MOISE (Monterey BayOcean Bottom Seismic Experiment), diverse geophysical data sets were recorded, including seismic signal, temperature, pressure, magnetic field. The experiment successfully conducted from June to September 1997 demonstrates that it is now possible to install of a permanent broadband seismic and geophysical observatory at the bottom of the ocean. The seafloor seismic noise level is comparable to terrestrial station noise for periods smaller than 1 sec. At longer periods, the noise level remains low on the vertical component up to 30 sec, and increases at longer periods. The seismic noise level remains stable during the experiment but varies strongly during the day.
For the three seismic components, the pressure, temperature, current velocity and magnetic fiel dare highly coherent at very low frequencies(below 0.04m Hz), as a consequence of tidal effects. In the frequency range 0.1-0.3m Hz, the seismic signal is more coherent with temperature and pressure than with current velocity or vertical magnetic field. The coherence with temperature breaks down below 0.5mHz.
We also combine pressure signal from an hydrophone installed next to the MOISE observatory with the seismic data to investigate crustal

JWA34/W/12-B2 1050

A NEW WAY OF REAL-TIME SEISMIC MEASUREMENT: THE GEO-TOC IZU CABLE OBS USING TPC-1, A DECOMMISSIONED SUBMARINE CABLE BETWEEN JAPAN AND GUAM

Junzo KASAHARA, Toshinori SATO, Hisashi Utada (all at ERI, University of Tokyo, 1,1,1, Yayoi, Bunkyo, Tokyo, Japan, e-mail: kasa2@eri.u-tokyo.ac.jp ; satot@eri.u-tokyo.ac.jp ; utada@eri.u-tokyo.ac.jp); Hajimu Kinoshita (JAMSTEC, 2-15 Natsushima, Yokosuka, Japan, email: jimmy@jamstec.go.jp)

In order to obtain precise images of earthquake generation, tectonics at plate boundaries, and the Earth's deep structures, real-time geophysical measurements in the ocean are required. To achieve the above objectives, we used a decommissioned submarine cable, TPC-1, which runs between Japan and Guam. The cable length is 2,700km. Using TPC-1, an OBS was successfully installed at 2,800m deep on the landward slope of the Izu-Bonin Trench in 1997. The OBS contains three accelerometers, single hydrophone, and a water pressure-temperature sensor. When a Mw6.1 earthquake occurred just below the station at 80 km-deep, accelerometers showed co-seismic and gradual changes after the main shock onset. A pressure sensor showed a 50 cm sea-level change during the earthquake. This suggests a high possibility detecting silent earthquakes or earthquake precursors if they exist. These activities proved that decommissioned submarine cables are great global resources for real-time geophysical measurements on a deep-sea floor. Using such decommissioned submarine cables, cost-effective, real-time measurements will be realized.

JWA34/W/11-B2 1110

MULTI-DISCIPLINARY GEOPHYSICAL MEASUREMENTS ON THE OCEAN FLOOR USING DECOMMISSIONED SUBMARINE CABLES: VENUS PROJECT

Junzo Kasahara (University of tokyo, Yayoi, Bunkyo, Tokyo, Japan; email: kasa2@eri.u-tokyo.ac.jp); Yuichi shirasaki(k-marine co., Ltd., Nakameguro, Meguro, tokyo, japan; email: sirasaki@k-marine.co.jp); Ryoichi iwase, and katsuyuki kawaguchi (both at Jamstec, 2-15

natsushima, yokosuaka, Japan, email: iwaser@jamstec.go.jp ; kawak@jamstec.go.jp)

The deployment of an ocean floor geophysical and Multi-disciplinary real-time observatory has been Attempted by reuse of a decommissioned submarine Cable. The venus project reuses the tpc-2, which Is one of decommissioned submarine coaxial-cable Systems and runs across the entire philippine sea Plate between guam island and okinawa island. The cable length is 2,500km. The venus system Comprises i) seven sensor units, ii) junction Box, iii)data-telemetry unit, iv)data-coupling Unit, v)main coaxial cables, vi)shore station, And vii) yokosuka data center. There are eight Sensor units including broadband seismometers. The data obtained by the ocean floor observatory Will be transmitted to the yokosuka data center Through the shore cable station. A part of the Bottom equipment was deployed at 2,200 m deep of The landward slope of the ryukyu trench in fall, 1998 and 12 hours tsunami data were obtained. The Tsunami data showed that the system worked well. The whole system is planned to be re-deployed in Summer, 1999.

JWA34/E/05-B2 Invited 1130

THE NEED FOR OCEAN BOTTOM GEOMAGNETIC OBSERVATORIES WITH GOOD BASELINE CONTROL

GREEN, Arthur W., (U.S. Geological Survey, Golden, CO, USA)

A recent study concluded, that to produce a spherical harmonic model of the Earth's main field with an error range of from 7 to 11 nT would require about 92 high quality observatories evenly spaced around the globe. The spacing would be about 20 degrees. An inventory of existing observatories showed that to achieve the uniform distribution of 92 observatories, some existing sites must be upgraded to INTERMAGNET standards, and that 40 new observatories must be established, of which 8 would be in remote, deep ocean areas. To meet modeling needs, each ocean bottom observatory should have baseline control of less than 5 nT over periods of many years. This would be accomplished by taking weekly measuremts by means of independent absolute instruments such as a Declination-Inclination magnetometer and a Proton magnetometer. This process requires accurate knowledge of the local vertical and of the direction of Geographic North. In this paper, we examine the effects of various distributions of observatories and suggest how absolute measurements may be made on the ocean bottom without celestial references.

JWA34/W/09-B2 1150

THE FRENCH PROGRAM OF SEAFLOOR GEOMAGNETIC OBSERVATORIES

Pascal TARITS (UBO/IUEM, UMR CNRS ' Domaines Oceaniques' Place Nicolas Copernic, Brest F-29280, France, email: tarits@univ-brest.fr); Mioara Alexandrescu (IPGP, Observatoire Magnetique de Chambon La Foret, Beaune la Rolande F-45340, France , email: mioara@ipgp.jussieu.fr); Dt Insu team (Division Technique de l'INSU)

The accurate determination of the main magnetic field and its secular variation at the global scale remains limited by the number of observatories and their poor distribution over the Earth's surface, particularly over the ocean areas. This biases significantly the determination of the source field geometry even at very long wavelength.
We present results illustrating the importance of semi-permanent geomagnetic observatories on islands and seafloor to describe globally the main magnetic field and its secular variation. While the technology to install semi-automatic observatories on islands already exists, seafloor geomagnetic observatories are not yet available for installation.
In France, a collaborative action is undertaken to build a semi-permanent seafloor observatory that matches the INTERMAGNET measurement requirements. This observatory comprises a triaxial variometer and an Overhauser magnetometer measuring absolute total field intensity. The main difficulty remains the measurement of the geomagnetic declination, which needs a known geographical reference within a few tens of arc-seconds.We show that the declination may be obtained using a precise mechanical gyro. Preliminary tests to reach this level of precision are presented.

JWA34/E/02-B2 Invited 1210

FULLY AUTOMATIC ABSOLUTE MAGNETOMETER SUITABLE FOR SEA-BOTTOM USE

JEAN L. RASSON, (Institut Royal Meteorologique, Centre de Physique du Globe, B-5670 Dourbes Belgique)

In this talk, we present our ongoing project to build a fully automaticabsolute observatory magnetometer suitable for sea-bottom use. We specifically address the problems of finding true North automatically and of making unattended DIflux measurements. We show that the magnetic cleanliness problems can be solved. Also addressed are the methods of installation and deployment. The dimensions are compatible with cylindrical high-pressure casing.

JWA34/E/08-B2 1230

DEVELOPMENT OF A SEAFLOOR POSITIONING SYSTEM WITH GPS-ACOUSTIC LINK

Koichiro OBANA, Hiroshi Katao and Masataka Ando (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji 611-0011, Japan, email: obana@rcep.dpri.kyoto-u.ac.jp)

The observation of seafloor crustal deformation will contribute significantly to understanding the nature of the tectonic processes at the plate boundaries. We develop a seafloor positioning system for crustal dynamics observation. This system consists of two main components; (1) surface positioning by differential GPS and (2) precise acoustic ranging using the M-sequence between the surface and seafloor references. In this system, the position and attitude (heading, pitch and roll) of the surface GPS-acoustic link unit is determined by the differential GPS observation. The surface unit equips with an acoustic transducer and performs acoustic ranging for the seafloor references. The two-way acoustic travel time between the surface and seafloor is measured. The positions of seafloor references are determined from these observations and assumed sound-speed structure model of the sea water. We performed preliminary seafloor positioning tests. The locations of seafloor reference units are determined as to minimize the two-way travel time residual using the least square method. In these analyses, we used simple 1-D sound-speed structure models. The results show that the positions of the seafloor references are estimated with a ten centimeter-level accuracy. The systematic trend still remains in the residuals. It is important to apply the ``real" sound-speed model for more precise positioning.

DESIGN FOR AN OCEAN BOTTOM GEOMAGNETIC OBSERVATORY WITH GOOD BASELINE CONTROL

GREEN, Arthur W., U.S. (Geological Survey, Golden, CO, USA, e-mail: awgreen@gldfs.cr.usgs.gov); Alan Chave, Woods Hole Oceanographic Institution, Woods Hole, MA, USA e-mail: alan@faraday.whoi.edu)

In a previous paper in this session we demonstrated the need for geomagnetic observatories with good baseline control at selected ocean bottom sites. In this paper, we describe an ocean bottom system which will provide the required data to INTERMAGNET standards. The system will be set in place by a Remotely Operated Vehicle (ROV) in depths of 5000 meters or more and will have a lifetime of 4 years or more. After 4 years,the entire system, including the battery package, will be retrieved and replaced by a new system. The data, which consist of one minute filtered values of the three components of the magnetic field plus total field,will be recovered at 6 to 12 month intervals by acoustic interrogation from oceanographic "ships of opportunity". At very remote locations, data recovery will be by messenger bouys which periodically float to the surface and communicate by radio with polar orbiting satellites. We also show how the local vertical and Geographic North may be obtained on the ocean bottom, thus permitting an automated absolute instrument, such as a Declination-Inclination Magnetometer (DIM), to automatically make periodic absolute measurements.

JAPANESE RESEARCH INITIATIVES IN THE NANKAI TROUGH

Yoshiyuki KANEDA and the Frontier Research Program for Subduction Dynamics (Japan Marine Science and Technology Center, 2-15 Natsushima-cho, Yokosuka, Japan, email: kaneday@jamstec.go.jp)

More than 80% of the seismic foci of large (M>7) earthquakes around Japan are located in the vicinity of ocean trenches and troughs. It is well known that the Nankai Trough area, offshore southwestern Japan, is one of the most dangerous parts of the world in terms of destructive subduction zone earthquakes. The last earthquakes in the Nankai Trough occurred in 1944 and 1946, and are thought to be successive ruptures in a narrow region along the Nankai Trough. The repeatability of earthquakes in the Nankai Trough region is well established through historical records.
A major effort of the Japanese marine seismological community is the determination of detailed seismic structure in the Nankai Trough region, in order to delineate the seismogenic zone there. Japanese and American scientists will collaborate in a 3-D seismic survey by the US R/V M. Ewing this summer, which will done in combination with refraction and wide-angle surveys using Japanese OBS's. Additional research facilities which are involved in the effort to study the Nankai Trough include: a 150-channel MCS system, more than 100 pop-up OBS's, and a line of cable-connected long-term ocean bottom observatories, which includes three seismographs, two tsunami gauges and other instruments about 120 km to the south of Cape Muroto (Shikoku, Japan). These are utilized in combination with ROV's, manned submersibles, and other conventional research vessels for detailed studies of the Nankai seismogenic zone.the bandaurora and tanspolar arc sometimes occur.

JWA34/W/08-B2 1500

H2O: THE HAWAII-2 OBSERVATORY

A.D. CHAVE (Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA; e-mail: alan@whoi.edu) R. Butler (IRIS, 1200 New York Ave NW, Washington D.C. 20005, USA); F.K. Duennebier (SOEST, University of Hawaii, Honolulu, HI 96822, USA)

A permanent deep ocean scientific research facility--the Hawaii-2 Observatory or H2O--was installed on a retired submarine telephone cable in September 1998. H2O receives power and communications from a 1960's vintage analog submarine telephone cable. The facility consists of a seafloor junction box located in 5000 m of water near 28˚N, 142˚W, or about halfway between Hawaii and California. The junction box derives 400 watts of power from the cable and provides bi-directional real time communications through six digital and two analog ports. The H2O junction box is a "smart" design which incorporates full control of instrument and junction box functions from shore. Instruments may be connected to the junction box at wet-mateable connectors using a remotely-operated vehicle. Initial instrumentation at the H2O site includes a broadband three-component seismometer, a short period geophone, a standard hydrophone, and ancillary instruments.
H2O was installed from a large research vessel using the Jason ROV for most installation functions. Initially, the ROV located the cable and cut it at a pre-chosen point for subsequent recovery using the ship's trawl wire. A termination with wet-mateable connector was spliced onto the end of the cable. The termination was then redeployed to the seafloor. The junction box and scientific package were placed nearby and wired up using Jason. Finally, the seismometer was hydraulically buried beneath the sediment-water interface by the ROV.

JWA34/W/05-B2 1540

RECENT DEVELOPMENTS IN OCEAN BOTTOM SEISMOMETERS AND SEISMIC SENSORS

Spahr C. WEBB, (Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093.
E-mail: scwebb@ucsd.edu)

The ocean floor is a peculiar place to put seismometers or other seismic sensors. The noise climate is different from land, sites are remote and rugged and energy is limited. I describe systems, sensors and strategies optimized for the ocean floor. Recent developments include a broad band pressure sensor, a low power, low noise, low cost, broad band seismic sensor derived from a short period sensor, a long period ocean bottom seismometer based on a LaCoste Romberg gravimeter, and a broad band OBS based on a STS-2. Wave and wind climate determine noise levels at seafloor sites. Some strategies for reducing effective noise levels and for siting instruments are described.

JWA34/E/06-B2 1600

"CORK" BOREHOLE OBSERVATORIES TO STUDY SUBSEAFLOOR HYDROGEOLOGY

Keir BECKER (RSMAS, University of Miami, Miami, FL 33149, USA,
email: kbecker@rsmas.miami.edu) and Earl Davis (Geological Survey of Canada, PO Box 6000, Sidney, BC, Canada, email: davis@pgc-gsc.nrcan.gc.ca)

CORKs or "Circulation Obviation Retrofit Kits" are hydrogeological observatories that seal ODP boreholes and allow long-term observations to be made with subseafloor pressure and temperature sensors and fluid samplers; the instrumentation can be utilized for long-term monitoring of fluid flow processes and direct testing of formation properties using seafloor tidal loading signals or pumps deployed from submersibles. Since 1991, 13 CORKs have been installed in three characteristic subseafloor hydrologic settings: the Middle Valley sedimented ridge hydrothermal system on the Juan de Fuca Ridge, accretionary prisms of the Cascadia and Barbados subduction margins, and, ridge-flank hydrothermal systems in young oceanic crust east of the Juan de Fuca Ridge and west of the Mid-Atlantic Ridge. We will review the results, which confirm prior inferences that fluid flow is a key process in all these settings, and clearly demonstrate that the driving forces, permeabilility structures, and styles of fluid flow vary greatly among settings. We will also discuss plans for future CORKs and opportunities for integration with other seafloor observatory objectives. Major changes are in progress for future Advanced CORKs," to allow for multi-level monitoring in single holes, serviceability by wireline vehicles, and enhanced sensor/sampler capabilities. These changes will allow a greater range of scientific objectives (e.g., in situ studies of gas hydrates and subsurface microbiology) to be addressed with Advanced CORKs that incorporate seal spacing corresponding much more closely to natural permeability structures.

JWA34/W/02-B2 1620

ABSOLUTE PROTON OVERHAUSER MAGNETOMETERS: DESIGNS AND PROPETIES

Vladimir SAPUNOV, Dmitry SAVELIEV, Sergey Kiselev, Alex Denisov, Olga Dekusar (Ural State Technical University, Quantum Magnetometry Laboratory, Mira St., 19, Ekaterinburg, 620002, RUSSIA, email: sva@dpt.ustu.ru)

The total geomagnetic field Overhauser's magnetometers are promising for the long term ocean bottom observatories due to low power (1-3 Wt), high sensitivity (0.1 - 0.01 nT), low drift (up to 0,05 nT/year) and precision measurements (absolute accuracy 0.1-1 nT).
In this report, designs and properties of the LETI, GEM Systems, USTU and DTU sensors and magnetometers are considered. The free radicals DNP and ESR properties are a cause for choose of magnetometer mode and/or sensor's design.
The QMLab series of the processor Overhauser sensors POS was developed for observatories and ground application. These magnetometers and gradiometers interfaced only via RS232 port and based on unified proton Larmor counter (0.001 nT resolution at 3 sec sample rate, 0.5 Wt power, size 80x120x15mm). Report presents an actual digital processing of proton signals that afford high sensitivity and broadband operation.
The design of the omnidirectional marine proton Overhauser sensor is submitted. Sensor contains a new stable free radical with very long lifetime up to 10 years. This radical allows to design world's smallest size Overhauser sensors.

JWA34/E/10-B2 1640

CALIBRATION OF OCEAN BOTTOM MAGNETOMETER

Valery KOREPANOV and Fedir Dudkin (Lviv Centre of Institute of Space Research, 5-A Naukova str., 290601, Lviv, Ukraine, e-mail: vakor@isr.lviv.ua)

The study of Earth's magnetic field structure around the Globe is one of the most important geophysical problems. Taking into account that 2/3 of the Globe is covered by World Ocean, the installation necessity of long-term autonomous ocean bottom magnetometers is obvious. Practically all technological problems connected with such magnetometers construction, manufacturing, deployment on the bottom and data exchange are sufficiently resolved. The only moment is still waiting appropriate solution - in-situ magnetometer calibration. Here two tasks arise: knowledge of the exact magnetometer axes orientation in order to reduce its data to geomagnetic coordinates and magnetometer calibration: its long-term drift should not surpass 0.005% of the total measured value. The first task seems to be easy to solve with necessary exactness using modern tiltmeters and some mathematics transformations. The attempts to solve the second one trying to automatize the commonly used procedure of absolute measurements are undertaken now but no satisfactory practical results are still obtained. Also the idea to make calibration of the bottom magnetometer using space-born magnetometers of low orbiting satellites was reported. The detailed investigations of the method showed that at present state of its development there is no hope to get necessary calibration precision. Further development of such method is discussed in the report. A floating or towed platform is proposed containing three exact devices: star imager for orientation determination, GPS receiver for platform positioning and reference magnetometer. The possible errors of each device and of the whole system are analyzed, taking into account the main disturbing effects: sea surface and floating platform constant motion and light refraction. The primary estimation is made that practical implementation of the method is possible.

JWA34/E/04-B2 1700

MAGNETIC FIELDS INDUCED BY STEADY FLOWS AND BY ACOUSTIC WAVES IN THE OCEAN

Arthur W. GREEN (USGS Denver Federal Center, MS 966 Box25046, USA) Yuri Kopytenko, Polina Serebryanaya, Lidia Nikitina (SPbF IZMIRAN, Muchnoi 2, St.-Petersburg, 191023, Russia, e-mail: gorbunov@neva.spb.ru)

Large vortices are generated along sea and ocean streams and have typical flow velocities of about 0.5 m/s. It was shown that the large-scale structures on a water-area in the presence of Earth's magnetic field induce quasiconstant magnetic fields of the order of 10 -100 nT that depend on scale of structures and velocity of flow. It can be used in studies of such physic characteristics of large-scale vortex structures at a water area as, for example, scales and velocities of vortex structures and currents. It was shown that variable magnetic field has the same temporal dependence as the velocity field. This conclusion can be used by consideration an interaction of rarefaction-compression waves on acoustic frequencies with undisturbed ocean surface. The magnitude of induced magnetic field generating by LF acoustic wave was estimated as 0.1pT. Recently investigations of action of acoustic waves on jets or wakes showed a possibility of resonance amplification of turbulent pulsations on acoustic frequencies. This leads to resonance growth of turbulent velocity in a vortex at the forcing frequency. The increase of turbulent velocity by several orders will lead to corresponding amplification of pulsation amplitude of magnetic field under the action of rarefaction-compression wave. The magnetic field can reach to 0.1 81 nT. It can give a useful information about nature processes, accompanying by LF acoustic waves (from earthquakes, aircraft, from active atmospherical formations as typhoons, cyclones).

JWA34/E/03-B2 1720

INDUCED MAGNETIC FIELDS OVER UNDERWATER VOLCANOES

Arthur W. GREEN (USGS Denver Federal Center, MS 966 Box 25046, USA) Yuri Kopytenko, Polina Serebryanaya, Lidia NIKITINA (SPbF IZMIRAN, Muchnoi 2, St.-Petersburg, 191023, Russia, e-mail: gorbunov@neva.spb.ru)

It is known that underwater volcanoes activity leads to the appearance of hot-water areas. Hot jet interacting with ambient media creates mesoscale flows over underwater seismic zones. The process of mesoscale flows formation was considered and the basic hydrodynamical parameters of the flow were estimated. In the presence of Earths magnetic field different structures of flow (such as stream or vortex) in conducting sea water induce quasiconstant magnetic fields of the order that depends on scale of structures and velocity of flow. Value of magnetic fields induced by mesoscale flow were is about 100 nT. Intensification of tectonic activity near faults and under-water volcanoes is accompanied by rarefaction-compression waves at frequencies in a band 1 - 100 Hz. It is known from laboratory experiments that a strong rarefaction-compression wave interacting with flow leads to resonance amplification of turbulent velocities on forcing frequency. The average amplification of the spectrum is more than 20 dB. Magnetic field has the same temporal dependence as the velocity field. Hence, the increase of turbulent velocity by several orders will lead to corresponding amplification of amplitude of variable magnetic field under the action of rarefaction-compression wave and magnetic fields achieve values of 100 pT. We believe the fluid structures over underwater volcanoes can be used as an indicator of seismic activity of a sea bottom by measuring of anomalous magnetic fields.

JWA34/E/01-B2 1740

DEEP-WATER ELECTROMAGNETIC UNIT WITH ON-SHORE DATA GATHERING FOR BAYKAL RIFT GEOPHYSICAL STUDY

Vitaly S. SHNEYER, Igor L. Trofimov and Sergey P. Gaidash (Geoelectromagnetic Research Institute of Russian Academy of Sciences, p.o.box 30, Troitsk, Moscow Region, 142092 Russia, email: shneyer@geo.igemi.troitsk.ru, gaidash@helios.izmiran.rssi.ru); Leonid L. Vanyan and Wladimir Kh.Rucol (Shirshov Institute of Oceanology of Russian Academy of Sciences, Nakhimovsky pr., 36, Moscow, 117851 Russia, email: vanyan@geo.sio.rssi.ru); Wladimir A.Zhukov, Andrey I.Panfilov (Nuclear Research Institute of Russian Academy of Sciences, pr. 60-letija Octjabrja, 7a, Moscow, 117312 Russia)

We are developing a new method of deep-water measurements with on-shore data gathering of electromagnetic fields for magnetotelluric soundings and seismo-electromagnetic monitoring of geodynamical processes. It is different from traditional method, when full autonomous instruments are used. The advantage of this metod compare with autonomous methods is possibility to get deep-water information in the real time and to control of measuring process. Intracontinental Baykal rift zone is very interesting object for geophysical investigation. Deep-water complex of neutrino telescop NT-200 had been set up 10 years ago on the lake bottom at South-Baykal depression near of deep tectonic fracture . Deep-water unit NT-200 is well connected with data collecting coastal center. In this site will be set up the electromagnetic unit, which consist of three-component elecrtic field instrument and total magnetic field vertical gradient unit. For electromagnetic digital data trasmission the telecommunication lines of NT-200 will be used. The depth of lake at the setting site is 1360 m; the distance from coast is 3600 m. Instruments will be lowered down the lake bottom in winter season through ice hole with NT-200 ancillary equipment use.

RECENT MULTI-INSTRUMENT OBSERVATIONS OF LAYERING IN THE MLT REGION ABOVE ARECIBO

KANE, Prof Tim (Penn State, Email: tjk7@psu.ed)

During the past year, considerable observational data concerning layering of both neutral and charged constituents above Arecibo, Puerto Rico have been obtained. These include measurements taken by incoherent scatter radar (ISR), VHF coherent scatter radar, lidar, airglow imagers and rocket-borne in-situ payloads. These data shall be presented and probable correlations/causes shall be discussed.

JSA35/E/03-B1 Invited 0930

ON THE VARIABILITY OF POSITIVE AND NEGATIVE IONS IN THE MIDDLE ATMOSPHERE

Ernest KOPP (University of Bern, Sidlerstrasse 5, CH-3012 Bern, Switzerland,
email: ernest.kopp@phim.unibe.ch)

Primary ions result from ionization of abundant neutral N2 and O2 producing N2+, N+, O2+, and O+. The only but important exception from this is the production of NO+ by Lyman-a in the mesosphere. Due to a relatively large neutral density below an altitude of 90 km three body reactions become important and the primary ions are transferred to large families of positive and negative ions in a fraction of seconds. This chemistry is controlled by less abundant neutrals such as H2O, O3, NO, HCl, HNO3, H2SO4 in the abundance range of ppm to ppt. Ions are lost by recombination with electrons or ions, and in the stratosphere loss to liquid or solid aerosol surfaces becomes important. Even though the neutral density changes between the mesopause (90 km) and the tropopause (15 km) by a factor of 105 the ion density varies less than two orders of magnitude around 103 cm-3. Due to this large decrease of mixing ratios of ions to neutrals, mass spectrometric measurements are much more difficult at lower altitudes.
This review will concentrate on positive and negative ion chemistry in the mesosphere and stratosphere, the natural variability and changes due to the presence of aerosol particles.

JSA35/E/04-B1 Invited **1010**

CHARGED DUST PARTICLES IN THE EARTH'S MESOSPHERE

Ove HAVNES (Faculty of Science, Department of Physics, University of Tromsø, N-9037 Tromsø, Norway)

The Earth's polar mesosphere is the site of several strange phenomena such as noctilucent clouds and anomalous radar backscattering layers. They occur at heights between 80 and 90 km during the summer season when the mesosphere temperature is low. In situ measurements by rockets have shown that charged dust particles can be present in large numbers and that they can totally dominate the local charge balance. The dust may have positive or negative charges at different occasions. We will discuss the nature of the mesospheric dust, its charges and charging mechanisms, size distribution, number density and influence on other mesospheric phenomena. We have no direct knowledge of the material and structure of the dust particles. Although ice probably is a major constituent other elements with much lower work functions for photoionization must be present in the dust to explain the posit The dust clouds have similar structure as the radar backscattering layers, which they seem to be closely associated with. The overall cloud thicknesses are of the order of a few km with much internal structure down to thin layers and "holes" of only a few meter thickness. We will discuss the structure of the dust clouds and the effects and forces which influence the structure of them.
We expect to be able to present results from rocket launches during the summer '99, aimed at dust and plasma conditions at different phases of the radar backscattering and noctilucent cloud layers.

LARGE MIDDLE-ATMOSPHERE ELECTRIC FIELDS AND THEIR RELATIONSHIP TO DUST PARTICLES

Alexander M. ZADOROZHNY (Novosibirsk State University, Pirogova 2, Novosibirsk, 630090, Russia, E-mail: zadorozh@phys.nsu.ru)

During the last two decades, different groups have carried out more than fifty rocket measurements of vertical electric fields in the middle atmosphere with different instruments. In about a half of these measurements a mesospheric maximum of vertical electric field of the order of a few V/m has been observed. In this paper all available rocket measurement data of the vertical electric fields in the middle atmosphere are analysed and a possible mechanism of generation of the fields caused by gravitational sedimentation of charged dust particles is discussed. There are many experimental evidences of the existence of charged dust particles both in the lower mesosphere and in the polar summer mesopause. Simultaneous measurements of the electric field strength, positive ion density and aerosols point out both an ion-aerosol interaction and a connection between the mesospheric electric fields and dust particle content. The observed height correlation of the electric field disturbances with the noctilucent cloud (NLC) position also indicates the importance of the dust particles in the generation of the vertical electric fields under NLC conditions. The simultaneous existence of both negative and positive multiply charged dust particles of different size is assuming for explanation of the V/m vertical electric fields. In this model, more massive charged particles falling with larger velocities initiate a charge separation. Smaller particles carrying charges of other sign are need to reduce the effective conductivity of the atmosphere. The proposed model could explain the existence of the large vertical electric fields observed both in the lower mesosphere and in the NLC vicinity. In both cases, the model predicts the effective conductivity of the atmosphere, which is about two to three orders of magnitude less than the measured ion conductivity.

JSA35/W/01-B1 **1120**

EFFECTS OF ELECTRIC FIELDS ON MIDDLE ATMOSPHERE AEROSOLS

S. KIRKWOOD, (Swedish Institude of Space Physics, Box 812, 981 28 Kiruna, Sweden.)

The role of magnetospheric electric fields in producing and modifying sporadic-E layers has become well established in recent years. Such sporadic-E layers are usually observed at heights 95-11 km but have been observed as low as 89 km. In summer, charged aerosol layers (PMSE and NLC) are known to form at only slightly lower altitudes (80-90 km). The expected effects of magnetospheric electric field on PMSE height are significant. Simulations and comparisons with observations (daily variation and specific events) will be presented. It is also of interest to consider whether electric fields can affect stratospheric aerosol layers, such as polar stratospheric clouds at 20- 30 km altitude. Aerosol mobilities at these heights are a thousand times less than at 80-90 km. However, the vertical electric fields are a thousand times stronger. Simulations of expected effects will be presented.

JSA35/W/05-B1 Invited **1140**

ELECTIRC FIELDS IN THE POLAR CAP AND CUSP AND THEIR LIKELY EFFECTS ON THE MIDDLE ATMOSPHERE

NILSSON, (Swedish Institute of Space Physics, Box 812, 981 28 Kiruna, Sweden, email: hans.nilsson@irf.se)

The cusp and polar cap ionosphere are the regions in the Earth's upper atmosphere most directly connected to the solar wind / magnetosheath. The source (generator) at the magnetopause is coupled to the load (the ionosphere) through field-aligned currents along a simple magnetic topology. The electric field in the ionosphere will therefore be strongly correlated with source region conditions and thus with interplanetary conditions. However, ionospheric conductance will determine the ionospheric response time and therefore the characteristic time scale of electric field variations observed in the Earth's ionosphere. A short review of the ionospheric electric fields of the cusp and polar cap typically associated with varying solar wind conditions will be presented. For example the signature of a strong well defined flow channel (150 mV/m over 200 km and a very sharp decline of the E field at the borders) will be shown. Finally a brief survey of expected effects in the middle atmosphere will be presented.

JSA35/E/08-B1 **1210**

INTERACTION BETWEEN THE GLOBAL ATMOSPHERIC CIRCUIT AND IONOSPHERE-MAGNETOSPHERE PHENOMENA

Evgenia BELOVA, Sheila Kirkwood (MRI Atmospheric Research Programme, Swedish Institute of Space Physics, Box 812, SE-981 28 Kiruna, Sweden, email: belova@irf.se); Tapio Tuomi (Department of Geophysics, Finnish Meteorological Institute, Helsinki, Finland); Hannes Tammet (Department of Environmental Physics, Tartu University, Tartu, Estonia)

Ionosphere-magnetosphere disturbances at high latitudes, such as magnetic substorms, are accompanied by energetic particle precipitation, strong variations of the ionospheric electric fields and currents. It can result in changed distribution of ionospheric conductivity that can essentially influence the state of the global electric circuit. The aim of this work is to investigate the probable effect of ionosphere-magnetosphere disturbances on atmospheric electricity elements. For this purpose the data of air-earth electric currents were analysed together with the magnetic data. The air-earth electric currents were measured using the similar methods at two points in Northern Scandinavia (Esrange, 68ƒN, 21ƒE, Sweden and Sodankyla, 67ƒN, 27ƒE, Finland) for time interval from August 1998 to June 1999. The data were sorted to exclude the influence of near-earth winds and others atmospheric factors. Some correlation between the strong magnetic disturbances and variations of the air-earth electric currents was found. Theoretical estimates of magnetic substorm effect on electric current were obtained and compared with observed ones.

Monday 26 July PM

JSA35/W/06-B1 **1400**

VARIATIONS OF ATMOSPHEREIC ELECTRIC FIELDS IN THE NEAR-POLE REGION RELATED TO THE INTERPLANETARY MAGNETIC FIELD

Alexander Frank-Kamenetsky and Oleg TROSHICHEV (both at Arctic and Antarctic Research Institute, 199397, St.Petersburg, Russia, email: olegtro@aari.nw.ru); Gary Burns (Australian Antarctic Division, Hobart, Tasmania, email: gary_bur@antdiv.gov.au); Volodya Papitashvili (Space Physics Research Laboratory, University of Michigan, Ann Arbor, MI 48109-2143, USA, email: papita@umich.edu)

The atmospheric vertical electric fields Ez observed at the Russian Antarctic station Vostok (corrected geomagnetic latitude (=-83.3() in 1979-1980 and 1998 are analyzed. The best days were selected from these intervals satisfying the "good weather" criterion, that is, absence of a strong wind, falling or drifting snow, clouds, and an electric field "pollution" from a station power plant. It is shown that the average diurnal variation of Ez, derived for these days is close to zero in winter season (May-August) and follows the global geolectric field "fair-weather" diurnal variation, that is, the so-called Carnegie curve, in summer season (November-February). It is commonly supposed that the Carnegie curve describes the global electric circuit formed by the global thunderstorm activity occurring mostly in the equatorial regions. We found that the vertical electric field measured at Vostok is strongly affected by variations in the interplanetary magnetic field (IMF). The Ez increases when the IMF By0 and decreases when By<0; however, variations in the IMF Bz component are also important. We conclude that the IMF affects the global electric circuit at high latitudes via the magnetosphere-ionosphere coupling link.

JSA35/L/01-B1 **1420**

MESOSPHERIC AEROSOL AND ELECTRODYNAMICS

Les HALE

Although the largest particles that form near the cold summer polar mesopause are clearly visible, there is extensive evidence for "invisible" mesospheric aerosol extending to lower latitudes. Anomalously low mesospheric conductivities were observed as early as 1950 and numerous workers pointed out the need for a fast 2-body process to explain "D-region" data. In the 1966 solar eclipse in Brazil the extremely rapid loss of free electrons during totality confirmed the aerosol hypothesis (a result repeated in 1979 in Kenya and 1980 in Canada). The large (~5%/ C) temperature coefficient of positive conductivity in the cosmic ray region was consistent with ice or ice-coated particles (Chesworth and Hale, GRL 1, 347, 1974), with a Boltzmann partition between water vapor and ice.
The low conductivity of the mesosphere allows the penetration of electromagnetic energy to the base of the ionosphere, usually about 80 km at night. This includes unipolar millisecond "slow tail" wavelets which provide global unipolar fields up to hundreds of millivolts/meter for larger lightning strokes. These are still inadequate to directly.explain the several volt/meter vertical mesospheric fields observed by Russian and US groups, which at mid and low latitudes appear to follow the "Carnegie"curve (Zadorozhny). However, they may separate electrons which then attach at lower altitudes to extend the time duration of the fields.
The aerosol particles may be related to "sprites." They can grow at night due to cooling, possibly causing stratified conductivity layers under the influence of gravity waves. They may also provide a source of free electrons (necessary to explain VHF data) due to photo detachment caused by lightning and/or sites for the initiation of breakdown phenomena.

JSA35/W/07-B1 Invited **1440**

SPRITE ELECTRODYNAMICS AS SEEN FROM ELECTROMAGNETIC OBSERVATIONS

Steven A. CUMMER (NASA/Goddard Space Flight Center, Greenbelt, MD 20771, USA, Email: steve.cummer@gsfc.nasa.gov)

Sprites, the transient high altitude optical flashes which occur in association with some large lightning discharges, are unarguably a spectacular optical phenomenon. High resolution optical observations from the summer of 1998 by a number of research groups have served to confirm this fact. However, much of the current understanding of this phenomenon has not come from optical observations but rather from electrodynamic observations from analysis of the very low frequency (VLF, 3-30 kHz) and extremely low frequency (ELF, 3-3000 Hz) electromagnetic radiation associated with these events. In this talk we will discuss sprite-related electromagnetic observations which have been made in the past five years and have lead to discoveries regarding the characteristics of lightning discharges which produce sprites, the discovery of the daytime occurrence of sprites, and the discovery of large electric currents flowing in the sprite itself at mesospheric altitudes. We will discuss the observed magnitudes of these so-called sprite currents and their relationship to the global electric circuit. We will also discuss various theories proposed to explain sprites and the constraints which these electromagnetic obser

JSA35/E/01-B1 **1510**

ELECTROSTATIC FIELD ENHANCEMENT DUE TO THE NON-UNIFORM IONISATION CREATED ABOVE A LARGE THUNDERCLOUD

Michael RYCROFT (International Space University, Boul. Gonthier d'Andernach, 6700 Illkirch, France); Mengu Cho (Kyushu Institute of Technology, 1-1 Sensui Tobata-Kitakyushu 804, Japan)

Two-dimensional numerical studies have been conducted to investigate the effects of a positive cloud-to-ground lightning discharge on the upper atmosphere. Electromaganetic waves radiated by a horizontal lightning discharge curent interfence with their reflections from the ground and from the ionosphere. This interference leads to a spatially non-uniform distribution of the ionosphere as specified by certain values of the elctron density and the electrical conductivity becomes very structured on a scale of a few km, with protrusions pointing downwards (like short lived stalactites). After the positive discharge , a negative

charge remains in the thundercloud and downward electrostatic field is enhanced at the tips of the protrusions, typically by a factor or two. This produces favourable condition for positive streamers to develop downward from these points and to create the cores of columniform sprites

JSA35/W/04-B1 1550

THE THUNDERSTORM LARGE-SCALE ELECTRIC FIELDS IN THE IONOSPHERE

V.V. PLOTKIN (Institute of Geophysics SB RAS, Koptyug av., 3, Novosibirsk, 630090, Russia, e- mail: plotkin@uiggm.nsc.ru)

The large-scale electric fields caused by global thunderstorms in the ionosphere are calculated. Is taken into account an assumption for equipotential geomagnetic field lines at ionosphere altitudes. The influence of changes of conductivity high-altitude profiles of an atmosphere in region between the ground and the ionosphere on value of irregularity of ionosphere potential caused by global thunderstorms is investigated. Is shown that electrical fields, penetrating into the ionosphere from below, essentially depend on such important parameters, as integrated conductivity and resistance of an atmosphere. In particular, the average value of potential on the top border depends on resistance of an atmosphere. The irregularity of an ionosphere in a greater degree is determined by integrated conductivity of an atmosphere and with its reduction can become appreciable. In particular, in night conditions, and also in case of conductivity abnormal decrease (for example, during Forbush decrease), the thunderstorm electrical fields in the ionosphere can reach appreciable values.

JSA35/E/07-B1 1610

TEMPERATURE DEPENDENT REDISTRIBUTION OF GLOBAL LIGHTNING AVTIVITY ON DIFFERENT TIME SCALES AS SHOWN BY SCHUMANN RESONANCES

Gabriella SATORI (Geodetic and Geophysical Research Institute of the Hungarian Academy of Sciences, Csatkai u. 6-8., H-9400 Sopron, Hungary, email: satori@ggki.hu)

The excitation source of Schumann resonances (SR) is the global lightning activity. As the SR frequencies depend on the source-observer geometry they are responsive for the redistribution of global lightning activity driven by surface temperature variations. This is shown on diurnal,seasonal, annual and El Nino time scales by SR observations at Nagycenk (47.6N, 16.7E, Hungary). The SR frequencies are also indicative to the areal extension of global lightning activity, as well as to the speed of north-south annual migration of thunderstorm regions. It is suggested that the north-south asymmetry of the land/ocean ratio plays an important role in the origin of the spring-autumn asymmetry and the El Nino related redistribution of global lightning activity.

JSA35/E/05-B1 1630

THE IMPACT OF THE AUGUST 27,1998 GAMMA RAY BURST ON THE SCHUMANN RESONANCE

Colin PRICE (Department of Geophysics and Planetary Sciences, Tel Aviv University, Ramat Aviv 69978, Israel, email: cprice@flash.tau.ac.il); Vadim Mushtak (Box 212 Ulster Heights Road, Woodburne, NY 12788, USA, email: vcm@usa.net)

In 1998 a new Schumann resonance monitoring station in the Negev desert, Israel, started collecting magnetic and electric field data in the extremely low frequency (ELF:1-50 Hz) range. These ELF waves are related primarily to global lightning activity. On 27 August, 1998, at 10:22 UT, and extremely intense gamma ray flare passed through the solar system. The gamma ray burst lasted only 5 minutes and resulted in the ionization of the earth's nightside upper atmosphere to levels found only during the daytime. During this period we were continuously monitoring the ELF waves arriving at our field site in Israel. At the same time a group of researchers at Stanford University were observing this event in the VLF (20 kHz) band.
Due to the enormous change in the height of the nighttime ionosphere caused by this event, the Stanford group noticed huge changes in the amplitude of the VLF signals transmitted from Hawaii, and observed in Colorado, during this five minute period. However, our ELF measurements of global lightning signals in Israel showed no influence at all. No change in the ELF time series is seen during the period of the gamma ray burst.In addition, no changes in either amplitude or frequency were oberved in the Schumann resonance bands during this period. This is surprising given that the ELF signals from lightning travel around the globe a few times before decaying, and therefore would have to propagate in the earth-ionospheric waveguide that was so strongly influenced by the gamma ray burst.We have performed some theoretical calculations to try explain the different responses in the VLF and ELF frequency bands to this massive gamma ray burst. These results will be presented together with the detailed observations of the Schumann resonances during this short period.

THE MERAPI-POJECT - MULTIPARAMETER MONITORING AND INTERDISCIPLINARY INVESTIGATION OF A HIGH-RISK VOLCANO

Birger-G. Lühr, Malte Westerhaus and Jochen ZSCHAU (all GFZ-Potsdam, Telegrafenberg Haus E, 14473 Potsdam, Germany, email: zschau@gfz-potsdam.de). Mas Atje Purbawinata (BPPTK, Jl. Cendana 15, Yogyakarta 55166, Indonesia, fax:+62-274-563 630). R. Sukhyar (VSI, Jl. Diponegoro 57, Bandung 40122, Indonesia, fax: +62-22-702761)

Merapi volcano in Central Java belongs to the most active volcanoes in the world. Located at the subduction zone between the Eurasian and the Indo-Australian Plate, the dominant magmatic mechanism is andesitic, i.e. explosive. In 32 of 67 reported historical eruptions, pyroclastic flows took place. Since 1994 pyroclastic flows with a length between 2 km and 8 km occur about once per year. Even small volcanic events are a permanent danger to life and limb within the densely populated area at the flanks of the volcano. IAVCEI has classified Merapi as a high-risk volcano and included it into the list of 15 Decade Volcanoes. In cooperation with the Volcanological Survey of Indonesia and other institutions in Indonesia and Germany, the GeoForschungsZentrum initiated an interdisciplinary monitoring program in 1994, supplementing a number of ongoing national and international activities on this volcano. The MERAPI project (Mechanism Evaluation, Risk Assessment, Prediction Improvement) is supposed to contribute to the development of prediction and warning strategies on different time scales, including intermediate and short term prediction of volcanic events as well as early warning. Special emphasis has been put on continuously monitoring activity indicators such as seismicity, deformation and gas emanation. Directional microphones are expected to facilitate discrimination between shallow volcanic quakes and rock avalanches, which would be of basic importance for an automatically working early warning system. Investigation of the internal structure of the edifice, of magmatism and of the explosive history of the volcano form the basis for a better understanding of the complex processes prior to an eruption.

JSV36/W/22-B3 0915

AN INTEGRATED APPROACH FOR THE MODELING OF MAGMA PLUMBING SYSTEM AND ERUPTION PREDICTION OF IZU-OSHIMA VOLCANO, JAPAN

Hidefumi WATANABE (Earthquake Research Institute, University of Tokyo, Yayoi 1-1-1, Bunkyo-ku, Tokyo 113-0032, Japan, email: watanabe@eri.u-tokyo.ac.jp)

An integration of the results of extensive observation before, during and after the 1986 eruption of Izu-Oshima volcano, give us essential information on the physical nature of its magma plumbing system. A gradual rise of seismic activity, inflation of the volcano and anomalous decrease in the geomagnetic total intensity, had continued for more than 10 years until around 1980. After 1981, the volcano showed a small deflation and low seismicity at the caldera area until beginning of the eruption, while we observed anomalous changes in the subsurface resistivity and the magnetic field localised around the summit crater, that indicating a gradual rise of the temperature beneath the crater. By integrating the precursors we propose that the accumulation of magma had continued for more than 10 years until 1980, and then the basalt magma started to rise up through the well-developed conduit. After the 1986 eruption, we clarified the drain-back process of degassed magma in the conduit based on microgravity and magnetic observation around the summit crater. Since 1987 after the eruption, the EDM and GPS measurements have revealed a re- inflation of the volcano. A continuous magma supply and a well-developed conduit connecting the magma reservoir and the summit crater, characterise the magma plumbing system of Izu- Oshima volcano. The convection of volatile- containing and degassed magma might control the ascent and drain-back process in the conduit. The proposed model for the magma plumbing system provides a basis for not only the short-term but also mid-term prediction of the future eruption of Izu-Oshima volcano.

JSV36/W/02-B3 0930

MODELING VOLCANO-HYDROTHERMAL SYSTEM OF WHITE ISLAND VOLCANO FROM SEISMIC, SELF-POTENTIAL AND AUDIO MAGNETOTELLURIC DATA

Yuji NISHI, Mituhiko Sugihara, Toshiyuki Tosha, Tuneo Ishido, Yasuo Ogawa(Geological Survey of Japan, Higashi 1-1-3, Tsukuba, Ibaraki 305-8567, Japan, email: uwest@gsj.go.jp); Bradley .J. Scott, Steven Sherburn and ChrisBromley (Institute of Geological & Nuclear Sciences, State Highway 1,Wairakei, Taupo, New Zealand, email: S.Sherburn@gns.cri.nz)

White Island is one of the most active volcanoes in the world and it has avigorous volcano-hydrothermal system that has existed for at least 10,000years (Giggenbach and Glasby, 1977). Volcano-tectonic earthquakes in thisvolcano are concentrated in the eastern Main Crater at depths of less than1 km (Nishi et al., 1996). Space-autocorrelation analysis of seismictremor suggests an unknown high-velocity layer at very shallow depth beneath the Main Crater floor. Self-potential anomalies suggest subsurface fluid flow patterns (Nishi et al., 1996). Three audio-magnetotelluric soundings in the Main Crater show low resistivity (approx. 10 ohm-m) at a shallow depth (Ogawa et al., 1996). Based on these data, we made a

conceptual model of the volcano-hydrothermal system; heat supplied fromthe deep magmatic system beneath the active vent causes upflow to thermal features along the edge of the subcraters, and downflow overlies at the centre of the eastern sub crater and the north-eastern half of the central subcrater. To integrate the various data, thermohydraulic numerical simulations were also performed.

JSV36/E/14-B3 0945

AN APPROACH TO THREE - DIMENSIONAL MAGNETOTELLURIC IMAGING AND MONITORING VOLCANIC ENVIRONMENTS

Vjacheslav SPICHAK (Geophysical Research Centre, Moscow, Russia, e-mail: spichak@dol.ru)

An approach to step-by-step deepening of our knowledge about volcanic interior and long-term forecasting its activity basing on current MT measurements, information available from other methods and sophisticated analysis of past inversion results is suggested. It is based on using methodology of data interpretation, which closely links the monitoring results with knowledge on the internal structure at the moment of the last measurements. Three-dimensional Bayesian inversion and Artificial Neural Network (ANN) - based recognition tools developed recently in (Spichak, 1995; Spichak et al., 1995; Spichak and Popova, 1998) support a new paradigm of MT -data interpretation taking into account the geological information known, noise level in the data, a'priori estimates of unknown parameters, new hypotheses formulated in probabilistic terms, data available from other methods and formalized human experience. Imaging volcanic interior and step-by-step updating 3D-conductivity model are carried out via application of the Bayesian inversion procedure after each MT survey. Along this way the ranges of uncertainties of unknown parameters are reduced each time when new MT sounding data or other information are involved into the inversion process. After each cycle of MT data measurement and interpretation a'posteriori values and multi-dimensional probability density function of the ensemble of monitored parameters are saved and used then as a'priori ones in the next cycle, and so on. Set of these values updated after each new MT survey forms a knowledge base to be used by the ANN - based expert system in order to recognise the tendencies in the parameters' dynamics and to determine the integrated quantitative measure of the risk of future volcanic activity. In order to estimate the effectiveness of the general scheme, simulation of the imaging and monitoring processes using synthetic MT data is carried out.

JSV36/E/27-B3 1040

MONITORING THE CHEMICAL COMPOSITION OF VOLCANIC GASES: WHY?

Marino MARTINI (Department of Earth Sciences, University of Florence, Via La Pira 4, 50121, Florence, Italy, email: mmartini@cesit1.unifi.it)

Eruptive activities after short or long periods of quiescence of volcanic systems are always preceded by natural phenomena which can allow some kind of forecast: in extensional areas seismic activities along with ground deformations are mainly recorded as short-term forerunners of effusive events, while in compressional areas important degassing is also expected to occur in advance to any eruptive episode. When considering that, for most of the recent disasters produced by resumed activities at quiescent volcanoes, a clear evidence of forerunning seismicities and deformations is not reported, and that the occurrence of significant phenomena of this kind was not always followed by volcanic activity, the study of fluids released in volcanic areas appears to deserve a special attention, in order to evidentiate chemical anomalies possibly related to the instability of deep-seated magmatic systems. The interaction of uprising hot magmatic fluids with deep or shallow aquifers appears as an important factor in triggering eruptive activities whose characters strongly depend on the mass balance between the energy output from magma bodies and the water availability. Sufficient vapour pressure to initiate explosive eruptions are expected when both components are operating, while effusive phenomena are observed for exceeding heatflows, and substantially hydrothermal activities appear as due to overwhelming water recharges. The results obtained during the last decade through geochemical investigations on volcanic gases from different areas of active or quiescent volcanism, allowed to estimate relative extents of magmatic or geothermal conditions for the systems considered, and not negligible contributions for volcano prediction have been derived; examples are given, and case histories are described.

JSV36/E/02-B3 1100

CHEMICAL GAS MONITORING ON MERAPI VOLCANO, INDONESIA

Martin Zimmer (1), Joerg ERZINGER (1) & Yustinus Sulistiyo (2) (1)Geo Forschungs Zentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany, email: weihei@gfz-potsdam.de, (2) BPPTK, Jalan Cendana 15, 55166 Yogyakarta, Indonesia

A specially designed device consisting of a gas chromatograph, an alphaszintillometer and a temperature sensor was successfully installed during August and September 1998 at the Merapi summit. The complete unit operates automatically and can be remote controlled by radio link. Concentration levels of H2O, CO2, SO2, N2, H2 and 222Rn and 220Rn (thoron) as well as the fumarole temperature were measured every 35 minutes over several weeks. In addition gas and fumarole condensate samples were analysed for C-, He- and H- and O-isotopes at the GeoResearchCenter Potsdam. Results of the on-line gas measurements to date show a significant variation of the volcanic gas composition. Periodically SO2, CO2 and H2 concentrations increase while H2O and N2 amounts decrease. Simultaneously the 220Rn concentration increases due to a higher gas velocity. Lower fumarole gas temperatures occur during periods of high water concentrations in the gas. These periodical gas pulses are correlated with higher seismic energies measured in the summit area. The 3He/4He-ratios in Merapi gas samples are between 8-8.8*10-6 which are typical for volcanic gases released at convergent plate boundaries. The d13C-value in CO2 from Merapi gas is -4.9‰. H- and O-isotope investigations on spring water and fumarole condensate samples indicate that the water present in the fumarole is mainly local rainwater. This cold surface fluid circulates within the volcano edifice and mixes and dilutes with ascending volcanic fluids. A regular stronger degassing of the magma causes an increase in gas flux, gas velocity and gas temperature as well as an increase in the ratio of magmatic gas to meteoric water. This leads to higher CO2, SO2 and H2 and lower H2O and N2 concentrations in the fumarole gas. The geochemical data series were correlated with geophysical parameters such as seismicity and deformation rates to create a seismo-geochemical model of the Merapi volcano and, thus, to deduce conclusions on the actual amount of ascending magma and herewith very crucial data on dome growth and volcanic activity.

JSV36/W/04-B3 1115

HYDROGEOCHEMICAL MONITORING OF THE SEISMIC-VOLCANIC ACTIVITY AT MT. TEIDE, TENERIFE, CANARY ISLANDS, SPAIN

Nemesio PEREZ, José M. L. Salazar, J. M. Navarro (all at Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Canary Islands, Spain; e-mail: nperez@iter.rcanaria.es), Giovanni Chiodini (Osservatorio Vesuviano, 80123 Napoli, Italy), and Pedro A. Hernández (Laboratory for Earthquake Chemistry, Univ. Tokyo, Bunkyo-ku, Tokyo 113, Japan)

Mt. Teide (3,716 m of elevation) is a Decade volcano situated at Cañadas caldera, a giant volcanic structure (16 x 9 Km) open to the sea by the north side, in the central part of Tenerife island. Most of the recent volcanic activity at Tenerife takes place along major volcanic rift-zones where had occurred six volcanic eruptions during the last 500 yrs. Most of the fresh water supplies at Tenerife comes from its ground water reserves, and the exploitation of these ground waters by means of thousands of horizontal "gallery" and vertical "well" drillings allow us to reach the volcanic aquifer at many different depth and elevations. These drillings are quite favourable to establish a hydrogeochemical monitoring program for the seismic-volcanic surveillance of Mt. Teide. Monitoring subsurface diffuse degassing of CO2 from Teide volcano by means of a water mass balance and the total inorganic carbon (TIC) content of the ground waters from the Cañadas caldera's aquifer is one of the most significant part of our hydrogeochemical monitoring program. Our results from 1994 and 1996 surveys showed a steady-state level about 94 t·d-1 of subsurface diffuse emission of CO2 from Teide volcano. Controlled and non-controlled discharges of CO2 into Cañadas' aquifer are estimated about 55 t·d-1 and 39 t·d-1, respectively. Secular variations of physico-chemical components in Tenerife's ground waters are also performed by means of a network of observation sites all over the island. Four monitoring sites are operative since 1997, and the results are quite promising for the seismic-volcano monitoring of Mt. Teide.

JSV36/P/01-B3 1130

HYDROTHERMAL FLUIDS ON THE SUBMERGED FLANKS OF VOLCANICALLY ACTIVE ISLANDS IN THE LESSER ANTILLES

Alan Johnson and DAVID CRONAN (both at T. H. Huxley School, Imperial College, London, SW7 2BP, United Kingdom, email: d.cronan@ic.ac.uk

Submarine hydrothermal activity occurs off St. Lucia, Dominica, Montserrat, St. Kitts, Nevis and Saba in the Lesser Antilles. Minor elements in the hydrothermal fluids show significant enrichments over normal seawater values. Manganese is enriched in almost all the vent fluids sampled and Fe, As, Si and Zn are enriched in many of them. Mg and S are depleted. The composition of the hydrothermal fluids varies off island to island.
Observations off Montserrat before and during the early stages of the current eruption showed markedly different degrees of offshore hydrothermal activity, fluid temperature and composition between January 1995 and December 1996. Mn, Fe and As were low in the hydrothermal fluids before the eruption, high at the time of its commencement, and intermediate later. By contrast, terrestrial hydrothermal fluids on Montserrat showed no regular pattern of compositional variation over the same two years.
We deduce that the compositional variability of the submarine hydrothermal discharges off Montserrat reflects the variable leaching of magmatic rock by seawater at different stages of the current volcanic cycle. This has important implications in understanding processes under coastal volcanoes and in predicting their eruptions on the basis of monitoring submarine hydrothermal fluid composition. It also implies that inter-island variability in hydrothermal fluid composition will, in part, reflect the stage of its eruptive cycle that each volcanic island is in.

JSV36/W/05-B3 1145

MAGMA DEGASSING: IMPACT ON GEOCHEMICAL FIELD PARAMETERS, MODELLING AND IMPLICATIONS FOR VOLCANIC HAZARD

P. Mario Nuccio and Antonio PAONITA (both at Dipartimento di chimica e Fisica della terra ed Applicazioni – CFTA, 90123 Palermo, Italy, e-mail: paonita@cfta.math.unipa.it)

Volatiles are dissolved in magma in concentrations related to genesis, composition and evolution of magma itself. At static pressure, magma degassing normally occurs by diffusion, nevertheless, as a consequence of magma ascent and depressurisation, the principal dissolved volatiles (H2O and O2) can reach saturation, forming gas bubbles. Composition of partitioned gas phase will depend by equilibrium processes, which will give a different signature with respect to diffusive ones. The progressive improving of knowledge of gas solubility in magmas permits us to quantitatively describe the above processes, following a thermodynamic and numerical approach. Then, given the initial chemical-physical conditions (P, T, X) of a magma, we can theoretically foresee the composition of released gas, on the basis of a degassing model. From an inverse point of view, we can interpret observed geochemical field parameters (i.e. chemical composition of fumarolic gases) and, above all, their time modifications in term of magma degassing process. By using few but regularly sampled volatile species, the degassing model can be parameterised with regard to the input chemical-physical conditions, so to principally know pressure (and depth) of magma and to detect its ascent toward the surface during the time. We can asses the time scale of the process of magma ascent, having the possibility to extrapolate the depth of magmatic body at a fixed time, above all when a consistent time record of the ascent has been aquired. Since volcanic eruption is the final expression of magma ascent, we can use the above modelling to evaluate volcanic hazard and in forecasting of eruptions.

JSV36/W/18-B3 1200

DIFFUSE DEGASSING OF POPOCATÉPETL, MEXICO

VARLEY, Nick (Instituto de Geofmsica, Ciudad Universitaria, Coyoacan CP 04360 Mexico, email: eruption@iname.com)

The stratovolcano Popocatépetl started its current phase of activity in Dec. 1994. Since then, ash emissions have been occurring and very large quantities of SO2 and CO2 have been measured in the summit plume: up to 50,000 tons/day of SO2. Pyroclastic deposits from previous eruptions are found beneath nearby Mexico City, and the potential for a catastrophic eruption, affecting a huge number of people, cannot be ignored. It is clear that a vigilant and diverse monitoring program is of the utmost importance. A project was initiated in August 1997 to measure the concentration of various soil gases. Certain other active volcanoes, such as Etna, have been found to have large concentrations of particularly CO2 in the soil gas. Although generally concentrated along faults, significant levels of magmatic gases can be often found passively diffusing to any point on the edifice. Monitoring soil gases over time has the potential of indicating changes in the dynamics of a volcano, whilst spatial variation can provide important evidence of structural detail. Measurements such as these are particularly important where, as in the case of Popocatépetl, there is an absence of accessible fumaroles. Surprisingly at Popocatépetl the diffuse component of its degassing budget has been found to be low. Over 400 measurements of Rn and CO2 in soil gas have been performed, using active field methods, with extensive coverage of the volcano. Although levels of up to 14% CO2 have been measured, 13d values of between -21 and 25‰ suggest a largely biogenic origin. 70%

of the results have concentration of CO2 less than 2%. Some samples were analysed for He isotopes, with the resulting ratios having values >1 RA, suggesting a radiogenic, rather than magmatic origin. Some large ravines in the edifice are thought to mark the location of faults. Some have shown large displacements, but here too only low concentrations of soil gases have been measured. Interestingly there is no evidence of a geothermal system associated with the volcano. A model for the edifice has been proposed to offer an explanation.

JSV36/W/26-B3 1215

ANOMALOUS DIFFUSE EMISSION OF CO2 FROM USU VOLCANO, HOKKAIDO, JAPAN

Pedro A. HERNÁNDEZ, Toshiya Mori, Kenji Notsu (all at Laboratory for Earthquake Chemistry, University of Tokyo, Bunkyo-ku 113-0033, Japan; e-mail: hernandez@eqchem.s.u-tokyo.ac.jp), Hiromi Okada (Usu Volcano Observatory, Sohbetsu-cho, Hokkaido 052-0103, Japan), and Nemesio Pérez (Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Canary Islands, Spain).

Usu volcano is located in the SW of Hokkaido and is one of the most active volcanoes in Japan. Seven major eruptions have been recorded at this volcano since 1663. Fumarole temperatures range from 100°C to 480°C. Large amounts of HF, HCl, SO2 and H2 are discharged by high-temperature fumaroles whereas those of low temperatures are CO2-rich. To evaluate the diffuse degassing of CO2 from Usu volcano, a soil CO2 flux survey of about 210 sampling sites was carried out from August 26 to September 3, 1998. Soil CO2 flux measurements were performed by using a NDIR spectrophotometer, and the values ranged from 0.7 to 8,210 g·m-2·d-1. Statistical graphical analysis of the data showed three overlapping populations. The background mean is 37-g·m-2·d-1 and represents 81.5% of the total data. The peak group showed a mean of 2,420-g·m-2·d-1 and represents 9.8% of the total data. The highest levels of diffuse degassing of CO2 are identified at the summit of Usu and along the Usu-Shinzan fault. Other areas with anomalous CO2 flux levels are identified along the NW-SE direction, being probably related with the structure of the southern wall of Toya caldera. Spatial distribution of soil CO2 flux levels shows a good agreement with anomalous soil gas CO2 concentrations and high soil temperatures (up to 64°C). Carbon isotopic analysis of selected samples range from -32.4‰ to -2.6‰ suggesting a mixed biogenic and magmatic origin for these emanations. An output of 183 t·d-1 of CO2 is estimated for the summit of Usu.

JSV36/E/04-B3 1230

HELIUM ISOTOPES AS TRACERS OF INCIPIENT MAGMATISM FOLLOWING THE 1996/1997 SEISMO-TECTONIC CRISIS ON NISYROS VOLCANO (GREECE)

Volker J. DIETRICH (Inst. Mineraology & Petrography ETH Zürich, CH-8092 Zürich, Switzerland, email: wumme@erdw.ethz.ch) Florian M. Schwandner (Inst. Mineraology & Petrography ETH Zürich, CH-8092 Zürich, Switzerland, email: florimax@erdw.ethz.ch) Rolf Kipfer (EAWAG, CH-8600 Dübendorf, Switzerland, email: kipfer@eawag.ch)

The islands of Nisyros, Santorini, Milos and Methana are considered today the most active areas of the Hellenic Island arc in terms of a potential volcanic reactivation. Although the last volcanic activity on Nisyros dates back at least 25 000 years, the geodynamic activity, expressed by high seismic unrest, fumarolic activity and hydrothermal explosions is continuously present. Violent earthquakes, gas detonations and fire accompanied the most recent hydroclastic eruptions in 1873 and 1888. The latter effects are due to high gas emanations of H2S, CO2, H2 and CH4 from fracture zones, which cut the caldera and extend towards NNW through the vicinity of the village of Mandraki into the island of Yali and even towards Kos. In 1996 and in 1997 high-seismic activity (magnitudes of earthquakes up to 5.5 on the Richter scale) occurred on Nisyros and was accompanied by increased tectonic and fumarolic activity. In this respect, the scheme of events as comparable with the violent activity in 1873 and 1888, required serious examination. Besides the permanent residents of the island of Nisyros, several hundred of tourists enter the hydrothermal field of the Nisyros caldera daily without awareness of the entire risk situation. The high 3He/4He ratios of 5.9 to 7.5 x 10E-6 in the Nisyros fumarolic condensates, sampled in October 1997 after the long period of strong earthquake activity, overlap entirely with the helium isotopic ratios measured in the high temperature fumaroles at Vulcano island (Aoelian island arc) during the magmatic/volcanic crisis in 1988 and 1989. In the case of Nisyros, it may be related to magma degassing, indicating an influx of the gases from a replenished magma reservoir at shallow depth.

AN INTEGRATED APPROACH TO THREE-DIMENSIONAL STRATIGRAPHIC RECONSTRUCTIONS OF LONG-LIVED QUATERNARY ARC VOLCANOES: TATARA-SAN PEDRO COMPLEX (TSPC), 36° S, CHILEAN ANDES

Michael DUNGAN and Brad Singer (Département de Minéralogie, Université de Genève, 13 rue des Maraîchers, 1211 Genève 4, Switzerland, email: dungan@terre.unige.ch) Ren Thompson (U.S. Geological Survey MS910, Denver Federal Center, Denver, CO 80225 USA) Laurie Brown, Jim Pickens and Andrew Wulff (Department of Geology and Geography, University of Massachusetts, Amherst, MA 01003)

The TSPC is a large frontal arc center of the Andean Southern Volcanic Zone dissected on all flanks by glacial valleys exposing the eruptive products of seven edifices ranging in age from 930 ka to Holocene (Singer et al, 1997; GSA Bull). Sequences older than 200 ka are remnants of spatially overlapping volcanoes reduced in volume (50-90 %) by glaciation and sector collapse, and preserved remnants generally record short durations relative to intervening lacunae. Digitised photogrammetric projections based on stereo imagery of canyon walls represent stratigraphic relations and the geometries of erosion surfaces in far greater detail and more accurately than conventional mapping would permit. The internal stratigraphy of several sequences has been reconstructed on the basis of geochemical data (650 samples collected in 25 flow-by-flow canyon sections) plus photogrammetric, geochronologic and paleomagnetic constraints. This composite stratigraphy is far more complete than the records present in any single section due to the eccentric distributions of the products of consecutive eruptive events and the effects of erosion. Many stratigraphic successions record temporal trends lacking in evidence for progressive differentiation. The resulting constraints on petrologic models are far different than if apparently co-magmatic lavas were assumed to reflect single-stage differentiation. Most eruptive events reflect arrival of small quantities (<1-2 km3) of diverse mafic magma into shallow conduit-reservoir systems where they mixed in varying proportions with variably evolved resident magmas.

JSV36/C/JSA15/W/34-B3 1415

EVOLUTION OF MONTSERRAT USING 40AR/39AR GEOCHRONOLOGY

CHLOE L HARFORD and R Stephen J Sparks (Department of Earth Sciences, Bristol University, Bristol BS8 1RJ, UK; email: chloe.harford@bris.ac.uk); Malcolm S Pringle (Scottish Universities Research and Reactor Centre, East Kilbride, UK); Simon R Young (British Geological Survey, Edinburgh, UK)

40Ar/39Ar ages of volcanic rocks representing the major stratigraphic units of Montserrat facilitate a substantial reinterpretation of the evolution of the island. These ages are more precise and significantly different from existing conventional K-Ar ages. We identify three distinct volcanic centres: Silver Hills (c.1.2 to 2.6 Ma); Centre Hills (at least c.950 to 550 ka); Soufriere Hills (at least c.150 ka to present). Volcanism on Montserrat has migrated southwards through time, at a time averaged rate of c. 6 km/m.y. parallel to the trench and c.2 km/m.y. away from the trench, consistent with work elsewhere in the arc.
Six new ages give insights into the life cycle of the youngest centre. The history of the currently active Soufriere Hills Volcano, dominated by andesitic lava dome eruptions, is extended back to 150 ±3 ka (1_ error), well beyond the oldest radiocarbon age of 31.6 ±0.2 ka. We estimate its time-averaged eruption rate to be c.0.0015 m3/s. Ages for three pyroclastic flow deposits and two domes indicate that preservation of domes is incomplete, and large scale collapse may play a significant role in the volcano's history.
An age of 959 ±19 ka from Roche's Bluff, south-east of Perches dome (Soufriere Hills), facilitates the interpretation of this intensely disrupted pyroclastic sequence as part of the uplifted submarine fan of the Centre Hills. We further propose that St George's Hill and Garibaldi Hill to the north-west of the Soufriere Hills are uplifted pyroclastic sequences. An age of 282 ±8 ka from Garibaldi Hill suggests this sequence may represent the early stages of the Soufriere Hills.
Step heating experiments on material from the current eruption give an age indistinguishable from zero (21 ±22 ka) for groundmass separates but an age significantly greater than zero (426 ±95 ka) for separated plagioclase phenocrysts, indicating no extraneous argon in the groundmass but xenocrysts in the plagioclase phenocrysts. Thus, groundmass separates should be used whenever possible for dating crystal-rich andesites.

JSV36/W/09-B3 1430

SHALLOW SEISMICITY AND CRUSTAL DEFORMATION ASSOCIATED WITH THE 1998 INTRUSION EVENT AT IWATE VOLCANO, NORTH-EASTERN JAPAN

Satoru TANAKA, Sadato Ueki, Minemori Sato, and Hiroyuki Hamaguchi (all at Graduate School of Science, Tohoku University, Sendai 980-8578, Japan, email: tanaka@aob.geophys.tohoku.ac.jp)

Since we first observed volcanic tremors in Iwate volcano in September 1995, we have gradually extended seismic stations in and around the volcano and, at the present, we have 20 stations in the area of 15 km x 20 km. We have succeeded to catch a new seismic activity and revealed that the activity is related with intrusion of magmatic fluid beneath the volcano. The activity had started in January 1998 beneath a crater rim adjoining the west of the summit. Magnitudes of the events were less than 0.5, focal depths were 2 - 6 km, and the occurrence rate of the earthquakes was about 10 per month till the middle of March. Suddenly on March 20, the first earthquake swarm had occurred. The source region had extended westward up to 2 km in distance, magnitudes had grown to 0.5 - 1.0, and focal depth had moved to 0-2 km. After this swarm, the rate had increased to about 50 per month till the middle of April. On April 29, the second swarm had occurred. Source region had extended westward more, and earthquakes with magnitude greater than 2 had occurred. After the second swarm, the rate had increased to about 150 per month. Since June, the source region of the seismic activity had gradually extended westward with lapse of time. Then the last geometry of source region is a rectangular shape with 10-km length from east to west and 3km width from north to south in August. Critical comparisons of the above seismicity with crustal deformations observed by borehole strain and tilt meters at 3 stations and GPS (Ueki et al., 1999) clarified upward and westward movements of a pressure source beneath the volcano. Thus we conclude that the both activities are induced from intrusion of fluid like magma. At the final stage of the intrusion event, on September 3, an earthquake M6.1 has occurred at the point close to the western tip of the seismic source region. The mechanism of the earthquake is the explained by a thrust type fault presumably affected by the above intrusion.

JSV36/E/13-B3 1445

APPLICATIONS OF GPS GEODESY ON ACTIVE STRATO-VOLCANOES: CASE STUDIES OF SOUFRIERE HILLS, MONTSERRAT, POPOCATEPETL, MEXICO, AND MISTI, PERU

Glen MATTIOLI, Lizzette Rodriguez, Alan Smith (all at Department of Geology, University of Puerto Rico, Mayaguez, PR 00681 USA, Email: glen@geology.uprm.edu); Enrique Cabral, Edmundo Norabuena, and Timothy Dixon (all at Department of Marine Geology and Geophysics, RSMAS, University of Miami, Miami, FL 33149 USA, Email: tim@corsica.rsmas.miami.edu)

Ground deformation is important for monitoring volcanoes for hazard assessment and elucidation of sub-surface magmatic processes. GPS geodesy is now used exclusively or in concert with traditional deformation techniques, such as telemetered electronic tiltmeters, precision leveling, and electronic distance measurement, to study volcanic systems at different stages of evolution. While each technique is useful, GPS geodesy has some unique characteristics, which makes it a powerful tool for the study of volcanoes. Continuous GPS (CGPS) systems have special difficulties related to maintenance during intense volcanic activity. We report here results obtained from 1995 to 1999 using mixed-mode and CGPS geodesy from three stratovolcanoes: Soufriere Hills (SH), Montserrat; Popocatepetl (Popo), Mexico; and Misti, Peru. CGPS systems have been deployed at SH and Popo since mid 1996 and Misti since late 1998. In the case of Soufriere Hills, GPS data span the period of phreato-magmatic venting, andesitic lava effusion, dome building and collapse, vulcanian to sub-plinian explosions, and apparent quiescence. CGPS data from Popo span the period of high SO2 gas emission and venting. While CGPS provides dense temporal sampling, additional mixed-mode and campaign style GPS data are essential to constrain spatially variable deformation fields at the scale of 1 to 10 km. Data spanning distinct eruption events and changes in eruption magnitude or style provide constraints on sub-surface deformation sources. Magma storage depths, volumes, and viscosities may be deduced using elastic and finite-element models.

JSV36/W/17-B3 1500

REMOTE SENSING AND GPS FOR DIGITAL TERRAIN MODELS EXTRACTION: VALIDATION AND COMPARISON OF OBSERVATIONS FOR VOLCANIC MODELLING

Baldi P. - Dip. di Fisica, Università di Bologna, Bonvalot S. - ORSTOM Bondy Briole P. - Institut de Physique du Globe de Paris, Gwinner K. - German Aerospace Center (DLR), Institute of Planetary Exploration, Berlin, Germany M. Coltelli, G. Puglisi - C.N.R. - International Institute of Volcanology (IIV), Catania, Italy MARSELLA M. - DITS, Università di Roma "La Sapienza"

Satellite and airborne remote sensed images provide a powerful tool for Digital Terrain Model (DTM) extraction especially when coupled with the use of Global Positioning System (GPS) techniques for georeferencing and validating results. 3D topographic observations acquired periodically over volcanic areas can be used for deformation monitoring and morphological changes detection. Different studies for monitoring and modelling volcanic processes can be performed depending on the quality and the resolution of the available DTM.
The performance of different methods for DTM extraction are analysed by comparing results over a test area on the Vulcano Island: high resolution DTM obtained by automatic digital processing of airborne stereoimages from a photogrammetric camera (Wild RC20) and a High Resolution Stereo Camera (HRSC) are analysed and compared. A SAR interferometric DTM is also derived in support of studies with low accuracy requirements, such as those dedicated to landslides and lava flows monitoring. High accurate height profiles from a GPS kinematic ground survey is used for DTM validation.

JSV36/W/23-B3 1515

DYNAMIC DEFORMATION OF ETNA VOLCANO OBSERVED BY GPS AND SAR INTERFEROMETRY

P. LUNDGREN, P. Rosen, and F. Webb (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109, USA, e-mail: paul@dagobah.jpl.nasa.gov) R. Lanari, M. Tesauro, and E. Ssosti (IRECE, Via Diocleziano, 328, 80124 Napoli, Italy, e-mail: lanari@irece1.irece.na.cnr.it) G. Puglisi, A. Bonforte, and M. Coltelli (Istituto Internazionale di Vulcanologia-CNR, Piazza Roma, 295123 Catania, Italy, e-mail: geo@iiv.ct.cnr.it)

Synthetic aperture radar (SAR) interferometry and GPS have shown that during the quiescent period from 1993-1995 Mt. Etna volcano, Italy inflated. Since the initiation of eruptive activity since late 1995 the deformation has been more contentious. We will explore the detailed deformation during the period from 1995-1996 spanning the late stages of inflation and the beginning of eruptive activity. We use SAR interferometry and GPS data to measure the volcano deformation. We invert the observed deformation for both simple point or tensile crack elastic sources or if warranted for a spheroidal pressure source. In particular, we will examine the evolution of the inflation and the transition to a lesser deflation observed at the end of 1995. We use ERS-1/2 SAR data from both ascending and descending passes to allow for dense temporalsampling of the deformation and to allow us to critically assess atmospheric noise. Preliminary results from interferometry suggest that the inflation rate accelerated prior to resumption of activity in 1995, while GPS data suggest a more steady inflation with some fluctuation following the start of activity. This study will compare and contrast the interferometric SAR and GPS results and will address the strengths and weaknesses of each technique towards volcano deformation studies.

JSV36/E/01-B3 1610

STUDYING THE DEFORMATION CHARACTERISTICS OF GUNTUR VOLCANO (INDONESIA) BY USING GPS, GRAVITY, AND EDM DATA

Hasanuddin Z. ABIDIN , I. Meilano, M. A. Kusuma , B. Setyadji , J. Kahar (all at Department of Geodetic Engineering, Institute of Technology Bandung, Jl. Ganesha 10, Bandung, Indonesia, email: hzabidin@indo.net.id) Oni K. Suganda, Edi Suhanto, R. Sukhyar (all at Volcanological Survey of Indonesia, Jl. Diponegoro 57, Bandung, Indonesia) Torao Tanaka (Disaster Prevention Research Institute, Kyoto University, Uji, Kyoto, Japan)

Guntur is an andesitic strato volcano and based on the criteria used by the Volcanological Survey of Indonesia it is classified as the type-A volcano, i.e. very active volcano. It is located a few km from town of Garut and about 40-km southeast of Bandung, the capital city of West Java province,Indonesia. Due to its potentially active nature, Guntur volcano is being monitored using several methods, i.e. visual, seismic, deformation (i.e.tiltmeter, EDM, levelling, and GPS survey), and eochemical (i.e.temperature measurements) methods.
In this paper the deformation study of Guntur volcano using repeated GPS surveys, micro gravity surveys, and EDM (Electronic Distance Measurement) methods will be described and discussed. The deformation characteristics of Guntur volcano are investigated using the data from seven repeated GPS surveys, two repeated microgravity surveys, and three EDM surveys that have been conducted in the deformation monitoring network covering Guntur volcano and her urrounding. The main goal of this deformation study is to derive the depth and size of the magma chamber of Guntur volcano from the displacement vectors obtained from the aforementioned surveys, and also to predict the magma supply rate to the volcano and its outgoing volume in case of eruption. This paper will mainly discuss the aspects related to achieving that main goal of deformation study in Guntur. These includes planning and execution of the surveys in the volcano environment, elimination of errors and biases in the data, data processing strategy, deformation modelling, and interpretation of the results. The paper would be sum up with some closing remarks.

JSV36/E/30-B3 1625

MAGMA COMPRESSIBILITY IN SHALLOW CHAMBERS BENEATH CALDERAS

Hazel RYMER and John B Murray (both at Department of Earth Sciences, The Open University, Walton Hall, Milton Keynes, Bucks, MK7 6AA, UK, email: h.rymer@open.ac.uk); Corinne A Locke and John Cassidy (both at Department of Geology, The University of Auckland, email: c.locke@auckland.ac.nz); Clive Roberts (School of Applied Sciences, University of Wolverhampton, email: in5359@wlv.ac.uk)

The simple and much used Mogi model relates the change in edifice volume (DVe) measured by ground deformation to the change in sub-surface magma chamber volume (DVch). Variations in gravity can also be monitored on active volcanoes and the change in sub-surface magma mass (D Mm) can be quantified. Gravity has been particularly useful in identifying sub-surface mass changes (often interpreted in terms of shallow magma movements within the volcanic edifice) at basaltic and andesitic volcanoes with cones, where the ground deformation is relatively small. At calderas in a state of unrest, the gravity-height gradient is usually close to the free-air-gradient (FAG), but the changes occur over such a large area that DMm is of the order 1010-1012 kg. At these volcanoes, the source of the ground deformation and gravity changes is likely to be the same, relatively deep magma chamber (2-3 km typically), whereas for stratocones the sources are not necessarily the same (the cone may be fracturing and collapsing while magma is infiltrating a surface feeding conduit). It is remarkable that the range of measured DVe and inferred DMm observed at calderas in a state of unrest is less than 2 orders of magnitude. A logical conclusion from the similarity in DVe and DMm might be that the magma and country rock physical properties are similar at each of the sites studied, however subtle variations in the gravity-height gradients (i.e. deviations from the FAG) indicate that there are contrasts in the sub-surface conditions. Since magma movement characteristics are dominated by magma properties rather than by country rock properties, these variations may provide an index of magma fluid dynamic properties, most notably magma compressibility (Km). By assuming a magma density, a relationship between magma and edifice volume change and the ratio between country rock rigidity (me) and Km can be derived.

JSV36/E/16-B3 1640

DISPLACEMENTS, GRAVITY CHANGES AND DEFORMATION FIELD DUE TO DIFFERENT SOURCES OF ANOMALOUS HEAT FLOW IN ELASTIC AND VISCOELASTIC MEDIUM

Ladislav BRIMICH (Geophysical Institute, Slovak Academy of Sciences, Dubravska 9, 842 28 Bratislava, Slovakia, email: geofbrim@savba.sk)

Theoretical formulae and results of numerical calculation of the deformation field, displacements and gravity changes, due to magmatic bodies approximated by a three dimensional prism embedded in an elastic and viscoelastic halfspace are presented. It is shown that surface displacements cause a pronounced dome in the epicentral region and that surface tensile stresses attain values that compare well with the critical stress required to cause creep or fractures at the surface of the halfspace. Important effect of magmatic bodies is their upward pressure induced by the presence of various hot gases, fluids and by less density of magma in comparison with ambient solid rocks. A concentrated vertical force acting in the elastic halfspace approximates this effect. The results are in good agreement with known patterns of the displacements, the stresses and the faults observed in the regions of near-surface igneous bodies (e.g. laccolithes or diapires).

JSV36/E/15-B3 1655

ON THE INTERPRETATION OF THE MICROGRAVITY AND GPS MEASUREMENTSIN MAYON VOLCANO, PHILIPPINES

JOSE FERNANDEZ (Institute of Astronomy and Geodesy, Fac. Ciencias Matematicas, Ciudad Universitaria, 28040-Madrid, Spain, email: jft@iagmat1.mat.ucm.es) Kristy F. Tiampo (CIRES, University of Colorado, Boulder, CO, USA, email: kristy@fractal.colorado.edu) Gerhard Jentzsch (Institute for Geosciences, FSU Jena, Germany, email: jentzsch@geo.uni-jena.de) John B. Rundle (CIRES, University of Colorado, Boulder, CO, USA, email: rundle@hopfield.colorado.edu).

Mayon volcano is part of the Bicol volcanic chain of the island of Luzon, Philippines. During this century there have been 10 active periods distributed at regular intervals. Because of the dense population living in the vecinity of the volcano, seismological observatories are in operation in addition to measurements of gravity begun in 1992. Two profiles at the slope were established, connected to a regional network around the volcano. The height control is provided by parallel Global Positional System (GPS) measurements. During 5 campaigns within four years the differential GPS gives no significant changes in elevation (around 4 cm), but the gravity increased significantly by up to 1500 nm/s2 (Jentzsch et al, 1999). Both facts can not be explained with the classical Mogi model (Mogi, 1958). Jentzsch et al. (1999) explain the existing gravity changes without changes in elevation by density changes within a vent system. They do not obtain a perfect fit of data and model results. In this paper we made an interpretation of the geodetic signals observed on Mayon volcano using genetic algorithm inversion technique and considering elastic gravitational Earth models in place of purely elastic ones. The obtained results are described.

JSV36/E/25-B3 1710

THE STROMBOLI VOLCANO AS A NATURAL MULTIDISCIPLINARY LABORATORY A PROPOSAL

Carlo Bellecci (II Universita di Roma, Tor Vergata, Roma, Italy); Gino M. Crisci (UNICAL, Arcavacata di Rende, Cosenza, Italy) Giuseppe de Natale (Osservatorio Vesuviano, Napoli, Italy) Giovanni P. Gregori (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy; e-mail: gregori@atmos.ifa.rm.cnr.it) Iginio Marson (Universita di Trieste, Italy) Gabriele PAPARO (IDAC-CNR, Roma, Italy), and Domenico Patella (Universita Federico II, Napoli, Italy)

Stromboli is a volcanic island slightly North of Sicily, within a tectonic setting characterised by a Benioff zone, that is curved like a Greek theatre opened towards the Tyrrhenian Sea, with very deep earthquakes. It is the unique volcano of entire world that explodes very regularly, every ~15-20 min, since at least ~3,000 years. A permanent Laboratory has recently been established on it, and an extensive interdisciplinary programme is being started. The monitored phenomena are (including their respective time evolution after every volcanic explosion): soil deformation, stress and strain; seismicity, microseismicity and acoustic emissions; gas exhalation and exchanges between soil and atmosphere and/or by submarine fumaroles; shallow and deep geothermic s; geo-e.m. (spontaneous potentials, geomagnetic field, aeromagnetism, Coulomb charge of the ejecta, atmospheric electrical gradient and conductivity, lightning discharges within the plume, eventual coupling between volcanic explosions and ionospheric dis t urbances); mineralogical, geochemical, and isotopic information; volume and speed of the ejecta; aerosols; atmospheric chemistry and radiative balance; meteorological and environmental impact; boundary layer meteorology either with or without the volcanic injection; etc.

SMALL SCALE THERMAL DEMAGNETIZATION AFTER SEISMIC SWARM DETECTED FROM DENSE OBSERVATION USING ARGOS SYSTEM

Tsuneomi KAGIYAMA, Maroka Neki and Fumio Masutani (Earthquake Research Institute, University of Tokyo, Tokyo 113-0032, Japan, email: kagiyama@eri.u-tokyo.ac.jp, neki@eri.u-tokyo.ac.jp, masutani@kirishima.eri.u-tokyo.ac.jp)

Significant information is frequently obtained only at crater zones. Volcano Research Center, ERI developed our own suitable interface for ARGOS system to control the observation and acquisition system to obtain and process the data. Five sets of the ARGOS transmitters were installed just around the crater of Shinmoe-Dake, Kirishima Volcanoes in Japan for total intensity of geomagnetic field and ground temperature. Geomagnetic observation found annual changes up to 1 nT for each site, and clarified an anomalous change up to 2 nT of total intensity from 1993 to 1994 after eliminating the annual changes. The position of this anomalous change is determined within the ÔShallow Low Resistivity RegionÕ, which has already been detected by MT survey and was interpreted as a water saturated layer beneath the crater. After precise seismological and other geophysical observations, it is found that this change followed the outbreak of the earthquake swarm at the top of the ÔDeep Low Resistivity RegionÕ, which is also detected by MT survey, and upward migration of seismic activity. This

evidence suggests that this thermal demagnetization be caused by the increase of the temperature within the ÔSLRRÕ following the supply of magma or magmatic gas associated with the seismic swarm from the top of the ÔDLRRÕ. From the end of 1998, fumarolic temperature was also observed within the crater of Shinmoe-Dake to detect an anomalous change of fumarolic temperature.

MORPHOLGICAL INSIGHTS OF SELF-POTENTIAL ANOMALIES

Yasunori NISHIDA (Department of Earth and Planetary Sciences, Hokkaido University, Sapporo, 060-8010 Japan. Email: nishida@ares.hokudai.ac.jp) Jacques Zlotnicki (Laboratoire de ophysique(a), UMR 6530, 3d av de la recherche scientifique 45071 Orl=E9ans cedex 02, France. Email: jacques.zlotnicki@cnrs-orleans.fr)

During several tens of years Self-Potential (SP) prospectings have been carried out in order to evidence hydrothermal systems associated with geothermal fields. During the last decade a new interest of this technique has appeared. Many teams have tried to extrapolate such studies onvolcanoes. Nowadays we have numerous examples of detailed SP mappings on volcanoes; some of them being active. The comparison of the spatial distribution of SP anomalies and their respective amplitudes allow us to synthesise the general features of SP anomalies on volcanoes.- On Mount Pel=E9e (Fr), which is an andesitic volcano in a rest period, essentially negative anomalies, up to -1500 mV in amplitude, are observed. They are related to existing calderas and infiltration of meteoric water on the slopes ("topographic effect"). Such anomalies are also observed on Mt Esan (Jp). - On Soufri=E8re of Guadeloupe (Fr), Komogatake (Jp), Usu (Jp) or Vulcano (It) where an active hydrothermal system produces a strong superficial argillisation, the SP anomalies are smooth and positive. The amplitude generally does not exceed several hundreds mV. - On volcanoes like Piton de la Fournaise (Fr) or Miyake-Jima (Jp) where an hydrothermal system is well-developed in the central part, one can observe the superimposition of sharp and large (< 2 V) positive anomalies. These ones disappear away off the summit where the so-called "topographic effect" is predominant. (Jp: Japan; Fr: France; It: Italy).

JSV36/E/28-B3 Poster 0900-03

SELF-POTENTIAL MEASUREMENTS ON A CALDERA LAKE

Mituhiko SUGIHARA and Tsuneo Ishido (both at Geothermal Research Department, Geological Survey of Japan, 1-1-3, Higashi, Tsukuba, 305-8567, Japan, email: sugihara@gsj.go.jp)

Lake bourne self-potential (SP) measurements can be made by towing electrode pairs behind a boat. The potential gradient distribution are evaluated from the observed potential differences, and integrated into the potential distribution along the track line. Offset between the electrodes must be evaluated accurately because the integration process amplifies it. Outgoing and returning on the same track line is essential to determine the offset value accurately. Continuous kinematic GPS survey makes it possible to evaluate how the track lines coincide with an accuracy of a few centimeters. We succeeded in determining SP distribution with a resolution better than 1 mV on Lake Kutcharo, which is the largest caldera lake in Japan. This experiment shows SP measurements on lake are better in resolution than on land. SP anomalies often observed in volcanic areas. Crater lakes and caldera lakes must be potential fields to apply the lake bourne SP measurements to detect volcanic SP anomalies.

JSV36/W/25-B3 Poster 0900-04

RESISTIVITY IMAGING AND SELF POTENTIAL MONITORING AT MERAPI

S. FRIEDEL, F. Jacobs (both Institut für Geophysik und Geologie, Universitat Leipzig, Talstraáe 35, 04103 Leipzig, email: friedel@rz.uni-leipzig.de)

The presentation reports a) results of a near surface resistivity calibration survey in an active solfatara region of Merapi volcano, b) acquisition and processing technology and results of 2.7 km dipole-dipole resistivity survey, and c) results of self potential (SP) mapping and monitoring at the summit.
Near surface resistivity surveys indicate great variability of resistivity in the solfatara region (rho=2...2000 Ohmm) depending on fluid saturation and presence of alteration minerals. Resistivity and SP profiles across active solfatara show strong correlation and are consistent with a model of a two-phase convection cell.
A 2.7 km long dipole-dipole profile with was set out radially along the West flank of Merapi between 1300 m and 2000 m above sea level. A special field procedure and data processing schemes are presented. A portable, light-weight DC-transmitter allowed the acquisition of a large number of data despite the rough volcanic terrain. Using 24-bit stand-alone data receiver technology (RefTek) and special data enhancement procedures electrical field amlitudes as low as 100 nV/m could be detected reliably. 2D-Inversion was carried out to a depth of 750 m. The resulting model can be interpreted as a high resistivity top layer of unsaturated pyro-clastics (rho=1...10 kOhmm, t=200...350 m) following an intermediate layer (rho=100...500 Ohm, t=150 m 200 m) and a low resistivity zone (rho<100 Ohm, starting between 350 m and 550 m) of partly saturated and hydrothermally altered pyroclastic and effusive material. SP monitoring at two channels near the solfatara and a remote reference show changes in the order of 10 mV within hours but are only weakly correlated.

JSV36/W/27-B3 Poster 0900-05

RESISTIVITY STRUCTURE IN THE SOUTHERN KYUSHU AREA, SOUTHWEST JAPAN, REVEALED BY MAGNETOTELLURIC METHODS

Hiroshi MUNEKANE, Tsuneomi Kagiyama and Hisashi Utada, Earthquake Research Institute, University of Tokyo, 1-1-1, Yayoi, Bunkyo-ku, Tokyo, 113-0032, Japan (email: munekane@eri.u-tokyo.ac.jp, kagiyama@eri.u-tokyo.ac.jp, utada@utada-sun.eri.u-tokyo.ac.jp)

The southern part of Kyushu, southwest Japan, is an area of high volcanic activity in which a number of volcanoes are distributed such as the Kaimon-dake, the Sakura-jima, the Kirishima volcanoes or the Aso. However, distribution of these volcanoes is not spatially uniform, and types of the volcanism have large locality. This apparent heterogeneity of volcanism in this area may deeply related to that of magma supply system at depths, which may be reflected by the deep crustal structure. The present paper studies the relation between regional volcanism and electrical resistivity structure by Magnetotelluric (MT) method. Prior to the investigation of the resistivity structure, the method to remove galvanic effect developed in Munekane and Utada (1998) is applied to the obtained MT responses. The method has an advantage that it can be theoretically applicable even when a regional structure has three dimensional characteristics, which is a common case in a complex region such as Japan. Although a full 3-D resistivity model should finally be presented, preliminary 1-D modelling show that the resistivity structure in the area have two characteristic features. One is the shallow low resistivity regions (SLRR), which are located at several hundreds of meters depth and have resistivities around 10(Ohm-m) or less. Another feature is the deep low resistivity regions (DLRR), which are located around 10km or deeper and have resistivities around 10(Ohm-m). The DLRR and SLRR can only be seen in the western part of the volcanic front in this area. The distribution of the SLRR shows good agreement with volcanic regions in Cenozoic era. This implies that the SLRR is possibly related to hydro-thermal activity under this area. The DLRR, on the other hand, not only exists around the Kirishima volcano area but also looks to extend toward north where no volcano exists between the Kirishima and Aso volcanoes. The DLRR may be interpreted as a deep region containning partial melt or free water.

JSV36/E/08-B3 Poster 0900-06

THE ELECTRICAL STRUCTURE BENEATH WUDALIANCHI VOLCANIC CLUSTER IN HEILONGJIANG PROVINCE OF CHINA

Guoze ZHAO, Denghai Bai, Yan Zhan, Jijun Wang, Guangwen Jin and Zhao Jiang Institute of Geology, Seismological Bureau of China, Beijing 10029, China email: zhaogz@public.bta.net.cn

Wudalianchi volcanic cluster located in northern part of North-East China,with coordinates of longitude E 126¡ã00--126¡ã20¡ä and latitude of N 48¡ã34¡ä--48¡ã48¡ä. It consists of 14 cones. The last eruption of the volcanoes was in the year of 1719 to 1721 and two of cones, Laoheishan cone and Huoshaoshan cone were formed. MT measurement are recently carried out at 71 sites along three EW profiles and four NS profiles in the volcanic cluster and the vicinity in order to study the magma chamber and deep structure and volcanic activity. The periods of the data ranged from 256Hz to about 4096 sec.
The real part of magnetic induction arrows at most of MT sites for periods from several to dozens seconds direct to the cluster center (to high resistivity) showing there is a resistive body in the upper crust. Those for longer periods (around 1000sec) tend to direct to outside of the cluster showing us that there is lower resistivity body in the deeper depth. The 2-D inversion results by RRI method for EW profiles show that there is a high resistivity body like as rivet form from surface to about 20 km depth. The width of the body in EW direction at depth less than 5 km is about 20 km. The width for the lower part of the body is less than 10km. However the tip of the rivet body extends continuously down to several tens kilometers and resistivity deceased with increasing depth. The seismic activity is, recent year, significant in southwestern part of the cluster where low resistivivity appeared at depth deeper than 5 km. Most of micro shocks were at shallower depth than 5 km. It is postulated that the high resistivity body with rivet form is a cooling magma chamber. A passage for the magma exited in the deeper depth.

JSV36/E/23-B3 Poster 0900-07

MAGNETOTELLRUC SOUNDINGS ON MIYAKE-JIMA VOLCANO: A TOOL TO UNDERSTAND THE STRUCTURE AND ITS DYNAMISM

Jacques ZLOTNICKI (Laboratoire de Geophysique(a), UMR 6530, 3d av de la recherche scientifique 45071 Orleans cedex 02, France. Email: jacques.zlotnicki@cnrs-orleans.fr) Yochi Sasai (Earthquake Research Institute(b), Tokyo University, 1-1 yayoi 1-chome, Tokyo, 113 Japan. Email: sasai@eri.u-tokyo.ac.jp) Paul Yvetot(a), Yasunori Nishida (Faculty of Sciences, Sapporo, Japan) & Makoto Uyeshima(b).

Miyake-Jima Island is located on the Izu-Bonin trench extending SSW of Tokyo bay. Miyake-jima is a very active stratobasaltic volcano that can erupt about every twenty years. Large eruptions have occurred in 1940, 1962 and 1983. A new one is excepted in the next ten years. To better understand the monitoring of the volcano with electromagnetic methods we have undertaken several campaigns of Magnetotelluric soundings on the island. The objectives were to recognise the existing calderas which form the upper part of the volcano, the main fissural axes along which the last eruptions have taken place, the seawater penetration through the inner part of the island, and the hydrothermal system(s) mainly located in the summit part of the volcano. More than 80 soundings were done in the band 70 kHz-0.1 Hz. We have used an antenna in the band 70 kHz-1 kHz in order to get data when the natural EM field was too weak or in existing. These data give information between a few tens meters and several kilometres deep. The preliminary results are the following: The seawater infiltrates the massif over several hundreds meters depending on existing fissural eruptive axes (SSW, N, NE) and craters bordering the coast. The main fissural axes along which the last eruptions have taken place are well evidenced from the coast to the summit. Some caldera borders are also evidenced; some of them favour the formation of hydrothermal systems in their inner part.

DIFUSSE DEGASSING OF CO2 AND 222RN IN AND AROUND THE VOLCANIC RIFT-ZONES OF EL HIERRO, CANARY ISLANDS, SPAIN

Ancor TRUJILLO, Yurima Gimeno, Sofía Medina (all at the Faculty of Chemistry, Univ. La Laguna, 38206 La Laguna, Tenerife, Spain), José M. Salazar, José M. Navarro, Nemesio M. Pérez (all at the Environmental Research Division, ITER, 38611 Granadilla, Tenerife, Spain) and Pedro A. Hernández (Lab. for Earthquake Chemistry, Univ. Tokyo, Tokyo 113, Japan)

El Hierro (278 Km2) is situated in the southwestern part of the Canary Islands. Subaerial volcanic activity has mainly occurred along three major volcanic rift-zones during the last 1Ma. Gravitational depressions had also occurred at El Hierro, and this type of geological process is responsible for the formation of geomorphological features such as El Golfo Valley. The objective of this study is to evaluate the spatial distribution of soil CO2 flux and soil gas 222Rn levels for monitoring magma movement and seismicity changes in the island.
A soil gas 222Rn and CO2 flux survey was performed at 626 sampling sites using a portable radon sensor and a NDIR spectrophotometer, respectively, in 1998. Statistical-graphycal analysis of soil gas 222Rn data showed three geochemical populations. The background has a mean of 10.4 pCi/L and represents a 59% of the total data. The peak population showed a mean of 74 pCi/L and represents a 1.8% of the total data. Soil CO2 flux data showed also three geochemical populations. The background mean is 0.3 g·m-2·d-1 and represents 83% of the total data. T he mean of the peak group is 48 g·m-2·d-1 and represents 0.5% of the total data. Anomalous levels of soil CO2 flux and soil gas 222Rn leves were detected at the intersection of the three major volcanic rift-zones as well as in the central and western part of El Golfo. Other peak values were found along the NE rift-zone, some of them associated to recent fracture/faults. Total diffuse emission of soil CO2 from El Hierro is about 190 t·d-1.

JSV36/W/20-B3 Poster 0900-09

SOIL CO2 FLUX MONITORING NETWORK FOR THE SEISMIC-VOLCANIC SURVEILLANCE OF TENERIFE, CANARY ISLANDS, SPAIN

Dácil CARBALLO, Carolina Méndez, Francisco Martín (all at Faculty of Chemistry, Univ. La Laguna, 38206 La Laguna, Tenerife, Canary Is., Spain; e-mail: timanfaya@iter.rcanaria.es), José M. L. Salazar, Nemesio M. Pérez (ITER, 38594 Granadilla, Tenerife, Canary Islands,Spain), and Pedro A. Hernández (Lab. for Earthquake Chemistry, Univ. Tokyo, Bunkyo-ku, Tokyo 113, Japan)

Tenerife is the largest island (2.034 Km2) of the Canarian Archipelago. Most of the historial volcanic activity at Tenerife, about 6 eruptions during the las 500 yrs, has occurred along its rift-zones the last eruption being in 1909, Chinyero volcano. Fumarolic degassing (85ºC)

occurs just at the summit of Teide volcano (3.716 m of elevation), but diffuse mantle degassing can occur along the rift-zones (Pérez et al., 1996). The role of carbon dioxide as the main pressure-generating component in basaltic magmas, the lack of fumarolic activity, and the geological evidence of significant and recent volcanic activity along the rift-zones support the use of soil CO2 flux monitoring network as an additional geochemical tool for volcanic surveillance at Tenerife. Soil CO2 flux measurements are performed since March 1997 by using alkaline traps (NaOH 1N) which are exposed to the soil atmosphere for one week period. This integrated technique for soil CO2 flux monitoring is being applied at 23 stations which are distributed all over Tenerife. Estimated soil CO2 flux values are quite similar to those observed by a portable NDIR, especially for low flux levels. Significant spatial variations of soil CO2 fluz levels have been detected. Most of the monitoring stations along the rift-zones showed soil CO2 flux levels from 1.2 to 27.8 g·m-2·d-1, and the average level ranged from 8.1 to 11.3 g·m-2·d-1. In the central part of the island soil CO2 flux leves were higher, up to 43.1 g·m-2·d-1, than those observed along the rift-zones. To this date, soil CO2 flux secular variations are closely related to meteorological fluctuations.

SOIL PH MAPPING TO EVALUATE INTENSIVE MAGMATIC-HYDROTHERMAL DIFFUSE DEGASSING ON ACTIVE VOLCANOES

Marcos VALIENTE, Belen Meneses, Paqui Rodríguez (all at Faculty of Chemistry, Univ. La Laguna, 38206 La Laguna, Tenerife, Canary Islands, Spain; e-mail: teide@iter.rcanaria.es), José M. L. Salazar, Nemesio Pérez (Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Canary Islands,Spain), and Pedro A. Hernández (Laboratory for Earthquake Chemistry, Univ. Tokyo, Bunkyo-ku, Tokyo 113, Japan)

Soil gas concentration and flux surveys have been applied successfully to understand processes related to magmatic reactivation in active volcanoes, but some problems related to the interpretation of the spatial variations of soil gas content and flux pattern are still significant because of the soil heterogeneity through volcanic edifices. Physico-chemical parameters of the soil environment can affect the distribution pattern of the volatile species and their flux levels because of their effects on the adsorption-desorption, diffusion, and mass transport processes. Therefore, soil pH measurements could be a simple, inexpensive, and "quasi" integrated geochemical tool for detecting areas which are affected by an intensive level of diffuse magmatic-hydrothermal degassing.Soil pH mapping geochemical tool has been performed at Kilauea (Hawaii), Rabaul (Papua New Guinea), Campi Flegrei (Italy), Long Valley (California, USA), Miyake-jima, Usu (Japan), La Palma, El Hierro, and Teide (Canary Islands) volcanoes. Soil pH data of active volcanoes with low levels of magmatic-hydrothermal diffuse degassing showed just one geochemical population: background group. Background soil pH levels showed a range of soil pH average values between 6.5 and 7.5. On the other hand, soil pH data of active volcanoes with high levels of diffuse degassing showed two overlapping geochemical populations: background and an intermediate "threshold" population characterized by soil pH levels (< 4) between background soil pH values (6.5 - 7.5) and typical low pH values (2 - 3) of magmatic-hydrothermal discharges.

JSV36/W/14-B3 Poster 0900-11

GEOCHEMICAL MONITORING OF CUMBRE VIEJA VOLCANO (LA PALMA, CANARY ISLANDS) BY MEANS OF CONTINUOUS MEASUREMENTS OF DISSOLVED GAS 222RN IN GROUND WATER

Francisco J. HERNÁNDEZ, Jose M. Salazar, Nemesio M. Pérez (all at the Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Spain; email: fhdez@iter.rcanaria.es), George Igarashi, Kenji Notsu, and Pedro A. Hernández (all at the Lab. for Earthquake Chemistry, Univ. of Tokyo, Bunkyo-ku, Tokyo 113, Japan)

La Palma is one of the most active volcanic islands of the Canarian archipielago. Cumbre Vieja volcano is situated in the southern part of La Palma, where had occurred 6 eruptions during the last 500 years. Since fumarolic degassing is not present at Cumbre Vieja volcano, geochemical continuous monitoring of dissolved gases in ground water is a useful tool for volcanic prediction research. With this purpose, continuous monitoring of dissolved gas 222Rn is carried out at Amargavinos well (La Palma) since September 1997. This well is 400 m deep and is located along the NE rift-zone of Cumbre Vieja volcano. The dissolved gas 222Rn monitoring system consist of a 222Rn detection chamber, a 256-channel high-speed analog-to-digital converter (AD) and a personal computer. The 222Rn detection chamber is an electrostatic collector, and the a particles emitted mainly by the decays of 214Po and 218Po (daughters of 222Rn) are detected as electrical currents through a PIN photodiode. To this date, dissolved gas 222Rn in ground water at Amargavinos show a steady-state level of 950 pCi/L, and it might be due to the lack of seismic-volcanic activity during this period. The same type of 222Rn monitoring system was used to detect precursory 222Rn signatures related to Kobe (Japan) and Galician (Spain) earthquakes. Other gas components will be soon measured by means of QMS at this observation site to improve our continuous geochemical monitoring of Cumbre Vieja volcano.

JSV36/W/01-B3 Poster 0900-12

SOIL CO2 AND 222RN DEGASSING AT MIYAKE-JIMA VOLCANO, JAPAN

Pedro A. HERNANDEZ, Yoichi Shimoike, Toshiya Mori, Kenji Notsu (all at Laboratory for Earthquake Chemistry, Univ. Tokyo, Bunkyo-Ku, Tokyo 113-0033, Japan; e-mail: hernandez@eqchem.s.u-tokyo.ac.jp), José M. L. Salazar, Nemesio M. Pérez (Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Spain), and T. Aotani (Miyake High School, Miyake-jima, Tokyo, Japan).

Miyake-jima is situated about 200 km south of Tokyo and is one of the most active basaltic stratovolcanoes in Japan. During this century, volcanic eruptions have regularly occurred at Miyake-jima, almost every 22 years, and the most recent eruption was on October, 1983. Fumarolic activity (79 to 87°C) is mainly located at the summit cone of Oyama volcano, in the central part of Miyake-jima. A soil gas survey of 150 sampling sites was performed at Miyake-jima from May 23 to June 2, 1998. Soil gas 222Rn and CO2 flux measurements were performed by using a portable radon sensor and a NDIR spectrophotometer, respectively. Statistical-graphical analysis of soil gas 222Rn measurements showed three overlapping populations. The background mean is 13.1 pCi/L (95% of the total data) and the peak group showed a mean of 43 pCi/L (0.9% of the total data). Soil CO2 flux measurements showed also three geochemical populations. The background mean is 94 g·m-2·d-1 and represents 59% of the total data. The peak group showed a mean of 9,500 g·m-2·d-1 and represents 2.7% of the total data. Most of the study area showed background levels of diffuse degassing of 222Rn and CO2. Anomalous levels of diffuse degassing of 222Rn and CO2 were identified in the summit crater of Miyake-jima and surrounding areas, showing a good spatial relationship with the radial dike pattern of Miyake-jima. A mixed magmatic and biogenic origin is suggested for the diffuse degassing inside summit crater, while a clear biogenic origin is observed for the CO2 degassing outside. Diffuse emission of CO2 from the summit crater is about 327 t·d-1.

JSV36/W/03-B3 Poster 0900-13

SECULAR VARATIONS OF CO2 DIFFUSE DEGASSING RELATED TO THE 1997 VOLCANIC ACTIVITY AT RABAUL CALDERA, PAPUA NEW GUINEA

Nemesio PEREZ (Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Canary Islands,Spain; e-mail: nperez@iter.rcanaria.es), David Lolok, Patrice de Saint Ours, and Ben Talai (all at Rabaul Volcano Observatory, P.O. Box 386, Rabaul, East New Britain, Papua New Guinea)

Vulcan and Tavurvur volcanoes did erupt simultaneously on September 1994, almost 9 years after the end of the seismic-uplift crisis at Rabaul caldera. An eruptive stage is still taking place at Tavurvur volcano, which had experienced several strombolian eruptions during these recent years. Geophysical conventional techniques are manily used for monitoring the volcanic activity at Rabaul caldera. In order to establish a multidisciplinary volcano monitoring program research at Rabaul Volcano Observatory, simple geochemical tools were applied for the volcanic surveillance: ash-leachates chemistry and soil CO2 flux monitoring. A network of 14 observation sites for soil CO2 flux measurements all over Rabaul caldera was operative from November 1996 to November 1997. During this period two strombolian and lava-producing eruptions occurred on January 1997 and March 14. Other four minor strombolian eruptions did also occur during this period. At each observation site, soil CO2 flux level was evaluated by means of an integrated technique, which use alkaline solutions (NaOH 1N) exposed to the soil atmosphere for one week period. Estimated soil CO2 flux values showed significant spatial variations from one observation site to another. The highest levels were detected at the flank of Vulcan and Tavurvur volcanoes, about 70 g·m-2·d-1, and the lowest levels at Beehives. Anomalous temporal changes of soil CO2 flux levels had been observed prior to strombolian eruptions during 1997. Even though these levels of soil CO2 flux could be underestimated, this simple and inexpensive soil CO2 flux network could be a useful tool for volcano monitoring at Rabaul caldera.

JSV36/W/08-B3 Poster 0900-14

TRACE ELEMENT AND ISOTOPE GEOCHEMISTRY OF HIGH-K CALC-ALKALINE VOLCANIC ROCKS FROM MERAPI VOLCANO, CENTRAL JAVA, INDONESIA

Ralf GERTISSER and Jörg Keller (Institut für Mineralogie, Petrologie und Geochemie, Universität Freiburg, 79104 Freiburg, Germany, email: gertisse@ruf.uni-freiburg.de, jkeller@ruf.uni-freiburg.de)

Merapi volcano (Central Java, Indonesia) has erupted frequently during Holocene time, producing mainly high-K basaltic andesites with a restricted compositional range from 52-57 wt.% SiO2. Mantle-normalised trace element signatures show similar patterns for all Merapi rocks with LILE and Th enrichment relative to LREE and HFSE, as well as negative Nb, Ta and Ti anomalies. REE patterns display LREE enrichment (40-90x chondritic) relative to the HREE (10-15x chondritic). No Eu anomalies are observed. Nd isotope compositions of the studied Merapi samples define a range similar to that given by Whitford et al. (1981) for the Sunda arc in Java. In contrast, Sr isotope ratios of Merapi rocks tend to be more radiogenic than those from adjacent volcanic centers in Java. The elevated values of 87Sr/86Sr for a given 143Nd/144Nd in relation to the "mantle array" point to the presence of a component of altered oceanic crust or sediment in the source region of Merapi magmas. Pb isotope data further illustrate the role of sediments in the genesis of Merapi magmas. Pb isotope ratios of Merapi are distinctly radiogenic and display small-scale variations with linear arrays in 207Pb/204Pb and 208Pb/204Pb vs. 206Pb/204Pb plots, that are steeper than for oceanic basalts. Furthermore our data extend the Pb isotope range for Merapi rocks (McDermott & Hawkesworth, 1991) to more radiogenic Pb isotope ratios, that plot within the field for oceanic sediments adjacent to the West Sunda arc and well outside the Indian Ocean MORB field (Ben Othman et al., 1989).In general, mixing of a suggested MORB-like mantle source with sediments adjacent to the West Sunda arc may account for the observed isotopic variations in Merapi magmas. Trace element and isotope signatures of Merapi are thought to be derived mainly by contamination of the mantle wedge with partial melts of subducted sediments and LILE-enriched slab-derived fluids. The lack of correlation between radiogenic isotope ratios and differentiation indices such as SiO2 precludes a significant role of crustal contamination by AFC-type processes in the evolution of magma at Merapi.

DYNAMIC MIXING OF THE RECENT POPOCATEPETL (MEXICO) MELTS

ANA LILLIAN MARTIN (Instituto de Geofisica, UNAM,Ciudad Universitaria, Mexico D.F.04510, Mexico. Email: analil@tonatiuh.igeofcu.unam.mx) Susanne Straub(Geomar, Wischhofstr 1-3, 24148 Kiel,Germany. email: sstraub@geomar.de E. Cabral, E. Garcia, G. Cifuentes,G. Sanchez and M. Reyes(all at UNAM)

Geochemical studies of the recent Popocatepetl ejecta(major and trace element data of bulk samples and mineral compositions)correlated with geophysical parameters are consistent with a model of recurrent dynamic mixing between mafic(<57%SiO2)and evolved melts(64%SiO2). The mafic end member is equilibrated only with olivene(Fo90)and Cr-spinel. Mineral-melt equilibria and clinopyroxene and amphibole barometry suggest that the mafic component rises from over 45km depth and then mixes with the cooler more evolved melt at upper crustal levels. Recurrence of small eruptions spaced mainly over weeks and sometimes days is thought to be related to periodic ascent of mafic melts. Volcanotectonic events generally precede the eruptions by several hours. Small magma pulses are also consistent with magnetic anomalies. Chemical and textural disequilibria (e.g. mineral zoning, quench texture) also suggest a rapid ascent of the mafic melt to crustal levels and mixing with the evolved melt immediately before eruption.

THE GEOCHEMICAL MONITORING SYSTEM (GMS II) PROTOTYPE INSTALLED AT THE "ACQUA DIFESA" WELL (BELPASSO, CATANIA), IN THE ETNA REGION, ADDRESSED TO SEISMIC AND VOLCANIC SURVEILLANCE: FIRST DATA

Fedora QUATTROCCHI , Luca Pizzino , Francesco Pongetti , Gianni Romeo , Piergiorgio Scarlato , Umberto Sciacca , Giuseppe Urbini.Istituto Nazionale di Geofisica, Via di Vigna Murata 605, 00143, Roma, Italy. E-mail: geochimica@ing750.ingrm.it

The drop in the costs/benefits ratio as regard both the hardware (i.e., PC-IBM compatible, electronics box, telecommunication systems, etc.) and sensors devices, as well as the exponential development of different techniques to measure geochemical-hydrologic variables, strongly recommend the continuous monitoring geochemical network strategy, more than discrete monitoring, allowing to obtain scientific results, unthinking since a few time ago. To develop a multidisciplinary approach to seismic/volcanic hazards prediction, using a really multivariable strategy, either in software-hardware as well as in sensors selection, the ING laboratories developed the second prototype of Geochemical Monitoring System (GMS II), that was conceived, designed, assembled and tested in laboratory and in a remote site, specifically addressed to geological-natural hazards surveillance, but it could be easily used for environmental problems too (i.e., bio-geochemical surveillance).

Actually the GMS II prototype is running, recording data every 10 minutes, and the first months of data acquisition have been performed in a test-remote site, "Acqua Difesa" well, located in the Etna region. The results are discussed.
Despite the continuous 222Rn monitoring devices have been assembled still without hardware-station linking and the H2S and He sensor devices are under mounting phase, all the other sensors and the automatic sampler are on line (water temperature, pH, Eh, electrical conductivity, CO2 partial pressure, air temperature, barometric pressure).

A NEW METHOD FOR VOLCANIC GAS FLUX MEASUREMENT: APPLICATION TO KUJU VOLCANO, JAPAN

Genji SAITO, Kohei Kazahaya, Hiroshi Shinohara, Masaya Yasuhara (Geological Survey of Japan, 1-1-3, Higashi, Tsukuba, Ibaraki, 305-8567, Japan, email: gsaito@gsj.go.jp)

Gas flux from active volcanoes is one of important parameters for evaluation of volcanic activity and magma degassing processes. A new tool for volcanic gas flux measurement was applied at Kuju volcano, Japan. Fumarolic activity existed at Kuju volcano since at least 14th century. A new phreatic eruption began on October 11, 1995 forming new craters, and intense fumarolic activity at these new craters continued till now. Flux measurements of fumarolic gases from the new craters were carried out together with sampling of the fumarolic gases from March 1996 to March 1998. Fluxes of water (steam) from each crater can be calculated based on distribution on the gas velocity (30~70 m/s) in a cross section of each crater outlet (~0.5 m2). Flow velocity of the fumarolic gases is obtained by dynamic pressure measured with the Pitot tube and calculated density of the gas at the outlet temperature, according to Bernoulli's theorem. The flux of water from some craters where we could not measure the gas velocity, was estimated by comparing volumetric rate of the plume generation with that from the crater where gas velocity was measured. The plume generation rates were estimated on the base of the plume size and the rising speed observed with a video camera. Total flux of water from the volcano is obtained by summation of these fluxes. Fluxes of magmatic water, meteoric water and other volatile components can be obtained by combination of the total water flux and isotopic and chemical composition of the fumarolic gases. SO2 flux, estimated by this method, decreased from 140 t/d in March 1996 to 44 t/d in October 1996, that is consistent with the results of COSPEC measurement performed by Kyushu Univ., indicating reliability of the new method. The magmatic gas fluxes have decreased since the eruption, from 23 kt/d in October 1995 to 8 kt/d in October 1996 for magmatic water and from 1600 t/d to 400 t/d for CO2, implying decreasing trend of magmatic activity at this volcano.

USING GEOCHEMISTRY TO ASSESS THE POSSIBILITY OF FUTURE LARGE SCALE ERUPTIONS AT MERAPI VOLCANO, CENTRAL JAVA, INDONESIA

Supriyati Andreastuti and Ian SMITH (both at Geology Department, University of Auckland, Private Bag 92019, Auckland, New Zealand, email: s.andreastuti.@auckland.ac.nz; and ie.smith@auckland.ac.nz) Brent Alloway (Institute of Geological and Nuclear Sciences Ltd, Lower Hutt, New Zealand, email: b.alloway@gns.cri.nz)

Stratigraphic and geochemical studies of historical eruptions (> 3000 BP to 1800 AD) from Merapi Volcano in Central Java have revealed significant changes in the pattern of eruptive behavior through time. This observation allows two levels of volcanic risk to be determined, namely low probability/high risk and high probability/low risk. The average frequency of eruptions during historic times is about once every 80 years; large eruptions occurred every 150 to 500 years and were predominantly sub-plinian to plinian (up to VEI 4) to vulcanian in style. In contrast during recent times (since 1800AD) the return period for large eruptions (up to VEI 3) has been 30 years and for small eruptions 2 years; these events have been mostly dome collapse explosions of vulcanian type.
The frequency and nature of eruptions from Merapi can be correlated with the chemical composition of erupted material on both short (10-100 years) and long (100-1000 years) time scales. Magmatic processes operating at different levels beneath the volcano can explain this. Understanding these processes provides a tool for predicting future activity and associated risk. Merapi is one of the world's most active volcanoes and is situated in a densely populated area. Geochemistry offers the potential for predicting the patterns of future eruptive activity.

INVERSION FOR MULTIPLE VOLCANIC SOURCES USING A GENETIC ALGORITHM TECHNIQUE

K. F. TIAMPO and J. B. Rundle (both at CIRES, University of Colorado, Boulder, CO 80309; Email: kristy@fractal.colorado.edu); Jose M. Fernandez (Instituto de Astronomoa y Geodesia (CSIC-UCM), Facultad de Ciencias Matematicas, Ciudad Universitaria, 28040, Madrid, Espana). John Langbein (USGS, Menlo Park, CA, USA).

Significant ground deformation has long been associated with magma injection in volcanic areas. As a result, many such areas are well monitored today, and their activity status is based, at least in part, on the size and pattern of that deformation. We have employed magmatic source models for a prolate ellipsoid, and compared it to spherical sources for an active volcanic area using a genetic algorithm inversion technique (Davis, 1986; Yang and Davis, 1988). A genetic algorithm (GA) is a directed search technique, which combines the principle of survival of the fittest with a prescribed random information exchange. These volcanic source models were compared with deformation data from Long Valley, California. Topographic data from a tri lateration network consisting of both two-colour electronic distance meters (EDMs) and levelling measurements has been in place since 1989 in Long Valley, when the second episode of uplift within a span of 10 years began. Additional features include the capability to invert for both laser altimeter and gravity data in conjunction with the above data types. The GA was used to find and compare the optimal source mechanisms for Long Valley deformation, in conjunction with other potential sources such as faulting.

DEFORMATION MONITORING OF MOUNT MERAPI WITH DINSAR

C. Gerstenecker, G. LAEUFER (Institute of Physical Geodesy, Darmstadt University of Technology, email: laeufer@geod.tu-darmstadt.de) B. Wrobel (Institute of Photogrammetry, Darmstadt University of Technology)

Within the Indonesian-German project MERAPI the activities of the volcano Mount Merapi are monitored with different tools. Classical methods of deformation measurements will be combined with spaceborn DINSAR. Differential Interferometric Analysis of Synthetic Aperture Radar data can yield information about areal ground deformation In a first attempt we are using four SAR-scenes, taken from ERS-1 between April 1996 and October 1996, covering an area of 10.000 km2. The interferograms are computed with different software packages as JPL/SIR-C, ENVI/IDL, EASI/ PACE including Antis and JenaSAR. A synthetic interferogram is produced with the help of a Digital Elevation Model (DEM) of the region, which we got by combining SPOT-images, topographic maps, and GPS- measurements. The limits and problems of DINSAR-analysis in tropic regions and steep slopes are discussed and first results of the analysis are given.

INVERSION OF THE GRAVITY FIELD OF MOUNT MERAPI AND MOUNT MERBABU, CENTRAL JAVA, INDONESIA

C. GERSTENECKER (Darmstadt University of Technology, Darmstadt, FRG, email: gerstenecker@geod.tu-darmstadt.de); S. Kirbani, I. Suyanto (Gadjah Mada University, Yogyakarta, Indonesia)

In winter 1996/97 we have mapped the gravity field of the volcanoes Merapi and Merbabu located in Central Java, Indonesia. Altogether we have measured 380 points covering a range of 50*50 km2. Point positioning was done by differential GPS. Gravity values were observed with the LaCoste&Romberg gravimeter LCR-G1029.
Bouguer anomalies were corrected for topography using a digital elevation model with 20*20 m2 grid size. Surface density was determined using Parasni's method. A 3-parameter linear regression model represents the regional Bouguer anomaly field mostly influenced by the subduction zone South of Java. The residual Bouguer anomalies were merged with gravity data collected by other groups between 1968 and 1994.The inversion is done in two approaches. The first approach is using the program system IGMAS where density subsurface models are fitted interactively to the observed residual Bouguer anomalies. The second method determines the densities of subsurface cubes with the help of L1-norm.

STRUCTURE OF ACTIVE CENTRAL VOLCANOES IN ICELAND DEDUCED FROM GRAVITY MODELLING

Magnus T. GUDMUNDSSON and Thordis Hognadottir (Science Institute, University of Iceland, Hofsvallagata 54, 107 Reykjavik, Iceland, email: mtg@raunvis.hi.is)

Iceland has an anomalously thick ocean-type crust due to the high magma production rate of the Iceland mantle plume. The volcanic zones in Iceland are divided into volcanic systems consisting of a fissure swarm and one or two central volcanoes. Volcanism is greatest within the central volcanoes, which produce both silicic and basaltic rocks. The gravity field associated with several central volcanoes has now been mapped and the internal structure studied with forward modelling. For the volcanoes studied, the gravity signature can be broadly divided into two categories: the volcanoes that have developed calderas, and those that have not. The calderas are associated with gravity highs (10-40 mGal), caused by massive basic intrusions in the shallow crust. The intrusions are located under the calderas but have a somewhat greater diameter. A relative gravity low is often associated with the center of the caldera while the caldera faults seem to be underlain by dense dyke swarms. Volume of molten magma chambers in the upper crust seems to be only a few percent of the volume of the solid intrusions. The volcanoes that have not developed calderas have a much more subdued gravity signature, suggesting a relatively small volume of basic intrusions. For those volcanic systems that have two central volcanoes, one of the two may be well developed with a large caldera while the other is smaller and without a clear caldera. In some cases, the two are connected by ridge in the gravity field, suggesting a dense dyke swarm. This may imply some of the smaller volcanoes are parasitic, i.e. fed by the larger volcano. The gravity signature of the central volcanoes seems unrelated to exposure of rhyolites on the surface, indicating that the rhyolites are confined to the volcanic edifices and do not make up a significant part of the underlying volume.

DEFORMATION MEASUREMENTS AND DIGITAL ELEVATION MODELS AT MOUNT MERAPI, INDONESIA

C. Gerstenecker, G. Laeufer, B. SNITIL (Institute of Physical Geodesy, Darmstadt University of Technology, Germany, email: snitil@geod.tu-darmstadt.de) G. Jentzsch, A. Weise (Institute of Geosciences, Friedrich-Schiller-University Jena, Germany) I.Suyanto (Gadjah Mada University, Yogyakarta, Indonesia)

Mount Merapi, located in Central Java, Indonesia, is one of the most active volcanoes of the world. One of the aims of the Indonesian-German project MERAPI is to determine secular changes of the Earth's gravitational field. Gravity changes in the area of volcanoes may result from vertical movements of the crust, mass displacements inside and outside the Earth and density changes. Together with knowledge of deformation in position and height, the residuals of temporal changes of gravity anomalies will be estimated. For the observation of gravity changes in time a combined gravity and GPS network has been established. The changes in the horizontal and vertical positions of these stations are recorded by using differential GPS measurements.
For the estimation of residual gravity changes accurate digital elevation models have to be available. The data of a gravity field mapping campaign, combined with model data based on SPOT images was used to develop a digital elevation model (DEM) of Mount Merapi. Its raster size is 20m*20m with an altitude accuracy < 50m. Beneath the topographic reduction of gravity anomalies the DEM is used for the correction of seismic and electromagnetic observations as well as for the calculation of synthetic interferograms within the DINSAR-analysis of SAR-images of Merapi.

Cendana 15, Yogyakarta 55166, Indonesia, email: mvopgm@yogya.wasantara.net.id)

The Indonesian-German deformation experiment, focused on the high-risk volcano Merapi in Central Java, is ingrained in the interdisciplinary research project MERAPI, a contribution to the IDNDR program. Between 1995 and 1997, four multiparameter stations have been installed at the flanks of Merapi, each including one GPS-receiver and an array of three biaxial borehole tiltmeters. In addition, several sensors record local meteorological and hydrological data, permitting the recognition of potentially influencing environmental quantities. Infact, the high resolution of the borehole tiltmeters (0.2 microrad), lets them also be sensitive to small poro-elastic deformations due to rainfall. After correction of the rain-induced tilts, three types of tilt variations of 1 to 8 microrad amplitudes are observed, which appear to be related to volcanic activity: (i) pre-eruptive tilt changes,correlated with an increase of multiphase events preceding the eruptions of Merapi in January 1997 and July 1998; (ii) a co-eruptive tilt anomaly coinciding with the eruption in August 1996; (iii) a local tilt signal, probably a loading effect caused by the mass of debris of pyroclastic flows of the eruption in July 1998. The experimental data conform with numerical modeling results. It is concluded that the recent activity of Merapi is associated with small deformations of the volcano's edifice and, presumably, pressure changes in its interior.

STUDYING KILAUEA VOLCANO'S FAULTS AND RIFTS WITH GPS

Susan OWEN (Dept. of Earth Sciences, University of Southern California, Los Angeles, CA, 90089-0740, USA, email: owen@seismo.berkeley.edu); Paul Segall (Dept. of Geophysics, Stanford University, Stanford, CA, 94305, USA) Michael Lisowski, and Asta Miklius (both at Hawaiian Volcano Observatory, Hawaii Volcanoes National Park, HI, 96718, USA)

Kilauea Volcano, Hawaii, is the youngest and most recently active subaerial volcano in the Hawaiian Island chain. Kilauea's south flank has generated several large earthquakes in the past twenty-five years (M7.2 1975, M6.1 1989). These earthquakes are generated by seaward displacement along a subhorizontal fault plane approximately 9 km beneath Kilauea's south flank. Since 1983, Kilauea has been erupting almost continuously from Pu'u O'o or Kupaianaha, located near each other along the East Rift Zone. GPS campaigns have been conducted on Kilauea since 1990. In addition, a continuous GPS network was installed starting in 1995. These GPS data have been successfully used to constrain the geometry of the fault and rift zones, understand rift eruptions, and infer the distribution of active fault slip and rift opening.
The horizontal GPS velocities show rapid south flank displacement rates of as much as ~8 cm/yr. Subsidence along the rift system occurs at similar rates. The set of sources required to fit these data include rift opening along the upper east and east rift zone, fault slip along a subhorizontal plane near the base of the volcano, and deflation near the summit caldera. In the best-fitting model, the fault plane dips north-northwestward (islandward) and extends offshore. The detailed fault slip modelling results indicate that the highest fault slip rates occur beneath the central south flank. The model includes significant fault slip offshore and in the western south flank, both seismically inactive areas between 1990 and 1996. Fault slip rates are low near the epicenters of the most recent large earthquakes. Model rift dilation extends from the upper east rift zone to Heiheiahulu, ~15 km downrift of Pu'u O'o. The continuous GPS network captured pre-eruptive opening of the east rift zone and contributed data crucial to the interpretation of the January 30, 1997 eruptive event.

DIMENSIONS, TEMPERATURES AND EVOLUTION OF CRUSTAL MAGMA CHAMBERS OF VOLCANOES CALCULATED ON THE BASE OF VOLCANOLOGICAL, GEOPHYSICAL, GEODETICAL, AND PETROLOGICAL DATA

Sergei A. FEDOTOV, Iona S. Utkin, and Ludmila I. Utkina (Institute of Volcanology, Far East Division, Russian Academy of Sciences, Petropavlovsk-Kamchatsky, 683006 Russia;
email: volcan@svyaz.kamchatka.su)

Dimensions, volume, temperature, and evolution of crustal magma chambers of volcanoes are calculated and studied. It is accepted in our model that volcano magma chambers located in the crust are formed mainly by melting, erosion, and removal of their wall rocks. Equations of heat balance of magma flowing through magma feeding system and of its wall rocks are used in calculations. Initial data on magma production rate and chemical composition of erupted products of volcano and their changes in time, on location of magma chambers and the structure of the crust, on geotherm and parameters of magma and wall rocks are taken from results of volcanological, petrological, geophysical, geodetical, and geothermal studies. Calculations were made for representative volcanoes of Kamchatka (Avachinsky, Klyuchevskoy, and others).
The active Avachinsky stratovolcano in Kamchatka is 60000 years old, its products are andesito-basalts and andesites, their volume is 190 km3, magma production rate declines in time and equals 2.5◊106 t/year during the last 5500 years. The depth of its shallow magma chamber is ~4 km. It was found that magma chamber had reached quasistationary conditions and its maximum radius 2 km and volume 33.4 km3 during first 15000 years of the volcano activity that magma chamber is decreasing during the last 20000 years and its present radius and volume can be 1 km and 4.2 km3.
Such modelling and calculations are useful part of complex studies on features and structure of volcano magma feeding systems, on magma formation and mixing, on evolution of volcanoes and volcanic centers, on potential size of large eruptions and accumulated geothermal resources.

CATALOGUE OF QUATERNARY VOLCANOES IN JAPAN

Tadahide, UI (Graduate School of Science, Hokkaido University, N10W8, Kita-ku, Sapporo 060-0810, Japan, e-mail: ui@cosmos.sci.hokudai.ac.jp); Shintaro Hayashi (Akita University, e-mail: hayashi@ipc.akita-u.ac.jp); Masaki Takahashi (Ibaraki University, e-mail: takama@mito.ipc.ibaraki.ac.jp); Shigeo Aramaki (Nihon University, e-mail aramaki@chs.nihon-u.ac.jp);, Tatsuro Chiba and Shin Shishikura (Asia Air Survey Co.Ltd, e-mail: sn.shishikura@ajiko.co.jp); Koji Umeda (Nuclear Cycle Development Institute, e-mail: umeda@tono.pnc.go.jp)

We are now compiling a new database on Quaternary volcanoes in Japan. Since the publication of the geologic map of Quaternary volcanoes in Japan (Ono et al., 1981), many research works have been appeared. Number of radiometric age data for volcanic ejecta are drastically increased. This allows us to update the imag e of Quaternary volcanism in the Japanese Islands. Our database for more than 700 volcanic edifices includes the informations of location of eruption center, area and volume of volcanic ejecta, age of activity, chemistry, representative references and so on. Our database revealed temporal and space variation of Quaternary volcanoes and change of magma production rate during Quaternary period.

GPS CONTROL NETWORK AT FOGO VOLCANO, CAPE VERDE

J. Nuno LIMA, J. Pereira Osorio, Clara Lazaro (Centro de Geodesia, Instituto de Investigacao Cientifica Tropical, Rua da Junqueira, 534, 1300 Lisboa, Portugal, email: cgeod@iict.pt) Sandra I N Heleno, Joao L Matos and Joao F B D Fonseca (all at IST, Av Rovisco Pais, 1, 1049-001 LISBOA, Portugal, email: sisilva@alfa.ist.utl.pt)

Fogo Island, in Cape Verde Archipelago (North Atlantic), is a roughly conical volcanic edifice with less than 25 Km of base diameter and reaching nearly 3000 m above sea level. Several volcanic eruptions in Fogo have been reported since the discovery of the archipelago in the 15th century. The activity in the 20th century is mainly represented by the two eruptions in 1951 and 1995.
A high precision GPS network for periodic reobservation (campaigns with intervals of about six months) was designed and implemented for supporting the development of models to understand the mechanisms behind seismic or volcanic activity. This network covers all the island and it consists of 23 reinforced concrete pillars with good foundations. The first GPS campaign was performed from September 1 to September 8, 1998, with occupations of all the 23 sites. All the GPS data has been processed with the BERNESE version 4.0 software.
In the paper details of the network, the GPS campaign, the data processing and the results obtained so far will be presented.

FRACTAL ROCK FAILURE AND ERUPTION FORECASTS

S. VINCIGUERRA, C.R.J. Kilburn, V. Rocchi, W.J. McGuire (Benfield Greig Hazard Research Centre, Department of Geological Sciences, University College London, Gower Street, London WC1E 6BT, Email: s.vinciguerra@ucl.ac.uk, c.kilburn@ucl.ac.uk, v.rocchi@ucl.ac.uk, w.mcguire@ ucl.ac.uk/Fax: +44-171-3887614.)

The fractal distribution of earthquakes is consistent with a state of 'self-organised criticality' in the earth's crust. Scale invariant hierarchical structure was also observed in volcanic areas where variation of time and spatial fractal properties of seismic patterns have been observed to act at long (order of years), mid (order of months), and short term (order of days). Moreover it has been shown that rates of cracks and the coalescence of minor fractures in major patterns in a rock under stress are ruled too by self-accelerating processes. Thus focusing on the interrelationships between seismicity clustering variation in volcanic areas and cracks patterns evolution under volcano stress conditions are strongly expected to provide relevant information on volcano dynamic processes at different length time scales. Information can be used as a diagnostic tool in volcano hazard evaluation as well as in eruption forecasting.

JSV36/E/20-B3 Poster **1400-12**

TIME AND SPACE PROPERTIES OF RECENT SEISMICITY AT CANARY ISLANDS.

S. Vinciguerra, S.J. DAY and W.J. McGuire (Benfield Greig Hazard Research Centre, Department of Geological Sciences, University College London, Gower Street, London WC1E 6BT, UK, e-mail: s.vinciguerra@ucl.ac.uk, s.day@ucl.ac.uk, w.mcguire@ucl.ac.uk).

A variety of models exist for magmatism in the Canary Islands, some of which imply the development of large - scale regional deformation and seismicity of tectonic origin. However, the many marine seismic surveys around the islands in recent years have revealed the presence of thick sequences of undisturbed sediments around the islands and thus a lack of major regional deformation at least since the middle Tertiary when the oldest volcanic islands in the archipelago appeared. Thus we consider it more likely that seismicity in the Canaries is fundamentally of magmatic origin, although the development of volcano - tectonic or gravitational - loading earthquakes is also possible. Space-time clustering properties of seismic activity at Etna volcano have been shown to be very useful to distinguish variations in the eruptive style as well as volcanic and tectonic processes acting at different time scales. Here variability and origins of recent seismicity (1989 - 1995) of the Canary islands are investigated. 3 periods of activity are recognized: from 1989 to 1991 (the period of the most recent seismic swarm) activity was relatively shallow and strongly clustered, whereas from 1992 to 1994 it was mainly very deep (30 - 60 km depth). More recently, activity has become more widespread and is migrating toward the surface again. We suggest on the basis of these results that a new cycle of magma supply from depth in beginning and that a further seismic crisis or eruption may occur in the next several years.

CRUSTAL DEFORMATION ASSOCIATED WITH THE 1998 SEISMO-VOLCANIC CRISIS OF IWATE VOLCANO, NORTHEASTERN JAPAN, AS OBSERVED BY A DENSE GPS NETWORK

S.UEKI, S.Miura, T.Sato, K.Tachibana and H.Hamaguchi (all at Graduate School of Science, Tohoku University, Sendai 980-8578, Japan, Email: ueki@aob.geophys.tohoku.ac.jp)

Iwate volcano is an active volcano located in northeastern Japan and having histories of magmatic eruptions in 1686 and 1732. Unrest of Iwate volcano started in September, 1995 with intermediate-depth tremor. The shallow seismicity in the west of the summit gradually became active in February, 1998, and reached a peak at the end of April. The active seismicity continued till the middle of August. Increase in fumarolic activity was also reported during the same period. Associated with the seismo-volcanic crisis, notable crustal deformation was observed by our dense GPS network. The network consists of 20 stations. At 12 sites, continuous observations have been carried out. We deployed two-frequency receivers at all the stations. The data were collected by using wire telephones, cellular telephones or radio modems for analysis. The radio modems powered by solar panels were newly designed for the stations at the summit area. After smoothing the data for the period from February to August, we obtained significant deformations amounting to about 5 cm in horizontal components and 2 cm in vertical one at the northern and southern foots of the volcano. In general, the pattern of the horizontal displacements is characterised by radial displacements pointing outward from a region of the volcano. The deformation rate raised from less than 0.5 cm/month in February toabout 1 cm/month in July. Assuming a simple pressure source, we tried to locate the source for each two months. The result shows that the source was located at about 4 km WSW of the summit and 10 km in depth in February-March, and it moved to a region about 10 km W of the summit and 3 km in depth in June-July. It is noteworthy that the

pressure source projected onto the epicentral distribution is nearly coincided with the western end of the seismic area for each period. The synchronicity of the crustal deformation and seismic activity suggests that the both phenomena were caused by a movement of magmatic liquid from depths beneath the summit to the western shallow part.

GEODETIC AND SEISMIC CONSTRAINTS ON RECENT ACTIVITY AND SHALLOW MAGMATIC PROPERTIES AT LONG VALLEY CALDERA, CA, USA

Andrew V. NEWMAN (Department of Geological Sciences, Northwestern University, 1847 Sheridan Rd., Evanston, IL, USA 60208, email: andrew@earth.nwu.edu) Jacqueline E. Dixon & Timothy H. Dixon (both at Rosenstiel School of Marine and Atmospheric Science, University of Miami, 4600 Rickenbacker Cswy., Miami, FL, USA 33149, email: tim@corsica.rsmas.miami.edu, jdixon@rsmas.miami.edu)

The average rate of surface deformation on the resurgent dome of Long Valley Caldera, a volcanic region in east central California, increased by more than an order of magnitude over the six month period July to December 1997, compared to the previous 3 year average. However, the three dimensional location of the immediate (shallow) source of deformation remained essentially constant compared with the earlier period, at a depth of 5-7 km beneath the dome, near the top of the seismically defined magma chamber. Similarly, although the rate of seismic moment release increased dramatically, earthquake locations remained similar to earlier periods. The rate of deformation increased exponentially with a time constant of ~45 days over a period of 5 months, after which it decreased exponentially with about the same time constant. This range of time constants is considerably longer than those characterising typical deformation events at basaltic volcanos, and may be related to the visco-elastic properties of rhyolitic material believed to exist at the top of the density-stratified magma chamber.

TEMPORAL AND THREE-DIMENSIONAL SPATIAL ANALYSES OF THE FREQUENCY-MAGNITUDE DISTRIBUTION NEAR LONG VALLEY CALDERA, CALIFORNIA

Stephen R. MCNUTT, Stefan Wiemer, and Max Wyss (Geophysical Institute, University of Alaska Fairbanks, P.O. Box 757320, Fairbanks, AK, 99775, USA. email: steve@giseis.alaska.edu, stefan@giseis.alaska.edu, max@giseis.alaska.edu.

The three-dimensional distribution of the b-value of the frequency-magnitude distribution is analysed in the seismically active parts of the crust near Long Valley Caldera, California. The seismicity is sampled in spherical volumes, containing N=150 earthquakes and centred at nodes of a grid separated by 0.3 km. Significant variations in the b-value are detected, with b ranging from b~0.6 to b~2.0. High b-value volumes are located near the resurgent dome, and at depths below 5 km at Mammoth Mountain. b-values are found to be much lower south of the Long Valley Caldera. We interpret this to indicate that an active magma body has advanced from depths below 8 km to depths of 4 to 5 km beneath Mammoth Mountain in 1989, and that anomalous crust, either highly fractured or containing unusually high pore pressure, such as is the case in the vicinity of active magma bodies, exists north of the seisrnically active area beneath the resurgent dome at all depths. We also investigate the spatial distribution of temporal variations of the frequency-magnitude distribution by introducing differential b-value maps. b-values increased from b~0.8 to b~1.5 underneath Mammoth Mountain at the onset of the 1989 earthquake swarm and remained high thereafter. This suggests that an intrusion permanently altered the average distribution of cracks at 5- 10 km depth, or that the pore pressure permanently increased. No significant change in the earthquake size distribution was detected during the 1997 episode of increased activity at Long Valley Caldera. This indicates that a slight stress change caused by the inflation of the magma chamber is causing a significant change in the rate of earthquakes produced, but no change in their size distribution. We propose that high b-values are a necessary (but not sufficient) condition in the vicinity adjacent to a magmatic body, and, therefore, spatial b-value mapping can be used to aid in the identification of active magma bodies.

GEOLOGICAL INVESTIGATION OF VILLA ALOTA-PASTO GRANDE AREA (BOLIVIAN ANDES) USING RADARSAT

Jose Luis LIZECA (Applied Geology, SERGEOMIN, La Paz, Bolivia Email: abtema@coord.rds.org.bo Wooil M. Moon (Geophysics, The University of Manitoba, Winnipeg, R3T 2N2 Canada ((204)-474-9833 (O); (204)-474-7623 (FAX); Email: wmoon@cc.umanitoba.ca and also with Dept. of Earth System Science, Seoul NationalUniversity, Seoul 151-742 Korea ((82)-2-880-6526 (O); (82)-2-871-3267(FAX); Email: wmoon@eos1.snu.ac.kr

The Villa Alota - Laguna Past Grande study area in Bolivian Andes is located in the major Cenozoic volcano tectonic province, which appears to represent an effusive andesitic - dacitic volcanism that became active in late Tertiary and that waned in the late Miocene. The average altitude of the study area is between 4,500 m and 5,400 m above sea level and the study area is one of the driest areas on Earth, resulting in extensive evaporite deposits and almost no vegetation cover over the whole study area. A detailed ground truthing, including surface mapping and geochemical sampling, was carried out during the summer of 1998 as a GlobeSAR II campaign. Two RADARSAT image data sets were acquired and processed for this study and interpreted in detail to extract the surface volcanological and geological characteristics over the study area. A number of geochemical samples were also taken mostly from dried evaporite lakes to study chemical and mineralogical composition of the surface material and their dielectric properties. From the pair of RADARSAT data a detailed DEM was also computed to investigate the accuracy and reliability of the morphological characteristics which can be extracted directly from the standard mode RADARSAT data. Preliminary results indicate that (i) for detailed surface feature study, RADARSAT DEM is an effective tool, (ii) for detailed DEM generation, carefully selected ground control points (GCP) are very important, (iii) a large scale volcanological features such as collapsed caldera could easily be mapped using RADARSAT DEM with considerably improved accuracy, and (iv) the changes in dielectric properties over evaporite lakes do neither alter the final DEM nor affect the overall backscattering coefficient values as much as it was expected initially.

GEOMAGNETIC STRUCTURES OF THE SUBMARINE CALDERA LOCATED BETWEEN HACHIJOJIMA ISLAND AND AOGASHIMA ISLAND, NORTHERN PART OF THE IZU-OGASAWARA ARC

Mitsuo ISHIDA (School of High-Technology for Human Welfare, University of Tokai,Nishino 317, Numazu, Shizuoka, JAPAN, email: wyvern@wing.ncc.u-tokai.ac.jp); Izumi Sakamoto (Deep Sea Research Dept.,Japan Marine Science and Technology Center, Natsushima 2-15, Yokohama, JAPAN, Email: izumis@jamstec.go.jp)

The South-Hachijo Submarine Caldera(SHSC) is located on latitude 32-40.0N, longitude 139-46.0E, about45km south from the Hachijojima Island, and situated at southern end of insular shelf of the Hachijojima Island. Positive anomalies are dominant over insular shelf of the Hachijojima Island. The highest positive anomalies are situated in northern part of insular shelf of the Hchijojima Island, where shows higher topographic relief than the around. Central area of the SHSC is covered by weak negative anomalies, which are surrounded by positive anomalies. Positive high anomalies exist in between southern part of central area and southern flank of the SHSC. Positive high anomalies in southern part of central area coincide with the shallowest part of the SHSC. It is considered that positive high anomalies of the SHSC and the northern area of insular shelf of the Hachijojima Island are caused by magnetic bodies near to sea bottom, from the results of analyses of geomagnetic anomalies. It is considered that magnetic body under the SHSC is different from under the insular shelf's, though these magnetic bodies have same magnetization direction as that of present earth's field. SHSC may relate to recent basaltic activity in volcanic front considering the results of geochemical composition of volcanic rocks dredged from the SHSC.

GASES OF PLANET EARTH: MANTLE ORIGINS AND ATMOSPHERIC IMPLICATIONS

Bernard MARTY (Centre de Recherches Pétrographiques et Géochimiques et Ecole Nationale Supérieure de Géologie, BP 20, 54501 Vandoeuvre Cedex France, Email: bmarty@crpg.cnrs-nancy.fr)

Most of volatiles (water, carbon dioxide, nitrogen, halogens, rare gases) present at the Earth's surface were contributed early during accretionary processes. Since then, volcanism is supplying gases in proportions roughly proportional to its activity rate. Part of these volatiles are recycled back into the mantle, so that each species has its own geochemical cycle. Some are cycled between the mantle and the surface with time constants lower than the age of the Earth (e.g., C, S), so that it is possible to derive a mean residence time at the surface. For others (e.g., nitrogen, rare gases), the flux from the mantle to the surface exceeds the return flux, allowing primitive isotope heterogeneities between the surface and the deep Earth to survive. Since the mantle is chemically heterogeneous, it is possible to characterise mantle sources of lavas and corresponding tectonic settings by analysing the isotope composition of some of these elements. Helium provides a sensitive provenance tracer since its isotopic composition in volcanic rocks and gases varies over an order of magnitude between arc-type, and plume-type volcanisms. Rare gases allow also to derive quantitative fluxes of major volatiles (e.g., carbon dioxide), and to model their geochemical history. Volatile isotope geochemistry has recently allowed to demonstrate that major LIP provinces are linked with the development of plumes originating below the convective mantle feeding mid-ocean ridge volcanism. Since the emission of CFB and related felsic volcanism occurs in a limited interval of time, it is likely that such gigantic volcanism has had noticeable climatic impact. The case of the Afar-Ethiopian plume province (CFB and ignimbrite emissions at 30 Ma) will be discussed in this context.

THE PRESENT STATE OF THE MAGMATIC SYSTEM OF THE ISCHIA ISLAND (ITALY)

Monica PIOCHI, Lucia Civetta and Giovanni Orsi (Osservatorio Vesuviano 80056, Ercolano - Napoli, Italy, email: piochi@osve.unina.it)

The island of Ischia, home to about 50,000 people, is an active caldera in the Gulf of Naples. Its volcanism in the past 10 ka was very intense and strictly connected to the resurgence dynamics of the Mt. Epomeo block. The last eruption occurred in 1302 A.D. The eruptions of this period have generated mostly alkali-trachytic and trachytic, and subordinately latitic rocks. Most of the units are composed of homogeneous trachytic and alkali-trachytic rocks that contain crystals in mineralogical and isotopical equilibrium with the groundmass, throughout the sequence. Some units vary in composition from latitic to trachytic and are characterized by complex petrochemical imprint due to mineralogical disequilibrium, chemical inhomogeneity of the glass, and isotopic variability. The main evolutionary magma processes are crystal fractionation and mingling between a highly crystallized alkali-trachytic magma with low Sr-isotope ratio (0.7060-0.7061), and an isotopically distinct (0.7068) latitic-to-trachytic magma. Petrochemical data and modeling of magnetic data suggest that at present the magmatic system includes a deeper, less-evolved magma chamber and shallower, more-evolved bodies. The homogeneous alkali-trachytic and trachytic units were generated by eruptions fed by the shallow magma bodies. The vents for these eruptions were located on the normal faults within the sector of the resurgent block under tensional stress regime. The eruptions that produced units characterized by mineralogical and isotopical disequilibria occurred along parts of regional faults and were generated by mingling of a deep latitic-to-trachytic magma with batches of the shallower alkali-trachytic magma bodies.

SURFACE GAS GEOCHEMISTRY OF CO2 AND 222RN AT CUMBRE VIEJA VOLCANO, LA PALMA, CANARY ISLANDS, SPAIN

Lourdes CÁRDENES, José M. L. Salazar, Nemesio M. Pérez (all at the Environmental Research Division, ITER, 38594 Granadilla, Tenerife, Spain, email: lcardenes@iter.rcanaria.es), José A. Cobas, Gladys Melián (both at Faculty of Chemistry, Univ. La Laguna, 38206 La Laguna, Tenerife, Spain), and Pedro A. Hernández (Laboratory for Earthquake Chemistry, Univ. Tokyo, Bunkyo-Ku, Tokyo 113, Japan)

La Palma is the northwesternmost island of the Canarian archipelago and rises 6.5 Km from the surrounding ocean floor. Most of the historical volcanic activity in the Canary Islands has ocurred at La Palma where recent volcanic activity is mainly concentrated at Cumbre Vieja volcano, in the southern part of the island. Since fumarolic degassing is not present in and around Cumbre Vieja volcano, spatial distribution analysis of soil gases is an ideal geochemical tool for monitoring magma movement and seismicity changes in this basaltic volcano. Soil gas 222Rn and CO2 flux survey of 470 sampling sites at Cumbre Vieja was performed by using a portable radon sensor and a NDIR spectrophotometer, respectively. Statistical-graphycal analysis of soil gas 222Rn measurements showed three overlapping geochemical populations. The background mean is 7.7 pCi/L and represents 21.5% of the total data. The peak population has a mean of 145 pCi/L and represents 7.7% of the total data. Soil CO2 flux measurements showed also three geochemical populations. The background mean is 2.1 g·m-2·d-1 and represents 90% of the total data. The peak population has a mean of 440 g·m-2·d-1 and represents 3% of the total data. Most of the study area and its surrondings showed background and intermediate levels of diffuse degassing of CO2 and 222Rn.

Anomalous levels of diffuse degassing of 222Rn and CO2 are closely related to the volcanic rift-zones in the southern part of La Palma. Diffuse emission of CO2 from Cumbre Vieja volcano and its surroundings is about 590 t·d-1.

CHEMICAL PRECURSOS OF THE 1998 ERUPTION OF COLIMA VOLCANO, MEXICO

Yuri TARAN, Maria Aurora Armienta (Institute of Geophysics, UNAM, Mexico D.F., 04510, Mexico. E-mail: taran@tonatiuh.igeofcu.unam.mx); Juan Carlos Gavilanes, Abel Cortes (Observatorio del Vulcan Colima, University of Colima, Mexico. E-mail: gavil@ucol.mx)

Colima volcano is the most active in Mexico with the last effusive eruption in 1991. Geochemical monitoring of the volcano started in January 1996 with: 1) airborn measurements of the SO2 flux by COSPEC; 2) collection of fumarolic gases from the summit crater every two months, and 3) monthly collection of water samples from three springs on the S-SW slopes of the volcano.The SO2 flux from the volcano until September 1998 was at a low level, less than 100 t/d, often below the detection limit of the instrument. A gradual increase in the SO2 flux has been recorded from 200 t/d in September 1998 to 400+-50 t/d two days before the new lava, which occured on 20 November, 1998. During November 1998, before the eruption started, the SO2 flux was in a good correlation with seismicity.Chemical compositions of volcanic gases did not show special trends, except of isotopic composition of the volcanic vapor. Starting from the summer of 1997, the volcanic water became gradualy enriched in deuterium, which indicates a contribution from deep, less degassed magma.Three main effects in the ground water chemistry can be considered as precursos for the eruption: 1) a gradual increase in Mg/Cl ratio since the summer of 1997; 2) increase in the calculated partial pressure of dissolved CO2 since the same date, and 3) a two to three-fold "peak" in the boron concentration approximately 4 months before the eruption.

ORIGIN CONDITIONS FOR VITIM BASALTS

ASHCHEPKOV I.V. (United Institute of Geology Geophysics and Mineralogy, SD RASc, e-mail: garnet@uiggm.nsc.ru)

Liquidus thermobarometry for Vitim basalts suggest that in initial stage in Bereya block hydrous OIB picrite basalts (mg9270) came from depth of 40-60 kbar heated to 1500oC. Associated Hi-K silisic basalts differentiated in the crust. The main plateau (14-7Ma) (mg9265-60) basanites with the slightly convex down LMREE part originated from peridotites gently U shaped and Cpx deficient as result of melt percolation in 32-25 kbar interval while more differentiated are close to Ga-Sp boundary. Subalkaline ol-basalts interacted with peridotites ascending from garnet to spinel facie with the relic garnet revealing more gentle PT pass. Typical Quaternary OIB Ne-mela-hawaiites (25-15 kbar) and more differentiated Ne- leico-hawaites with hydrous phases demonstrate more cold conditions of differentiation. The later are contaminated in host peridotites as well as Miocene basanites mixed with the DM (MORB) type mantle. Geochemistry of HFSE elements suggest primary OIB type magmas in 1st and last stages to be individual representing heard and tail of the small plume. Megacrystalline pyroxenite assemblages demonstrate intermediate heating conditions between basalts and lherzolites and mixing signatures being originated in pre-eruption small magma chambers or large veins. TOPOGRAPHICAL AND GEOLOGICAL CHARACTERS OF SUBMARINE CALDERA LOCATED BETWEEN HACHIJOJIMA IS. AND AOGASHIMA IS, IZU-OGASAWARA ARC.

Izumi SAKAMOTO, Toshiya FUJIWARA (Deep Sea Res. Dept., Japan Marine Science & Technology Center, email: izumis@jamstec.go.jp), Fumitoshi MURAKAMI (Geological Survey of Japan), and Mitsuo ISHIDA (Univ. TOKAI)

South Hachijyo Submarine Caldera (SHSC) is located between Hachijojima Is. and Aogashima Is., and consisted the recent volcanic front of Izu-Ogasawara Arc. Diameters of SHSC are about 20km (E-W direction) _~13km (N-S direction). Caldera floor is about 5km across with -500m depth. The somma is consisted with some continuos knolls (height is about 300 m from the caldera floor). A small central cone with 100m in height is observed in the central part of caldera floor.
The acoustic basement in the flank of the SHSC is overlain by thin layer (L-1), and L-1 layer is covered by stratified layer (L-2) unconformably, from single-channel seismic profiles. L-1&2 layers are considered to Hachijyo volcanic ejecta. Stratified layer (L-3) is observed in the caldera, and estimated to volcanic product of SHSC.
Rhyolitic pumices, basalts, and granites were dredged from the SHSC. These volcanic rocks indicate the bimodal volcanism. Trace element pattern from the SHSC rhyolite plotted similar to the granite, rather than the data from volcanic front activity. It is considered that the pumices are caused by remelt of the granite at the time when basaltic activity occurred in the volcanic front recently.

LUNDY VOLCANO, BRISTOL CHANNEL, U.K: FACT OR FICTION?

Clive ROBERTS (School of Applied Sciences, University of Wolverhampton, Wulfruna Street, Wolverhampton WV1 1SB, UK, email: in5359@wlv.ac.uk); Hazel Rymer (Department of Earth Sciences, Open University, Walton Hall, Milton Keynes, MK7 6AA, email: h.rymer@open.ac.uk)

Lundy Island is the southernmost expression of Tertiary volcanism in Great Britain and consists of granite intruded by around 200 dykes. The Lundy Igneous Complex (LIC) as a whole is associated with a large positive gravity anomaly and several small magnetic anomalies. The Lundy Dyke Swarm comprises basalt/dolerite and trachyte to rhyolite intrusions (54.3 to 56.4 Ma) within the host Tertiary granite (58.7 +/- 1.6 Ma) and Devonian sediments. Dykes have a radial disposition superimposed on an ENE-WSW trend.
The LIC is situated close to the intersection of the Variscan Front and Welsh Caledonides massif where the continental thickness is between 25 and 27 km. A large positive gravity anomaly to the north-west of the island (of comparable magnitude to other Tertiary centres in Scotland) does not have a corresponding magnetic signature. Gravity modelling indicates this may reflect dense basement rocks within the Lundy Horst rather than a large near-surface body of basic rocks. Although the heavily fractured nature of the host sediments assisted the passage of magma, the intra-chamber pressure of ponded magma bodies may not have exceeded the overlying lithostatic load to any great extent and so the postulated Lundy Volcano probably did not produce sub-aerial volcanic activity within the outer Bristol Channel.

KOMATIITES AND THEIR GEOLOGICAL, GEOCHEMICAL AND GEOPHYSICAL CHARACTERISTICS OF PALEO-YANGTZE PLATE FROM SOUTH CHINA

Yuehua Jiang and Douke Xie N a njing Institute of Geology and Mineral Resources, Nanjing 210016, P. R. China, email: nigmr@ public1.ptt.js.cn.

A Paleo-Mesoproterozoic komatiitic zone (1600-240OMa) exists in the southeastern margin of Paleo-Yangtze plate from South China, especially along the line of Hunan-Guizhou-Guangxi-Hainan provinces. Komatiitic lavas are 3-50m thick and have spinifex textures. The spinifex of skeletal crystal is 0.3-1.5cm in length and are mainly olivine and pyroxene which have alterated into serpentine, hornblende, tremolite or chlorite. Chemical compositions of komatiites are: MgO 11-30%, TiO2 0.5-0.9%, (LU/Sm)N<0.7, (La/Sm)N = 2.78-2.88, more than 0.75,87Sr/86 Sr = O.7039, 143Nd/144Nd=0.5120520. 5 13146, Nd (t)=+2.6+5. 9. MgO content ofkomatiitic basalts is generally lower (3-9%), but komatiitic basalts also have spinifex textures and are different from those in the other areas of the world. It is considered that komatiites represented palco-volcanic hot-spots of paleo-oceanic plateau which are formed directly by partial melting of rising, deep plume, and were composed of the Lower-Middle Proterozoic growth layers in Paleo-Yangtze plate which are similar to the primitive mantle in isotope. The lastest S wave three-dimension velocity plane image displays that there is a columnar low-velocity anormaly area (-O.6%) at depths of 350km and 410km at 110°E and 26-31°N of the middle South China, which verifies that the residual hot paleoplume exists under the lithophere. The continent crustal structure is closely related to underlying plume structure.

AN INTERNATIONAL DECADE OF POTENTIAL FIELD RESEARCH

Eigil FRIIS-CHRISTENSEN (Danish Space Research Institute, Juliane Maries Vej 30, DK-2100 Copenhagen, email: efc@dsri.dk)

During the recent years progress in geopotential field research has been severely limited by the available amount of high precision measurements of the global gravity and geomagnetic field. Since 1980, at the end of the Magsat mission, there have been no further global measurements of the near-Earth magnetic field and there has never been one for the gravity field. This situation will soon change; there are several planned and proposed geopotential field satellites. The scientific community has made an effort to co-ordinate all these endeavours in announcing an "International Decade of Geopotential Field Research" in order to encourage the provision of a set of continuous measurements from space of the Earth's potential fields. Such a continuous and homogeneous series of measurements would have a great impact on the quality of science that can be done and will also provide the foundation for new and improved applications that depend on up-to-date high precision mapping of these fields.

JSA37/E/01-B3 Invited **0915**

DEDICATED GRAVITY FIELD SATELLITE MISSIONS - PRINCIPLES AND AIMS

Reiner RUMMEL (IAPG, Techn.Univ.Muenchen, Arcisstrasse 21, D-80333 Muenchen, Germany, email: rummel@step.iapg.verm.tu-muenchen.de)

All our current global gravity field models are based upon a sophisticated patchwork of satellite orbit perturbations, satellite altimetry, and terrestrial gravity combined with height information. This method has been developed to its very limit. Fundamental further improvement must therefore come from dedicated gravity field satellite missions. The underlying principle for any such mission is the reconstruction of perfect free fall in the Earth's gravitational field of one or more test masses in low orbit. This may be achieved by measuring - with highest possible precision - either (1) the relative motion between the high orbiting GPS satellites and a low orbiter (satellite-to satellite tracking in the high-low mode (SST hi-lo)), as will be applied for the CHAMP mission, or (2) by combining this concept with the measurement of the relative motion between two low orbiters (satellite-to-satellite tracking in the low-low mode (SST lo-lo)), as for the case of GRACE, or (3) by combining SST hi-lo with satellite gradiometry as proposed for GOCE. Whereas GRACE aims at the recovery of the large and medium spatial scales of the gravity field with ultimate precision so as to reveal its variations in time, GOCE will focus on the determination of the stationary field with maximum spatial resolution. Gradiometry, based on the principle of differential accelerometry, requires the elimination of all possible spurious perturbations on its test masses due to non-gravitational linear accelerations, spacecraft rotation or time-variable self-gravitation. The satellite becomes integral part of the gradiometer. GOCE aims at the resolution of the gravity field up to al least degree and order 200 in terms of spherical harmonics with a cumulative geoid error of below 2cm or gravity anomaly error of below 0.6 mGal.

JSA37/W/05-B3 Invited **0945**

CHAMP AND THE GEOPOTENTIAL FIELDS

Ch. REIGBER, H. Lühr, P. Schwintzer (GeoForschungsZentrum Potsdam, Telegrafenberg A6, 14473 Potsdam, Germany, Email: reigber@gfz-potsdam.de)

CHAMP is the first low-cost satellite mission aiming at the simultaneous precise observation of both the gravity and magnetic field from a low altitude orbit. Thanks to the dedicated orbit design, an unprecedented low altitude in a near polar orbit, its continuous undisturbed observation of the magnetic field vector through scalar and vector magnetometers and its continuous GPS satellite-to-satellite tracking capability together with a direct on-board measurement of the non-gravitational orbit perturbations, a dramatic improvement in the global modelling of the magnetic field and also an order of magnitude improvement for the broad to mesoscale structures of the gravity field can be expected. In addition, due to the designed 5 years mission duration, temporal changes in both fields will be detectable with a higher signal/noise ratio and at increased spacial resolution as it is possible now. Therefore a

number of fast to slowly changing gravity and magnetic signals will become measurable, which are related to processes taking place in the various constituents of the system Earth. The discrimination of various signal sources, the combined use of observed irregularities or variations in time, the inversion and correlation of observed field data will become interesting research issues for atmospheric, ocean and solid Earth sciences. CHAMP fulfils the criteria of a small satellite mission, i.e. short development time through the usage of existing sensors and commercial subsystem components and reduced cost through proto-flight approach, suitable quality standards and streamlined test efforts. The CHAMP development started in January 1997 and the satellite structure, subsystems and payload has been integrated. Launch on a COSMOS rocket is planned for late 1999. The presentation will focus on mission goals, S/C and payload technical characteristics and the expected system performance for the modelling of the gravity and magnetic fields.

JSA37/E/04-B3 1015

INVESTIGATIONS ON THE POLAR GAP PROBLEM IN ESA'S GRAVITY FIELD AND STEADY-STATE OCEAN CIRCULATION EXPLORER MISSION (GOCE)

Stephan RUDOLPH, Karl-Heinz Ilk, Juergen Kusche (Institute of Theoretical Geodesy, University of Bonn, Nussallee 17, 53111 Bonn, Germany, email: stephan@theor.geod.uni-bonn.de)

GOCE (Gravity Field and Steady-State Ocean Circulation Explorer Mission) is one of the candidates to become the first ESA's Earth Explorer core mission. It is a high resolution gravity field mission concept based on SGG (satellite gravity gradiometry) combined with GPS-SST (satellite-to-satellite tracking) and will open a completely new range of spatial scales of the earth's gravitational field spectrum down to 100km wavelength. Due to the sun-synchronous orbit the two polar regions with a radius of about 700km cannot be observed. Therefore these regions represent data gaps, resulting in poorly determined frequency bands in the spectral representation of the gravity field. Although these data gaps cover only approximately 2% of the planet's surface, especially the polar regions play an important role in climate change, mass-balance and ocean circulation. From a mathematical point of view, the problem of gravity recovery from observations in satellite altitude is seriously ill-conditioned. The polar gaps additionally aggravate the degree of instability. A theoretical analysis concerning the capabilities of a full tensor gradiometer to "look into" the polar gaps is performed. Special emphasis is laid on the effects of the specific tensor components and of the supplementary high-low SST data. Besides the additional instability effects in the downward continuation process due to the polar gaps are considered. First results using regional recovery strategies are presented.

JSA37/W/09-B3 Invited 1100

THE CONTRIBUTION OF FUTURE DEDICATED SATELLITE GRAVITY MISSIONS TO MEASURING TEMPORAL VARIATIONS OF THE EARTH'S GRAVITATIONAL FIELD

R.S. NEREM, S.V. Bettadpur, R.J. Eanes, B.D. Tapley (all at the Center for Space Research, The University of Texas at Austin, Austin, TX, 78712, email: nerem@csr.utexas.edu); J. Wahr (Department of Physics, University of Colorado, Boulder, Colorado, 80309-0390, USA, email: wahr@lemond.colorado.edu)

Mass redistributes itself in the coupled Earth system on a variety of temporal and spatial scales reflecting complex interrelated processes in the oceans, atmosphere, groundwater, and glacial/polar ice. The measurement of these variations is thus important for a variety of studies attempting to understand the interactions of the different components of the Earth system, and how they may change with time due to anthropogenic influences. This presentation will discuss the spatial and temporal characteristics of observations of the temporal varying gravity field expected to be made by future dedicated satellite gravity missions (e.g. CHAMP, GRACE, GOCE) early in the next decade. The subject will be introduced by summarizing the relatively limited results available from current space geodetic techniques (e.g. SLR). The spatial and temporal properties of the expected time varying gravity signals arising from different components of the time varying gravity field (ocean mass, atmospheric mass, continental water mass, snow mass, etc.) will be assessed using a variety of geophysical models. These geophysical signals will then be compared to the expected performance of future satellite gravity missions. The limiting error sources influencing these observations will be summarized. Finally, the expected benefits to Earth system science studies will be discussed, based on the magnitude of the signals predicted by the geophysical models, and the expected performance of the satellite measurements. Central to this discussion will be a consideration of how to separate the different sources of mass redistribution given that the satellite observations will reflect contributions from many different components of the Earth system.

JSA37/E/05-B3 1130

DATA COMBINATION IN ILL-POSED DOWNWARD CONTINUATION PROBLEMS

Karl Heinz ILK, Juergen Kusche, Stephan Rudolph (Institute of Theoretical Geodesy, University of Bonn, Nussallee 17, D-53115 Bonn, Germany, email ilk@theor.geod.uni-bonn.de)

It is a well-known fact that the computation of gravity field parameters from pure satellite data is improperly posed from a theoretical point of view in so far as the recovery results do not continuously depend on the observations. Despite the fact that the numerical implementation takes the edge out of the problem, at least to a certain amount, it remains a seriously ill-conditioned problem. The standard procedure to overcome this problem is to introduce stochastic prior information, in most cases in form of an appropriate degree variance model. Formally this procedure corresponds to Tikhonov's regularization where the regularization parameter balances the noise and the signal content of the observations. While the combination of data of different origin is comparably well-understood in well-posed problems there are some open questions in combining various data sets in improperly posed problems: What is the information content of the various data, as a set and as individual observations, contributing to the recovered gravity parameters? How does the gravity field parameters change if the observations are changed by minor amounts? Is there a difference of globally and locally defined parameters? What is the effect of data gaps on the spatial and spectral distribution of data? The present investigation trys to tackle a clarification of these questions. Results of simulations of future gravity field mission scenarios are presented to demonstrate the problems. Possibilities to overcome these problems are discussed.

JSA37/P/01-B3 1145

APPLICATION OF THE TIDAL GRAVITY OBSERVATIONONS ON GEODYNAMICS OBTAINED WITH SUPERCONDUCTING GRAVIMETER

He-Ping SUN, Hou-Tze Hsu, Jian-Qiao Xu, Guo-Qing Tao (Institute of Geodesy and Geophysics, CAS, 54 Xu-dong Road, 430077, Wuhan, China, email: heping@asch.whigg.ac.cn)

The superconducting gravimeter is the most reliable instrument at present on the study of the small change in earth gravity field, since it possess with the wider dynamic linear measuring range and can be used to detect the available signals which are usually below the normal instrumental noise level. The long term (non-) tidal gravity observations for 10 years with sampling of 20 s observed with superconducting gravimeters at station Wuhan in China are studied comprehensively. The corresponding results at various wave bands are used to study the gravity signals due to (1) the change in the atmospheric pressure; (2) the influence of the oceanic loading; (3) the influence of the dynamics of the Earth's core and (4) the effect of the Earth's rotation.
Using a slipped window function, the abnormal signals as jumps, tars and spikes are detected and eliminated. The missing data due to the power interruptions, earthquakes, refilling liquid helium are filled using a spline interpolation method based on the synthetic tide. Using a symmetric digital low-pass filter with a truncate period of 3 hours, the hourly sampling intervals of the tidal gravity and pressure are obtained after a smoothing processing. The efficiency when using various procedures on improving accuracy of the tidal parameters is discussed. The residual amplitudes and the average standard deviations are determined using the Fast Fourier Transformation method. We used the station air pressure data and the regression method to determine the atmospheric gravity admittances in both temporal and frequency domains. We applied the oceanic loading correction based on the various most recent global ocean tidal models. We used the staking method to determine the resonance parameters of the Nearly Diurnal Free Wobble.

JSA37/W/04-B3 1200

THE ALPINE SWISS FRENCH AIRBORNE GRAVIMETRY PROJECT

J. VERDUN (a) (email: verdun@dstu.univ-montp2.fr), R. Bayer (a)
(email: roger@dstu.univ-montp2.fr), E. Klingelé (b) (email: emile@geod.ethz.ch); M. Cocard (b) (email: cocard@geod.ethz.ch), M.Cerniar (b) (email: mace@geod.ethz.ch), A. Geiger (b) (email: geiger@geod.ethz.ch), M.Halliday (c) (email: MrHalliday@aol.com) [(a) CNRS-ISTEEM, Université de Montpellier II, France; (b) GGL, ETH-Hönggerberg, Zürich, Switzerland; (c) Lacoste&Romberg Gravimeters Inc., Austin, Texas, USA]

This airborne gravity suvey was realized in the frame of the "GEOFRANCE 3D Alpes" project in the Western ALps, from the Rhone Valley to the Pô-Plain in Italy. Four objectives were followed: accurate airborne measurements of the alpine gravity field, combination of both GPS data and those provided by a classical navigational system (INS), comparison between airborne gravity data and upward prolongated ground data, 3D modelling of the alpine crust using several Bouguer anomaly maps. In February 1998, 18 NS lines were flown, crossed by 16 EW lines, spaced respectively by 10 and 20 km. The survey was performed with a Twin-Hotter aircraft owned by the Swiss Federal Directorate of Cadastral Surveying at barometric altitude of 5100 m above sea level. The aircraft was equipped with 5 GPS receivers (working frequencies: from 1 to 8 Hz) for relative positionning to 7 ground fixed GPS stations and for monitoring both aircraft velocities and accelerations. Gravity field was measured with a L&R airborne gravimeter, type SA, mounted on a laser gyro stabilized platform (working frequencies: 1Hz for the spring tension, 10 Hz for the beam position).Various strategies for computing the kinematic properties of the aircraft(softwares, choice of the reference GPS ground station) are discussed. A preliminary long-wavelength "free-air" anomaly map is presented and compared with some previous published.

JSA37/E/03-B3 1215

GLOBAL POWER SPECTRAL DENSITIES FOR GRAVITY AND MAGNETIC FIELDS

Roger HIPKIN, Thomas Kalscheuer (Department of Geology & Geophysics, University of Edinburgh, Kings Buildings, Edinburgh EH9 3JW, UK, email: roger.hipkin@ed.ac.uk)

This paper presents a re-interpretation of the power spectral density of the Earth's gravity field which implies that lithospheric sources dominate the spectrum for spherical harmonic degrees above about 14, the same result as with the geomagnetic spectrum. At lower degrees, both power spectra identify sources largely concentrated at a single depth but, for gravity, they are within the lower mantle, compared with just below the core-mantle boundary for geomagnetism. The low source power from upper mantle asthenosphere results from convection there needing only very small bouyancy forces to overcome viscous drag. Significant sources of the gravity anomaly are thus confined to either the lithosphere (where they are supported by elastic forces), or the lower mantle (where a higher viscosity slows their dissipation).
This result is not due solely to new data: the global gravity models OSU91A and EGM96 have a similar spectrum. Contrary to the conventional picture often described as Kaula's Law, the gravity power spectrum in fact looks very much like the geomagnetic spectrum. Failure to identify this earlier may have been due to a different spherical harmonic normalisation used in geodesy and geomagnetism.

RECENT PROGRESS IN EXPLORING THE NEAR-EARTH MAGNETIC FIELD WITH LOW-ALTITUDE SATELLITES

Nils OLSEN (Danish Space Research Institute, Juliane Maries Vej 30, DK-2100 Copenhagen, e-mail: nio@dsri.dk)

Data from high-precision geomagnetic satellites in low-altitude orbits are a unique opportunity to investigate the near-Earth magnetic field from space. Almost 20 years after the MAGSAT mission, at least three satellites will provide high-quality data during the next years: Oersted (launched in January 1999), SAC-C/MMP, and CHAMP. They all carry similar high-precision instrumentation for measuring the magnetic field vector with an accuracy better than 2 nT absolute. Each mission, however, has its own advantages given the different altitude, local-time coverage, sampling rate and lifetime of the satellites. Data from single satellite missions are not able to accomplish the accurate determination of the spatial and temporal structure of all sources that contribute to the near-Earth magnetic field. A great challenge is therefore the combined analysis of data from different satellites, and from ground based observatories. This is the only way to take full advantage of the accuracy of the instrumentation, which has improved enormously in comparison to previous missions. The results of such a comprehensive modelling effort will be presented and plans for further improvement of the model will be discussed.

JSA37/W/08-B3 1430

SEARCHING FOR AN OPTIMAL SATELLITE NETWORK FOR MONITORING FAST CHANGES WITHIN THE EARTH'S MAIN MAGNETIC FIELD

Benoit LANGLAIS, Pascale Ultré-Guérard, Gauthier Hulot, Yves Cohen, Mioara Mandea (Alexandrescu Institut de Physique du Globe de Paris, 4 Place Jussieu, 75252 Paris Cedex 05, France, email: langlais, ultre, gh, cohen, mioara@ipgp.jussieu.fr)

In addition to the Danish satellite OERSTED (due to be launched in January 1999), several satellite missions devoted to observing and mapping the Earth's magnetic field are planned to be launched in the near future (e.g.,SAC-C, CHAMP). These are one-satellite missions, with both scalar and vectorial magnetometers on board. Combined with observatory data, this data will make it possible to better describe part of the large scale external field and characterise the crustal field, the main field and the secular variation down to time scales of the order of three to six months. Further improvement of our knowledge will only come with the possibility of having missions involving several satellites flying at the same time, such as the proposed SWARM (European) or UNIMAG (Russian and Indian) missions. The purpose of the present study is to assess how much improvement such configurations would bring, especially with respect to our ability to better characterize the evolution of the main field on the shortest time scales. By making use of synthetic data produced by realistic internal and external sources to which a plausible noise is being added, various orbital configurations are being considered. The synthetic data is produced for each satellite and present observatory locations and is then inverted for internal and external sources. It is shown that a very robust configuration would consist in having six vectorial satellites orbiting on polar orbits together with one vectorial satellite orbiting on a near equatorial orbit. It appears for instance that a potential downgrading of the six polar satellites to simple intensity satellites would virtually not affect the quality of main field models which could still be computed on a week by week basis. Adding more satellites would allow to slightly reduce this time step, but this would probably not bring much additional information with respect to the temporal evolution of the main field, the shortest time scales of which are being filtered out by the mantle. By contrast, it will be shown that adding two to three new observatories near the equator would prove very useful.

JSA37/W/02-B3 1445

UNIVERSAL GLOBAL SURVEY OF THE EARTH MAGNETIC FIELD "UNIMAG"

Victor N. Oraevsky, Vadim P. GOLOVKOV (both at IZMIRAN, 142092 Troitsk, Moscow region, Russia, email: golovkov@izmiran.rssi.ru); A.V. Zaitsev (Lavochkin Association, 141400 Leningradskoe sh., 24, Khimki, Moscow region, Russia)

The main goals of UNIMAG mission being the following:
(1).The precise modelling of the main geomagnetic field on epoch of launching and deriving the secular variation model.(2).The Earth's crust magnetic anomaly mapping.(3).The Earth's mantle electrical conductivity mapping.(4).The ionospheric and magnetospheric current systems separation and modelling.for the practical needs the mission will give data for the International Geomagnetic Reference Field modelling as well as for regional geomagnetic field mapping which can be used for:(5). The prospecting and magnetic mapping.(6). The marine and airborne navigation and for other aims of the first necessity. For this aim it is supposed to realise the UNIMAG project by the launching a few small satellites to the orbits separated in altitude and in local time. The first satellite, equipped by the complete set of magnetometers and star imager should be launched to the Sun-synchronised orbit with inclination 96, altitude 500-700 km and local time of the equator crossing - 6 and 18 hour. The second satellite (for anomalous field survey) should be launched as well to the Sun-synchronised orbit with inclination 96, altitude 300-1000 km and local time of equator crossing 6 and 18 hour. Else 3 satellites should be launched on near polar orbits to pass whole range of local timei

SATELLITE MONITORING OF THE MAGNETIC FIELD AND FLUID MOTION AT THE TOP OF THE EARTH'S CORE

A. JACKSON, M. Walker (School of Earth Sciences, Leeds University, Leeds LS2 9JT, UK)

The distribution of magnetic observatories on the Earth's surface is such that accurate monitoring of the conditions at the top of the core necessarily requires spaceborne instrumentation in order to attain full geographical coverage and concomitant accuracy. We are currently entering a new era in spaceborne observation of the geomagnetic field that promises great rewards.
We will describe progress in the analysis of satellite data for core magnetic fields and fluid motions. The overriding limitation on accuracy of the core field is the crustal field, which limits resolution to below spherical harmonic degree 14. We compare the most recent results with models derived from Magsat data in order to analyse the conservation of magnetic flux within the so-called "null-flux patches" on the core surface. Additionally we can address the conservation of radial vorticity within these patches. The construction of magnetic fields conserving such quantities is, we argue, a necessary prerequisite for the self-consistent derivation of fluid motion at the core surface.

JSA37/W/07-B3 Invited 1600

MODELING THE MAGNETIC FIELDS OF IONOSPHERIC AND MAGNETOSPHERIC CURRENTS

Arthur D. RICHMOND (NCAR High Altitude Observatory, P.O. Box 3000, Boulder, CO 80302-3000, USA, email: richmond@ucar.edu)

Electric currents in the ionosphere and magnetosphere produce magnetic perturbation fields on the ground and at low Earth orbit ranging from tens to thousands of nanoteslas. At the ground these are potential fields, but in space there are strong non-potential components, especially those due to geomagnetic-field-aligned currents. This talk describes the simulation modelling of ionospheric and field-aligned currents and their magnetic perturbations. Simplified methods of calculating the perturbations associated with field-aligned currents are presented.

JSA37/W/03-B3 1630

TECHNIQUES FOR IDENTIFYING EXTERNAL FIELD CONTRIBUTIONS IN SATELLITE DATA

H. LUEHR, U. Engels, M. Rother, M. Förster (GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany)

The upcoming decade will see a whole fleet of geomagnetic field missions. The high resolution of the new and advanced instrumentation can only be fully utilised for main and crustal field modelling, if we succeed in improving the separation between contributions from internal and external field sources.
There is no straightforward mathematical method which could be used for the separation. Our approach is to make intensive use of the special features of external current circuits and include it as a priori information in the calculations. We assume for example that currents at orbital height flow solely along the field lines. All ionospheric currents are confined to a thin layer. If also the electric field is measured, the two currents and the E-field can be combined in a single relation which can be used for consistency checks. Other currents flowing across the field lines occur only further out in the magnetosphere (e.g., ring current, magnetopause, magneto-tail) thus produce large-scale variations.
We have applied our technique to real satellite data. From in situ measurements we estimate the ionospheric and the field-aligned currents in the vicinity of the satellite orbit. Contributions from the large-scale currents are estimated by employing a magnetospheric current model. Scaling the size of the configuration and the intensity of the currents requires a parameterization of the model. The appropriate parameters have to be deduced from activity indices and/or in situ measurements. First results of our analysis will be presented.

JSA37/W/06-B3 Invited 1645

CRUSTAL MAGNETIC FIELDS

Patrick T. TAYLOR (Geodynamics Branch, Code 921, NASA/GSFC, Greenbelt, MD 20771, USA, email: ptaylor@ltpmail.gsfc.nasa.gov); D. Ravat (Department of Geology, MS 4324, Southern Illinois University at Carbondale, Carbondale, IL 62901, USA, email: tiku@denali.gsfc.nasa.gov); James J. Frawley (Herring Bay Geophysics, Dunkirk, MD 20754, USA, email hbgjjf@ltpmail.gsfc.nasa.gov)

Cosmos 49, POGO (OGO-2, 4 and 6) and Magsat have been the only low-earth orbiting satellites to measure the crustal magnetic field on a global scale. These missions revealed the presence of long-wavelength (> 500 km) crustal anomalies predominantly located over continents. Ground based methods were, for the most part, unable to record these very large-scale features; no doubt due to the problems of assembling continental scale maps from numerous smaller surveys acquired over many years. Questions arose as to the source and nature of these long-wavelength anomalies. As a result there was a great stimulant given to the study of the magnetic properties of the lower crust and upper mantle. Some indication as to the nature of these deep sources has been provided by the recent results from the deep crustal drilling programs. In addition, the mechanism of magnetization, induced or remanent, was largely unknown. For computational ease these anomalies were considered to result solely from induced magnetization. However, recent results from MOLA, a magnetometer-bearing mission to Mars, have revealed crustal anomalies with dimensions similar to the largest anomalies on Earth. These Martian features could only have been produced by remanent magnetization, since Mars lacks an inducing field. The origin of long-wavelength crustal anomalies, however, has not been completely determined. Several large crustal magnetic anomalies (e.g., Bangui, Kursk, Kiruna and Central Europe) will be discussed and the role of future satellite magnetometer missions (Orsted, SUNSAT and Champ) in their interpretation evaluated.

MAGSAT ANOMALY CORRELATIONS AMONG THE CONTINENTAL SEGMENTS OF THE EAST GONDWANALAND

O.P. PANDEY, P.K. Agrawal (National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India, email: postmast@csngri.rec.nic.in)

Long wavelength satellite magnetic (MAGSAT) anomalies have been found very useful in studying geodynamical evolution and regional plate tectonic problems. The present work analyses these and long wavelength gravity signatures together with geotectonic informations available over the constitutents of East Gondwanaland. We discover that during the pre-breakup period, India together with Madagascar, Sri Lanka and Enderby Land of Antarctica formed a "Super South Indian Shield" till about 130 Ma. The study reveals one to one correspondence between the MAGSAT anomalies across these continents, suggesting that they have common deep seated magnetic properties, which were acquired when all the fragments were joined together. It is observed that the ancient cratonic blocks of Archean-early Proterozoic age, are associated with high order positive MAGSAT anomalies compared to younger counterpart of middle to late Proterozoic age, which are characterised by negative anomalies. Further, the MAGSAT anomaly patterns would also indicate that (i) the Archean Napier complex of Enderby Land (Antarctica) may be continuing underneath the Reyner's complex towards the Lutzow Holm Bay region, and (ii) Madagascar never rifted away from Africa, rather it was a continental fragment of Super Dharwar craton of India till about 88 Ma.

CRUSTAL MAGNETIC ANOMALIES OVER SOUTH EAST ASIA: MAGSAT AND OERSTED

B.P. Singh, Mita RAJARAM (Indian Institute of Geomagnetism, Colaba, Mumbai-400005, INDIA)

The Oersted data will be analysed to prepare a crustal magnetic anomaly map over S.E. Asia to study the lithospheric dynamics and tectonic processes. This map will be compared with the Magsat crustal anomaly map over this region. Although the altitude of the Oersted is higher than Magsat, it is expected that the anomaly maps will have smaller errors and will bring out the broad tectonics of the region.

THE GEOID HEIGHTS FIELD INTERPRETATION METHODS FOR THE INVESTIGATION OF THE LITHOSPHERE STRUCTURE

A.A. BULYCHEV (Lomonosovs MSU, Geology faculty, Moscow, Leninsky Gory, MSU, Russia, email: bulychev@geophys.geol.msu.ru); A.G.Gainanov (Lomonosovs MSU, Geology faculty, Moscow, Leninsky Gory, MSU, Russia)

The satellite altimetry data acquire particular significance for studying the density inhomogeneities of MOR and adjacent deep-sea basins. Two main approaches to studying the Earth have been developed: the transformation of geoid heights into the gravity field and investigation of deep structure of the Earth using data on geoid height anomalies. The geoid height field, obtained from satellite altimeter data, is the original high-precision information about the Earth-gravity potential. The gravity effect of the water lay must be taken into account in quantitative interpretation the geoid heights field and construction the density models of the tectonosphere. The method of the reduction's computation was worked out. The geoid heights field anomalies in different reductions were computed (Bouger, Glennie and isostatic) for the Angola-Brazil geotransect (8°-18°) and Bouvet triple junction. The gravity effects of the water lay, bottom topography and deep density inhomogeneities (3-D) were taken into consideration for these reductions. The first 3-D density models of the tectonosphere structure were constructed based on the results the 2-D modeling along the profiles, which crossed the main morphotectonic structures of the investigated areas, and the correlation between bottom age (by the geomagnetic data) and lithosphere deepness. The gravity effects in gravity anomalies and geoid heights were computed from the 3-D density model and then this model was corrected according the residual fields. Residual fields were obtained by subtracting the model's effects from the observed fields. The regional part of the field is very important in the interpretation geoid heights. It was computed by the spherical garmonic of the Earth potential.

CONCERNING CONFORMITY OF PLANETARY FEATURES OF GRAVITATIONAL AND MAGNETIC FIELDS

D. Kh. RASULOV

The work gives in detail a new piezoelectric model of terrestrial magnetism which permits all the main features of geomagnetic field to be explained from the unified positions. In accordance with the model, piezoelectrical textures may be formed in the Earth's crust which are oriented along a direction close to the geographic parallels. The presence of mechanical strains in Erth's crust rocks caused by an action of terrestrial gravity is to lead to an emergence of a potential difference along the piezoelectric textures. As a result, an electric current runs along these directions forming a weak quasi-stable magnetic field, which direction is to be close to that of the geographic terrestrial axis.
Therefore, in accordance with the model, local gravitational anomalies fixed on the terrestrial surface cause the corresponding local anomalies in the mechanical stressed state of the Earth's crust rocks that must lead to the observed conformity of the planetary features of gravitational and magnetic fields. Mechanical stresses in rocks, naturally, may be caused also by other reasons. These stresses are superimposed to the stress caused by Earth gravitation and may be a reason of various anomalies of the geomagnetic field. Diurnal variations of the geomagnetic field are caused by Sun's and Moon's gravitational attraction to the Earth's crust rocks.

FLUID DYNAMICS AND SOME KEY APPLICATIONS TO UNDERSTANDING GLOBAL CHEMICAL-CLIMATIC CHANGE

Michael E. McINTYRE (Centre for Atmospheric Science at the Dept. of Applied Mathematics and Theoretical Physics, Cambridge CB3 9EW, UK, email: mem@damtp.cam.ac.uk)

This overview will focus on several very fundamental aspects of our global fluid environment, through some thought-experiments designed to expose key mechanisms controlling global-scale mean circulations in the atmosphere and ocean, and the resulting transports of heat and chemical constituents such as greenhouse gases.
The best understood fluid subsystem is the middle atmosphere - roughly 10-100 km altitude - whose mean stratification is primarily under UV/IR radiative control and whose mean circulation is driven not, as some mythologies have it, by solar heating, but by a persistent mechanical, Coriolis-mediated `gyroscopic pumping'. The pumping action depends on Rossby and gravity waves propagating or diffracting from below: more precisely, it depends on the interplay of the Coriolis force with the irreversible angular momentum transport that results from wave generation in one place and dissipation in another by breaking and radiative damping.
Viewed as statistical fluctuations about a mean state, the disturbances characteristically have a net effect opposite to what was expected from classical ideas about spatially near-homogeneous `turbulent' fluctuations. As well as pumping mean circulations, the fluctuations tend to drive the mean state not toward, but away from, a state of solid rotation; and spatial inhomogeneity is an essential, leading-order feature. In the case of Rossby waves, such `anti-classical' behaviour (seen also in general vortex-interaction scenarios) is almost inevitable consequence of the transport and `inversion' properties of the Rossby--Ertel potential vorticity. There is an unexpected spinoff for understanding the Sun's interior.
The troposphere and oceans are more complicated, because of the non-global span of stratification surfaces and for other reasons as well. For instance the climate system's 'thermal powerhouse', the tropical troposphere, simplified as a subsystem with a fixed sea-surface temperature, has stable stratification under moist-convective control - temperature profiles clamped to the moist adiabat - and a persistent deep-convective upward mass flux in the intertropical convergence zone consisting of two contributions having somewhat comparable magnitudes, the one controlled by radiative cooling of the tropics and the other by gyroscopic pumping from the extratropics. If both these controls were to be switched off then the deep convection would also switch off. The oceans are more complicated still...

THE ROLE OF LABORATORY EXPERIMENTS IN ROTATING STRATIFIED FLOWS

Prof. Paul LINDEN (University of California, San Diego, USA, email: pflinden@ames.ucsd.edu)

This talk will review the role of laboratory experiments in research into the dynamics of rotating stratified flows (RSF) with particular relevance to geophysical fluid dynamics. Experiments have provided a major input into the understanding of RSF, both by revealing new phenomena and by providing data against which theoretical ideas can be tested and developed. The first major impact of experiments came with the annulus studies of the atmospheric circulation in the 1950s, and from that time there has been a (generally) increasing activity in RSF experiments. This talk will outline some of the successes of laboratory experiments in modelling RSF and will describe recent work in which the experiments interface with numerical simulations. The limitations of experiments of geophysical flows will be described and some speculations will be made about possible future developments.

TURBULENT CONVECTION IN ROTATING AND STRATIFIED FLUIDS

H.J.S. FERNANDO, M.A. Levy (Environmental Fluid Dynamics Program, Arizona State University, Tempe, AZ 85287-9809, USA)

Turbulent convection induced by heating the bottom boundary of a wide, linearly (temperature) stratified, rotating fluid layer is studied using a series of laboratory experiments. It is shown that the growth of the convective mixed-layer is dynamically affected by background rotation (or Coriolis forces) when the parameter R = (h**2\W**3/q)**{2/3} exceeds a critical value, R1, which is approximately 100. Here h is the depth of the convective layer, W is the rate of rotation and q is the buoyancy flux at the bottom boundary. When R > R2, where R2 is approximately 300, the buoyancy gradient in the mixed-layer was profoundly affected by background rotation. Conversely, when R < R1, the buoyancy gradient in the convective layer is independent of the rate of rotation and approaches that of convection in non-rotating fluids. When R > R2, the entrainment velocity was found to be dependent on the buoyancy frequency of the overlying stratified layer, the rate of rotation and the conventional (Deardorff) convection velocity. A simple theoretical formulation for the rate of entrainment was derived, which was found to be in good agreement with the experimental results. The experimental results also indicate that entrainment in this case is dominated by non-penetrative convection.

SEPARATION PHENOMENA IN STRATIFIED FLOW ALONG A SLOPING SIDEWALL

Geno PAWLAK, Parker MacCready (School of Oceanography, University of Washington, Box 357940, Seattle, WA 98195, USA, email: gpawlak@ocean.washington.edu)

Experiments examining the separation of a stratified flow along a sloping boundary are presented. Separation phenomena are the source of much of the transfer of vorticity-containing fluid within sidewall boundary layers into the interior inviscid flow, which may contribute to a significant part of the mixing in estuarine and coastal processes. Obstacles along the inclined sidewall induce both cross and along-isopycnal components to the mixing and allow the isolation of the competition between stratification and form induced pressure variations. Experimental results presented, examine obstacles of wavenumber, k, such that N/U << k << d, where d is the boundary layer thickness. These experiments explore the origin and structure of separation zones for a variety of stratified flow configurations including uniform stratified flow, two-layer and stratified shear flows and tidally modulated stratified flow. Particle imaging velocimetry and flow visualization results are presented along with observations on internal wave generation and drag. Experimental observations are compared to analytical and numerical analyses.

EDDY-DRIVEN BASIN-SCALE RESPONSE TO LOCALISED FORCING OF A ROTATING STRATIFIED FLUID

J. N. HACKER, S. B. Dalziel (D.A.M.T.P., Cambridge University, Silver Street, Cambridge CB3 9EW, UK; email: j.hacker@damtp.cam.ac.uk), P. F. Linden (A.M.E.S., University of California, San Diego, 9500 Gilman Drive, La Jolla, CA 92093-0411, USA)

Mesoscale eddies, produced for example by the instability of density fronts, are a ubiquitous feature of the flow in the oceans. These eddies typically have kinetic energy and vorticity levels exceeding those of the mean motion, and are widely considered to have a profound influence on the flow at larger-scales. Although the nature of this relationship is not well understood at present, the ability of eddies to transport momentum away from regions of eddy production to more quiescent regions may be an important effect influencing the character of the general oceanic circulation. Here we report laboratory experiments in which eddies were produced in a rotating stratified fluid by injecting and withdrawing fluid through sources and sinks situated along some part of the boundary of a laboratory tank. Energetic eddies continually formed and were dissipated at the sources and sinks, but also intermittently escaped from the forcing region, propagating away into the interior of the basin in the form of anticyclone-cyclone pairs. These eddies interacted in the interior of the basin and set up gyre-like circulation patterns. The character and localised nature of the source-sink forcing, together with the geometry of the basin, imposed dynamical constraints on the flow, in particular on the manner in which eddies were produced and the form of eddy interactions, with the results that a coherent basin-scale mean circulation was established.

LABORATORY EXPERIMENTS ABOUT UPWELLING FRONTS

P. BOURUET-AUBERTOT, P.F. Linden (D.A.M.T.P., Univ. of Cambridge, Silver Street, Cambridge CB9 3EW, U.K; Dept of Applied Mechanics and Engineering Sciences, Univ. of California San Diego, La Jolla, CA 92093-0411, USA)

We investigate experimentally the instability and later evolution of a front in a two-layer stratification near a coast and over sloping topography. The front is produced through the adjustment of a buoyant fluid that is initially confined within a bottomless cylinder. Typically, a front in quasi-cyclostrophic balance is established after two rotation periods, for appropriate values of the radius of deformation, after which it becomes unstable. We focus here on the influence of the coast and on the effect of conical bottom topography. Quantitative measurements of the velocity and vorticity fields at the surface are made which provide detailed information on the evolution of the front as the instability grows to finite amplitude. The effect of the coast is crucial with respect to the instability of the front and leads to the enhancement of cyclonic eddies consisting of coastal waters. This has significant impact on exchanges across the front. When a conical topography cross-frontal exchanges are weakened as the cyclonic eddies remain confined to the slope region.

A GRAVITY JET DISCHARGED HORIZONTALLY INTO A ROTATING AND/OR STRATIFIED FLUID

Yoshito IKEHATA (Dept. of Earth System Sci. & Tech., Kyushu University, Japan,
email: ikehata@esst.kyushu-u.ac.jp)

A gravity jet discharged horizontally into a rotating and/or stratified fluid is of great interest in oceanography and hydraulics. Two typical examples of such a jet are a high-density current which flows out of the Mediterranean Sea into the Atlantic Ocean and an inflow of muddy river water into an inner bay. Thus a large variety of different scales are associated with the horizontally-discharged gravity jet, which strongly influences coastal and off-shore flow systems. A three-dimensional round jet discharged into a linearly stratified rotating fluid has been investigated experimentally. A 130 x 30 x 30 cm glass water tank was filled with a linearly stratified salt water and placed on a counter-clockwise rotating table with the diameter of 1.0 m. A nozzle with the inside diameter of 3.00 mm was attached horizontally to a smaller side wall of the tank at the height of 18.5 cm. Through this nozzle was discharged horizontally a salt water, which has the same density as the ambient water near the nozzle or a density higher than the ambient water density. The discharged turbulent jet initially moves downward deflecting to the right (when viewed from above the tank) by the action of the Colioris force. Eventually, the jet reaches a larger side wall and proceeds along it forming a Kelvin-wave like pattern subject to a geostrophic balance and diffusion. In the very long time, steady two-dimensional two to six cellular vortices, were formed in the tank. The jet was marked with a dye and the overall flow patterns were visualized with suspended polystyrene beads. For comparison's sake, the non-rotating case was also investigated. The result shows that similar cellular vortices were formed in the long time, although the horizontal diffusion pattern of the

jet was different from that for the rotating case. The behaviour of the horizontally discharged turbulent jet was also analyzed numerically by means of LES. The eddy viscosity was evaluated based on a Smagorinsky type model, which takes into account the turbulence caused by the buoyancy energy of the subgrid scale. The numerical results are generally in accordance with the experimental ones. Such characteristic quantities associated with the jet as the velocity distribution, the vorticity distribution, and the time-series of turbulent spectra are calculated.

JSP39/W/29-B2 1130

EVOLUTION OF VORTICES GENERATED BY THE COLLAPSE OF A STRATIFIED, TURBULENT WAKE

Alan BRANDT (Johns Hopkins University, Applied Physics Laboratory, Johns Hopkins Road, Laurel MD 20723-6099, USA, email: alan.brandt@jhuapl.edu)

Recent laboratory studies of turbulent wakes of spheres and self-propelled bodies in stratified fluids have shown that late-wake vortices ("pancake eddies") are present over a wide range of Reynolds and Froude numbers and that they persist for very long times. This late-wake, quasi-two dimensional structure results from the stratification induced collapse and transfer of the vertical turbulent energy and the wake-induced shear in the horizontal plane. As the energy supply is non-uniform, due to the turbulent nature of the wake, the resulting vertical vorticity is not uniformly distributed. The late-wake eddies are interconnected and evolve as dipoles with unequal vortex strengths at each pole, and thus do not behave as dipoles that are generated in laminar flow experiments which can be described theoretically. Based on laboratory experiments, a statistical analysis of the late-wake, turbulent dipole evolution has been carried out in order to describe the evolution of the size and motion of the dipoles as a function of Froude number. Implications of these scaling laws for the persistence of eddies in the ocean (that can result from shear induced instabilities and can affect the distribution of the planktonic biomass and anthropogenic pollutants) will also be discussed.

JSP39/W/08-B2 1150

SPIRAL MONOPOLES AND DIPOLES IN ROTATING STRATIFIED FLUIDS

Sergey VOROPAYEV (Arizona State University, Tempe, AZ 85287-6106, USA and Institute of Oceanology, Russian Academy of Sciences, Moscow, 117851, Russia, email: s.voropayev@asu.edu)

Monopoles and dipoles are most frequent structures observed in the stratified and/or rotating systems. Typical examples are mushroom-like currents in the upper ocean and inter-thermocline lenses in the deep ocean. To reproduce these characteristic flows in experiments, a controllable horizontal momentum source (jet emerging from a nozzle into a rotating stratified fluid) was used. The jet either (i) deflects from the direction of injection, forming an anticyclonic spiral monopole (monopole regime), or (ii) propagates along the injection direction, forming a dipolar structure (dipole regime). Which of these flows occurs depends on the system parameters, the Reynolds number Re and the buoyancy frequency to Coriolis parameter ratio N/f. A flow regime diagram is developed for a range of these parameters. A theoretical analysis is advanced to explain the conditions under which the monopole or dipole regimes occur, including the transition curve between the two regimes, which is calculated as N/f = 2Re1/3. The theory is supported by laboratory experiments. In accordance with the flow regime diagram, one may expect that dipolar structures should occur more frequently in the upper ocean, while monopolar structures should occur more frequently in the deep ocean. These conclusions are in agreement with numerous remote observations and direct field measurements.

JSP39/W/19-B2 1210

INTERACTIONS BETWEEN TOPOGRAPHY AND AN INTERMEDIATE CURRENT: AN EXPERIMENTAL STUDY

Sylvian SADOUX (LEGI-Coriolis, 21 ave des martyrs, Grenoble, 38000, France, email: sadoux@hmg.inpg.fr)

To study the effects of a cape or a canyon upon an intermediate water current, experiments were performed on the 13m diameter tank filled with a linearly stratified fluid. The upstream current was either stable (Ro1) or unstable (i.e. anticyclonic lense generating, Ro<0.2) (Sadoux et al., 1999). From horizontal velocitiy fields recorded in several (up to 29) levels using a Correlation Imaging Velocimetry (CIV) technique it is possible to reconstruct 3D velocity and vorticity fields as functions of time. The cape-current interaction experiments focussed on a simplified model of Cape Saint Vincent at depth 1000m (i.e. a 70° cape). When the upstream current is unstable, they show that there is anticyclonic lense production at the cape; these anticyclonic lenses are at first surrounded by a cyclonic ring. As they propagate, the cyclonic ring tends to weaken but upper and lower (and weaker) cyclones remains attached to the anticyclone. When Ro increases, (1) there is dipole formation at the cape and (2) the negative to positive vorticity ratio increases too. The formation period, the vorticity and the spin-up time of the lenses generated at the cape agree with in situ observations (Bower et al., 1997). In the canyon-current interaction experiments the mean current level was either above or at the upper bound of the canyon. In both cases, when the upstream current is unstable, the canyon is a possible (but not only) place for anti-cyclonic lense generation. When the upstream current is stable, there is only cyclone generation, starting in the canyon region and growing in diameter with time. These cyclones are then advected downstream by the current. The rate of growth of the cyclones is maximum when the Rossby radius of deformation is larger than the canyon width.

THE ROLE OF ROTATION & STRATIFICATION IN THE DYNAMICS OF EARTH'S CORE

Paul ROBERTS (Institute of Geophysics and Planetary Physics, UCLA, Los Angeles, CA 90095, USA, email: roberts@math.ucla)

The directional property of the magnetic compass needle is enough to establish how important the rotation of the Earth is for the MHD of its core; of all the forces that act on the core fluid, the Coriolis force alone has a preferred direction. The study of RMHD (rotating MHD) shows how rotation retards most flows. giving them slow time scales that have been identified with those of the geomagnetic secular variation. The time scale of the geostrophic component of flow, and it to has been seen in analyses of geomagnetic data.
Most simulations of core RMHD assume that the bulk of the core is weakly but stably stratified because of tiny compositional and thermal superadiabatic gradients that are however large enough to provide the buoyancy necessary to supply kinetic and magnetic energy. It has also been suggested that there is a layer of stably stratified fluid at the top of the core, and Braginsky has called this "the stratified ocean of the core". This presentation will focus on the present status of the topics adumbrated above.

JSP39/E/10-B2 Invited 1430

INFERENCES ON CORE STRUCTURE AND FLOW FROM SURFACE OBSERVATIONS

David CROSSLEY (Saint Louis University, Department of Earth and Atmospheric Sciences, 3507 Laclede Ave., St. Louis, MO 63103, USA, email: crossley@eas.slu.edu)

There can be no direct observations of the Earth's core; all geophysical measurements have to be heavily processed to reveal subtleties that might reflect structure and motions deep within the Earth. The most effective techniques are seismology, gravity, geodesy and geomagnetism. The most likely motions that may be detectable are short period waves (predominantly hydrodynamic) of periods hours to days, rotational phenomena associated with angular momentum changes between the inner core, outer core and mantle with periods of hours to decades, and decadal changes in core flow associated with steady convection of the hydromagnetic fluid. In all successful observational campaigns, three criteria need to be satisfied:
(1) the theoretically possible motions have to be stimulated by a sufficiently energetic source,
(2) the signal to noise ratio of the surface phenomena must be adequate and (3) the damping of the motions must be weak (i.e. long) enough to permit the required data to be collected.
This review will begin with the best known data we have at long periods, i.e. the Earth rotation data and the magnetic field variations over several decades to centuries. We will end with the possible observations we may get from seismology and super-conducting gravimeters over the next few years.

JSP39/W/34-B2 1500

PRECESSION DRIVEN FLOW IN SPHERICAL SHELLS

A. Tilgner, F.H. BUSSE (Institute of Physics, University of Bayreuth, D-95440 Bayreuth, Germany)

Precession has long ago been proposed as a possible driving mechanism for the geodynamo. In the case of exactly spherical boundaries, only viscous forces transmit the motion of the boundaries to the fluid. In the simplest approximation, the flow inside the shell is described as a solid body rotation about an axis that differs from the axis of rotation of the shell. The velocity profile inside processing spherical shells has been investigated numerically for different Ekman numbers, precession rates and gap sizes. The simulations reveal significant deviations from a pure solid body rotation. These deviations determine the shape of internal shear layers and the stability of the flow. The numerical results are compared with analytical expressions in the cases of the full sphere and in the thin shell limit.

JSP39/E/17-B2 1520

ASYMPTOTIC MODELS FOR RESISTIVE INSTABILITY IN THE EARTH'S OUTER CORE

Steven D. LONDON (Department of Computer and Mathematical Sciences, University of Houston-Downtown, One Main Street, Houston, Texas 77002, USA)

Numerical work indicates that resistive instability may be the dominant mode of instability in the Earth's outer core for realistic core parameter regimes. In this work, we are able to study resistive instability analytically by choosing a parameter regime in which the Elsasser number, while assumed to be large, is an order of magnitude smaller than the magnetic Reynolds number. Applied to an electrically conducting fluid confined to a thin rotating cylindrical shell, these assumptions allow us to analyze the linearized equations of motion using standard analytical techniques. We first discuss the equations which have been linearized about an ambient field which varies only in the direction perpendicular to the axis of rotation. The study is then extended to ambient fields which vary in directions both parallel and perpendicular to the axis of rotation. We will also discuss the extension of this work to spherical geometry.

JSP39/E/20-B2 1540

HYDRODYNAMIC MODEL OF THE TOPOGRAPHY VARIATIONS ACROSS THE RIDGE CREST

V. CHERNIAVSKI (Paleogeodynamics, Institute of Oceanology of RAS, Moscow, 117851, Russia, email: cherniav@chip.sio.rssi.ru); Suetnova E. (United Institute of the Physics of the Earth of RAS, Moscow, 123810, Russia, email: elena@uipe-ras.scgis.ru)

It is considered the stability of the stationary flow of high viscosity liquid. Well known stationary solution of a jet moving from infinity toward a wall is suggested to be considered as a flow caused by the force acting along the boundary deformable surface. Undisturbed surface is horizontal and horizontal velocity on the surface is the step function. It is studied the developing of infinitesimal disturbances. The disturbed solution is defined by the solutions of two Laplace equations with boundary conditions on the undisturbed surface. It is given a procedure of numerical investigation that is based on the method of conformal mapping the region of the flow to the circle. The problem can be regarded as a model of the topography variations across the ridge crest. It is suggested hydrodynamic model of mantle flow with deformable upper boundary at the mid-ocean ridge crest. It is well known the mantle media can be regarded as a high viscosity liquid (1019-1021puas) at geological intervals of time (1-100 MY). Some observations show that the mantle matter flows from the ridge crest toward borders along the upper boundary. The model is developed under the assumption a hydrodynamic flow causes deformation of the upper boundary depending on time.

JSP39/W/40-B2 1620

DIFFERENTIAL ROTATION OF LITHOSPHERE AND MANTLE AND ITS BEARING ON PLATE DRIVING FORCES AND THE CAUSES OF INTRAPLATE VOLCANISM

A. SMITH (Dept. Earth Sciences, Cheng Kung University, Tainan, Taiwan; email: mochinm@mail.ncku.edu.tw); C. Lewis (Dept. Mining & Petroleum Engineering, Cheng Kung University, Tainan, Taiwan)

Uncertainties regarding the relative importance of basal drag and boundary forces in plate tectonic models are a consequence of flawed assumptions imposed by the use of the hotspot reference frame. Velocities of lithospheric plates are influenced not only by lateral boundary forces, but also by basal drag forces resulting from Earth rotation. Drag is exerted on the base of the asthenosphere and motion transmitted upwards to the lithosphere. As the transmission of stress in the mantle is viscosity-dependent, the reduction in viscosity through the asthenosphere results in plates suffering a net westward lag. This differential rotation effect causes continental plates to be more strongly coupled to the deep mantle as they are separated from the mesosphere by only relatively thin regions of asthenosphere. For such plates the calculated drag forces are of the same order of magnitude as boundary forces. The motion of oceanic plates is dominated by conventional plate boundary forces which may either

reinforce or oppose drag from eastward mantle flow. Reinforcement (e.g. Nazca plate) gives rise to Couette flow in the asthenosphere. Opposition (e.g Pacific plate) results in counter-flow. Shear stresses in both regimes are concentrated in the upper asthenosphere and lead to generation of intraplate melts from concentrations of hydrous minerals (wetspots) introduced into the oceanic asthenosphere by lateral asthenospheric flow. Under a counter-flow regime, melt collects in a stationary layer at the crossover point between plate- and mesosphere-induced flow regimes. Release of melt to the surface is governed by lithospheric stress trajectories set up by convergence along plate boundaries, giving an illusion of a series of quasi-fixed melting anomalies, though in reality both these and the lithospheric plates are moving relative to the deep mantle.

JSP39/E/03-B2 1640

THE NUMERICAL MODELING OF NON-LINEAR TIDE WAVE PROPAGATION IN STRATIFIED OCEAN

Tatjana TALIPOVA (Laboratory of Hydrophysical and Non-linear Acoustics, Institute of Applied Physics, 46 Uljanov str., Nizhny Novgorod, 603 600 Russia, email: tata@appl.sci-nnov.ru)

The numerical model of the non-linear internal tide evolution in the coastal zone is developed. It is based on the finite-difference scheme of the solution of the generalized Korteweg – de Vries equation. The model includes quadratic and cubic non-linearity, dispersion, the Earth rotation, quadratic bottom friction and horizontal variability of the density stratification. Numerical algorithm is described. Observed data of the density stratification for different shelves in Atlantic and Indian Oceans (North-west Shelf of Australia, Iberian shelf, Malin Edge Shelf, Mediterranean, Baltic and Black Seas) are used to calculate the coefficients of the generalized Korteweg – de Vries equation. Model simulations of the internal sine tide evolution have been done, they show the contribution of the different effects on the non-linear wave evolution for different areas of the World Ocean.

JSP39/W/36-B2 1700

THE DYNAMICS OF TURBULENCE ACCOMPANYING KELVIN-HELMHOLTZ INSTABILITY

David C. FRITTS, Joseph A. Werne, Teresa L. Palmer (Colorado Research Associates, 3380 Mitchell Lane Boulder, CO 80301, USA)

Numerical simulations of Kelvin-Helmholtz (KH) instabilities now span sufficient spatial scales to allow a broad inertial range of turbulence accompanying billow breakdown. Turbulence arises in response to secondary and tertiary convective and dynamical instabilities within the KH billows which drive the transition from 2D to 3D flow. These instabilities lead to vortical structures which undergo vigorous subsequent interactions. Vortex interactions lead, in turn, to perturbations of the vortices which contribute to their fragmentation and thus to the cascade to smaller scales of motion. This talk will describe the instability and turbulence dynamics accounting for the transition to and the cascade within the turbulent flow.

STRATIFIED FLOW AROUND A UNIFORMLY MOVING CYLINDER IN A CONTINUOUSLY STRATIFIED LIQUID

Yuli D. CHASHECHKIN, Vladimir V. Mitkin (both at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, email: chakin@ipmnet.ru)

We study experimentally pattern of flow past a horizontal cylinder with diameters 1,5; 2,5; 5 and 7,6 cm. moving with constant velocity from 0,01 to 6 cm/s in a uniformly stratified liquid with buoyancy period from 5,0 to 25,2 s. Visualisation of flow pattern is performed by different schlieren methods (knife, filament natural rainbow), by dyeing and vertical markers. Internal waves are measured by a conductivity probe. On results of more then 800 experiments expanded flow regimes diagram is drown. Any particular regime of flow is occupied compact domain in the space Froude number-Reynolds number and separated from neighbours ones by sharp boundaries. It is shown that there is no overlapping of regimes in the complete flow regimes cube where axis are Reynolds number-internal Froude number-ratio of external scales. The special class of small scale structures for which thickness of general structure identified elements is determined by effects of viscosity and diffusivity is introduced. Detailed measurements of velocity profiles in a forming and stationary upstream disturbance are carried out. The horizontal size of an area of completely blocked fluid is measured and compared with calculations on different models of upstream wake, the best agreement with the simplest model of singular dipole. Geometry of soaring and imbedded in to the downstream wake vortices and vortex arrays is defined.

FREE AND LEE WAVES INTERACTION IN NEAR-SURFACE PYCNOCLINE

Olga SHISHKINA (Institute of Applied Physics, RAS, 16 Uljanovsk st., Nizhni Novgorod, 603600 Russia, email: ols@hydro.appl.sci-nnov.ru)

Experimental results on the lee internal waves' propagation in a fluid with a thermocline-type stratification in the presence of favourable and opposite regular plane internal waves are presented. After stationary background internal wave recording a cylinder of the diameter 0.4m was towed along the tank in both directions with respect to the background waves propagation and resulting internal wave profiles were fixed.
The body's draft T and velocity U were chosen to provide the first and the second internal wave modes generation (0.5£T/H£1.5, 0.25£U/C1£1.5, where H is the tank's depth and C1 is the first mode phase velocity). Background internal waves had first-mode structure at the frequency of 2/3 Nmax (Nmax is the maximum buoyancy frequency). Almost plane lee waves with propagation angles 60deg£b£90deg provide intensive interaction of two wave systems. The amplitude of internal waves increased almost twice under the influence of favourable background internal waves. This work was supported by the RFBR (grant no.: 99-05-64394)

CORIOLIS EFFECTS ON OROGRAGPHIC AND MESOSCALE FLOWS

J. C. R. HUNT (Cerfacs and IMFT, Toulouse and Arizona State University); H. Olafsson (Icelandic Met. Services, Reykjavik, Island); P. Boulgeault (CNRM, Meteo-France, Toulouse)

Using a theoretical approach based on perturbations to stably stratified flow and on the recently developed understanding of flow over mountains at low Froude number (F=Ud/(NH), where N is the buoyancy frequency, Uo is the wind speed and H is the mountain height), the effects of rotation have been studied. The Rossby number Ro=U/(fD) where f is the Coriolis parameter, and D the diameter of the mountain, is assumed to be a large number. Typically it is found to lie in the range 3-10. The results are compared with the recent numerical simulations. It is found that as the flow impacts on the mountain it turns to the left (with your back to the wind) and wave activity over the top of the mountain is greatest on the left side but the pressure drop is greatest on the right. Over a distance of the order of HN/f, e.g. 150 km for the Pyrenees, a new wake structure develops that can extend to 1000 km (or a spin down distance). There is a momentum defect within the wake but the wind speed increases either side of the wake. Coriolis forces induce a deflection upward of the isopycnals on the left and downward on the right. This seems to explain some differences in meso-scale weather and climate phenomena between the different sides of mountains and wide valleys and of wakes of mesoscale convection. The large perturbation pressure change predicted by the theory is of the order of rho U^2/F, which is consistent with the magnitude of the terms introduced into the recent ECMWF orographic parameterizations. However a fluid-dynamically justified parameterization would allow for asymmetric Rossby number effects on the pressure field and the effective wave flux.

JSP39/W/21-B3 Invited 0900

MEASUREMENT AND MODELING OF THE TRANSPORT OF SNOW, SAND, ICE AND DUST PARTICLES OVER COMPLEX TERRAIN

Kouichi NISHIMURA (Inst. of Low Temp. Sci., Hokkaido Univ., Sapporo, JAPAN, email: nishi@orange.lowtem.hokudai.ac.jp)

Aeolian particle transports occur in many geophysical contexts, including desert sand, soil erosion and snow drifting, and affect a variety of aspects of human life. For instance, the drift of snow around the structures and transportation systems can cause delays and produces access problems; the mass transport by the blowing snow in the Antarctica can be an important factor in the global climate system. It should be noted the evidence of the aeolian activity has been also found on Mars, Venus and a moon of Saturn. After BagnoldÕs pioneering work (1941), some progress has been made in the modeling of aeolian particle transport in the last decade, but there are still significant quantitative uncertainties. In this paper, our wind tunnel experiments with spherical particles of different diameters, densities and coefficient of restitution will be also introduced. From the measurements of the ejection velocities of the particles and the mean wind speed profile, the horizontal flux profiles were computed, and compared with our measurements. For the higher wind speeds, we examine the changes in the velocity statistics of the particle as they move randomly under the influence of turbulence in a state of ÔsuspensionÕ, and examine whether they continue to be ejected from the surface as a result of collision between impacting particles and those in the bed, or whether their movements are more determined by random aerodynamic forces acting on them.

JSP39/W/46-B3 0930

PHASE RELATIONS BETWEEN MOVING HEATING AND THE RESULTANT TEMPERATURE PERTURBATIONS

Brian MAPES (NOAA-CIRES Climate Diagnostics Center, Boulder, CO USA 80303-3328, email: bem@cdc.noaa.gov); Matthew Wheeler (National Center for Atmospheric Research, Boulder CO USA, email: mwheeler@cgd.ucar.edu)

In order to interpret observational studies of the thermal structure of waves of tropical convection, we need to understand the thermal structures generated by moving heat sources without any feedback. To this end, we have constructed translating heating processes that resemble observed convective variability, and imposed them in analytical and numerical linear and non-linear atmospheric models. For slowly moving deep heating, a quadrature relation between heating and temperature is established. For more rapidly moving heating, things get more complicated and interesting.

JSP39/W/27-B3 0950

SUPERCRITICAL CONDITIONS IN THE SUMMER MARINE BOUNDARY LAYER ON THE WEST COAST OF THE UNITED STATES

Clive DORMAN (Center for Coastal Studies, Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA 92092-0209, USA, email: cdorman@ucsd.edu); David Rogers (Physical Oceanography Research Division, Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA 92092-0209, USA, email: drogers@ucsd.edu); Teddy Holt (Naval Research Laboratory, Marine Meteorology Division, Monterey, CA 93943-5502, USA, email: holt@nrlmry.navy.mil)

Field measurements show that the summer conditions along the US West coast include a strong, subsidence inversion capping a weakly stratified marine boundary layer (MBL). The MBL is lower than the topography lining the coast which forms an eastern wall. Mean surface winds increase to the south along California, reaching a maximum near Pt Conception in Southern California. Mean MBL depths are a broad minimum along California with greater depths north of California and south of Pt Conception, California. Direct aircraft measurements show that the MBL is super-critical along portions of southern Oregon and California that is narrow along Oregon (50 km) and broad off Central California (more than 120 km). In the lee of Capes, the MBL speed accelerates, the depth decreases and the Froude number increases in the nature of an expansion fan with rotation and friction. The tendency for supercritical flow conditions to broaden to the south along California is proposed to be a larger scale expansion fan that is be caused by the coast bending to the east as the latitude decreases.

JSP39/E/08-B3 1010

GRAVITY WAVES AND VORTICES IN THE WAKE OF ISOLATED MOUNTAINS

Dieter ETLING (Institute of Meteorology and Climatology, University Hannover, Herrenhauser Str. 2, 30419 Hannover, Germany, email: etling@muk.uni-hannover.de)

The influence of stable stratification on the wake of obstacles in the laboratory as well as in the atmosphere has been investigated intensively in recent years. Most important, the production of potential vorticity due to non-viscous effects, like gravity wave breaking or flow splitting, has been proposed by several authors. We present some examples where both, gravity waves and Karman vortex streets, can be observed simultaneously in the wake of island mountains. By analysing the meteorological upstream conditions, we will give some insight into the ongoing discussion on PV production in the wake of obstacles in stably stratified flows.

JSP39/W/14-B3 1050

COHERENT VORTICES ALONG THE TROPOPAUSE

John NIELSEN-GAMMON, John Fulton (Texas A&M University, College Station, TX 77843-3150 USA, email: n-g@tamu.edu)

A climatology of coherent vortices along the tropopause is constructed using the NCEP/NCAR reanalysis data for 1978-1997. Coherent vortices are identified by the presence on multiple isentropic layers of closed contours of the dynamic tropopause (1.5 PVU) which maintain their structure and intensity through several 6-hourly analysis cycles. We find that such vortices are more common in the Southern Hemisphere than the Northern Hemisphere, and occur most often during the winter (SH) and spring (NH). Cyclonic vortices are more frequent than anticyclonic vortices.
Ongoing work will focus on the spatial distribution of coherent vortices with respect to the Earth and to the instantaneous position of the jet stream. We shall also investigate the mechanisms for formation, maintenance, and destruction. Preliminary results indicate that most cyclonic vortices do not dissipate in situ, but instead are ripped apart by an increase in the background horizontal deformation.

JSP39/W/15-B3 1110

DYNAMICS OF ROTATION, CYCLONES AND SCALING GYROSCOPES CASCADE

I. TCHIGURINSKAYA (E.E.&S. Dept., Clemson University, 342 Computer Court, Anderson, SC29625, USA, E-mail: iouliat@clemson.edu); D. Schertzer (L.M.M., Université Pierre et Marie Curie, 4 Place Jussieu F-75252 Paris Cedex 05, France); S. Lovejoy (Physics Dept., McGill University, 3600 University st., Montréal, Qué., H3A 2T8, Canada)

New experimental data on the structure of the atmospheric boundary layers have indicated that very often despite strong mixing, there are coherent structures. A visual confirmation of the occurrence of such structures in atmospheric boundary layer is given by the ordered "cloud streets" structures observed in photographs of the earth's cloud cover. The stratification of such boundary layers is rather extreme, since the horizontal extension of these structures reach easily hundreds of kilometers, whereas their heights do not exceed 3 kilometres. The expeditions Typhoon 89-91 over South China Sea lead to investigate the stratification, including situations on the periphery and in the eye of tropical cyclones. To understand this phenomena on the theoretical level, we developed the dynamical space-time cascade model for the velocity field, named the Scaling Gyroscopes Cascade. This model was obtained by partial truncations of direct interactions of the Navier-Stokes equations. And it based on the analogy between the Lie structure of the equations of perfect fluid motion inside of rotating ellipsoid and the equations of a rigid body rotation with fixed point (the gyroscope). The effects of viscosity are obtained due to cascade structure of the model. We present high resolution (e.g. scale ratio 2**20) and long time simulations of this model, leading to universal multifractal behavior which exponents are very close to the empirical estimates for the stratified tropical atmosphere data of Typhoon 89-91 expeditions. It also displays a first order multifractal phase transition with associated self-organized criticality of stratified structures.

THE COUNTER-PROPAGATING ROSSBY WAVE PERSPECTIVE ON INSTABILITY: APPLICATION TO REALISTIC JETS

John METHVEN (University of Reading, UK); Eyal Heifetz (Tel-Aviv University, Israel) Brian Hoskins (University of Reading, UK); Craig Bishop (Penn-State University, USA)

Bretherton's (1966) view of baroclinic instability as the interaction of two counter-propagating Rossby waves is extended to general zonal flows for which potential vorticity (PV) is conserved. The CRWs are constructed from a growing normal mode and its decaying conjugate so that the material displacements associated with each of the waves (a) have no zonal tilt (b) are orthogonal with respect to each other when density weighted, and (c) are localised in regions of large, opposing PV gradients by the requirement that the CRW displacements are also orthogonal with respect to wave activity. Although each CRW could not continue to exist alone, they can together describe the time development of any zonal flow whose initial conditions can be described by the pair of normal modes.
The structure and interaction of these CRWs is shown for growth on a realistic jet with a tropopause, for a range of zonal wavenumbers, m. It is found that one CRW is always located on the ground where strong temperature gradients act as large negative PV gradients. The location of the upper CRW's maximum wave activity density varies with m; for m > 7 it lies just above the steering level. Both CRW structures are very similar to those from the Charney model. This structure is also seen in inverse Ertel PV, (1/P)', whilst Ertel PV perturbations, P', are large only near the tropopause, even though the tropopause plays virtually no role in the instability. As m decreases, the depth-scale of the CRWs increases and there is a secondary maximum in upper CRW amplitude at the tropopause. For m < 5 this tropopause perturbation begins to dominate the associated flow and the picture of instability resembles the Eady model. Some examples of finite time baroclinic growth, described by CRWs, are given including development from initial conditions where upper and lower level perturbations are dominant.

EFFECTS OF NEWTONIAN COOLING IN THE SEMIGEOSTROPHIC FRONTOGENESIS PROBLEM

Georgy I. BURDE (Ben-Gurion University, J. Blaustein Institute for Desert Research, Sede Boker Campus 84990, Israel, email: georg@bgumail.bgu.ac.il)

Frontogenesis - the formation of fronts -is a fundamental fluid dynamical problem: it is remarkable that air flow should generate such sharp zones, with horizontal scales in the atmosphere of only a few tens of kilometers, rather than maintaining a weaker, broader thermal contrast between equator and pole. Because rain and snowfall are concentrated at fronts, the problem is of considerable meteorological importance. The geostrophic momentum model of frontogenesis introduced by Hoskins and Bretherton in 1972 appears to capture basic physical aspects of frontogenesis. Since then semigeostrophic models have remained a mainstay of frontogenesis theory and numerous research papers have emphasized various aspects of the theoretical model. In the present paper, the semigeostrophic, two-dimensional, uniform potential vorticity, Eady-wave model developed by Hoskins and Bretherton has been generalized by embedding the Newtonian (radiative) cooling. The observation, that with this modification the potential vorticity varies in a known manner following fluid particles, has provided the retention of the advantage of analytical representation of the solution inherent in the traditional Eady-wave model. A principal result of this study is that the effects of radiation may critically change the dynamics of semigeostrophic frontogenesis promoted by Eady wave instability even though the radiative damping timescale exceeds significantly the flow time scale. In particular, the formation of a frontal discontinuity from short wave initial disturbances, with the wavenumbers beyond the short wave cutoff of the adiabatic theory, becomes possible.

INSTABILITY OF ZONAL FLOWS IN ROTATING SPHERICAL SHELLS, AN APPLICATION TO JUPITER

Johannes WICHT (Institut fuer Geophysik, Universitaet Goettingen, Herzberger Landtrasse 180, 37075 Goettingen, Germany, email: wicht@willi.uni-geophysik.gwdg.de); Keke Zhang, Chris Jones (both at Mathematics Department, Exeter University, Exeter EX4 4QE, UK, emails: CAJones@maths.exeter.ac.uk and KZhang@maths.exeter.ac.uk)

Measurements from the Galileo probe promote the idea that the zonal winds are deep rooted. Considering Jupiter's high rotation rate and the possible vigor of the convection, it seems indeed likely that the whole outer molecular H/He layer is involved in the flows. Three-dimensional simulations of convection in rotating spherical shells have shown, that these systems are capable of producing strong zonal flows that show as a banded structure on the surface.
Assuming that the primary flows are geostrophic, and that the banded surface structure stretches right through the molecular He/H layer, we examine under which conditions such flows would be stable. As a first step we consider the linear stability of different prescribed banded zonal flows in a rotating spherical shell. Incompressibility is assumed for simplicity, the boundary condition is stress free. We compare solutions for two aspect ratios, for the Earth's outer core and Jupiter's molecular He/H layer, and two Taylor numbers (T=10**4 and T=10**8). Convective and shear flow instabilities compete in our system. While the convective instability is of the well-known columnar structure, we find two different shear flow instabilities. At the smaller Taylor number it is similar to the Taylor-Couette instability in rotating annuli, but the flow remains close to geostrophy for the higher Taylor number. Both shear flow instabilities break the azimuthal symmetry.
Since thermal and shear flow instabilities can have different preferred azimuthal wave numbers, we expect an interesting interaction of the two scales in the non-linear regime, which has not been reached so fare. We will try to extrapolate our results to Jupiter, in spite of the numerical difficulties in reaching appropriate parameters.

OUTER CORE FLOW DRIVEN BY LATERAL HEAT-FLUX VARIATION AT THE CMB

Steven John GIBBONS (School of Mathematical Sciences, University of Exeter, Exeter EX4 4QJ, UK, email: sgibbons@maths.ex.ac.uk)

Moving core fluid maintains an isothermal core-mantle-boundary (CMB) and so lateral variations in the CMB heat flow result from mantle convection. Such variations will drive thermal wind type flows, even in a layer of stable density stratification at the top of the core. Such flows may contribute to the magnetic secular variation. Large scale equatorially symmetric (ES) heat flux variations at the outer surface of a rapidly rotating spherical shell drive deeply penetrating flows which are strongly suppressed in stratified fluid. Smaller scale ES heat flux variation drives flow less dominated by rotation and so less inhibited by stratification.
Equatorially anti-symmetric flux variations drive flows an order of magnitude less energetic than those driven by ES patterns but, due to the nature of the Coriolis force, are less suppressed by stratification. The response of the rotating core fluid to a general CMB heat flow pattern will then depend strongly on the subadiabatic temperature profile.

DYNAMICS OF STRATIFIED, FLUTE STRUCTURED CHARGED PARTICLE JETS AND WAKES IN THE IONOSPHERE UNDER THE GEOMAGNETIC FIELD EFFECT

Maxim G. PONOMARJOV (Physics Dept., State Academy of Aviation Technology, Promyshlennaya str.1 (Box 22), 152300 Tutaev, Yaroslavl region, Russian Federation, email: pmg@univ.uniyar.ac.ru)

General methods are proposed for simulations of time-dependent charged particle jets and wakes in the geomagnetic field based on the kinetic approach. The Boltzmann equation solved taking into account the ambient electric and magnetic fields. Using this solution the analytical results are obtained, which describe developing geomagnetic field aligned stratification of charged particle jets in the ionosphere. For geomagnetic field aligned drifting velocity of jets, the formation of flute structures along the edges of the jets is obtained analytically. Using the image method (see [1], [2]) the wakes of different objects in the satellite altitude regime (above 200 km) are simulated. Different kinds of interactions of the ambient particles with object surfaces are considered as absorption, direct and diffuse reflection. The analytical results describe the flute structure of wakes of objects in motion along the geomagnetic field and stratification of wakes in different cases.

AN ENSEMBLE OF RANDOM-PHASE INTERNAL GRAVITY WAVES IS CONSIDERED IN THE DYNAMICAL FRAMEWORK OF THE EULER - BOUSSINESQ EQUATIONS

Vladimir ZEITLIN (Laboratory of Dynamical Meteorology, France, email: zeitlin@lmd.ens.fr)

An ensemble of random-phase internal gravity waves is considered in the dynamical

framework of the Euler - Boussinesq equations. For flows with zero mean potential vorticity a kinetic equation for the mean spectral energy density of the waves is obtained under hypothesis of Gaussian statistics with zero correlation length. Exact stationary scaling solutions of this equation are found for almost vertically propagating waves. The resulting spectra are anisotropic in vertical and horizontal wave numbers. For flows with small but non-zero mean potential vorticity, under the same statistical hypothesis applied to the wave part of the flow, it is shown that the vortex part and the wave part decouple. The vortex part obeys a limiting dynamics equation exibiting vertical collapse and layering which contaminates the wave-part spectra. Relation of these results to the in situ measurements is discussed.

A FLUID PULSE DISTORTION ON THE SURFACE OF THE OCEAN AS A SOURCE OF WATER MOTION NEAR THE BOTTOM

Tatiana DEMIDOVA, Nikolai Korchagin (both at Department of Physics, P.P. Shirshov Institute of Oceanology, Moscow 117218, Russia, email: evita@redline.ru)

A model of propagation of a pulse of a surface horizontal water distortion (caused by a non-stationary wind field) from the surface to the bottom in a stratified medium is considered in the frameworks of linear theory of internal waves in a long-wave approximation. In the model, a three-layer fluid is presented as a two-step structure of the density profile with alteration of density discontinuities and homogeneous fluid layers. Rather simple equations for velocities for the first three modes (the barotropic and two baroclinic modes) are derived. The results of calculation show that the presence of sharp discontinuities in density leads to interrelation between the surface and bottom current fields. In this case, the transfer of the surface pulse into deep water is performed by internal wave.
The model of the propagation was tested using experimental moored and cast data as well as time distribution of the surface wind stresses during storms in winter of 1992 at the shelf and slope off the Sakhara coast. Well-developed surface and bottom boundary layers were approximately of the same thickness. High frequency maxima were revealed in energy spectra of the near bottom velocities. Whereas the peak at a period of about 24 min corresponded to the typical buoyancy frequency at the site, the model of the pulse propagation from the surface to the bottom allowed us to explain the peaks at periods 60-70 min. It shows that the model discussed describes one of mechanisms of the increase of current velocities in near-bottom layers.

DYNAMICS OF HYDROTHERMAL TURBULENT JETS IN A STRATIFIED FLUID

Nikolay KORCHAGIN (P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences. 36, Nakhimovskyii prospect, 117218, Moscow, Russia, email: niknik@sio.rssi.ru)

A new analytical method to the problem of the closure of the system of integral equations (SIE) describing the dynamics of a buoyant turbulent jet (BTJ) in a stratified fluid is suggested. As a result an analytical expression of the Taylor's "entrainment constant" was obtained from the parameters of the jet flow and a background water stratification. On the other hand, the suggested method of the SIE closure also describing the mechanism of the entrainment of a background fluid into a turbulent area of the same fluid. The numerical model of the SIE solution was made by Runge-Kutta method of the fourth order accuracy. The validity of the numerical model of the BTJ was carried out with using the measurement data of the characteristics of high temperature hydrothermal flows (from "black smokers") and background bottom waters in two ocean regions: the Mid-Atlantic Ridge and the East-Pacific Rising. The model construction of the BTJ was suggested, the use of which in the SIE allowed to obtain the analytical solution of SIE and expression of the maximum height for the rising hydrothermal jet and another characteristics.

JSP39/E/06-B3 Poster **1415-06**

OCEANIC UPWELLING AND DOWNWELLING FORCED BY A TROPICAL CYCLONE

Shin-Ichi SUZUKI (Ocean Research Institutes, University of Tokyo, 1-15-1, Minamidai, Nakano, Tokyo, Japan; E-mail: suzuki@ori.u-tokyo.ac.jp); Hiroshi Niino (email: niino@ori.u-tokyo.ac.jp); Ryuji Kimura (email: kimura@ori.u-tokyo.ac.jp)

While it is generally believed that an oceanic upwelling under a tropical cyclone is caused by the Ekman pumping, previous numerical simulations show that the center of the upwelling is located in the backside of a moving tropical cyclone. Furthermore, our recent numerical simulation with a better vertical resolution and a recent oceanic observation show that even a downwelling exists in the forward side of the cyclone center. The cause and the mechanism of the forward side downwelling and the backside upwelling are investigated by means of a linear theory of a two-dimensional viscous rotating stratified ocean, which is subjected to a prescribed wind stress coresponding to a moving cyclone. The results show that, when the moving speed U of the cyclone is greater than 10 m/s, the forward side downwelling and backside upwelling take place. The mechanism that causes the vertical motion is further investigated by examining oceanic responses to a moving sinusoidal wind stress with a wavenumber k. It is found that, when a Rossby number defined by Ro = Uk/f is less than 1, the vertical motion is mainly caused by the conventional Ekman pumping, where f is the Coriolis parameter. When the Rossby number is greater than 1, on the other hand, the vertical motion is caused by a horizontal divergence of inertial oscillations forced by the wind stress. The latter mechanism is responsible for the forward side downwelling and backside upwelling.

NON-LINEAR DYNAMICS OF LARGE-AMPLITUDE INTERNAL SOLITARY WAVES

Tatjana TALIPOVA, Efim Pelinovsky (Laboratory of Hydrophysics and Nonlinear Acoustics, Institute of Applied Physics, 46 Uljanov Str., Nizhny Novgorod, 603600, Russia, email: tata@appl.sci-nnov.ru); Alexey Slunyaev (Advanced School of General and Applied Physics, Nizhny Novgorod State University, 46 Uljanov Str., 603600 Nizhny Novgorod, Russia; email: avs@appl.sci-nnov.ru)

The nonlinear dynamics of large-amplitude long waves in a stratified ocean is studied. Theoretical model is based on the generalised Korteweg - de Vries equation incorporated the effects of the quadratic and cubic nonlinearity. Coefficients of the quadratic and cubic nonlinearity in this equation depend on the density and shear flow stratification and may have either sign. In particular, the coefficient of the cubic nonlinearity is negative for internal waves in the stratified ocean with one-peak distribution of the Vaisal frequency. If the high-order dispersion can be ignored (the corresponding conditions are discussed) the generalised Korteweg - de Vries equation is reduced to the Gardner equation which is integrable nonlinear system. It admits the existence of a large-amplitude "thick" soliton. The processes of the interaction and generation of solitons, including the "thick" solitons are studied. The evolution of the initial impulse disturbance is reported. It is shown that during the evolution process the solitons of the opposite polarity are appeared on the crest of the "thick" soliton.

HYSTERESIS OF WAVE SOLUTIONS IN THE QUASI-GEOSTROPHIC POTENTIAL VORTICITY EQUATIONS WITH A NONLINEAR BASIS STATE

Gregory M. LEWIS, Wayne Nagata (both of Institute of Applied Mathematics, University of British Columbia, Vancouver, BC, V6T 1Z4, Canada, email: lewis@math.ubc.ca and nagata@math.ubc.ca)

We analyze double-Hopf bifurcations observed in the two layer quasi-geostrophic potential vorticity equations with a non-linear basic state. This bifurcation occurs in the transition from the axisymmetric to the wave regimes when the linear part (of the equations) has two complex conjugate pairs of eigen-values with zero real part. Using center manifold reduction and normal form theory, the behaviour of the full system of partial differential equations near the bifurcation point may be deduced from the two dimensional ordinary differential amplitude equations.
Since the non-linear basic state leads to a non-self-adjoint linear part, it is not possible to compute the eigenvalues and eigenfunctions analytically. Therefore, the linear part is discretized and the eigen-values and eigen-functions are approximated from the resulting matrix eigen-value problem. The projection onto the center manifold and reduction to normal form can be done analytically, thus, numerical approximations of the normal form coefficients are obtained upon approximation of the appropriate inner products.
The results show that, for the geophysically relevant range of parameters, two periodic solutions (travelling waves with different wave numbers) are simultaneously stable for certain parameter values. This result, which is observed for several wave number pairs, indicates hystersis of the wave solutions. The quasi-periodicity, which is possible in these types of bifurcations, is not observed. It is straightforward to apply this analytical/numerical method to more complicated models. In particular, preliminary results will be shown of the analysis applied to a model of the differentially heated rotating annulus experiment.

LABORATORY EXPERIMENTS ON ROTATING COMPOSITIONAL CONVECTION AT LOW EKMAN NUMBERS

Sabine CLASSEN (Institut fuer Geophysik, Herzbergerlandstr. 180, 37075 Goettingen, Germany, email: sac@willi.uni-geophys.gwdg.de); Moritz Heimpel (Department of Earth and Space Sciences, UCLA, 595 Circle Drive East, Los Angeles, CA,USA 90095-1567, email: heimpel@zephyr.ess.ucla.edu)

The onset and structure of compositional convection in a rotating system are investigated experimentally. A vertically oriented cylindrical annulus filled with NH_{4}--H2O solution is cooled from the bottom and can be rotated about its axis at rates ranging up to 10.5 rad s^{-1}, corresponding to Ekman numbers down to 7.5 \times 10^{-6}. The Coriolis force has a strong effect on the structure of plumes above the mush-liquid interface. Helical motion of the conduit, which is weakly developed in the non-rotating case, is amplified by Coriolis forces that twist the plume conduits to lie nearly horizontally. This results in secondary plumes (or blobs) that rise from the sub-horizontal primary plume conduits. The rotation has a negligible influence on the solidification process. The main crystallization and convection features we find in the non-rotating system are retained in the presence of rotation. However, rotation seems slightly to speed up the transport of latent heat which controls the growth rate cause the growth rate coefficient increases with the rotation rate.

TURBULENT CONVECTION FROM ISOLATED SOURCES

Jordi COLOMER (Department of Physics, University of Girona, 17071 Girona, Spain); Boris M. Boubnov, A.M. Obukhov (Institute of Atmospheric Physics, Russian Academy of Sciences, 109017 Moscow, Russia); Harindra J.S. Fernando (Department of Mechanical and Aerospace Engineering, Environmental Fluid Dynamics Program, Arizona State University, Tempe, AZ 85287-9809, USA)

Laboratory experiments were conducted to investigate the evolution of a dense turbulent plume, specified by its buoyancy flux and source diameter D, issuing into a homogeneous environment. The study was motivated by its applications to geophysical, environmental and engineering flow situations. Special attention was given to study the evolution of plume following its initiation and the flow near the source. At short times, the descent of the plume front can be treated as one-dimensional with negligible lateral (entrainment) mean flow, the plume growth mechanism being the encroachment of underlying non-turbulent fluid. At larger times, the flow achieved a quasi-steady state, in which the plume width first decreases (region I) and then increases (region II). The quasi-steady state velocity and buoyancy measurements in region I showed that they are strongly influenced by the lateral entrainment (and hence D), and thus classical free convection scaling is inapplicable to such flows. On the other hand, at large z/D (in region II), the velocity and buoyancy scalings tend to be independent of D and follow point source scaling.

LARGE EDDIES BEHIND MANOEUVRING SELF-PROPELLED BODIES IN A STRATIFIED FLUIDS

Sergey VOROPAYEV (Arizona State University, Tempe, AZ 85287-6106, USA and Institute of Oceanology, Russian Academy of Sciences, Moscow, 117851, Russia, email s.voropayev@asu.edu); Ben McEachern (Arizona State University, Tempe, AZ 85287-6106, USA)

A large number of studies have been reported on wakes in stably stratified fluids either with towed or self-propelled bodies of different shapes. Although these studies have documented many interesting phenomena related with the wake signature, no studies have considered large eddies that may form in the late wakes during the manoeuvring of such bodies. When a self-propelled body makes a manoeuvre (e.g., accelerates or changes its direction of motion), significant horizontal momentum is transported to the surrounding fluid. Our experiments show that in a stratified fluid this may lead to the formation of unusually large eddies, which are much larger and have substantially different characteristics than those produced in the late wake during steady motion. A theory is proposed to explain this effect, and estimates show that when an oceanic submerged vehicle changes its velocity by as little as 10% or its direction of motion by roughly 5 degrees, large structures of characteristic size 1-2 km and with decay times of several days may be expected. Such effect may have potentially important applications and have not been studied previously. This study was supported by NOAA and ONR. For more detail see [1].

SELF PROPAGATING QUASI-MONOPOLES IN ROTATING FLUID

Sergey VOROPAYEV (Arizona State University, Tempe, AZ 85287-6106, USA and Institute of Oceanology, Russian Academy of Sciences, Moscow, 117851, Russia, email: s.voropayev@asu.edu); Ben McEachern (Arizona State University, Tempe, AZ 85287-6106, USA)

Recent results, based on the high-resolution satellite data, demonstrate that a significant dipolar component is present, for example, in most of the Gulf Stream rings. Taking into account the importance of rings and other quisi-monopolar eddies in large scale mixing in the ocean, the need for the developing of models for compact self-propagating vortices becomes obvious. In a recent paper (Stern & Radko, 1998, JPO) an attempt was made in this direction and some basic properties of single self-propagating quasi-monopolar vortex were predicted theoretically and numerically. At present detailed field data are still absent, and the only way to verify the model predictions is to conduct laboratory experiments. The main aim of this communication is (1) to present and discuss the results of laboratory experiments on the formation and dynamics of self-propagating quasi-monopolar vortices, with relatively large angular momentum and small linear momentum, which were generated in a homogeneous rotating fluid of constant depth (f-plane), (2) to make some comparison with the theoretical predictions. The results of our experiment show that such a vortex (1) exists and can be easily generated, (2) is stable and can propagate a significant distance from the origin, (3) survives after a non-elastic collision with a vertical wall and (4) its structure and behavior are very similar to that predicted by Stern and Radko.

BASIC SETS OF STRATIFIED FLOW EQUATIONS INVARIANTS

Vasiliy G. BAYDULOV, Yuli D. Chashechkin (both at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, E-mail: bayd@ipmnet.ru)

We investigated invariant properties of the basic sets of hydro- thermodynamic equations by Lie groups methods. For one component media group classification on stratification type has been performed. Set of equations of double diffusive convection also was classified with respect to type of state equation and thermodynamic properties of all dissipative coefficients. Obtained classifications make possible to compare invariant properties and mutual reducibility of basic 1D, 2D and 3D models of stratified flows. Several types of stratification that are characterised by the widest group of symmetry are distinguished. Invariant properties of governing equations with and without diffusion effects are the same only in case of linear stratification. A wide set of non-trivial groups of self-similarity is constructed when dissipative coefficients (viscosity, diffusivity, thermal conductivity) depend on thermodynamic parameters of the medium. On basis of this groups new exact and self-similar solutions equations of double diffusive convection are constructed. Using the obtained groups to reduce the number of independent variables allows to simplify the search of numerical solutions governing equations. Examples and comparison with laboratory experiments are given.

TURBULENCE MODELING IN COMPRESSIBLE SHEAR LAYERS

Suresh CHANDRA (Department of Mechanical Engineering, North Carolina A&T State University, Greensboro, NC 27411, USA, Email: chandra@ncat.edu)

For high speed shear layers, variable density extensions of standard incompressible turbulence models have not proven to be adequate in explaining the experimentally observed reduction in growth rate with increase in the convective Mach number. Turbulence modeling for compressible flows has to account for additional correlations involving both thermodynamic quantities and the fluctuating dilatation. In recent years, Sarkar et al. suggested that, in addition to modeling the pressure dilatation, another dilatational correlation (the compressible dissipation) should be considered because of the enhanced dissipation known to be present in compressible turbulence. Specifically, this compressible dissipation correction is proportional to the second and fourth powers of the turbulent Mach number, which is defined in terms of the turbulent kinetic energy and the local speed of sound. Narayan and Sekar have used the compressibility-corrected model - limited to the second power of the turbulent Mach number - with the SPARK code for the computation of high speed reacting layers and have obtained satisfactory agreement with some of the available data.
The simple algebraic compressibility model by Sarkar et al. has been modified to include a fourth order turbulent Mach number term. Comparison of the predictions with results of several analytical models and experimental work has been carried out; both agreement and discrepancies are analyzed. The modified turbulence model presented here has the potential of resolving fluid flows related to Earth's atmosphere as well as internal flows encountered in airbreathing hypersonic vehicles.

FINE STRUCTURE OF A FLOW AROUND STARTING OBSTACLES IN A STRATIFIED FLUID

Yuli D. CHASHECHKIN, Vasiliy G. Baydulov, Vladimir V.Mitkin (all at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, E-mail: chakin@ipmnet.ru)

We study analytically and experimentally onset of a stratified liquid motion around resting and starting plane, channel walls, cylinder and sphere. Analytical solutions are obtained by perturbation theory methods, visualised and compared with laboratory experiments data. Near a body at rest solutions describe diffusion induced transient internal boundary layer which is characterised by different scales of spatial variability of velocity and density or salinity. In limiting cases all solutions are uniformly matched among themselves and with well-known exact solutions. Near a starting body besides the internal boundary layer regular large scale convective motion is formed. Geometry of the flow around starting cylinder and sphere are described by simple trigonometrical functions. Pattern of flow is visualised by different Schlieren methods. Parameters of disturbances are measured by conductivity probes and density markers (vertical wakes past small falling crystal of salt or sugar). Profiles of horizontal component of velocity ahead of the body and perturbations of density gradient are fixed and compared with calculations. Theoretical and experimental results are in good agreement among themselves even beyond of the range of formal applicability of asymptotics.

INTERNAL WAVES AND INTERNAL BOUNDARY CURRENTS PAST A UNIFORMLY MOVING CYLINDER IN A CONTINUOUSLY STRATIFIED LIQUID

Yuli D. CHASHECHKIN, Vladimir V. Mitkin (both at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, E-mail: chakin@ipmnet.ru)

We investigate experimentally fine structure of flow around circular horizontal cylinder uniformly moving in a continuously stratified liquid. It was found that the basic elements of motion namely upstream disturbance, internal waves and downstream wake with imbedded or soaring vortices are presented at any large or small values of internal Froude number. General variations of a density containing mean displacement and wavy oscillating components as well as density profiles on the boundary of a density wake are measured by a conductivity probe. In a regime of narrow turbulent wake effect of recurrent and reconnection of downstream adjoined (lee) waves is found. In this regime regular anti-symmetric pattern of lee waves is consequently replaced firstly by irregular waves emitted by vortexes inside the turbulent wake and later by system of symmetric waves. Two kinds of thin interfaces inside and outside downstream wake are identified as a new eigen-form of a stratified fluid motion namely as internal boundary currents. These internal soaring boundary currents manifest itself as a surfaces of discontinuity in a wave part of the density gradient field without any features on their leading and trail edges. Sharp interfaces inside a wake are formed due to separation of internal boundary layer on the cylinder surface or directly inside the decaying stratified turbulence.

SIDEWALL DOUBLE DIFFUSION CONVECTION IN A WEAK GRADIENT

Yuli D. CHASHECHKIN, Anatoliy V. Kistovich, Vladimir V. Levitskiy (all at the Laboratory of Fluid Mechanics of the Institute for Problems in Mechanics of the RAS, Moscow, prospect Vernadskogo, 101-1, 117526, Russia, E-mail: chakin@ipmnet.ru)

We study theoretically and experimentally onset of a periodic layer structure formation near a heated or cooled sloping wall in a continuously strong or weakly stratified liquid. Analytically it is shown that side-wall heat flux leads to the formation of internal boundary current on a heated surface and of a fast propagating front of injection in a fluid interior. General properties of a double diffusion convection equations are examined by Lee groups method. Dependence of flow geometry parameters above near a point, cylinder or plane heat source on input buoyancy flux and scale of stratification is studied. Parameters of zero frequency internal waves emitted by convection cells in environment fluid are calculated in a linear approximation. Experimentally convection near a sloping wall inclined under the angle 90, 75, 60, 45, 30, 15 degrees to the horizon is studied. Both in a strong (buoyancy period Tb < 10 s) and in a weak (Tb > 20s) stratified liquid the height of the cell is proportional to the height of potential rise of a heated fluid particle. The fitting coefficient increases with the slope under the heater and weakly depends on it above the heater. The interval of flow formation increases near the critical Rayleigh number. The thickness of interfaces between cells does not depend on the initial density gradient value. In a wide range of flow parameters the number of interfaces is duplicated. Additional interfaces are formed on the upper boundary of inflowing wedge of a cold fluid. Theoretical and experimental results are in a good agreement.

COMPUTATIONS OF AXISYMMETRIC EIGENMODES IN A STABLE STRATIFIED ROTATING SPHERICAL SHELL

Boris DINTRANS (Observatoire Midi-Pyrenees, France, email: dintrans@obs-mip.fr)

We present computations of axisymmetric eigen-modes in a stable stratified rotating spherical shell using Boussinesq approximation. We first develop a geometric formalism based on the iteration of the underlying characteristics which propagate in the hyperbolic region. Periodic orbits and quasi-periodic orbits have been then found. Computing the corresponding eigen-modes, we prove the link that exists between the characteristic pattern and her associated non-adiabatic structure. Some important spectral consequences have been then deduced both in the adiabatic and non-adiabatic cases.

DYNAMICS OF HYDROTHERMAL TURBULENT JETS IN A STRATIFIED FLUID

Nikolay KORCHAGIN (P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences. 36, Nakhimovskyii prospect, 117218, Moscow, Russia, email: niknik@sio.rssi.ru)

A new analytical method to the problem of the closure of the system of integral equations (SIE) describing the dynamics of a buoyant turbulent jet (BTJ) in a stratified fluid is suggested. As a result an analytical expression of the Taylor's "entrainment constant" was obtained from the parameters of the jet flow and a background water stratification. On the other hand, the suggested method of the SIE closure also describing the mechanism of the entrainment of a background fluid into a turbulent area of the same fluid. The numerical model of the SIE solution was made by Runge-Kutta method of the fourth order accuracy. The validity of the numerical model of the BTJ was carried out with using the measurement data of the characteristics of high temperature hydrothermal flows (from "black smokers") and background bottom waters in two ocean regions: the Mid-Atlantic Ridge and the East-Pacific Rising. The model construction of the BTJ was suggested, the use of which in the SIE allowed to obtain the analytical solution of SIE and expression of the maximum height for the rising hydrothermal jet and another characteristics.

ABOUT ONE MODELS OF CHAOTIC ADVECTION IN BAROTROPIC BACKGROUND CURRENT

Vadim Kozlov, Konstantin KOSHEL (both at Pacific Oceanological Institute, FEB RAS, 43 Bultiyskay str., Vladivostok, 690068, Russia, Email: wave@online.vladivostok.ru)

The barotropic model of a chaotic advection in background current is considered [Kozlov V.F., Koshel K.V. A barotropic model of a chaotic advection in background currents [Izv. RAS, FAO, 1998, V.34, in press; Kozlov V.F., Background currents in geophysical hydrodynamics, Izv. RAS, FAO, 1995, V.31, N2, pg. 245-250], representing a sum fixed rotational planetary-topographical and non-stationary irrotational flowing component in a half-disk with a linear contour of bottom and system a radiant - drain in angular points of the boundary. With the help of numerical experiments the process of passive markers passing out from a vortex region in flowing in an outcome of periodic oscillations of the consumption is investigated. The influence

of parameters of oscillation (frequency, amplitude, phase) on a velocity and degree of washing away of markers is investigated. The evaluation of purely chaotic properties of the open system is hampered by standard methods (Lyapunov indexes, Poincare sections) in view of finite life time of trajectories with the most irregular behavior. For a research of zones with a regular and chaotic behavior and evaluation of a degree of intermixing is offered to use distribution of washing away time for markers uniformly distributed on basin. The similar approach is compared to evaluations obtained with the help of Lyapunov indexes and Poincare sections calculated for final time. Is concluded availability of chaotic intermixing in the given system.

SIMILARITY SOLUTIONS FOR TIME-DEPENDENT HORIZONTAL CONVECTION IN A STRATIFIED FLUID SUBJECT TO A DIFFERENTIAL COOLING FROM BELOW

Atsushi MORI (Department of Astronomy and Earth Science, Tokyo Gakugei University, Koganei-City, Tokyo, 184-8501, Japan, email: mori@buran.u-gakugei.ac.jp); Hiroshi Niino (Division of Marine Meteorology, Ocean Research Institute, University of Tokyo, Minamidai, Nakano-Ku, Tokyo, 164-8639, Japan, email: niino@ori.u-tokyo.ac.jp)

Time evolution of a horizontal convection which is caused by cooling a half of the bottom boundary of a viscous stratified Boussinesq fluid is investigated both theoretically and numerically.
In the most general situation, the evolution of the convection consists of three distinct stages: During the first stage, the horizontal diffusion of heat is dominant over the horizontal advection. During the second stage, the stratification is still less important. The flow is non-linear and can be regarded as a gravity current in which the vertical scale is determined by the diffusion length scale. Finally, during the third stage, the stratification becomes important and the flow is described by a linear dynamics.
A similarity solution of the time-dependent governing equations which describe the dynamics of each stage has been discovered. The solution for each stage is found to be only a function of the Prandtl number after relevant scalings of the variables are introduced. Numerical experiments with fully non-linear governing equations have confirmed the validity of the similarity solution at each stage. These solutions, for example, are useful for understanding the formation mechanism of an atmospheric heat island circulation in which convections first develop from the two edges of heated area and penetrate into the center to form a steady state convection eventually.

SIMILARITY CRITERIA FOR CONTINUOUSLY STRATIFIED FLOWS OVER OBSTACLES

Olga SHISHKINA (Institute of Applied Physics, RAS, 16 Uljanovsk st., Nizhni Novgorod, 603600 Russia, email: ols@hydro.appl.sci-nnov.ru)

The comparative analysis of wave-drag coefficient versus 'internal' Froude number for submerged and floating bodies moving uniformly in fluids with different stratification profiles showed similarity of functions Cx(Fi). An existence of linear dependence of Froude numbers Fi=U/(NR) for continuously stratified fluids (a linear stratification and a pycnocline) was observed. Such a phenomenon explanation was based on analysis of wave processes following the drag coefficient increase in the mentioned Froude number range. The similarity of wave induction accompanying the sphere movement in stratified flows with single wave-guide profiles as well as the physical parameters describing those processes of different wave-guide to body heights ratio was observed. A Thorough analysis of known experimental data allowed of choose the phase velocity coincidence of the first IW mode for both the linear stratification and the pycnocline to be the similarity criterion for internal wave processes. This provides an exact choice of the constant buoyancy frequency N corresponding to the pycnocline conditions.
The induced IW amplitude is proportional to the critical streamline displacement (z/R}=Fi) to interpret the physical meaning of the 'internal' Froude number for continuous stratification Fi£1 (z£R) as the relative amplitude of induced IW or as some kind of the performance coefficient for transformation of the flow energy to the energy of the internal waves.
This work was supported by the RFBR (grant no. 99-05-64394)

STABILITY OF POLYNOMIAL FLOWS ON A SPHERE

Yuri SKIBA (Centro de Ciencias de la Atmósfera, Universidad Nacional Autónoma de México, Circuito Exterior, CU, México, D.F., C.P. 04510, México, email: skiba@servidor.unam.mx)

The stability of the Rossby-Haurwitz waves and Legendre-polynomial flows is considered in the framework of an inviscid incompressible fluid on a rotating sphere. A conservation law of arbitrary perturbations of such flows is obtained, and the whole space of the perturbations is divided into four invariant manifolds defined by means of Fjortoft's spectral number of the perturbations. Liapunov instability of non-zonal Rossby-Haurwitz waves of degree n>1 is shown, and its mechanism is explained. The behavior of the kinetic energy and enstrophy of the perturbations from invariant sets is also considered. In particular, a hyperbolic dependence between the energy and Fjortoft's spectral number of the perturbations is discussed.
In the case that the basic flow has the form of a Legendre polynomial of degree n, invariant sets of exponentially and algebraically stable infinitesimal perturbations are found. For the other part of infinitesimal perturbations, not belonging to such sets of stable perturbations, it is obtained a necessary condition for the exponential instability, which is more simple that the famous condition by Kuo for the zonal flows.

DOUBLE-COMPONENT CONVECTION DUE TO THE DIFFERENT BOUNDARY CONDITIONS - REVIEW OF COMBINATIONS OF VERTICAL AND HORIZONTAL GRADIENTS

Naftali TSITVERBLIT (Tel-Aviv University, Tel Aviv, Israel)

The conceptual framework of conventional double-diffusive convection could apply directly to large-scale environmental processes through eddy double-diffusion---instabilities resulting from the unequal perturbed diffusion gradients forming due to the different boundary conditions. The original problem considered by Welander [Tellus 41A, 66 (1989)] is in this context analogous to the conventional diffusive regime, while the inverse type of stratification (Tsitverblit [Phys. Fluids 9(8) 2458 (1997)]) stands for the finger regime. This latter configuration describes the double component Langmuir circulation problem (Leibovich [Ann. Rev. Fluid Mech. 15, 391(1983)]) and, in combination with shear motion (induced, for example, by the horizontal non-uniformity in the temperature distribution), may be relevant to the ocean thermohaline circulation. Decrease of the ratio of the vertical and horizontal diffusion coefficients in this case eventually causes formation of multi-layered structures and may affect the criticality of bifurcations. Like in conventional double-diffusive convection, the instabilities also arise under a combination of the horizontal gradients. This was initially established in application to laterally heated stably stratified systems (Tsitverblit [Phys. Fluids, submitted]). Similar situation is expected when two equal (in terms of their effect on the density) and opposing horizontal gradients aintained by the different boundary conditions at the vertical walls are applied to the fluid being at rest between these boundaries. Trial computations with the equal diffusion coefficients indicated that, when the (joint) horizontal gradient (the mbox{Rayleigh} number) in this case becomes large enough, the onset of convection indeed takes place, and analysis of this problem with and without vertical stratification due to one of the components is to be reported. Combinations of the above effects arising when the gradients are applied between two inclined planes and their relevance to the ocean are also discussed.

THE CURRENT STATE OF OCEANIC FORECASTING (DEEP AND COASTAL OCEANS) AND THE PROSPECTS FOR THE FUTURE

Prof. Allan R. ROBINSON (Harvard University, Cambridge, MA, USA)

During the last decade remarkable progress has been made in the ability to predict describe, model and forecast the physical synoptic-mesoscale state of the ocean over regional to basin scale domains. This is a result of a new understanding of the underlying dynamical principals and the development of methods significantly and substantially based on data assimilation. (Sub) meso scale phenomena have two important sets of time and space scales - evolutionary and event (scales of intermittency). Multi-scale non-linear interactions are key to determining the underlying dynamics and developing the concomitant predictive capability. Interesting issues relate to validation, verification, predictive capability and limits to predictability. Presently, critically important problems are associated with interdisciplinary dynamics and coupling. The accurate estimation of the physical-acoustical-optical-biological-geochemical ocean is now essential and feasible for modern ocean science.
Such multiscale and multidisciplinary estimation and prediction requires a new level of understanding of the multi-disciplinary hierarchy of complex coupled dynamical processes, with non-linearities and feedbacks which span a multitude of scales in time and space. Fundamental interdisciplinary problems of ocean science, long recognized as of great importance, are now tractable. As the scope of interdisciplinary ocean science expands over the next decade, there will be formidable and challenging research tasks acquired to address the scientific problems through a systems approach.

FLUCTUATIONS OF SST AND CHL-A CONCENTRATION CAUSED BY BAROCLINIC INERTIA-GRAVITY WAVES

Roman GLAZMAN (Jet Propulsion Laboratory, Pasadena CA, 91109, USA,
email: reg@pacific.jpl.nasa.gov); Peter B. Weichman (Blackhawk Geometrics, Golden, CO 80401, USA, email: pbw@blackhawkgeo.com)

Satellite observations of sea surface temperature and chlorophyll-a concentration permitted detailed statistical analysis of spatial variations of these tracer fields in a broad range of scales. Estimated wave number spectra, on scales from a few to hundreds kilometres - as reported by many authors, display a rather unexpected behaviour: they strongly disagree with predictions of two-dimensional eddy turbulence theory (which requires the SST spectrum to roll of as k^(-1)) and they exhibit geographic and seasonal trends which have no simple explanation. Our attention is focused on possible effects of baroclinic inertia-gravity (BIG) wave motions on tracer fields. We present experimental and theoretical results indicating that observed variations are greatly affected by BIG waves, and classical eddy turbulence is not necessarily the main dynamical factor of tracer dispersion. Wave number spectra of BIG wave motions are presented along with observed spectra of SST and Chl-a fields. Typical rates of spectra roll-off, ranging between k^(-1.5) and k^(-3), agree with our theoretical predictions. The fact that BIG wave motions have such a profound effect on fluctuations of ocean tacers has important oceanographic implications.

JSP39/E/18-B4 **0930**

PARTICLE DISPERSION IN THE ATLANTIC

Michel OLLITRAULT (Laboratoire de Physique des Oceans, Ifremer, BP 70, 29280 Plouzane, FRANCE, email: mollitra@ifremer.fr); Alain Colin de Verdiere, Celine Gabillet (both at Laboratoire de Physique des Oceans, Universite de Bretagne Occidentale, BP 809, 29280 Brest cedex, FRANCE, email: acolindv@univ-brest.fr)

Absolute and relative dispersion of floats deployed in the Atlantic are estimated at the base of the main thermocline in the North Atlantic subtropical gyre and in the Brazil basin. The initial separations of the floats, a few kilometer to 20 kilometer are small compared to the eddy mesoscale but large compared to dissipation scales so that the results can be usefully compared with the scalings predicted from two dimensional turbulence theory. While the absolute dispersion usually computed from such data dominated by the lowest frequencies, the relative dispersion at scales less than the energy containing scale gives information on the high wave number end of the energy spectrum that is difficult to obtain otherwise. We compare the results of these oceanic field experiments with similar experiments carried out in the atmosphere, in laboratory experiments and in numerical experiments

JSP39/W/11-B4 **0950**

GENERATION OF STEP-LIKE STRUCTURE IN STRATIFIED ROTATED BOUNDARY LAYERS

Iossif LOZOVATSKY (Department of Mechanical and Aerospace Engineering, Arizona State University, Tempe, AZ, 85287-9809, USA; also at P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences, Moscow, 117851, Russia, email: i.lozovatsky@asu.edu); Alexander Ksenofontov (Kabardino-Balkarski State University, Nalchik, Russia, email: ask@ns.kbsu.ru)

Generation of turbulent quasi-homogeneous layers separated by narrow density interfaces in a stratified shear flow with a decreasing buoyancy flux upon increase of stratification has been argued by Phillips (1972). All previous laboratory experiments and theoretical models, which have explored this problem, were limited by non-rotating flows. We added the Coriolis force to this study to verify a rotation impact on the generation, evolution and decay of the layered structure within the pycnocline under the influence of surface stress. It makes our prognostic modeling more geophysical applicable. We employed e-? and e-l models of non-stationary, stratified, planetary boundary layer equations (e is the turbulent kinetic energy, ? is the energy dissipation, l is a Richardson number dependent turbulent length scale). The numerical simulations clearly showed that the use of Ri-dependent eddy viscosity and diffusivity results in a formation of pycnoclines with a prominent fine structure. It was found that pre-existed background shear is an important external parameter which may influence the development of the step-like structure. Time scale of the fine-structure generation is strongly dependent on inertial oscillations. It was shown that thin homogeneous layers merge each other forming

thicker steps owing to shear-induced turbulence at sharp density interfaces. The scales of the layers observed in simulations are close to those observed in the seasonal ocean pycnocline.

JSP39/W/31-B4 1010

THE SHEAR STRESS BETWEEN AIR AND WATER

John A. T. BYE (Faculty of Science and Engineering, Flinders University, GPO Box 2100, Adelaide, South Australia, 5001, Australia, email: John.Bye@flinders.edu.au); Jörg-O. Wolff (Antarctic CRC, University of Tasmania, GPO Box 252-80, Hobart, Tasmania, 7001, Australia, email: j.wolff@utas.edu.au)

Recently a new formulation for the surface shear stress between air and water, which is applicable in the Earth reference frame has been implemented in a quasigeostrophic general circulation model of the Antarctic Circumpolar Current. The results indicate that a momentum balance similar to that observed can be achieved with form stress, without the use of an unrealistically large bottom friction.
This shear stress is quite distinct from that measured in planetary boundary layer studies which use the local reference frame of the surface current. The implications of a shear stress which depends on a reference frame will be discussed. The presentation will be illustrated by experimental data obtained in a novel circular wind wave tank in which a fan drives a rotating air circulation, which generates a complementary water circulation beneath.

JSP39/W/17-B4 1050

A REGIONAL MODEL OF THE SEMI-DIURNAL INTERNAL TIDE ON THE AUSTRALIAN NORTH WEST SHELF

Peter E. HOLLOWAY (School of Geography and Oceanography, University College, University of New South Wales, Australian Defence Force Academy, Canberra ACT 2600, Australia)

The semi-diurnal internal tide on the Australian Northwest Shelf is investigated using a fully three dimensional, non-linear, free surface, hydrostatic, primitive equation numerical model, the Princeton Ocean Model. The model covers a domain 1700 by 700 km using a 4km horizontal grid and 51 vertical sigma levels. Forcing is via specification of the M2 surface elevation along the open boundaries with values taken from the FES-95 global tidal model. The barotropic tidal flow, generated from surface elevation gradients, interacts with the topography and produces an internal tide that is highly variable in space. Depth integrated baroclinic energy fluxes show regions of both onshore and offshore propagation and maximum of approximately 4000 W/m. Model predicted internal tide structures are compared to detailed in-situ observations and show reasonable agreement. The three-dimensional character of the topography is shown to be important in the generation process.

JSP39/E/12-B4 1110

KUROSHIO EDDIES IN THE LUZON STRAIT

Y. HSUEH (Department of Oceanography, Florida State University, Tallahassee, FL 32306-4320, USA, email: hsueh@re.ocean.fsu.edu)

Results from a high-resolution, limited area, primitive-equation model of the circulation of the Asian marginal seas show the Kuroshio bulges into the Luzon Strait and forms a loop current before resuming its northward course. The model run with monthly mean wind forcing indicates that the Southwest monsoon tends to reduce the bulge and the Northeast monsoon tends to promote its growth. In fact, model warm-core eddies often break away from the loop during the winter monsoon season. A reduced-gravity model is constructed to probe the dynamics of the eddy separation in the Luzon Strait. A solution is found in which anticyclonic eddies separate from the loop nearly periodically with a period predicted from an analytic solution. An important aside is the discovery that an anticyclonic eddy is often generated that moves downstream with the Kuroshio. The passage of this eddy produces Kuroshio variabilities detected in recent current measurements.

JSP39/E/14-B4 1130

MEAN FLOW GENERATION BY GEOMETRICALLY FOCUSED GYROSCOPIC WAVES

Leo MAAS (Netherlands Institute for Sea Research, PO Box 59, 1790 AB Texel, Netherlands, email: maas@nioz.nl)

A homogeneous fluid in stationary rotation is stably stratified in angular momentum (increasing radially). When this dynamic equilibrium is periodically perturbed, gyroscopic (or inertial) waves result, that propagate through the fluid along an angle with the vertical determined by the ratio of perturbation frequency to twice the angular frequency. Due to this constraint, in an infinitely long channel, such waves are, upon reflecting from sloping side walls, subject to focusing, much like internal waves are. In a tank of finite azimuthal extent, this result can only be approximately true, as the circular current patterns, associated with the gyroscopic wave, need to accommodate The presence of the plane side walls. As long as the tank is much longer in along-slope than cross-slope direction, attractors might still arise, a suggestion confirmed by a laboratory experiment in which the perturbation is generated by modulating the angular velocity of the tank. Focusing gyroscopic waves lead to mixing of angular momentum at the location where the attractor reflects from the sloping wall. This predicts a mean flow above that location, confirmed by velocity measurements and dye spreading.

HYDROTHERMAL PLUME FROM A WARM LUTOCLINE

Jordi COLOMER, Teresa Serra, Jaume Piera, Elena Roget, Xavier Casamitjana, (Department of Physics, University of Girona, 17071 Girona, Spain)

A hydrothermal plume with vertical and horizontal length scales of 18 and 300m approx., respectively, is generated by a warm lutocline at the mid-depths (29 m) of a karstic lake (lake Banyoles, situated in North-Catalonia, Spain). The rising particle-laden convective plume entrains colder hypolimnetic water and develops upward until it reaches the base of the seasonal thermocline. At the level of neutral buoyancy the plume spreads laterally, mainly to the northeast of the lake, as an hypolimnetic current. Measurements were carried out using a microstructure profiler, a laser in situ scattering and transmissometry probe, and water quality probes.

DIAGNOSTIC MODEL ACCOUNT BAROTROPIC SPEED MODE OF BAROCLINIC OCEAN BY SATELLITE ALTIMETRY DATA

Sergey A. LEBEDEV (Geophysical Center of Russian Academy of Sciences, Molodezhnaya 3, 117296, Moscow, Russia, email: lebedev@wdcb.rssi.ru)

As differentiated satellite altimetry data assimilation the diagnostic analysis of ocean dynamics gives complete hydrodynamic picture on that moment of time or for that temporary interval, when appropriate measurements were made. The given approach permits better to realize as the simulated phenomena, and representation of initial information.
As an initial system of offered model equations are considered equations of ocean dynamics in quasigeostrophic approximation. The boundary condition on surface for vertical mode of speed fields is replaced by «firm cover» condition, and a condition of sliding without friction is at the bottom taken. Integrated stream function, which is necessary for account barotropic speed mode is searched as anomaly from mean season significance. It is reasonably safe to suggest that changes of baroclinic layer thickness are insignificant and density anomaly linearly change by vertical from surface significance to zero on the baroclinic layer bottom border.
The model verification was conducted on independent data: satellite altimetry (ERM mission GEOSAT) and hydrological data (experiment NEWFAEXP-88 the program «Sections») for polygon near island Newfoundland in March 1988. The mean fields of dynamic topography and integrated stream function were determined by known data file LEVITUS.

MECHANISMS FOR EDDY FORMATION IN DENSE DOWNSLOPE FLOWS IN ROTATING SYSTEMS

Peter G. BAINES (CSIRO Atmospheric Research, PMB No. 1, Aspendale, Australia 3195)

The flow of dense fluid downslope occurs on a large scale in a number of locations in the deep ocean (the Mediterranean outflow, the Denmark Strait overflow, the Bass Strait overflow and at various locations around Antarctica), but there is considerable variety in its observed character for reasons not yet well understood. For steady inviscid flow there is no downslope motion at all, as a "geostrophic" balance obtains between buoyancy and the Coriolis force. Friction is apparently necessary in order to have downslope motion with rotation. Further, eddies have been observed in the Denmark Strait overflow, and in laboratory experiments that aim to provide simple models of these flows (Lane-Serff & Baines 1998, J. Fluid Mech. 63, 229). Bottom Ekman layers are conspicuous in these experiments, and the eddies also have a bearing on the downslope transport.
Three possible mechanisms for eddy production by downslope flows in two-layer systems have been identified by Lane-Serff & Baines. All of these involve stretching of the upper layer fluid column by motion of the lower layer, and consequent spin-up due to potential vorticity conservation. These are: (i) "dragging" of the upper layer fluid by downslope motion of the lower layer before the latter reaches approximate alongslope "geostrophic" balance, in the manner of a "captured" Taylor column; (ii) the collapse (or reduction of thickness) of the lower layer fluid as it approaches this "geostrophic" balance, and (iii) Ekman drainage from the (anticylonic) lower layer after it reaches this "geostrophic" balance, which also reduces its thickness. The first two only act during geostrophic adjustment, but the last acts continuously.Spall and Price (1998, J. Phys. Oceanog. 28, 1598) have proposed a fourth mechanism (that is similar to (i)) in which the inflow consists of two layers flowing into a third, and the upper inflowing layer is stretched by the motion of lower. They also propose that this process operates in Denmark Strait. A variety of experiments that demonstrate these mechanisms and the situations in which they are dominant will be presented.

STUDIES OF OCEAN DYNAMICS - FROM SMALL SCALE MIXING TO LARGE SCALE CIRCULATION

Greg IVEY (Department of Environmental Engineering, Centre for Water Research, The University of Western Australia, Nedlands, Western Australia, e-mail: ivey@cwr.uwa.edu.au)

The initiation of a de-stabilizing buoyancy flux across the surface of the ocean produces small-scale convective turbulence and mixing. In the ocean, the small-scale turbulence is only weakly affected by rotation but will erode the underlying stratified fluid. The combination of non-uniform lateral distribution of the surface buoyancy flux and this convectively driven deepening will generate firstly lateral density gradients and then, in turn, a mean circulation. If the scales are large enough, this circulation will be affected by rotation and large-scale baroclinic instabilities dominate the flow field. Recent laboratory studies have provided insight into these flows and have considered cases ranging from open ocean convection, where rotation is of primary importance, through to exchange flows between basins where topographic control is of primary importance. These studies will be reviewed with emphasis on describing how the buoyancy forcing, the ambient stratification, the rotation rate, the depth and the lateral length scales determine both the timescales of evolution of the flow to steady state as well as the final steady state property distributions, circulation and exchange rates.

JSP39/W/04-B4 1500

THE PROPAGATION OF INERTIAL-INTERNAL WAVES OVER SLOPING BOTTOM TOPOGRAHY: A REVISIT

Christopher N.K. MOOERS (Rosenstiel School of Marine and Atmospheric Science, University of Miami, 4600 Rickenbacker Cswy., Miami, FL33149-1098, USA, email: cmooers@rsmas.miami.edu)

Inertial-internal waves (i.e., waves under the joint influence of the Earth's rotation and density stratification) interact with sloping bottom topography in a fashion that depends upon the ratio of the slope of a frequency-dependent wave parameter (the slope of the wave characteristics or rays) to the slope of the bottom: if the ray slope is greater than the bottom slope, there is forward reflection; if otherwise, there is backward reflection. Of particular interest here is the propagation of inertial-internal waves into a wedge; for relatively high frequencies that are forward-reflected, a given wedge is termed subcritical; conversly, for relatively low frequencies that are backward-reflected, a given wedge is termed supercritical. By analysis of fiducial rays to reduce the frequency-dependent dynamical geometry to characteristic subdomains, a method for constructing solutions is defined for both subcritical and supercritical wedges.

JSP39/E/02-B4 1520

THE USE OF LABORATORY MEASUREMENTS TO VALIDATE OCEAN NUMERICAL MODELS

Nicolas PERENNE, David Smith, Don L. Boyer (Environmental Fluid Dynamics Program, Department of Mechanical and Aerospace Engineering, Arizona State University Tempe, AZ 85287-6106, USA, email: perenne@enws606.eas.asu.edu); Dale Haidvogel (Institute of Marine and Coastal Sciences, Rutgers University, P.O. Box 231, New Brunswick, NJ 08903, USA, email: dale@ahab.rutgers.edu)

In order to develop data sets which can be used as benchmarks for current coastal circulation models, laboratory experiments are conducted in a cylindrical tank in which a continuous continental shelf model, interrupted only by a single smooth canyon, is placed along the periphery of the test cell. Prior to experimentation, the tank is filled with a linearly stratified fluid and the tank is then slowly brought up to solid body rotation with Coriolis parameter f. To initiate the experiments, the turntable rotation rate is then modulated sinusoidally about the background rotation rate f/2. This effectively drives an oscillatory background current along the coastline. The objectives of the experiments are to (i) observe and better understand the motion field in the vicinity of a submarine canyon and (ii) provide horizontal maps of the velocity, vertical vorticity and horizontal divergence fields, including a determination of the errors associated therewith, that can be compared with current numerical models. The principal governing dynamical parameters are the Rossby, temporal Rossby, Burger and Ekman numbers.
Observations at numerous vertical locations, including those above and below the canyon rim, are presented. Particle tracking techniques are used to delineate the velocity, vorticity and divergence fields. Special attention is given to the mean currents driven by this physical system. Comparisons are made between the laboratory results and two coastal circulation models (i.e., finite difference and finite element). An assessment is made concerning the differences noted between the laboratory and the numerical models.

JSP39/W/28-B4 1540

MESOSCALE OCEAN EDDY DYNAMICS: HIGH RESOLUTION SHALLOW WATER SIMULATIONS WITH REALISTIC TOPOGRAPHY

Robert B. SCOTT, Ted Johnson, S. A. Sorenson (Mathematics, UCL, Gower Street, London, WC1E 6BT, UK)

The western boundary current off the southern tip of Africa, the very fast Agulhas current, regularly produces mesoscale eddies. Their westward propagation to the South Atlantic has been captured with TOPEX/Poseidon satellite altimeter data. This provides an excellent opportunity to study the eddy dynamics using simplified models while verifying the accuracy using the real data. We present results produced with a state of the art shallow water code featuring an adaptive grid that provides very high resolution following the eddy. The affects of realistic topography are investigated using the ETOPO5 5 minute resolution data. The possible influences of finer scale topography on eddy spin down is analyzed with artificial topography. Insofar as the most serious limitation of the model is its vertical homogeneity, the comparison between the observations and simulations provides an assessment of the importance of density stratification.

JSP39/W/39-B4 1620

MIXING EFFICIENCY OF STRONG DENSITY INTERFACES

J.M. REDONDO, M.A. Sanchez (Dept. Fisica Aplicada, UPC, Barcelona, Spain)

A series of high resolution experiments have been performed in order to examine the structure of a sharp density interface under zero-mean-flow. The evaluation of the mixing efficiency of the grid-stirred turbulence is made comparing the increase of potential energy with the power of the grid. The interface is visualized with a thin laser sheet of 532 nm and rodamine is used to mark the turbulent side of the interface. The structure of the density and velocity fields are imaged using DigImage fluid dynamics software and particle tracking of pliolite suspended near the interface. The reduction of interface thickness with Richardson follows a power law with exponent -2/3. There is a maximum in mixing efficiency at intermediate Ri when a high rate of vortex dipoles resonate with the Brunt-Vaisalla frecuency at the interface.

JSP39/E/05-B4 1640

LONG-DISTANCE PROPAGATION AND FEATURES OF TIDAL INTERNAL WAVES IN THE CENTRAL INDIAN OCEAN

Tatiana Demidova, Eugene MOROZOV (both at Department of Physics, P.P. Shirshov Institute of Oceanology, Moscow 117218, Russia, email: evita@redline.ru)

Propagation of tidal internal waves generated over the slopes of the Mascarene Ridge at a distance over 10 wavelengths in the Central Indian Ocean was studied from a joint analysis of the results of calculations with the use of a non-linear numerical model and experimental cast and mooring data. The barotropic tide over the ridge was assumed to be a 2-D flow in a continuously stratified rotating ocean of changing depth. The modelling was fulfilled for quite large number of steps in time. This allows us to study the evolution of the internal waves at distances over 1500 km from the source. Long-term measurements of temperature and currents at subsurface buoys in direction of the wave propagation were used to get statistically proven experimental parameter of internal waves and to study its time evolution. The results of the modelling and experimental measurements were used to estimate the amplitudes of the waves, the character of their decay and energy flow both near the ridge and at a significant distance from it. . Oscillation parameters of the first mode remains unchanged at quite long distances, whereas the higher modes dissipate rapidly already at first periods of oscillation. Approximately 5%-decay per wavelenght in the far zone was found. The modelling and measurement results are in a good agreement.

JSP39/E/24-B4 1700

INTERACTION OF INERTIA-GRAVITY WAVES WITH A POTENTIAL VORTICITY BARRIER

Gael Huerre, Chantal STAQUET (LEGI, BP 53, 38041 Grenoble cdx 9, France,
email: chantal.staquet@hmg.inpg.fr)

The purpose of this work is to investigate the permeability of a dynamical barrier with respect to wave breaking events. This work is motivated by a conjecture proposed by McIntyre (1995) according to which the edge of the polar vortex, which behaves as a dynamical barrier with respect to large scale quasi-two-dimensional turbulence, would be permeable to wave breaking events. McIntyre (1995) suggested that inertia-gravity wave motions, in breaking intermittently near the vortex edge, could give rise to a quasi-horizontal transport across that edge. This conjecture was proposed to account for anomalous behaviours inferred from measurements in the atmosphere, such as low concentration of ozone at mid latitudes. To investigate this conjecture, we have performed three-dimensional numerical simulations of inertia-gravity waves interacting with the edge of a large scale vortex. Conditions under which breaking may occur have been investigated and the permeability of the vortex edge is studied by following the behaviour of a passive tracer. Preliminary results will be presented at the meeting.

JSP39/E/13-B4 1720

PARAMETER DEPENDENCE OF LINEAR AND NONLINEAR INSTABILITY OF BAROTROPIC AND BAROCLINIC SHEAR FLOWS

Kuniko M. YAMAZAKI, Akira Masuda (Dynamics Simulations Research Center, Research Institute for Applied Mechanics, Kyushu University, Kasuga-Koen 6-1, Fukuoka 816-8580, Japan, email: miki@masuda.riam.kyushu-u.ac.jp, masuda@riam.kyushu-u.ac.jp)

We examine the stability of equivalent barotropic and baroclinic shear flows in a periodic domain on an f-plane and on a beta-plane, as a preliminary to investigating the instability of the Kuroshio Current over the continental slope in the East China Sea. Linear analysis reveals that the instability of the equivalent barotropic shear flow is reduced by stratification, the beta effect, coastal boundaries, and along-flow bottom topography. For the baroclinic flow, however, the influence of stratification is more complex due to the influence of baroclinic instability. The non-linear evolution of such unstable flows is investigated by employing a numerical time-integration technique. An archetypical evolution is found to consist of four stages: primary instability to which linear analysis is applicable, saturated phase characterized by staggered rows of vortices, the onset of a secondary "subharmonic" instability which leads to the development of structures with smaller wavenumbers, and a final stage in which the flow becomes more irregular. It turns out that the long-term non-linear evolution of the flow is drastically altered by the influence of the planetary beta-effect. Furthermore, in the barotropic case, an asymmetry of the profile of the mean shear flow enhances the instability of jets insofar as their development is concerned, although the opposite is the case in the linear regime.

JSP39/W/20-B4 1740

EDDY-WAVE INTERACTIONS USING A POTENTIAL VORTICITY DIAGNOSTICS

Maria VALDIVIESO DA COSTA, Alain Colin de Verdiere (both at Laboratoire de Physique des Oceans, Universite de Bretagne Occidentale, email: mvaldi@deneb-gw.univ-brest.fr).

Process-oriented numerical experiments are carried out to study the dynamics of intermediate density boudary currents and associated lenslike eddies. The model used in the experiments is the pure-isopycnic coordinate primitive equation model of Bleck and Boudra (1986), configured on a semi-open channel with two active layers, and forced by a steady mid-level density flux through one channel wall. Non-linear interactions between neighbouring eddy structures were generally observed within 50 and 100 inertial periods after the geostrophic adjustment phase of the experiments. Most of the clearly visible interactions occurred between large-scale eddies with weak downstream phase velocities, and faster propagating smaller scale waves.
A diagnostic framework based on the model isopycnic potential vorticity (IPV) balance is set out to examine the non-linear interaction processes between these two types of transient features. Specifically, we have calculated four tendency components of the low-frequency IPV field associated with individual large-scale eddies on the framework of the filtered IPV-tendency equation. We then compared each of the tendency components with the (total) observed tendency and the low-frequency IPV field itself. It is found that the sum of the two tendency components induced by each of the internal non-linear interaction processes determines the observed tendency of large-scale eddies. The largest tendency component is the tendency induced by the advection of large-scale eddy structures by the low-frequency component of the total flow, which primarily acts to make large-scale eddies propagate downstream. The tendency component due to self-interaction among high-frequency transients (feedback of high-frequency waves) is nearly out-phase with the mean tendency induced by the large-scale advection, retarding, in average, the downstream propagation of large-scale eddies. The tendency component induced by bi-harmonic dissipation of IPV along isopycnal surfaces is in the mean negligible relatively to the other mechanisms.

SPECIFICATION OF THE CRUSTAL MAGNETIC FIELD FOR DIRECTIONAL DRILLING

SUSAN MACMILLAN (British Geological Survey, Murchison House, West Mains Road, Edinburgh EH9 3LA, UK. email: S.Macmillan@bgs.ac.uk) and Paul Williamson (British Geological Survey, Kingsley Dunham Centre, Nicker Hill, Keyworth, Nottingham, NG12 5GG, UK. email: P.Williamson@bgs.ac.uk)

Real-time estimates of the geomagnetic field vector and associated uncertainties, ideally about 0.1° in direction and 50 nT in magnitude, are desired in the drilling of oil and gas wells using magnetic survey tools. To help achieve this level of accuracy a knowledge of the crustal field vector is required and a method to derive this from scalar aeromagnetic data is described. The problem of how to estimate the crustal field contribution and its likely uncertainties at the location of the downhole magnetic survey tool, which is considerably nearer the sources than the aeromagnetic data, is discussed. One possible approach is to use an inversion technique to map the magnetisation distribution, constrained by any available external information such as seismic data. This can then be used to calculate the magnetic anomalies at depths above the sources.

JSA40/W/12-B3 Invited 0920

USE OF EFFECTIVE MEDIUM TECHNIQUES TO INTEGRATE SEISMIC AND ELECTROMAGNETIC DATASETS

ANTHONY GREER and Martin Sinha University of Cambridge, Department of Earth Sciences, Cambridge, CB3 0EZ, email: greer@esc.cam.ac.uk

The study of rocks containing fluids by seismic or electromagnetic methods can reveal some of the rock's properties - seismic velocity, electrical resistivity - but a single technique can not uniquely determine the pore fractional volume, or the geometrical properties of the pore fraction. Effective medium techniques can be used to jointly interpret the two data types through relationships that map pore fractional volume into variations in resistivity and seismic P-wave velocity, for the case of either aqueous or magmatic fluids filling crustal pore spaces, and for given pore geometries. The models are parameterised using randomly orientated ellipsoidal cracks with variable aspect ratios. Electrical resistivity depends heavily on interconnected pathways of the highly conductive fluid phase, while seismic velocity depends less on interconnected pathways but heavily on pore geometry. Since these two geophysical properties respond differently to variations in pore geometry, it is possible by combining both types of data to overcome the trade off that otherwise exists between pore geometry and pore fractional volume.
We have successfully applied this approach to real, coincident data sets from mid-ocean ridge systems. These are dynamic geological environments where active processes are dominated by the presence of magmatic and hydrothermal fluids. The results provide new constraints on crustal porosity and fluid connectivity.

JSA40/E/07-B3 0950

TOWARDS AN INTERDISCIPLINARY 3-D MAPPING OF THE LITHOSPHERE AND ASTHENOSPHERE BENEATH ATLANTIC CANADA AND THE ARCTIC. PART-1: APPLICATION OF THE MULTIMODE/MULTISTRUCTURE METHOD OF SEISMOLOGY

Pierre ROULEAU (Department of Physics, Sir Wilfred Grenfell College, Memorial University of Newfoundland, NF, CANADA, A2H 6P9, email: prouleau@beothuk.swgc.mun.ca), Fred Schwab and Bob Melhman (both at Institute of Geophysics and Planetary Physics, University of California at Los Angeles, Box 95157, Los Angeles, California 90095-1567, USA, email: schwab@cyclop.ess.ucla.edu), Jose Frez and Jose Acosta (both at Centro de Investigacion Cientifica y de Educacion Superior de Ensenada, Av, Espinoza No, 843, Apartado Postal 2732, Ensenada, Baja California, MEXICO, email: jofrez@cicese.mx)

The ultimate goal of our work is to produce a 3-D digital map of the seismic, structural, gravimetric, geochemical, thermal, electromagnetic, and stress field properties beneath the combination of Atlantic Canada and the Arctic down to a nominal depth of 800 km, with a lateral resolution of 10 km. Towards this end, we apply a multi-step, evolving procedure for map improvement, originally elaborated by the IUGG's ICL/ILP Project II-4. The current level includes detailed treatment of geography (togography, bathymetry), geodesy (geoid), surface geology, within the multimode- multistructure (MM) seismological technique whose aim is to improve an initial model (an "I" data set) by minimising the residuals between complete theoretical seismograms and those recorded experimentally. Using reported data and auxiliary databases (e.g. CRUST 5.1, ETOPO30, EGM96, GLOBE), and specially-constructed software for automating the work, we first built an "I" data set for the Arctic-North Atlantic, and then for the continuation through Atlantic Canada. The current level of formulation of these 3-D maps (electronic databases) is described, as is the allowed variability of the iterative improvement, and the related problems of graphical display of 3-D results. We describe the nuclear, MM technique and its implementation; principally the hardware/software system that we have had to develop for routine 3-D mapping with full control over lateral resolution. We present extensive numerical results of the testing on the Arctic "I" data set; results from the later, preliminary numerical testing on the Atlantic Canada "I" data set are discussed.

JSA40/E/08-B3 1005

CONSTRAINTS ON CASCADIA SUBDUCTION FROM CONTRASTING MODELS OF CRUSTALAND MANTLE DENSITIES

Tanya ROMANYUK (IPE, B.Gruzinskaya 10, Moscow, 123 810, Russia, email: t.romanyuk@relcom.ru) Walter Mooney and Richard Blakely (USGS, 345 Middlefield Rd, MS 989,Menlo Park, CA 94025, USA; email: mooney@andreas.wr.usgs.gov; blakely@mojave.wr.usgs.gov)

The style of subduction of the Juan de Fuca plate beneath North America changes markedly along the length of the subduction zone, especially in the angle of subduction, distribution of earthquakes, geologic and seismic structure of the upper plate, and regional horizontal stress. To investigate density characteristics, we conducted detailed modeling experiments of the crust and mantle along two transects across the Cascadia subduction zone, one across Vancouver Island and the Canadian margin, the other across the Oregon margin of the United States. Models of crustal and mantle density were produced with a 2-D linear gravity inversion technique. This technique approximates the crust-mantle cross section by a set of blocks based on published seismic refraction models. Each block is allowed to have a range of densities, constrained where possible by borehole measurements, seismic velocities and petrological arguments. To further constrain the models, we assumed that oceanic crust has the same density-depth ratio at both transects and that the lithosphere is close to isostatic equilibrium in the deep ocean and east of the modern volcanic arc. Our results confirm that the downgoing slab beneath Vancouver Island dips significantly gentler than at Oregon, supporting the idea that the Juan de Fuca plate is segmented from north to south. The Oregon segment has an anomalous block within the mantle situated between the continental crust and the subducting Juan de Fuca plate. This block is located beneath the aseismic Western Cascades and is characterized by a density lower than the mantle density beneath the modern volcanic arc in both segments. This reduced density agrees with observed lower mantle velocities, extensional geodynamic regime, and other characteristics of the Oregon margin.

JSA40/E/10 -B3 1025

STRENGTHS AND WEAKNESSES OF GLOBAL, LOCAL, AND JOINT-INVERSION APPROACHES IN THE OPTIMISATION OF ELECTRICAL AND EM DATA

SAURABH K. VERMA (National Geophysical Research Institute, Uppal Road, Hyderabad-500 007, India, email: postmast@csngri.ren.nic.in) Sven-Erik Hjelt, Shashi P. Sharma, and Markku Pirttijarvi (all atDepartment of Geophysics, University of Oulu, 90750 Oulu, Finland, email: seh@babel.oulu.fi)

Easy accessibility to fast computers has provided an impetus to the application of global inversion methods in the optimisation of geophysical data. Though the apetite of these methods for computer memory and time is enormous, they are guaranteed to converge to a solution. Local inversion methods are computationally efficient but convergence to a solution is not always possible. Joint-inversion (JI) synergistically combines information from two or more data sets to provide a common model acceptable to various data sets. Both local and global search engines could be utilised to implement a JI scheme.
Performance of the above approaches in resolving i) simple and ii) relatively difficult (fine) 1-D structures is compared considering DC and MT sounding data. A comparison of local and global methods is also presented for a 2.5-D 'plate' model considering time-domain EM data. The results reveal that JI based on local search can provide a good resolution of difficult targets most economically. If multi-parametric information is not available to use JI, a local search approach could still be desirable if extraneous information is available to constrain the starting model. Global search may be resorted to only in the absence of multi-parametric data and extraneous information.

JSA40/E/02-B3 1045

LARGE-SCALE 3-D MODEL FOR THE LITHOSPHERE OF EUROPE INFERRED FROM SEISMIC AND GRAVITY DATA

Tamara P. YEGOROVA and Vitaly I. Starostenko (both at Institute of Geophysics, National Academy of Sciences, 32 Pr. Palladina, Kiev 252680, Ukraine, e-mail: egorova@igph.kiev.ua)

Presented large-scale 3-D model for the lithosphere of Europe is based on generalised velocity model, compiled by Giese and Pavlenkova and presented by structure maps for "seismic" basement and the Moho, and by a scheme of distribution of average P-wave velocity in the crystalline crust. This model, consisiting of three layers (two regional layers - sediments and the crystalline crust and a sea water layer offshore) was converted into its density equivalent with using the conversion functions between velocity and density. Through solving 3-D direct gravity problem an effect from the model has been computed. By removing the calculated effect from the observed gravity field, the residual gravity anomalies of -200 to +200 mGal amplitude, caused by density heterogeneities of the uppermost mantle, have been obtained. Mantle origin of the residual gravity anomalies is confirmed by their correlation with both velocity structure of the upper mantle according to seismotomography and geothermal data. The results of the modelling confirm general division of the lithosphere of the continent on two main blocks - activated Phanerosoic lithosphere of the Western Europe and Precambrian consolidated lithosphere of the East-European Platform.
Against this background there are distinguished two main types of contrast units characrised by negative and positive mantle anomalies. (1)Tapfrogenic and rift regime (Western Mediterranean, the Pannonian Basin, North Sea, Rhinegraben) with thin crust, shallow asthenosphere, low-velocity domains in the upper mantle, high-heat flow values and mantle anomalies of -150 to -200 mGal. (2) Orogenic regime (Alps, Pyrenees, Calabrian Arc, Dinarides, Caucasus) with thick lithosphere, high velocities in the upper mantle, moderate heat flow values and mantle anomalies -50 to +150 mGal.

JSA40/W/05-B3 1120

GEOPHYSICAL RECOGNITION OF POSSIBLE OCEANIC PLATEAUS IN THE LOWER CONTINENTAL CRUST

M Purucker (Geodynamics Branch, Goddard Space Flt Ct, Greenbelt, MD 20771 USA, email: purucker@geomag.gsfc.nasa.gov)

Recent studies of xenoliths and of granulites of the Arunta block suggest the presence of strongly magnetic mafic granulites in the lower crust. These mafic granulites, if present in substantial amounts, will produce significant magnetic anomalies at satellite altitude. What could be the origin of these mafic granulites? One idea is that they may arise from the accretion of oceanic plateaus to continents and the subsequent descent of these oceanic plateaus to lower crustal depths (cf. Condie, J.Geol, 1997,729-736; for counterpoint see Taira and Mann, Fall AGU, 1998). Oceanic plateaus in the present-day ocean exhibit a significant magnetic signature at satellite altitude because they contain a thickened sequence of mafic crust and they are the right size to be seen from satellite altitude. After initial accretion, the oceanic plateau would be largely in the upper crust at greenschist and amphibolite grade.As a general rule, mafic rocks at these metamorphic grades are weakly magnetic, with Fe largely locked up in nonmagnetic minerals such as chlorite and epidote. Granulite grade metamorphism frequently leads to the formation of highly magnetic, low-Ti magnetite. Interrogation of the CRUST 5.1 database for regions in the lower crust with P wave velocities and densities consistent with mafic granulite yields ten areas, five of which host significant satellite magnetic anomalies. Perhaps the lower crust in these regions was derived, at least in part, from oceanic plateaus?

JSA40/E/03-B3 Invited 1140

JOINT GRAVIMETRIC-SEISMIC MODELLING - PITFALLS AND PERSPECTIVES

Gabriel Strykowski (National Survey and Cadastre, Rentemestervej 8, DK-2400 Copenhagen NV, Denmark, email: gs@kms.min.dk)

The fundamental problem of geophysical modelling is that the information about the subsurface contained in surface data (gravity, seismics and others) is insufficient. It is the limitation in the information content that causes the ambiguity of a solution to the mathematical inverse problem. This explains the apparent paradox. A common sense argument implies the existence of a true and unique (as opposed to ambiguous) distribution of the physical sources of the measured surface signal. In practical modelling, this missing information is provided by 'mathematical assumptions' (such as a limited solution space, a minimization criterion, apriori error statistics, . etc), thus, transforming an inherently ill-posed mathematical inverse problem to a well-posed one. The role of joint geophysical modelling is to overcome the above inherent mathematical ill-posedness of monodisciplinary modelling problems by including 'independent information'. However, in practise one faces a problem of coupling different types of information. The obvious question is: Are the sources of different types of surface signals coherent? (For example: Is a seismic reflector always connected to a mass density contrast?) In this contribution we will address such general problems using gravimetric-seismic modelling as a specific example. Furthermore, we will discuss consequence of popular assumptions known in the literature (mass density-seismic velocity relation and apriori fixed mass density contrast across interface separating geological bodies or layers). From this discussion emerges a general frame for joint geophysical modelling. Specifically, for the gravimetric-seismic modelling problem, the hierarchy in which different pieces of information (seismic data, borehole data, and gravimetric data) should be used. All aspects of the general discussion will be illustrated by a field example: modelling of the source (an igneous intrusion within the crust) of Silkeborg Gravity High in Denmark.

LITOSPHERE AND UPPER MANTLE STRUCTURAL MODELS OF NORTH AMERICA DERIVED FROM INTEGRATED GEOPHYSICAL DATA

Gildo CALCAGNILE and Vincenzo Del Gaudio (Dipartimento di Geologia e Geofisica and Osservatorio di Geofisica e Fisica Cosmica, Università di Bari, via E. Orabona, 4, Bari, Italy; e-mail: scigeddi@tno.it, delga@geo.uniba.it) Umberto Mascia and Pierpaolo Pierri (Osservatorio di Geofisica e Fisica Cosmica, Università di Bari, via E. Orabona, 4, Bari, Italy; e-mail: mascia@geo.uniba.it, pierri@geo.uniba.it)

Surface dispersion data have been combined with the results of seismic refraction data to derive the regionalisation of lithosphere-asthenosphere system and to investigate the presence of significant heterogeneity in the mantle of North America. The older part of the shield shows lid thickness up to more than 100 km with, if any, weak shear velocity contrast to the underlying layer. The surrounding areas are characterised by a thinner lithosphere in the western and the south-eastern region with a relatively well-developed low-velocity zone (excluding the Colorado Plateau-Sierra Nevada area) where low velocity material may almost rise up to the Moho); in the central stable and eastern regions the contrast may be much milder with higher velocity. Other geophysical features like heat-flow, gravity anomalies and electrical conductivity correlate qualitatively rather well with the characteristics of the lithosphere-asthenosphere system. We attempt a more quantitative approach constraining the obtained seismological models with other geophysical data (mainly gravimetric and thermal data); the results of this integrated approach will be discussed.

THE APPLICATIONS OF DYADIC GREEN FUNCTIONS IN 3 - DIMENSIONAL MODELLING OF THE EAST AFRICAN RIFT SYSTEM USING BOTH SEISMOLOGY AND MAGNETOTELLURIC METHODS

Ebun Adefunmilayo Oni, Solid Earth and space Physics Research Laboratory, Department of Physics, University of Ibadan. P.O Box 4092, Ibadan, Nigeria. E-mail: ebunoni@sesp-ui.oauife.edu.ng

The East African Rift System has been under scientific investigation for a long period becuase of its importance in continental Rifting and modern theory of Plate Tectonics. The 3-Dimensional Mapping of the Lithosphere and Asthemosphere on the African Continent cannot be completed without paying special attention to the 3-Dimensional Modelling of the East African Rift System. In a recent paper, Oni (1995a) developed the use of Dyadic Green Functions for Magnetotelluric in Low Latitudes. The theory can be applied to the 3-Dimensional Modelling of the East African Rift System. In another paper, Oni (1995b) developed the use of Dyadic Green Functions for Seismic Waveguide Theory in 3-Dimensional Seismology. In this paper the Author makes use of the two theories to evolve an integrated Seismology and Magnetotelluric Theory for a 3-Dimensional Modelling of the East African Rift System.

WAVELET METHOD FOR THE HARMONIC ANALYSIS OF GRAVITY TIDES

H. T. Hsu (Institute of Geodesy and Geophysics, Chinese Academy of Sciences, 54 Xudong RD, Wuhan 430077, P. R. China, email: hsuh@asch.whigg.ac.cn) Lintao LIU (Institute of Geodesy and Geophysics, Chinese Academy of Sciences, 54 Xudong RD, Wuhan 430077, P. R. China, email: llt@asch.whigg.ac.cn)

In this contribution, we propose a new approach to the determination of gravity tidal parameters. Three pairs of compactly supported wavelets are introduced in the approach. They can efficiently extract the aimed tidal signals from the gravity tides. The new approach guarantees a direct and precise analysis of the tidal gravity records of any sampling rate. We apply the new approach to the harmonic analysis to Wuhan superconducting gravimeter records. The results clearly show the resonant effects of the Earth Nearly Diurnal Free Wobble (NDFW).

THREE TYPES OF THE EARTH'S MAGNETOACTIVE CRUST

Boris S.Barulin (Geophysical Trust, Novosibirsk, Krasny Prosp.,16, Russia), VLADISLAV N.LUGOVENKO, Aleksandr V.Pchelkin (both at Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Russian Academy of Sciences, Troitsk, Moscow Region, IZMIRAN, 142092, Russia, email: golovkov@)izmiran.rssi.ru) Igor V.Lugovenko (Institute of Spectroscopy,Russian Academy of Sciences, Troitsk, Moscow Region, 142092,Russia)

In 1990 (Lugovenko V.N. et al., Proc.Intern. Simp. on Geomagnetism. Shanghai.China. 1990) sufficiently reliable method of estimation of the vertical thickness of the Earth's magnetoactive crust by means of attenuation factor of mean amplitude of magnetic anomaly field by change of survey altitude was suggested.Three types of the Earth's magnetoactive crust (see also Lugovenko V.N. et al.Proc. Intern. Confer. on Marine Electromagnetics.. London, UK, 1997.) were extracted in frame of adopted geophysical model of the Earth's crust at present,using many magnetic anomaly field data for oceans, Russian, USA and Chinese territories:1.Vertical thickness of the typical continental crust of ancient platforms isapproximately 35 km.2.Vertical thickness of the Western-Siberian plate is near 10 km.3.Vertical thickness of the typical oceanic crust of mid-ocean ridges is almost 5 km.

FAST CALCULATION OF TEMPERATURE DISTRIBUTION IN OIL BASINS

ZHANG Minghua (Chinese Academy of Geoexploration, 31 College Road, Beijing, 100083, China, Email: zhmh-cag@china2.ygi.edu.cn) Liyan (Xinxing Petroleum Cor., 31 College Road, Beijing, 100083, China)

Temperature is one of the three most important factors for oil maturation, accumulation and transportation. Aimed at small scale, basin belt oil and gas prospecting, geothermal field studies were carried out all over China in the middle 90s, which include direct measurement down drill holes. So far, however, reliable method for calculating temperature distribution and geothermal gradients within a basin has not found, because the boundary conditions for the equation of conductive heat transfer could not be given in high resolution and direct temperature measurement is limited due to drill hole depth. The way we suggest here for fast calculation of thermal field with high resolution consists of two steps. First, determination of Curie depth in high resolution using nonlinear iteration method(Zhang, et al,1997) for aeromagnetic anomaly inversion. Second, solution of the conductive equation by finite-element algorithm with the bounder conditions of Curie depth and temperature, temperature measurement down drill holes, and strata and structure distribution within the basin from both geology and seismic and EM interpretation. We studied Southeast part of Songliao Basin in north China, using the way suggested above in 1997. Geological structure and temperature bore hole data, seismic interpretation and 1:200 000 aeromagnetic data were utilized. Heat production at depth of 10 kilometers under ground rH10=1.25mW/cm3. Thermal conductivity of sediments K1=1.5W/mK and of rocks from basement to Curie depth K2=2.6W/mK. Surface temperature Ts=10¡ãC. Curie temperature Tc=580¡ãC. The half-space in the earth were divided according to rock types, faults, and strata distribution into homogeneous triangular blocks. Temperature distribution and thermal gradients, heat flux along three long profiles in the basin were calculated. Known reservoirs in the southeast part of Songliao basin are coincide with the areas where calculated Curie depths are locally shallower in a regional depress, such as Shiwu, Hudian, Qingshan and Nongan. Results of finite-element calculation show that heat flux are from 55-68mW/m2, varying in the same up and down steps as the basement, and that fault angle contributes a lot to the accumulation of heat. A stipend fault...

JOINT INVERSION OF LITHOSPHERE STRUCTURE FROM LOVE AND RAYLEIGH WAVE DISPERSIONS

Yang WANG (Lab. for Geothermics, Institute of Geology, Chinese Academy of Sciences, P.O.Box 9825, Beijng 100029, China, email: thalassa@263.net)

Surface wave inversion is the common method to deduce lithosphere structure, but in general Love or Rayleigh wave dispersion data is used separately. We developed the joint inversion methods using both Love and Rayleigh wave dispersion data. Our first method inverses thickness and S-wave velocity of each layer from Love wave dispersion data, then takes the result as constraint to deduce P-wave velocity structure using Rayleigh wave dispersion data. In our second method we apply the overall optimization method, genetic algorithm, to misfit Love and Rayleigh wave dispersion data simultaneously, and obtain thickness, S- and P-wave velocities of each layer. Having S- and P-wave velocities, Poisson ratio is calculated for each layer.
The crustal seismic velocity structure of Tibetan Plateau was studied by our first inversion method, because of lacking Love and Rayleigh wave dispersion data along same path. The densities of sub layers were estimated by the empirical relationships between seismic velocity and rock density. In our results six sub layers are been identified, and the depths of their bottoms are 8, 30, 40, 62, 68, and 75 km separately. The S-wave velocities are 3.13, 3.32, 3.15, 3.92, 3.45, and 3.87 km/s for each layers, and P-wave velocities are 6.00, 6.10, 5.72, 6.35, 6.78, and 6.64 km/s, corresponding Poisson ratios are 0.31, 0.29, 0.28, 0.19, 0.32, and 0.24 separately. Our results were support by waveform modelling (Rodgers & Schwartz, 1998). We estimate the compositions of middle and lower crust of Tibetan plateau using P-wave velocities and Poisson ratios. The lower Poisson ratio of the 4th layer indicates that it maybe a quartz-riched layer, and implies that Indian crust had subducted beneath Tibetan Plateau. The joint inversion using both Love and Rayleigh wave dispersion data can provide the information about Poisson ratio of lithosphere.

FLEXURE OF LITHOSPHERE BENEATH EAST CARPATHIAN BELT

Ligia Narciza ATANASIU (Geological Institute of Romania, 1 Caransebes Str., 78344 Bucharest-32, Romania, email: ligia@igr.sfos.ro)

Analysis of deflection and gravity data along a profile crossing the major tectonic units of the East Carpathian Belt.
The late Miocene foredeep basin external to the outer East Carpathian are considered typical molassic foredeep that formed contemporaneously with thrusting in the adjacent mountain belt. A simple mechanical model in which the repose of the lithosphere to loading was approximated by a semi-infinite broken) elastic plate overlying a viscous mantle was used to analyse the deflection of the foredeep assign along a profile perpendicular to the thrust belt.
The deflection of the foreland basement caused by the observed topographic load was calculated for assumed effective plate thickness of 37 Km and several values of flexural rigidities. It can be seen that the maximum predicted depth are only one-half to one-third of the observed Carpathian foredeep, regardless of the flexural rigidities assumed.
We conclude therefore that the load represented by the thrust sheets and foredeep sediments in the profile across the Carpathian is insufficient to cause the observed deflection of the continental basement beneath the foredeep. This result implies the existence of an additional subsurface load that act on the subducted plate. We assume that the presence of the subsurface load is related to the existence of a crust consumption paleoplane.
A relative good fit is obtained between the shape predicted by gravity and magnetotelluric data and the results of the computations. Modelling results from the profile give as a thickness of around 47 Km for the sedimentary cover. We obtained for the Moho discontinuity a depth of 38 Km between the Siret Fault and the paleoplane subduction zone and 35 Km in the eastern and western part.

IMPROVED BP SOFTWARE FOR 3-D GRAVITY INVERSION FOR MULTI-INTERFACES

ZHANG Minghua(Chinese Academy of Geoexploration, 31 College Road, Beijing, 100083, China, Email: zhmh-cag@china2.ygi.edu.cn) Hou Junsheng(China University of Geosciences, 29 College Road, Beijing,100083,China); Liu Kuanhou(The second branch, Chinese Academy of Geoexploration, Longshou Bei Road, Xi'an, 710016, China)

In order to determine depths to multiple strata with high resolution, we improved BP network method software. The measure is to utilize as many as possible geophysical vectors as nodes in the input layer of the network. The ambiguity in inversion is thus reduced. Had passed theoretical tests, the improved BP method software IBPS was applied in Liaohe Oil Field to determine depths to two main density interfaces. Twelve samples scattered over studied area are chosen for training. Each sample consists of Bouguer anomaly and its three directional derivatives, and two depth data to the interfaces. Result showed that inversion was convergent to real depths form lots of drilling and 3-D seismic, and that similarity or paralleling of upper interface to lower one disappeared, and that character of interface does not depend much on the number of samples used to train the network in general. In Huebei Oil Field, reservoirs discovered in recent years are buried mountains of Paleozoic, especially in Ordovician. It is difficult, however, for 2-D Seismic to reveal them because Ordovician is too deep, more than 5000m. IBPS is applied to solve this problem. Two drilling data and depth data at eight reliable points from 2-D seismic interpretation made in 80s are used for training. 1:50000 Bouguer anomaly is used for the network generalization. Three interfaces between upper Tertiary and lower Tertiary, Mesozoic and Paleozoic, and upper Paleozoic and lower Paleozoic, buried mountains and main faults are revealed. A large buried mountain under Dou Zhang is quite clear and some smaller buried mountains can also be recognized. Drilling from gravity interpretation based on IBPS has found a large reservoir at well ZM in Dou Zhang area in November 1998. The effectiveness of IBPS shows that it can be used for 3-D interpretation of gravity anomalies due to multi-interfaces, and that it is better than conventional methods.

COUPLED INVERSION OF EARTH ROTATION AND GLOBAL MAGNETIC FIELD IN THE DECADAL TIME SCALE

L.BALLANI, H.Greiner-Mai and D.Stromeyer (all at GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany, email: bal@gfz-potsdam.de)

An overview is given on some inverse problems related to the Earth rotation, the fluid outer core motion and the global magnetic field. Especially, the non-harmonic downward continuation of the surface magnetic field, assuming a non-vanishing electrical mantle conductivity, appears as the solution of an inverse boundary value problem which is connected with the mantle induction equation. It is a suitable tool for calculating the coupling torques numerically. As one example for the joint inversion of the Earth rotation and the magnetic field, the rigid relative rotation of a fluid outer core layer is studied. The amount of an intermediate inertial moment of this layer can be estimated which is responsible for the coupling and the correlation observable in the data.

REGIONAL AND RESIDUEL ISOSTATIC ANOMALIES OF WESTERN TURKEY AND THEIR CORELATION WITH MAJOR TECTONIC PROVINCES

Mümtaz Hisarli (Engineering Faculty,University of Istanbul, Avcilar Kampüsü, Istanbul, Turkey, email: mhisarli@istanbul.edu.tr) Naci Orbay (Engineering Faculty,University of Istanbul, Avcilar Kampüsü, Istanbul,Turkey, email: norbay@istanbul.edu.tr)

The aim of this study is to display more clearly gravity anomalies by geologic bodies in the upper parts of the crust of the Western Turkey. The topographic data and gravity data set are taken from National Data Center and Mineral Resarch and Exploration Institute of Turkey (M.T.A.) which have a resolution 5 by 5 min., respectively. Regional isostatic gravity map is based on an Airy-Heiskanen model of local compensation, which assumes that surface topography is supported by crustal thickening. This model requires a choice of values for three parameters: 1- a depth of compensation for sea level elevations, 2- a density contrast across the bottom of the root, and 3- a density of topographic load. These parameters are determined directly from the topographic elevations, free-air gravity, and Bouguer gravity data set for Western Turkey. The depth of compensation for sea level elevation of 25 km is determined using a spectral method applied to free-air gravity data. The density contrast between the crust and mantle of 0.61 g/ cm3 is determined from crossplots of the Bouguer gravity values versus topographic elevations. The density of topographic load of 2.6 g/cm3 is determined using fractal technique.
In order to remove the isostatic component from the Bouguer gravity anomalies Airyroot algorithm used. The isostatic residual gravity anomalies are obtained by subtracting the regional isostatic anomaly values from the Bouguer gravity anomaly values of Western Turkey. The obtained residual gravity anomaly map is correlated with the tectonics structure of Western Turkey. As a result, the residual gravity anomalies are correspond to the E-W and NE-SW graben structures of the Western Anatolian.

GEOPHYSICAL INVESTIGATION OF A TERTIARY MAAR NEAR BARUTH (SAXONY, GERMANY)

GABRIEL, G., Pucher, R., Schulz, R., Wiederhold, H., Wonik, T. (Geowissenschaftliche Gemeinschaftsaufgaben, Stilleweg 2, 30657 Hannover, Germany;
e-mail: gerald.gabriel@gga-hannover.de)

From regional gravity studies two local minima in the vicinity of Kleinsaubernitz and Baruth (Saxony, Germany) are known. The gravity low of Kleinsaubernitz is caused by 300 m limnic sediments underlying 200 m of miocene series, as could be proofed by drilling in 1970. Therefore, new interpretations proceeded on the assumption that the source of the anomaly Baruth (-7 mGal) is also a tertiary maar, produced by a phreatomagmatic explosion. In 1998 two research boreholes (280 m and 100 m deep) were realized by Geowissenschaftliche Gemeinschaftsaufgaben (Hanover, Germany) in order to enable various geoscientific studies. Extensive prelimenary investigations were carried out with the aim to determine the best location for drilling. The different geophysical methods applied comprise gravity, magnetic, geoelectric and seismic surveys. Borehole measurements and VSP complemented these data sets later.
This poster presents a three-dimensional gravity modell, that shows a fit of the observed and calculated gravity field better than 0.3 mGal. The geometry of the geological bodies and their densities take into account the results of the different geophysical investigations. Thus, the modell can be seen as a synthesis of the actual state of the geoscientific knowledge. The tertiary maar of Baruth is nearly circular symmetric, its lateral extent is about 1200 m, whereas the thickness of the limnic sediments is 200 m.

GEOPHYSICAL CONSTRAINTS ON CONCEALED FAULTS – YORO FAULT AREA, CENTRAL JAPAN

Shigeo OKUMA, Yasuaki Murata, Masahiko Makino and Tadashi Nakatsuka (all at Geological Survey of Japan, 1-1-3 Higashi, Tsukuba, Ibaraki, 305-8567 Japan, email: okuma@gsj.go.jp)

High-resolution gravity and aeromagnetic surveys were conducted to reveal subsurface fault system at the western edge of the Nobi plain, Central Japan. Gravity values were observed at an interval of 20-50 m on the ground along three east-west lines with leveling. The gravity survey was successful to reveal buried faults in the eastern flank of the Yoro Mountains, showing small gravity changes (~ 2 mgal) which were not apparent in regional maps. A 2.5-dimensional model inversion was applied to interpret the gravity anomalies, referring to the result of a seismic reflection survey, which was conducted on the same line as the southernmost gravity profile. The resultant model show a concealed reverse fault, the Yoro fault, lying along the eastern flank of the Yoro Mountains with a vertical uplift of 2,000-3,000 m. The aeromagnetic survey was flown along east-west flight lines at an altitude of 300 m above ground and spaced 300 m apart, employing a kinematic GPS system. A magnetic high lies over the northern edge of the Yoro Mountains, showing a wider distribution of green rocks (altered basaltic volcanic rocks) than was expected. The magnetization intensity map derived from magnetic anomalies clearly shows that a magnetic body lies in the east flank of the northern part of the Yoro Mountains bounded by the assumed Yoro fault to the east. The results of combined analyses of gravity and magnetic anomalies for the area will be presented.

SOME RESULTS FROM THE REPRESENTATION OF THE LIVINGSTON ISLAND MAGNETIC ANOMALIES WITH A SET OF ELEMENTARY SOURCES

Zh. Zhelev (1), T.Petrova (1), Vl. Stanchev (2), D. Dimov (2) (1) Geophysical Institute, 1113 Sofia, Bulgaria, (2) Sofia University, Sofia, Bulgaria email: Jelev@geophys.bas.bg / Fax : (3592) - 70 02 26

The Livington island magnetic anomalies were studied with a set of elementary sources model. After some preliminary polynomial approximations to eliminate some residuals of the regional trend (so that to ease the optimisation), the local anomalies together with the rest of the trend are modeled with a set of point sources and a linear trend. The unknown parameters of the suggested model are determined through optimization. The obtained results seems to be quite in agreement with the intrusive bodies supposed to be in the upper part of the crust at different depths in this region.

JSA40/W/10-B3 Poster **1400-12**

SOME NEW RESULTS OF THE REPRESENTATION OF THE ALCALA DEL EBRO (ZARAGOZA) ANOMALY WITH A SET OF ELLEMENTARY POINT SOURSES

Zh. Zhelev (1), T. Petrova (1) ,R. Wiera (2) and F. Montesions (2) (1) Geophysical Institute, 1113 Sofia, Bulgaria, (2) Institute de Astronomia y Geodesia, 28040, Madrid, Spain email: Petrova@geophys.bas.bg / Fax: (3592) - 70 02 26

The Alcala del Ebro (Zaragoza) gravity anomaly was studied with a set of point masses model. After a preliminary polinomial approximation to eliminate the main part of the regional trend (so that to ease the optimization proccess) the local gravity anomalies together with the rest ot the trend are modeled with a set of elementary point sources and a linear trend. The unknown parameters of the suggested model are determined through optimization. The obtained results seems to be quite in agreement with carstic cavities filled with water or sediments supposed to be at depths of 12 to 20m. and the terrain colapces taken plase in the last years in this region (Alcala der Ebro villaga - Zaragoza, Spain).

JSA40/W/11-B3 Poster **1400-13**

SOME RESULTS ON THE REPRESENTATION OF SEVERAL MAGNETIC ANOMALIES OF BULGARIA WITH ELEMENTARY SOURCES

Zh. Zhelev (1), T. Petrova (1) (1) Geophysical Institute, 1113 Sofia, Bulgaria email: Jelev@geophys.bas.bg / Fax: (3592) - 70 02 26 email: Petrova@geophys.bas.bg / Fax: (3592) - 70 02 26

Several complicated magnetic anomalies from the territory of South Bulgaria are interpretate with a set of elementary sources. The unknown parameters of the model (the depths of the sourses and the respective masses) are approximately determined through optimizationnn. A model of the corresponding magnetic field in the obtained results seems to be with a good agreement with the expectations on the base of other independent information.

MODELING AND EXPERIMENTS AT REGIONAL MAGNETIC ANOMALY ON EASTERN EDGE OF THE RUSSIAN PLATFORM

Natalia Fedorova, Sergei Maksimovskikh, Natalia Vinnichuk (Institute of Geophysics, 100 Amundsen str., Ekaterinburg,620016, Russia. Fax:+7 3432 678872, Email: seva@maglab.mplik.ru

What kind of magnetisation - induced or remanent dominates in rocks in lower part of the crust is the problem under discussion. We examined the problem both by using modelling and experiment in situ at the regional magnetic anomalies located at the eastern part of the Russian platform. The sizes of anomalies are 60-200 km and total field intensities in their epicenters varies from 500 to 1500 nT. According to results of the anomalous magnetic field (AMF) interpretation the centres of magnetic sources disposes at the depths of 15-25 km. We assumed that rocks have only induced magnetisation and modeled changes of the AMF increment for different variations of external geomagnetic field: substorms, SQ and secular variations. In summer periods the total field magnitudes at our latitude are 20-30 nT while change in declination are 0.25 deg. Than according to our model AMF must have increment 0.5-1.5 nT and maximum of the increment must be disposed at the edge of anomaly but not in its epicenter. The induced effect was observed in situ during experiment at Manchagh anomaly in summer 1998. Besides the anomalous behaviuor of total field secular variation was revealed in the epicenter of the anomaly in 1969-1979. The result of modelling allowed us to explain this phenomenon as the manifestation of induced effect from magnetised rock.

A NEW APPROACH TO 2D INTERPRETATION OF POTENTIAL FIELD ANOMALIES

Nick Kostrov and Valery Kormiltsev (Institute of Geophysics, 100 Amundsen Str., Ekaterinburg, 620016, Russia. Email: root@maglab.mplik.ru, fax: +7 3432 678 880)

We developed a 2D interpretation complex to construct geophysical models of lithosphere utilizing potential fields data. The complex allow us to fit the anomalous magnetic field curves. The models can tell us about a range of magnetic susceptibility of Earth's crust based on potential fields observations. We represent cross-sections of the bodies and inhomogeneities as a set of arbitrary polygons with or without holes because a such delineation is more suitable from the geological point of view. Our method is based on the numerical solution of vector integral equation of Fredholm type 2 by means of triangulation of each source polygon into subareas so small that physical properties within them can be considered as constant. Green's function of a particular triangle is calculated analytically as a difference between inner complex logarithmic potentials of rectangle and outer one of the inscribed triangles adjoining to the particular.
Besides, the complex permits to interpret gravity field separately or magnetic and gravity field jointly. There are examples of practical implementation of our method including cases of highly magnetized objects with inhomogeneous distribution of magnetic susceptibility.

THE 3D GEOMETRY OF THE LINGLONG GRANITIC COMPLEX FROM 2D GRAVITY FORWARD MODELLING, SHANDONG PROVINCE, EAST CHINA

HUALIN ZENG(Department of Applied Geophysics, China University of Geosciences (Beijing),29 Xueyuan Road, Beijing 100083,China. E-mail: hualinzeng@sky.cugb.edu.cn.) Tianfeng Wan(Department of Geology and Mineral Resources, China Universityof Geosciences (Beijing),29 Xueyuan Road, Beijing 100083,China. E-mail: wantf@sky.cugb.edu.cn.) Christian Teyssier (Department of Geology and Geophysics, University of Minnesota, 108 Pillsburg Hall, 310 Pillsburg Drive S.E., Minneapolis, MN55455, USA. E-mail: teyssier@tc.umn.edu). Changli Yao(Department of Applied Geophysics, China University of Geosciences (Beijing),29 Xueyuan Road, Beijing 100083,China. E-mail: yaocl@sky.cugb.edu.cn.) Basil Tikoff (Department of Geology and Geophysics, University of Minnesota, 108 Pillsburg Hall, 310 Pillsburg Drive S.E., Minneapolis, MN 55455, USA. E-mail: btikoff@gold.tc.umn.edu.)

The three-dimensional geometry of the Linglong granitic complex, which hosts the largest gold deposit field in China, Shandong Province, East China, is derived from 2D gravity forward modeling, constrained by geological data. A study on the geometry of the granite body at depth is particularly significant in order to better understand emplacement mechanisms and guide gold exploration. The geometry of the granitic complex is analyzed using 2D gravity forward modeling, constrained by the outcrops of the granites along each modeled profile. Anomalies along the profile were modeled using an interactive program derived from 2.5D forward

modeling techniques. The results show that the Linglong granitic complex is a sheet-like body with 3100 km2 in areal extent, and a maximum thickness of 8 km. It is not a deeply rooted batholith as previously inferred.

INTEGRATED INTERPRETATION OF THE COMPONENTS OF THE ANOMALOUS OF THE GEOMAGNETIC FIELD IN CUBAN TERRITOR

Rosa ALVAREZ, Jose Luis Cuevas, Lazaro Diaz, Eduardo Perez. (Institute of Geophysics and Astronomy, Science, Technology and Environmental Minister, 212 N. 2906 e/29 y31, La Lisa, Havana, Cuba)

The integration of different interpretation methodologies of the anomalous geomagnetic field in the Cuban territory demonstrated a more effective use of the geomagnetic information in the application of the geology and tectonic studies.
For our purpose were use the vectorial primary information from land surveys in our territory and different kinds of the mathematical and graphical processing as well image processing of the three components and spectral analysis.
Finally, was possible to obtain one and two-dimensional models for the region in dependence of the methods of processing. Also a regional tectonic chart was obtained based on the geomagnetic and gravimetric interpretation

THE PHYSICAL NATURE OF THERMOELECTRIC EFFECT OF NATURAL MINERALS

RASULOV D.Kh. Lange Institute of Hydrogeology and Engineering Geology Tashkent, Uzbekistan, e-mail: root@ariel.tashkent.su

Despite the large volume of laboratory experimental data stored about thermoelectric effect of natural minerals the question of its origin has still remained open. Theoretical models suggested before could not explain the thermoelectric effect peculiarities. Therefore in work proposed the piezoelectric model formation of thermoelectric effect of natural minerals. According to this model, the mechanism of generation piezoelectric polarization take place as follows. Under influence the difference of temperature operating to speciment of mineral in it arise the mechanical tensions. These mechanical tensions stimulate the thruting pressure of combined water, that contain in minerals. Many natural minerals contain quartz, that is piezoelectric crystal. Under influence of mechanical stress in such crystals form the difference of potentials between opposite faces. Proposed model was made it possible to explain data of experimental observations. From experimental data the author estimated the value of variation mechanical tension of sub-crystalline rocks, when their temperature change on a one degree. This value equals 5000 Pa/degree.

EDGE ENHANCEMENT ON MAGNETIC DATA IN THE NORTHERN NILE VALLEY, EGYPT

MESBAH Maher A. Dept of Geological and Geophysical Engineering; Faculty of Pet. and Min. Eng., Suez Canal University. e-mail: mmesbah@frcu.eun.eg

Manual methods of the determination of faults from geophysical contour maps are influenced by personal experiences and views. In contrast, automated approaches give unbiased results. Therefore, the edge enhancement technique which is frequently used for mapping lineament on satellite images is adapted for detecting edges (faults) from magnetic data. the technique includes six sequential steps; three of them are typically applied in the digital processing of the remotely sensed images, while new three steps are added. Eight directional components are obtained by applying this technique. the adapted steps include vector to raster transformation, calculation of the directional components and smoothing them, contrast stretching, tracing of edges and frequency analysis of the extracted faults in the eight components. These steps are consequently applied on the reduced to the pole aeromagneticmap of the northern Nile Valley. Results of this application reflect the presence of faults in the eight directional components with various densities, extensions and patterns. Directions of these faults are recognized through eight directions (E-W, N-S, NW-SE, NE-SW, WNW-ESE, NNW, SSE, ENE-WSW, and NNE-SSW). The frequency analysis of these directions showed that the dominant directions of faults are the E-W, N-S, NNE-SSW, NE-SW and ENE-WSW directions, respectively.

A PROPOSED SEISMIC / GEODETIC SUBSURFACE ANALYSIS BASED ON THE BIHARMONIC EQUIVALENT OF POISSON'S EQUATION

HARDY Rolland L. (International Institutes of Science and Technology, U.S. Post Office Bldg., Suite 202, 305 Avenue B, Bogalusa, LA 70427)

The biharmonic equivalent of Poisson's equation is defined here as follows. The biharmonic operator on potential at a point density is doubled the right hand side of Poisson's equation for the same point density. The mathematical proof of this and other matters are provided in the body of this presentation. This relationship had brought about the replacement of the point mass model with a point density model as the first step of the procedure. The point density model avoids the difficulties associated with point masses. Point masses procedure impulse responses at zero distances. Point densities produce null responses at zero distances. Our point density model works extremely well for interpolating scattered geodetic surface data. The unknowns in our system of equations are interpretable as point density anomalies. It is customary to place the point density anomalies at shallow or near zero depths in the vicinity of the surface data. This cannot be done with point masses. We have not been concerned with the possible usefulness of the geodetically estimated point densities for other purposes. They simply provide the basis for smooth interpolation of several geodetic parameters, which fit data values exactly. In any case we are not competing with seismologists who in a sense are measuring densities, instead of estimating them. In fact we believe that geodetic interpolation could be improved with the use of seismic density data. That is why we are proposing a joint venture in seismic/geodetic subsurface analysis.

PHENOMENOLOGICAL MODEL OF THE LOCAL TIDAL VARIATIONS

A.Zanimonska (Appl. Math. Dep.,Kharkiv State Univ., Ukraine) J.Cisak (Institute of Geodesy and Cartography, Warsaw, Poland) Y.ZANIMONSKIY (Institute of Geodesy and Cartography, Warsaw, Poland, tempor.)

In the observatory Borowa Gora near Warsaw for the geodynamic researches the efforts for organization of permanent station with the portable ballistic gravimeter are applied. Due to absence a vibration damping system in this gravimeter, observation were organized during the nights and non-working days. The presence of essential breaks in data series make it necessary to reduce the spectral leakage of surplus local tidal variations. These variations cannot be calculated by means the ordinary tidal models and are estimated in the data of a relative gravimeter, reaching 0,01mGal. Data processing and modelling were carried out by means it description as an analytical signal with parameters obtained by Hilbert transformation. The basic attention was given to representation and interpretation data in time domain and usage of a short-term spectrum on a subday intervals.
The transitive characteristic with small nonlinearity and delay phenomenologically takes into account the tidal displacements of the TT-zone border. Tidal forces are fully determined and as the signal on the input of a black box make it possible to calculate the local amendments for the any moment of time. The choice of optimal strategy for a tidal gravimeter usage is going to discuss too.

TERRESTRIAL CLIMATE-RELATED OBSERVATIONS AND SATELLITE DATA

Josef Cihlar (GCOS/GTOS Terrestrial Observation Panel for Climate c/o Canada Centre for Remote Sensing Ottawa, Ontario, Canada. E-mail: josef/cihlar@ccrs.nrcan.gc.ca)

Concerns about the magnitude and rate of environmental changes at various spatial scales have led to the realization of the need for systematic, sustained observations that would help improve our understanding of these changes as well as facilitate the development and implementation of appropriate response actions. In the climate-terrestrial domain, the climate processes, climate impacts on the ecosystems and feedbacks to climate are of primary interest. To address these issues, the Global Climate Observing System (GCOS) and the Global Terrestrial Observing System (GTOS) have collaborated through a joint Terrestrial Observation Panel for Climate (TOPC). Following an analysis of scientific and modelling issues, TOPC identified a limited number of critical variables that need to be determined at various temporal frequencies and spatial resolutions, globally (GCOS-32). Given the extreme heterogeneity and the logistical as well as financial difficulties of collecting surface measurements, a combination of satellite and surface measurements is the only feasible response to these observation requirements. TOPC proposed a five-tier strategy, with Tier 1 consisting of few sites where many variables are observed using complex instruments (and possibly for a limited period) to Tier 5 consisting of a complete satellite coverage of the global landmass. The intermediate tiers consist of surface observatories focused on ecological, cryospheric, and hydrological processes and related variables. This tier-based framework takes advantage of the existing observation networks, employing their capabilities for climate studies and for an improved use of satellite data. Both surface and satellite observations to date have deficiencies with respect to climate applications because most of these were not intended to be used for this purpose. Aspects such as comprehensiveness of observations, consistency and comparability of methods, calibration, and others therefore need considerable improvements. These improvements, followed up by the establishments of long-term sustained observation programs are a major challenge for the global observing systems. They are being pursued in collaboration with surface regional networks and with the space agencies as part of an Integrated Global Observation Strategy. The numerous present and planned satellite missions will make possible major improvements in global terrestrial observations. The Kyoto Protocol and the importance of terrestrial carbon sinks therein, as well as recent emphasis the need for systematic climate observations by COP-4, have underlined the importance and urgency of these implementation activities.

JSM41/W/25-B3 Invited **0930**

THE ROLE OF SATELLITE DATA IN THE ATMOSPHERIC COMPONENT OF GCOS

M.J. Manton (Bureau of Meteorology Research Centre, Melbourne, Victoria, Australia, Email: m.manton@bom.gov.au)

The Global Climate Observing System (GCOS) is an international program aimed at ensuring that the overall global observing system accounts for the various needs of the world-wide climate community. In addition to supporting regional climate activities, GCOS provides key data for seasonal to inter-annual prediction and for activities under the UN Framework Convention on Climate Change. The atmospheric component of GCOS builds on the existing networks of the World Weather Watch (WWW) and the Global Atmosphere Watch (GAW) of the World Meteorological Organization (WMO). A significant component of the additional benefits of GCOS is the promotion of baseline measurements that allow both for the calibration of regional networks and for the monitoring of global features of the climate system. In situ baseline networks of GCOS are the GCOS Upper Air Network (GUAN) and the GCOS Surface Network (GSN). Satellite data play a vital role in complementing these in situ observations.First satellite observations are used to support the calibration and validation of in situ data, such as GUAN. Secondly they make a vital contribution to data assimilation by providing global coverage of atmospheric variables, and this contribution is especially apparent in reanalysis projects. The third contribution of satellite data is through the generation of specific products, such as cloud analyses and precipitation products. These routine data sets are recognised by GCOS as providing essential global products on the state of the climate system. Satellite data are of fundamental importance to GCOS in the monitoring of the global radiation budget. While satellite data are vital to the overall climate observing system, their value is limited unless rigorous standards of calibration and consistency are established and maintained. Long-term climate monitoring requires much more stringent quality control than that which is normally applied to satellite missions of short-term duration. One of the roles of GCOS is to work with the relevant agencies to ensure that these issues are taken into account in all relevant observation programs.

JSM41/W/33-B3 Invited **1000**

THE OCEAN OBSERVING SYSTEM FOR CLIMATE

Neville SMITH (Bureau of Meteorology Research Centre, Melbourne Vic. 3001, AUSTRALIA,

E-mail: N.Smith@BoM.GOV.AU)

The concepts of a Global Ocean Observing System and a Global Climate Observing System (GOOS and GCOS, respectively) were developed nearly ten years ago. Ocean observations for climate lie at the intersection of these two systems. Through the first half of this decade, a conceptual design for the ocean observing system for climate was developed, building upon the technical and scientific advances of Programs like the Tropical Oceans-Global Atmosphere Experiment (TOGA, 1985-94) and the World Ocean Circulation Experiment (WOCE, 1990-). The design described a system that would serve operational seasonal-to-interannual prediction, climate monitoring (e.g., sea level rise) and the development of various other climate products (e.g., global sea surface temperature and surface wind analyses). Subsequently there has been a concerted effort to identify the appropriate methods and mechanisms to implement and maintain the system. The observing system for seasonal-to-interannual prediction was given high priority, as was the development of a global in situ and remote network for monitoring variations in global sea level. A large fraction of the proposed elements now have long-term support. Unlike meteorology, oceanography did not have access to an implementation mechanism dedicated to the cause of ocean and climate observations. Recent decisions have now created such a body, the Joint Technical Commission for Oceanography and Marine Meteorology, to serve GOOS and GCOS plus research needs. Several other strategies are being developed to encourage long-term investment in the ocean observing system. The Global Ocean Data Assimilation Experiment (see Smith, "Toward Operational Oceanography And Climate Prediction", U7 Symposium on Integrated Global Monitoring Networks, this Conference) is being used to develop and promote an integrated approach and to develop and implement the required ocean estimation methods. GODAE is also working hard with the satellite community to ensure the requisite remote sensing systems are available. Argo, an initiative to populate the global oceans with profiling floats, will provide a greatly enhanced capability to sample the subsurface ocean. A set of ocean "observatories", using advanced mooring technology, are being proposed to provide on-going, improved estimates of ocean-atmosphere fluxes and provide extended Eulerian ocean time-series. The recent meeting of the Conference of the Parties to the Framework Convention on Climate Change accepted that increased efforts must be made to address gaps in the Global Observing Networks. Such recommendations have...

JSM41/L/02-B3 Invited 1050

TOWARD A SATELLITE-BASED CLIMATE OBSERVING SYSTEM

Graeme L Stephens (Colorado State University, Department of Atmospheric Science, Ft. Collins, CO 80523-1371, 970-491-8550 (voice), 970-491-3430 (fax), email: stephens@atmos.colostate.edu, cc: email: linin@atmos.colostate.edu).

Tracking the course of climate change requires a commitment to global-scale observations maintained over periods extending beyond decades and longer. The need to understand the nature of climate change to the point of ultimately assigning cause and effect places stringent and as yet not well understood requirements on these global-scale observations. In a statistical sense it is a difficult enough task to identify (typical) small trends in observed variables above the (typical) observed large climatic variability. This task is made all the more difficult by changing observing practices over the course of time. The problem of observing climate is now at an acute stage given the worldwide demise of conventional meteorological observing networks.
The scientific and programmatic challenge before us is to put in place an observing system or systems that provide observations of key parameters with both sufficient precision and accuracy on time scales that exceed duration of commitment.
The ongoing demise of conventional observing networks places increasing importance on use of satellite measurements not only to fulfil the operational needs of meteorological agencies but also to serve as the basis of a global climate observing system. The regular-in-time and global-in-space nature of these satellite observations makes them particularly attractive for climate research and monitoring purposes. Current operational satellite systems, however, are not optimized for this purpose. In using these operational-based satellite observations, scientists over the past decade have struggled in an attempt to understand and take account of such factors as lack of sensor calibration, sampling problems associated with platform drifts, lack of continuity of observations among a number of other issues.
The definition and design of a climate observing system is a topic of obvious importance in the realm of global climate change. It is also a topic under study by operational satellite agencies which now consider climate either as part of their mandate or are in the process of considering climate requirements in the planning for future observing systems. An example of this consideration has occurred through during the process of the convergence of the US military and civilian meteorological satellite programs under NPOESS.
This talk attempts to discuss critical elements of a climate observing system and will draw on examples and lessons learned from experience in using current satellite data. The distinction between monitoring versus climate process observations will be addressed and some suggestion as to the basic traits of observing systems that address these two distinct aspects of climate will be discussed.

Presiding Chair: P.Schluessel (Meteorologisches Institut, Universitaet Muenchen, Germany)

ATMOSPHERIC MONITORING

JSM41/L/05-B3 Invited 1120

REANALYSIS OF THE TOVS NOAA/NASA PATHFINDER ARCHIVE: APPLICATION TO CLIMATE RESEARCH

Alain CHEDIN

Improving our understanding of the Earth's climate natural variability as well as detecting potential anthropogenic climate change require, in particular, accurate estimates of many coherently determined surface, atmospheric, thermodynamic, and chemical variables. Among them, some vary quite slowly in time and space while others may vary by several orders of magnitude and in a very complex way, involving many factors. It is now recognized that the value of a global (time and space) description of their characteristics, both in the troposphere and in the stratosphere, is extremely high at this time.
Advances in the ongoing research are based on a multidisciplinary approach, using both modeling and observation. Only by using this approach can such advances be made in the understanding of the earth-ocean-atmosphere system and its sensitivity to anthropogenic changes and allow to make predictions about its short- and medium-term evolution. The basic tool for observing the planet on a global and continuous basis is the satellite, in either a polar or geostationary orbit. In this way, the main components of the Earth system can be observed with instruments which measure the radiances in either high of low spatial or spectral resolutions in a large variety of wavelengths (microwaves, infrared, visible and beyond). A few years ago, NOAA and NASA initiated the Pathfinder programme for the reanalysis of operational meteorological satellite observations.
We present, in this paper, the main characteristics of the TOVS Pathfinder 'Path-B' data set, resulting from the reanalysis of High resolution Infrared Radiation Sounder (HIRS-2) and Microwave Sounding Unit (MSU) observations with the 'Improved Initialization Inversion' (3I) physico-statistical retrieval algorithm. This method is 'model-independent' (no influence of any forecast of climate model products), and takes great care of eliminating systematic biases that might occur, during one satellite life, or from one satellite to another, between calculated and observed radiances. 3I-derived climate variables are: the temperature and the water vapor vertical structure, the surface temperature and characteristics (emissivity, presence of snow, ice, deserts, etc.), the cloud field description (top, amount, type), and more integrated products like the longwave vertical radiative fluxes. Several auxiliary data sets (RAOBs in-situ measurements, SSM/I, AVHRR or ERBE observations, ISCCP or model analyses, etc.) have been used to carry out extensive validations of 3I-derived variables. If the validation...

JSM41/E/04-B3 1150

RESULTS FROM THE NOAA AVHRR ATMOSPHERIC PATHFINDER PROJECT

GEORGE OHRING and Herbert Jacobowitz (NOAA/NESDIS Office of Research and Applications 5200 Auth Rd. Suitland, MD 20746-4304)

This paper reports on the data sets of the NOAA AVHRR Atmospheric Pathfinder Program and their applicability to climate studies. As part of the NOAA/NASA Pathfinder Program, NOAA is reprocessing the archived AVHRR observations since 1981 into research quality atmospheric data sets. The raw observations were recalibrated using a vicarious calibration technique for the visible and near-infrared channels and an improved treatment of non-linearity for the infrared channels. State-of-the-art algorithms are used to process the global observations into channel radiances, total cloud amount, the components of the Earth's radiation budget (Outgoing Longwave Radiation and Absorbed Solar Radiation), and aerosol optical thickness (ocean areas only). The radiances and Earth radiation components are determined for clear, cloudy, and all-sky conditions. The output products are generated on an equal area grid with a resolution of approximately 110 km (1o latitude by 1o longitude at the equator), twice daily, and averaged over 5 day (pentad) and monthly periods. Applications of the data sets to radiative forcing, aerosol-cloud interactions,surface temperature/absorbed solar radiation/cloud relationships, and monitoring volcanic aerosols are presented. Problems with the use of the AVHRR for some climate studies are also described.

JSM41/E/10-B3 1205

INTER-ANNUAL VARIABILITY OF ATMOSPHERIC WATER VAPOR AS SEEN FROM THE TOVS PATHFINDER PATH A DATA SET

AMITA MEHTA and Joel Susskind 910.4, NASA-Goddard Space Flight Center Greenbelt, MD USA 20771

The atmospheric water vapour is a major greenhouse gas and plays a critical role in determining energy and water cycle in the climate system. A new, global, long-term (1985-98) water vapour data set derived from the TIROS Operational Vertical Sounder (TOVS) Path A system will be introduced in the presentation. An assessment of the accuracy of the TOVS Path A water vapour data will be presented. The focus of this oral presentation will be on the inter-annual variability of the water vapour distribution in the atmosphere and how it affects clear-sky outgoing longwave radiation variability. A comparison of water vapour distribution during 1986/97 and 1997/98 ENSO will also be presented.

JSM41/W/30-B3 1220

DERIVATION OF GLOBAL WATER VAPOUR DISTRIBUTIONS FROM ATSR DATA

Ian BARTON (CSIRO Marine Research, Australia, Email: ian.barton@marine.csiro.au)

A new product to be provided by the ATSR instrument team is a global distribution of averaged infrared brightness temperatures on a spatial scale of 18 km (10 arc-minutes in latitude and longitude). Data for a one-month period are analysed to demonstrate the potential of these data to provide a vertical and horizontal distribution of water vapour amounts over the global oceans. The six ATSR infrared channels (nadir and forward views at three wavelengths) are applied in a similar manner to those on the infrared sounding channels on the operational meteorological satellites. The weighting functions of the ATSR channels are found to give better vertical resolution in the lower troposphere than the typical channels used in the latest operational instruments.

JSM41/P/01-B3 1235

SEASONAL AND INTERANNUAL VARIABRITY OF BRIGHTNESS TEMPERATURE OVER INDIAN SUBCONTINENT

Ramesh P. SINGH and Nrusingha C. Mshra (both at Department of Civil Engineering, Indian Institute of Technology, Kanpur - 208 016, India, email: ramesh@iitk.ac.in)

The seasonal and yearly variations of brightness temperature measured by SSM/I satellite over land and ocean regions of India during the years 1987 to 1995 show characteristic behaviour. The brightness temperature variations over Indian land region is attributed to the different geological divisions of India. The brightness temperature variations over Arabian ocean and Bay of Bengal show systematic pattern. The brightness temperature changes significantly with latitude which show typical pattern. These systematic and typical pattern is interpreted in relation to seasonal and interannual variability of Monsoon over India and surrounding regions. From the brightness temperature, the snow thickness in the northern part of India, liquid water path (LWP) and total precipitable water (TPW) have been deduced for different seasons and also analysed yearly during 1987 - 1995. The effect of the north-west and south-west monsoon is clearly seen on the seasonal and interannual variations of brightness temperature and meteorological parameters. The role of seasonal and interannual variations of brightness temperature will be discussed in the global change and climatic variations.

Wednesday 28 July PM

JSM41/W/13-B3 1400

GNSS OCCULATION SOUNDING FOR CLIMATE MONITORING AND ATMOSPHERIC CHANGE ANALYSIS

Gottfried Kirchengast and Andrea K. STEINER (Institut fuer Meteorologie und Geophysik, Universitaet Graz, Halbaerthgasse 1, A-8010 Graz, Austria, Email: andi.steiner@kfunigraz.ac.at), Luis Kornblueh, Elisa Manzini, and Lennart Bengtsson (Max-Planck-Institut fuer Meteorologie, Bundesstrasse55,D-20146 Hamburg, Germany)

The Global Navigation Satellite System (GPS and GLONASS, generically GNSS) based radio occultation technique is an active limb sounding technique exploiting quasi-horizontal transatmospheric sat-to-sat links. Both neutral atmospheric and ionospheric refractive

properties are probed and profiles of associated fundamental atmospheric variables such as temperature, humidity, and electron density can be retrieved with high quality. The method bears great utility for climate studies in providing an unique combination of global coverage, high vertical resolution and accuracy, long-term stability, and all-weather capability. A domain of highest strength of the method is the profiling of the thermal structure in the upper troposphere and stratosphere. As indications exist that the changing thermal structure in this domain is a sensitive indicator of atmospheric change (or climate change) and anthropogenic climatic impacts, respectively, we expect that occultation sounding can furnish unique data to globally monitor this changing structure with unprecedented accuracy.
We undertook to rigorously test the climate monitoring and atmospheric change detection capability of GNSS occultations by an integrated analysis involving: (i) realistic modeling of both the neutral atmosphere (T42L39-GCM up to the mesopause) and ionosphere (empirical, solar-activity dependent 4D model) over the time span 1995 to 2020, (ii) realistic observation system simulations of observables (phases and amplitudes) of a small GNSS receiver constellation (6 satellites) over this time period, (iii) a state-of-the-art occultation data processing chain for temperature profile retrieval in the upper troposphere/stratosphere (core region 8 to 40 km) for establishing a significant set of realistic simulated measurements over the period, (iv) a multivariate statistical analysis of 1996-2020 temporal trends in latitude-height slices of both the "true" states from the atmospheric modeling and the "measured" states from the database of retrieved temperature profiles, and (v) an assessment, by methods of statistical inference, of whether and to what degree the GNSS occultation observing system was able to detect trends in the atmospheric evolution (i.e., atmospheric change) from 1996 to 2020.
This ambitious study is expected to be still in progress at the time of the meeting and the latest status will thus be reported. We will discuss in some detail how we actually implemented steps (i) to (v) noted above, with emphasis on critical scientific and technical areas. Furthermore, we plan to present preliminary results on the climate trend analysis.

JSM41/E/23-B3 1415

CLOUD-RADIATIVE FORCING TO FORM A COLD AIR-MASS WITH LOW-LEVEL CLOUDS OVER THE SUBARCTIC NORTH PACIFIC DURING SPRING AND SUMMER

HIROSHI KAWAMURA, Hiroyuki Takeda and Nobuyuki Kikuchi Center for Atmospheric and Oceanic Studies, Tohoku University, Sendai 980, Japan

It is known by the ship observations that the subarctic North Pacific is frequently covered by low-level clouds (LLC) and fogs during spring to summer. It is also confirmed by the historical records of air temperature that the air-mass in the boundary layer over this ocean is rather uniform and colder, by about 5C, than that over lands in the same latitude band. This air mass occasionally blows toward south-west and bring cold summer to Japan, which causes serious agricultural damages and called "Yamase event".
In order to understand formation process of the cold air-mass over the subarctic ocean, the role of LLCs is investigated using the ISCCP (International Cloud Climatrogy Project) data set. It is shown that LLC amount over the ocean north of 40N exceeds 70% in summer season, and optical thickness of LLC increases with time and has a peak in July. A core of the optically thick cloud is located in the Bering Sea. To estimate the LLC radiative forcing, radiation at the top of LLC and cloud-free surface is calculated by a radiative transfer code. The ISCCP cloud parameters are used as well as atmospheric parameters of the ECMWF data. The grid and time step of calculation are 280x280km and 1 minute, respectively. The monthly statistics are derived from the estimates obtained for five years of 1988-1992. The short wave radiation is reduced to 50% because of reflection at the cloud top. In contrast, the upward long wave radiation at the cloud top does not differ so much from that at the ocean surface because the altitude of cloud is low and the top temperature is close to SST. The strong contrast in the net radiation over the lands and oceans north of 40N is evident, and this is the main reason for generation of the cold air mass over the subarctic North Pacific during spring to summer.

JSM41/W/11-B3 1430

A NEW SATELLITE-BASED CLIMATOLOGY OF CLOUDS IN THE NEW ZEALAND REGION

Howard LARSEN, Warren Gray, and Peter Norris, National Institute for Water and Atmospheric Research, PO Box 14-901, Wellington, New Zealand, email: h.larsen@niwa.cri.nz

A cloud climatology of the New Zealand - South West Pacific region has been derived from AVHRR satellite data using a new cloud classification algorithm. The high-resolution climatology covers a large area of the ocean region around New Zealand, some 3500 km square, from 22°S to 55°S and 150° E to 167° W. It is based on data from May 1997 to the present. Clouds have been classified directly into classes based on their radiative properties and their spatial variability rather than traditional 'cloud type' classes.
Results from the first year of operation show clearly differentiated patterns of cloud coverage at different cloud heights and the effects of the New Zealand landmass. Low, warm clouds, for example, were frequent in a band between 40ºS and 50ºS but their occurrence is suppressed for several hundred kilometres either side of the New Zealand landmass. Significant seasonal variations in the pattern of cloud cover over the region are also apparent. Current GCM output is not entirely consistent with the measurements represented in the climatology, suggesting refinements are needed in modelling cloud-climate interactions in this region. Some of the discrepancies in modelled low cloud estimates are consistent with ocean-atmosphere interactions.

JSM41/L/04-B3 1445

CLOUD CLIMATOLOGY FROM NOAA-9 SPLIT WINDOW AND COMPARISON BETWEEN CLOUD TYPE FROM SPLIT WINDOW AND TRMM RAIN OBSERVATIONS

Toshiro Inoue (Ph.D. Meteorological Research Institute, 1-1, Nagamine, Tsukuba, Ibaraki 305-0052, Japan TEL : +81-298-52-9046(direct) FAX : +81-298-55-2552 e-mail: tinoue@mri-jma.go.jp FAX : +81-298-55-2683)

Using split window data, we can classify optically thin ice cloud and optically thick clouds. We construct the monthly mean cloud cover map for three cloud types (cumulonimbus-, cirrus- and low-level stratocumulus/cumulus- type) over the quasi- global area (50N-50S) in 1987 and 1988 from the split window data on board NOAA-9. The meaning of the cloud type classification by split window is verified using the rainfall information observed from PR (Precipitation Radar) data on board TRMM(Tropical Rainfall Measuring Mission). The TRMM has also VIRS (Visible and Infrared Scanner) and TMI(TRMM Microwave Imager). Using the split window of VIRS, coincident and collocated cloud type information and PR rainfall information are compared. We found optically thicker and colder cloud classified by the split window corresponded well to the PR/TRMM rainfall data.

JSM41/W/10-B3 1500

VARIABILITY IN SURFACE TEMPERATURE, CLOUDS, AND SEA ICE COVER IN THE POLAR REGIONS INFERRED FROM INFRARED AND PASSIVE MICROWAVE DATA

JOSEFINO C. COMISO (Laboratory for Hydrospheric Processes, Code 971, NASA/Goddard Space Flight Center, Greenbelt, MD, USA, 20771, email: comiso@joey.gsfc.nasa.gov)

Two decades of satellite infrared and passive microwave data have been analyzed to study seasonal and decadal changes in surface temperature, cloud cover, and sea ice cover in the polar regions. The data analyzed were derived from three key sensors, namely: the Advanced Very High Resolution Radiometer (AVHRR), the Scanning Multichannel Microwave Radiometer (SMMR), and the Special Scanning Microwave Radiometer (SSM/I). To better understand what two decades of data can reveal compared to one or a fraction, we analyzed several decades of in-situ temperature measurements and our results indicates that the trend values tend to stabilize as soon as fifteen to twenty years of data are available. The results of our analysis indicate significant warming in both poles, similar to what has been observed from station data, while the sea ice cover show decreases in extent in the north and no significant change in the south. Large seasonal and interannual variability is however observed, and the presence of the Antarctic Circumpolar Wave in the south, that goes around the continent at a periodicity of eight years, may affect ability to detect changes in the extent of the ice cover. Surface temperatures inferred from infrared data are also biased because of inability to obtain data during cloudy conditions. Cloud statistics from AVHRR data and possible effects on the surface temperature and ice cover will be presented.

JSM 41/E/28-B3 1515

SIX YEARS OF COMPOSITE INFRA-RED IMAGES SOUTH OF FORTY DEGREES SOUTH AT THREE HOUR INTERVALS

Charles STEARNS, Bruce Sinkula, Rob Holmes, Matt Lazzara, and J.T. Young (all at Space Science and Engineering Center, Universsity of Wisconsin, 1225 West Dayton Street, Madison, Wisconsin 53711, USA)

At the University of Wisconsin Antarctic Meteorological Research Center (UWAMRC) a composite infrared (IR) image of Antarctica is formed every three hours and saved to an optical disk. The image is of the 11.5 to 12.5 micrometer (surface temperature) band: the image is 1.0 megabyte in size: the resolution is 10km. Regions without data in the 100 minute sampling window white. The initial geostationary satellites used and their longitude are GOES-7 , 112 degrees West; GMS, 140 degrees East; Meteosat-3, 0 degrees; Meteosat-4, 75 degrees West,. The initial polar orbiting are NOAA 11 and NOAA 12. The time of the composite images is within 50 minutes of the indicated time on the image. The image extends from the South Pole to approximately 34 degrees South in the corners with New Zealand in the upper left hand corner and to 58 degrees South at the edges closest to the South Pole. A VHS tape of the composite IR images from 31 October 1992 to 30 November 1998 is prepared from the archive at the UWAMRC. The original image resolution is 10 km but the transfer of the images to the tape increases the resolution to about 20 km. Each image is displayed for 0.3 seconds. Images are timed and dated for reference when requesting more detailed data from the UWAMRC.

JSM41/L/02-B3 Invited 1550

A SATELLITE-DERIVED FRESHWATER FLUX CLIMATOLOGY: THE HAMBURG OCEAN ATMOSPHERE PARAMETERS AND FLUXES FROM SATELLITE DATA

Jörg Schulz , Peter Bauer, Lars Schanz (German Aerospace Center, Linder Höhe, D-51147 Köln, Germany, email: joerg.schulz@dlr.de), Volker Jost (Meteorologisches Institut, Universität Hamburg, Bundesstraße 55, D-20146 Hamburg, Germany, email: jost@dkrz.de), Peter Schlüssel (Meteorologisches Institut, Universität München, Theresienstraße 37, D-80333 München, Germany, email: schluessel@meteo.physik.uni-muenchen.de)

Knowledge of turbulent fluxes between ocean and atmosphere is along with radiative fluxes of great importance to improve our understanding of the large scale climate system. Accurate estimates of these fields can be used as a direct forcing of ocean circulation models or for evaluating the results of coupled climate models that have obviously problems at the air-sea interface. In this talk a climatology of freshwater flux at the sea surface will be presented together with a review of the used retrieval schemes, a comprehensive error assessment, and some examples for the application of such a climatology. The climatology extends over 10.5 years of data and consists of global fields of latent heat flux, freshwater flux, net longwave flux, rainfall, and all associated atmospheric and oceanic parameters. The error assessment is based on validation of the retrieval algorithms and on comparisons to other climatologies constructed from different type of data. As an example comparisons to buoy data gained during the subduction experiment 1991 to 1993 in the eastern subtropical North Atlantic will be shown. This data set is one of the few data sets which are useful to compare not only instantaneous measurements but also long time averages.
Time sampling errors mostly concerning precipitation measurements in the tropics have been assessed by comparisons to radar data gained during TOGA COARE. The sampling error for a grid resolution of 2° by 3° and a sampling time of 3 weeks can be as high as 30% if only one satellite overpass per day was available. If data of two SSM/Is were combined this error can be diminished to less than 4% in the case of 4 overpasses a day.
Improvements of the climatology can be expected if knowledge gained from the Tropical Rainfall Measuring Mission (TRMM) is used to improve SSM/I rainfall algorithms. This shall reflect in both reduction of random error through higher accuracy of TRMM retrievals and reduction of systematic time sampling errors by knowing more about the mean diurnal cycle of precipitation over the ocean.

JSM41/E/01-B3 1620

GLOBAL MONITORING OF PRECIPITATION ON MONTHLY AND SHORTER TIME SCALES UTILIZING LOW-ORBIT AND GEOSYNCHRONOUS SATELLITE OBSERVATIONS

ROBERT ADLER, NASA/Goddard Space Flight Center, Code 912, Greenbelt, MD, 20771 ; Scott Curtis, NASA/GSFC, JCET/UMBC, Code 912, Greenbelt, MD, 20771 George Huffman, NASA/GSFC, SSAI, Code 912, Greenbelt, MD, 20771 David Bolvin, NASA/GSFC, SSAI, Code 912, Greenbelt, MD, 20771 Eric Nelkin, NASA/GSFC, SSAI, Code 912, Greenbelt, MD, 20771

A satellite-based system to monitor global precipitation on monthly and shorter time scales is described. The monitoring system is based primarily on the Global Precipitation Climatology Project (GPCP) global, monthly, 2.5ƒx 2.5ƒ latitude-longitude product which utilizes precipitation estimates from low-orbit microwave sensors (SSM/I) and geosynchronous IR sensors and raingauge information over land. The low-orbit microwave estimates are used to adjust or correct the geosynchronous IR estimates, thereby maximizing the utility of the more physically based microwave estimates and the finer time sampling of the geosynchronous observations. Information from raingauges is blended into the analyses over land. This globally complete, monthly product is available from January 1986 to the present, with an extension

back to January 1979 underway using non-SSM/I data.
The monthly GPCP merged data product is augmented in real-time by low-orbit microwave (SSM/I) estimates. Anomalies from climatological means are produced from both the GPCP and microwave fields to monitor the evolution of global precipitation, including the calculation of ENSO precipitation indices for real-time (five-day running means) climate monitoring and comparison with previous ENSO anomalies.
On an even shorter time scale, a new daily, 1ƒ x 1ƒ latitude-longitude global analysis has been developed starting in January 1997 utilizing low-orbit microwave and geosynchronous IR information using a similar method as is used to produce the monthly GPCP product.

SATELLITE REMOTE SENSING OF PRECIPITATION

ERIC BARRETT (School of Geographical Sciences, University of Bristol, Bristol, BS8 1SS, UK, Email: e.c.barrett@bris.ac.uk)

As recently as 30 years ago, knowledge of global precipitation amounts, distributions, and temporal variabilities relied almost entirely on measurements made by raingauges. Rainfall climatologies even from that era were almost all limited to the continental land masses, excluding Antarctica as well as the North Polar ice cap. More recently, much additional information has been gathered by remote sensing systems, notably by ground-based weather radar, but most of all from meteorological satellites operating passively in the visible, infrared, and microwave regions of the electromagnetic spectrum, and newly (since 1997) actively too, in the microwave region. Thus, although raingauge networks have generally declined in recent decades, as this paper illustrates our knowledge of global rainfall climatologies today has become much more advanced. This fact is important not only for its own sake, but also on account of the significance of precipitation for global modelling, especially of the atmosphere, hydrosphere, cryosphere and biosphere. This review paper first recalls some of the more significant findings of satellite remote sensing in respect of precipitation since 1969. Next, it identifies some of the greatest problems and challenges facing the satellite precipitation science community today. Finally, it suggests where related resources might be focused most usefully in the near-term future, not least to ensure that appropriate information on global precipitation on time-scales ranging from seasonal-interannual to decadal be secured for a wide range of potential end-users.

JSM41/W/01-B3 1705

A COMBINED INFRARED AND MICROWAVE TECHNIQUE FOR STUDYING THE DIURNAL VARIATION OF RAINFALL OVER AMAZONIA

ANDREW J. NEGRI (1), Emmanouil Anagnostou (2) and Robert F. Adler (1) (1) NASA/GSFC, Laboratory for Atmospheres, Greenbelt, MD 20771, e-mail: negri@erin.gsfc.nasa.gov (2) Dept. of Civil and Environmental Engineering, U. Conn., Storrs, CT 06269

Over 10 years of continuous data from the Special Sensor Microwave Imager (SSM/I) aboard a series of Defense Department satellites has made it possible to construct regional rainfall climatologies at high spatial resolution. Using the Goddard Profiling Algorithm (GPROF), monthly estimates of precipitation were made over the region of northern Brazil, including the Amazon Basin, for 1987 to 1998. GPROF is a physical approach to passive microwave precipitation retrieval, which uses the Goddard Cumulus Ensemble (cloud) model to establish prior probability densities of precipitation structures. Precipitation fields from GPROF were stratified into morning and evening satellite overpasses, and accumulated at monthly intervals at 0.5 degree spatial resolution. Important diurnal effects were noted in the analysis, the most pronounced being a land/sea breeze circulation along the northern coast of Brazil and a mountain/valley circulation along the Andes. There were also indications of morning rainfall maxima along the major rivers, and evening maxima between the rivers. The addition of simultaneous geosynchronous infrared (IR) data leads to the current technique, which takes advantage of the 30 minute sampling and 4 km spatial resolution of the infrared channel and the better physics of the microwave retrieval. The resultant IR method is subsequently used to derive the diurnal variability of rainfall over the Amazon basin, and further, to investigate the relative contribution from its convective and stratiform components.

JSM41/E/06-B3 1720

GLOBAL PRECIPITATION FIELDS FROM ACTIVE MICROWAVE SENSORS

G.D. Quartly, T.H. GUYMER and M.A. Srokosz Southampton Oceanography Centre, Empress Dock, Southampton, Hants, SO17 3SH

For over a decade precipitation information has been available from infrared satellites such as METEOSAT and passive microwave sensors such as SSM/I. Recently developments have been made in the processing of active microwave data from the TOPEX altimeter so that it too can provide information on rain. This talk will summarise the technique and examine the fields produced from 6 years of consistent data from one satellite. The processing yields not only the familiar geographical patterns of rainfall but reasonable estimates of the rain rates involved. The small footprint of the instrument allows studies of the short-scale variations in rainfall, which reveal the organization of rain events typically to have a larger size to the west of ocean basins than to the east. As the altimeter also provides estimates of the wave height and wind speed, we can observe which weather conditions the precipitation is preferentially associated with. We will compare our results with studies using infrared and passive microwave sensors, indicating both the advantages and disadvantages of a TOPEX- derived climatology, and discuss the prospects for further active microwave sensors, such as TRMM (launched in November 1997) and TRMM II.

JSM41/E/29-B3 1735

SSMI WIND SPEED CLIMATOLOGY OF THE TIME OF MONSOON WIND ONSET IN THE WESTERN ARABIAN SEA

DAVID HALPERN (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109-8099, U.S.A., email halpern@pacific.jpl.nasa.gov)

Forecasting the time of onset of monsoon wind in the western Arabian Sea is an important unsolved problem. Prior to measurements of the surface wind field by satellite, there was an absence of suitable surface wind observations over the Arabian Sea. The NASA scatterometer (NSCAT) surface wind vectors revealed that the time of the 1997 onset of 12 m/s south-west monsoon wind speeds in the western Arabian Sea preceded the onset of monsoon rainfall in Goa, India, by 3 - 4 days. Wind speed and direction data were necessary to establish a dynamical mechanism between times of onset of 12 m/s wind speed off Somalia and rainfall in Goa. Except for NSCAT, no satellite scatterometer wind product recorded adequately sampled 2-day 1° x 1° averaged wind vectors, which are the required space and time scales, to examine the onset of the Somali Jet. However, the greater-than-95% steadiness of summer monsoon winds allows the use of satellite measurements of surface wind speed. The Special Sensor Microwave Imager (SSMI) recorded surface wind speed with adequate sampling to produce a 1-day, 1° x 1° data product during 1988 - 1998. SSMI data had been uniformly processed throughout the period. Times of onset of SSMI 12 m/s wind speed off Somalia were 21 May 1988, 24 May 1989, 17 May 1990, 28 May 1991, 8 June 1992, 28 May 1993, 30 May 1994, 7 June 1995, 29 May 1996, 12 June 1997, and 15 May 1998. Uncertainty of the 1992 and 1996 times of onset were increased because of the absence of SSMI data on 6 and 7 June 1992 and on 30 May 1996. Correlations of the timing of monsoon wind onset with El Niño will be described. The difference between times of onset of 12 m/s wind speed and Goa rainfall will be discussed. At the time of abstract submission, Goa rainfall data have not arrived from the India Meteorological Department.

JSM41/E/17-B3 1750

SIMULTANEOUS REMOTE SENSING OF AEROSOL FEATURES AND SURFACE REFLECTANCE WITH SPACE-BORNE SPECTROMETRY

Daren LU, Mingzhen Duan,(Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029,CHINA, e-mail: ludr@sun.ihep.ac.cn)

In quantitative remote sensing of atmospheric and earth surface parameters with space-borne optically spectral sensors, atmospheric correction and surface (background) influence deduction are key steps for both surface and atmospheric remote sensing, respectively. In principle, these two steps are with same task, i.e., decoupling or separation of respective contributions to spectral radiance (or normalized reflectance) observed by space-borne sensors. A lot of efforts have been paid to solve this problem. Most of them are using supplementary information obtained by ground-based observation or climatological means for the atmosphere or surfaces. Owing to the limitations of simultaneous surface measurements and temporal and spatial variation of the atmosphere and earth surfaces, above-mentioned efforts are always faced significant error or very limited usefulness. It is commonly recognized that the best or ideal way is simultaneous remote sensing of the atmosphere and surface with space-borne sensors alone (with least assumptions). In general there are three approaches towards simultaneous remote sensing, i.e., multi-angle measurements, multi-spectral measurements, and multi-polarization measurements, and their combinations. In different assumptions, each of them may apply to simultaneous remote sensing. After general discussion, this paper will mainly focus on the approach with multi-spectral observation in Visible-NIR waveband. The present approach includes two steps, the first step is to establish approximate formulae which may explicitly give quantitative contribution of the atmosphere and surface to satellite-borne sensors measurements. The second step is to establish retrieval scheme by using the above mentioned formulae and the spectral dependence of both the atmospheric optical depth and surface reflectance. Details about principle and preliminary results are given in this paper.

ATMOSPHERIC MODELLING BY MONITORRING

JSM41/W/28-B4 0930

POTENTIAL OF METEOSAT SECOND GENERATION TO CLIMATE MONITORING

Yves M. Govaerts, Arlindo Arriaga and Johannes Schmetz (EUMETSAT, Am Kavalleriesand 31, D-64295 Darmstadt, Germany, email govaerts@eumetsat.de, arriaga@eumetsat.de, schmetz@eumetsat.de)

In 2000, EUMETSAT will launch the first Meteosat Second Generation (MSG-1) satellite centred on zero degree longitude. In comparison with the current Meteosat satellites, the MSG system will feature enhanced observation capabilities. Its Spinning Enhanced Visible and Infrared Imager (SEVIRI) provides data in 12 spectral channels instead of 3, distributed throughout the short and long wave parts of the electromagnetic spectrum. The imaging frequency is 15 minutes and the sampling resolution at the sub-satellite point is 3´ 3 km for all channels except the VIS high-resolution band which has a 1´ 1 km nadir resolution. The above enhancements have been driven by the increasingly stringent requirements of the meteorological user community in the areas of nowcasting and numerical weather prediction. The combined improvements in spectral coverage, imaging frequency and ground resolution were needed to better characterise clouds and the vertical structure of the atmosphere, to improve the sampling of dangerous weather patterns, and to derive more accurate atmospheric motion vectors. Calibration of the IR channels is carried out using on-board blackbody operated at two temperatures and vicarious calibration methods. The visible and near infrared channels calibration relies on vicarious method using bright desert targets. Calibration is a critical requirement for climate applications and the expected accuracy will be discussed first. The SEVIRI characteristics, in conjunction with the MSG mission duration (at least 12 years of continuous observations), provide the basis for improved and new products to be used for climate monitoring. The climate observations of SEVIRI are wide spread with enhanced capabilities for observing cloud micro-physical properties, water vapour and land surfaces. In particular, the increased spectral coverage and time-space sampling of MSG imagery are expected to open new avenues for the study of land surface properties, their diurnal variation, and the associated land surface and land-atmosphere interaction processes. Various examples of climate product derived form MSG observations will be given. MSG also carries a radiation budget scanner (GERB), the first instrument of this type in geostationary orbit. Simultaneous observations of spectral radiances from SEVIRI and broadband radiances from GERB will enable novel studies of regional radiation budget parameters.

JSM41/E/22-B4 0945

THE ANTARCTIC METEOROLOGY RESEARCH CENTER: AN INTEGRATED METEOROLOGICAL DATABASE FOR RESEARCH IN THE SOUTHERN HIGH LATITUDES

Matthew Lazzara, George WEIDNER, J.T. Young and Charles Stearns (all at the Space Sceince and Engineering Center Universsity of Wisconsin, 1225 West Dayton Street, Madison, Wisconsin 53706, USA)

The Antarctic Meteorological Research Center (AMRC) was created in 1992 with funding from the National Science Foundation's United States Antarctic Program (USAP) Office of Polar Programs (OPP) to provide improved access to meteorological data available in Antarctica to the wider scientific community, provide a single source for data from both ground based and satellite derived meteorological data and to provide real-time date to those tasked with providing weather forecasts in support of operations funded by USAP during the Austral Summer field season. Since, meteorological data from Antarctica is only some 40 years old, satellite derived data sets for the Antarctic represent a larger fraction of the recorded data than in other areas. For the Antarctic, the integration of satellite derived data with other data sets provides an important contribution to the study of climate change in the high latitudes and the connections at various time scales between the lower and higher latitudes. Since that time the AMRC has collected, archived and made available to users a significant amount of meteorological data in support of atmospheric research, research in other fields requiring meteorological data, operational forecasting and educational support. A review of the present

set of data collected and archived by the AMRC will be given. These data sets include satellite data from the geostationary and polar-orbiting satellites, synoptic observations, radiosonde observations, automatic weather (AWS) observations and National Meteorological Center's (NMC) Medium Range Forecast Model (MRF) analyses and forecast for use over Antarctica. Recent product additions are a low-mid level infrared wind product and satellite derived winds from the water vapour channel of the GMS-5 satellite in an online archive. Future data from anticipated new satellite platforms will be presented. Examples of the current uses of the AMRC database will be given.

THE STRATOSPHERIC AEROSOL AND GAS EXPERIMENT III

Larry W. Thomason (Atmospheric Sciences Division, NASA Langley Research Center, Hampton, VA 23681 USA, Email: l.w.thomason@larc.nasa.gov). Michael C. PITTS (Science Applications International Corporation, One Enterprise Parkway, Suite 250, Hampton, VA 23666, USA, email: m.c.pitts@larc.nasa.gov)

The Stratospheric Aerosol and Gas Experimen (SAGE) III is the latest in a series of satellite-based instruments to use the polar occultation technique to measure stratospheric and upper tropospheric aerosols and trace gas species. The first instrument will be launched aboard a Russian Meteor 3M platform in Fall 1999. Later flights are scheduled for the International Space Station in 2002 and a Flight-of-Opportunity between 2000 and 2005. SAGE III preserves the robust characteristics of the SAGE series, including self-calibration and high vertical resolution, and adds new capabilities designed to contribute to understanding global climate change. Among these enhancements is a lunar occultation mode in which night time species such as nitrogen trioxide and chlorine dioxide are measured (in addition to ozone and nitrogen dioxide). During solar occultation, measurements of the oxygen A band will be used to infer temperature and pressure profiles from 0 to 85 km. In addition, finer spectral resolution measurements of nitrogen dioxide features near 440 nm and ozone around 600 nm will improve the quality of inferences of those species relative to SAGE II measurements. The spectral coverage of aerosol extinction measurements has been extended to 8 measurements between 385 and 1550 nm compared to SAGE II measurements at 385, 453, 525, and 1020 nm. SAGE III should make significant contributions to understanding the long-term ozone trend and the processes that underlie it. In this presentation, we will discuss the SAGE III instrument design, retrieval algorithm, data products, and plans for validation.

AN EMPIRICAL MODEL FOR GLOBAL ATMOSPHERIC TEMPERATURE ANOMALIES

Olavi KARNER (Tartu Observatory, 61602 Toravere, Estonia, email: olavi@aai.ee)

Global record of temperature fluctuations in the lower troposphere (the lowest 5 miles of the atmosphere) and the lower stratosphere (covering an altitude range of about 9-12 miles) have been monitored by satellite since 1979. The monthly-averaged temperature anomalies for the entire length of record, available online http://www.ghcc.msfc.nasa.gov/temperature/), have been analysed by means of fitted autoregressive and integrated moving average (ARIMA) models. A nonstationary first order IMA model appears to be appropriate to represent the temporal variability of global temperature anomalies during the period. The model explains about 95 per cent of variance in the stratospheric case. This enables one to use it for short-term predictions of the anomalies. An example will be presented.

JSM41/E/32-B4 Poster **1010-03**

RADIOMETRIC CALIBRATION OF THE EARTH'S SCAN IMAGES TRANSMITTED BY GEOSTATIONARY SATELLITE GOMS IN THE VISUAL AND IR SPECTRAL RANGES

S.G.PUGACHEVA, V.V.Shevchenko (both at Sternberg State Astronomical Institute, Moscow University, Universitetskii pr.13, Moscow, 119899, Russia, email: pugach@sai.msu.su)

The technique of calibrating scan images using the Moon's image can be successfully used for the radiometric calibration of the onboard apparatus of the first Russian geostationary artificial meteorological satellite (GOMS) launched on October 31, 1994, in accordance with the program Meteorological Service for the Population. For realization of meteorologic observations satellite GOMS has television complex, which gives in actual time scale of the digital images of a cloudy, snow and ice cover and measures of radiation temperature of a surface of an ocean, land and high bound of a clouds. The calibration procedure is based on the comparison of the output data of the onboard apparatus of the geostationary satellite GOMS with a photometric database that includes measured values of brightness and temperature for a large number of lunar-surface areas. To this end, an automated database was created, which contains brightness and temperature values for 1954 areas of the lunar surface, measured by the global scanning of the illuminated lunar disk in the visual (0.445 micron) and infrared (10-12 micron) spectral ranges during a complete lunation. It is known that the emission of the lunar surface in the visual and infrared spectral ranges is stable and constant in space and time and can easily be described analytically. A generalized digital analytical model of the lunar brightness and thermal fields makes it possible to calculate the necessary photometric parameters, surface brightness and temperature for any geometry of the angular parameters of photography and illumination with an accuracy achieved by ground-based photometry. The root-mean-square errors in the determination of the rightness and of the radiation temperature are + 1.5 relative units and + 1.5 K, respectively. The IR channel records thermal fluxes objects with radiation temperatures between 213 and 313 K. The noise level does not exceed 1 K.

HIGH RESOLUTION SYNOPTIC TOTAL OZONE IMAGING FROM A GEOSTATIONARY SATELLITE : A CASE STUDY USING GOES-8 INFRARED RETRIEVALS, GOME OBSERVATIONS AND A NUMERICAL ADVECTION MODEL

Yvan J. ORSOLINI (Norwegian Institute for Air Research; email: orsolini@nilu.no) Fernand Karcher (METEO-FRANCE, Centre National de Recherches Meteorologiques, Toulouse)

The second generation European weather satellite to be launched near the year 2000 is designed to routinely and synoptically monitor total ozone using infrared remote sensing, with a full coverage of the Earth disk. These total ozone observations are likely to convey a wealth of information about dynamical processes in the lower stratosphere. Hence, there is a need for validation and characterization of total ozone structures observed from geostationary satellites before ozone IR remote sensing from such a platform could be routinely used for meteorological applications. A set of high spatial resolution (pixel size near .1 degree) total ozone synoptic images have been produced hourly for the period February 23 to 24 using the GOES-8 IR radiance in 13 channels. The GOES-derived total ozone in the imaging window, covering the eastern US and contiguous maritime areas, is validated against the total ozone measured by GOME. These images show with great detail fine-scale total ozone filaments. The reality of such features is corroborated by a 5-day numerical simulation of the ozone distribution using analysed ECMWF winds, and an initial 3D ozone field from Microwave Limb Sounder data from the Upper Atmosphere Research Satellite.

OCEAN MONITORING

JSM41/L/03-B4 Invited **1040**

GLOBAL SEA SURFACE TEMPERATURE MONITORING FROM SPACE; CURRENT ISSUES OF DEFINITION, ACCURACY AND VALIDATION.

Ian S. Robinson (School of Ocean and Earth Science, University of Southampton, Southampton Oceanography Centre, UK)

Sea surface temperature (SST) is a variable, readily measured from space, which has importance as a driver of air-sea interaction processes, for assimilation into coupled ocean-atmosphere models, and as an indicator of climate change. This talk reviews the differing requirements for accuracy and resolution of global SST data, which are driven by diverse applications of the data. These are compared with the current best achievements of satellite infrared systems in applying corrections for atmospheric effects on the measured radiation. Now that atmospheric correction accuracies using dual-view systems are approaching 0.1 C, it is becoming clear that both the application and the validation of space-derived SST are subject to the thermal structure of the upper ocean. Several reasons are presented to support the proposal that the skin temperature of the upper few microns of the sea surface is the most appropriate measure of SST. This is what is viewed directly by satellite sensors, it is what controls air-sea fluxes, and it is the only definition of SST which is not arbitrarily dependent on the depth of sampling. However, this raises issues of diurnal variability of the skin temperature which need to be handled in a consistent and systematic way in the compilation of SST databases, if SST is to be useful and unambiguous as an indicator of climate change. The potential synergy of geostationary and polar orbiting sensors for generating composite SST fields is considered in this context. Finally the question of validation is addressed, identifying the need for a more comprehensive availability of in situ radiometric measurements of the skin temperature.

JSM41/W/36-B4 **1110**

THE USE OF RADIATIVE TRANSFER MODELLING IN IMPROVING SATELLITE SEA SURFACE TEMPERATURE RETRIEVAL

BK MCATEE, M Boterhoven, A Rodger, and MJ Lynch (Remote Sensing and Satellite Research Group, School of Physical Sciences, Curtin University of Technology, GPO Box U1987, Perth WA 6845, Australia, email: pmcateebk@cc.curtin.edu.au) AF Pearce (CSIRO Marine Laboratories, PO Box 20, North Beach WA 6020, Australia, email: alan.pearce@marine.csiro.au)

Satellite-derived sea surface temperature (SST) may be improved by the incorporation of regional atmospheric information into the SST retrieval algorithm. Our discussion of satellite SST retrieval will include computer modelling of radiative transfer as well as the development, performance and sensitivity analysis of SST algorithms.
The algorithms currently under development are designed to improve the accuracy of SST retrieval by accounting for seasonal and latitudinal variation in climatic conditions through the incorporation of the computer simulation of the radiative transfer process into the scheme using an atmospheric transmittance model. Data input to the model may be derived from sources such as radiosonde and TOVS measurement of atmospheric properties.
Progress in algorithm development will be discussed along with the effectiveness of particular algorithms in various scenarios and a description of field measurements of SST and validation of the algorithms.

JSM41/W/15-B4 **1125**

SATELLITE OBSERVATIONS OF SEASONAL TO DECADAL VARIABILITY IN THE LARGE-SCALE OCEANIC FRONTAL ZONES

Alexander KAZMIN (Frontier Research System for Global Change/Institute for Global Change Research, SEAVANS N 7F,1-2-1 Shibaura, Minato-ku, Tokyo 105, Japan, email: kazmin@frontier.esto.or.jp)

Sea surface temperature (SST) from weekly global satellite data at 18 km resolution for the period of 1982-97 and estimates of the surface forcing due to wind stress and net heat flux were used to investigate global monthly climatology of the large-scale oceanic frontal zones (OFZ), seasonal and interannual variability of SST gradient in several frontal zones, response of OFZ to decadal climate changes, and the meridional frontogenesis in the North Pacific. A computer animation of the full-resolution monthly climatologies of SST gradient provided detailed dynamic global picture of OFZ seasonal variability. Spectrum analysis of time series of SST gradient revealed a seasonal signal as well as interannual variations that, in the equatorial zone, are related to ENSO events. While 16-year time series is insufficient to detect decadal cycle, it still was useful for documenting the changes in OFZ associated with specific climatic shift of late 1980s from cool to warm conditions in the mid-latitude North Pacific. Both subtropical and subpolar OFZ revealed response to this shift, evident in spatial structure and SST gradient anomalies pattern. Estimates of meridional frontogenesis in the North Pacific due to wind and heat forcing on seasonal and decadal timescales have been compared with observed rates of frontogenesis.

JSM41/E/20-B4 **1140**

A REVIEW ON STUDIES OF THE WARM-CORE RING IN THE KUROSHIO-OYASHIO TRANSITION ZONE USING SATELLITE-DERIVED SSTS AND PREDICTION OF ITS SHORT-TERM VARIATIONS

HIROSHI KAWAMURA Center for Atmospheric and Oceanic Studies, Faculty of Science, Tohoku University, Sendai 980, Japan

The Kuroshio and the Oyashio meet in the Pacific ocean east of Japan and a complex oceanic feature associated with warm and clod eddies appears in this region. Therefore, the Kuroshio-Oyashio transition zone is sometime called "the confluence zone" or "the perturbed region". This region is also well known as one of the good commercial fish grounds in the world ocean. Since the large temperature difference between the Kuroshio and Oyashio waters, there appear many temperature fronts. SSTs derived by AVHRR on board the NOAA series satellite have contributed to understand mechanisms of the oceanic variations and to monitor the front locations, which are associated with the promising commercial fish grounds. In the presentation, the oceanographic studies performed in this region using AVHRR-SSTs are reviewed, focusing on the evolution of understanding toward prediction of the short-term variations relating to the warm-core eddies. The contour dynamics was successfully introduced

to simulate a drastic variation of two warm-core rings, whose boundaries are visualized by the SST images. Predictability of the contour dynamics is examined for four spring seasons by using daily SST images with high-spatial resolution, and almost of the drastic events are well simulated for about three weeks. This means that combination of SST images and the contour dynamics model can be used to predict the short-term variation of warm-core rings. Social needs and practical methodology of the short-term prediction will be presented.

JSM41/W/24-B4 1155

SPACEBORNE SCATTEROMETERS AND MICROWAVE RADIOMETERS IN THE STUDIES OF OCEAN-ATMOSPHERE INTERACTION

W. Timothy LIU and Wenqing Tang (both at Jet Propulsion Laboratory, Caltech, email: liu@pacific.jpl.nasa.gov)

Spaceborne scatterometers are designed to measure ocean surface wind vectors and, therefore, ocean-atmosphere momentum flux, under both clear and cloudy conditions. The scatterometers on a series of European Remote Sensing Satellites (ERS) have provided surface wind measurements since 1991. The National Aeronautics and Space Administration (NASA) launched scatterometers NSCAT in 1996 and Quikscat in 1999, with continuous improvements in spatial resolution and coverage. The operational Special Sensor Microwave / Imagers (SSM/I) have monitored ocean surface wind speed, integrated water vapor (IWV), and rain since 1987. The Tropical Rain Measuring Mission (TRMM) Microwave Imager (TMI), which was launched in 1997 measures additional frequencies from which all weather sea surface temperature (SST) can be retrieved. Ocean surface evaporation or latent heat flux can be derived from the spacebased measurements of wind speed, IWV, and SST, or it can be retrieved directly from the radiances observed by TMI.
Three examples will be presented to show oceanic responses (as exhibited through spacebased SST and sea level changes) to surface wind and thermal forcing at different temporal and spatial scales - during the transition of a storm, the seasonal changes of monsoons, and an El Nino episode.

JSM41/E/08-B4 1210

SEA SURFACE TEMPERATURE OBSERVATION FROM TRMM MICROWAVE IMAGER

Misako KACHI, Akira Shibata, Hiroshi Murakami and Keiji Imaoka (Earth Observation Research Center (EORC), National Space Development Agency of Japan (NASDA), 1-9-9 Roppongi, Minato-ku, Tokyo 106-0032, JAPAN, email: kachi@eorc.nasda.go.jp)

The Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI) has an added 10 GHz channel compared to the Special Sensor Microwave Imager (SSM/I) which has been operating since 1987. The 10 GHz channel is more sensitive to sea surface temperature (SST) than higher frequency channels. The SST retrieved from TMI is compared to the monthly mean SST produced by Reynolds and Smith (1994), and accuracy of the monthly TMI SST is within 0.5 C, and it satisfies requirement for SST measurement.
In 1998, the El Nino warm episode was diminished from early to mid May, and sudden cooling of SST over the central and eastern equatorial Pacific was clearly observed from TMI. TMI can measure SST under clouds by using microwave signal from the sea surface, while the infrared sensors cannot. Since TRMM carries the visible infrared sensor, we could compare SST coincidentally observed by both microwave and infrared sensors. NASDA will launch ADEOS-II satellite that also carries both microwave sensor, the Advanced Microwave Scanning Radiometer (AMSR) and visible infrared sensor, the Global Imager (GLI) in 2000. In the same year, NASA will also launch the EOS-PM1 satellite, which carries AMSR-E modified from AMSR. We expect that coincidentally observations of SSTs from microwave and infrared sensors will continue after TRMM.

Thursday 29 July PM

OCEAN MONITORING (CONT)

JSM41/E/13-B4 Invited 1400

OCEAN COLOR REMOTE SENSING AND JAPANESE OCEAN COLOR SATELLITE ACTIVITIES

JOJI ISHIZAKA (Faculty of Fisheries, Nagasaki Univ., 1-14 Bunkyo, Nagasaki,852-8521 Japan, E-mail: ishizaka@net.nagasaki-u.ac.jp)

Ocean color is the only remote sensing technology to monitor biology in the ocean. The Coastal Zone Color Scanner (CZCS) launched by NASA is the first ocean color sensor specifically designed to detect phytoplankton pigments. The sensor collected data during 1978 to 1986, although the sensor was not continuously operated. The spatial and temporal variability of the CZCS phytoplankton pigments was far larger than the biological oceanographers had been expected. After ten years of blank, Ocean Color and Temperature Sensor (OCTS), developed by National Space Development Agency of Japan (NASDA), was onboard of Advanced Earth Observing Satellite (ADEOS) launched on August 1996. Although the satellite stopped operation on June 1997, OCTS collected 8-months (November to June) of fully global 1-km resolution ocean color data. Global composite data and Intensive Local Area Coverage (LAC) data around Japan of sea surface chlorophyll-a were available through internet with near real time. Those data were verified with sea truth data from the global ocean. The ocean color data time series is now continued by NASA SeaWifs. Ocean color remote sensing is now facing the new era. Global Imager (GLI) will be onboard of ADEOS-II launched on the fall of 2000 by NASDA. NASA is planing MODIS, and ESA is planing MERIS. Those sensors have larger numbers of channels than previous sensors and should be useful for the monitoring of coastal waters as well as open ocean. Multi-sensor operation should cover global ocean more frequently than by single-sensor operation. Future challenges of the ocean color remote sensing will be discussed.

JSM41/E/27-B4 Invited 1430

CONTRIBUTIONS OF SATELLITE ALTIMETRY TO GLOBAL OCEAN MONITORING

ROBERT CHENEY (NOAA/NESDIS National Oceanographic Data Center, 1315 East-West Highway, Silver Spring, MD 20910 USA, email: rcheney@nodc.noaa.gov)

An uninterrupted flow of satellite altimeter data has been available since the launch of ERS-1 in 1991 and Topex/Poseidon in 1992. With the Jason-1 and Envisat altimeters due to be launched in 2000, it is likely that we will continue to enjoy this observational wealth for years to come. Satellite altimetry has enabled a variety of phenomena to be monitored in near-real time. Operational applications include tracking of the Loop Current and its eddies in the Gulf of Mexico and assimilation of altimeter sea heights in ocean models used to forecast El Nino. With nearly 7 years of the highly-accurate Topex/Poseidon data already collected, low-frequency phenomena such as the North Atlantic Oscillation are being studied, and stable values for the rise of global sea level are being obtained. This presentation will review progress in these areas and discuss plans for future altimeter missions.

JSM41/W/14-B4 1500

MONITORING A WESTERN BOUNDARY CURRENT USING SATELLITE AND IN-SITU DATA

Richard COLEMAN, Ken Ridgway, Rick Bailey (CSIRO Marine Research, Hobart, Tasmania, Australia, email: r.coleman@marine.csiro.au), Dave Mickler (University of Colorado, Boulder, Colorado, USA)

We compare the circulation through two sections crossing a western boundary current (East Australian Current, EAC) in the Tasman Sea from in-situ XBT casts and T/P altimeter data. The sections cross the current in the north at 26S (Brisbane-Fiji), where the current intensifies and in the south at 34S, just beyond the main separation point of the EAC mean flow.
Surface steric height relative to 800 db (the depth of the casts) is inferred from the XBTs using a high-resolution T-S climatology with the along section mean (from 20 transects observed between 1992-1999) removed to obtain surface anomalies. We also project the steric height onto a deeper reference level (2000 db) using a regression method derived from historical data. Raw along-track T/P data are first mapped onto the location and date of each XBT cast using optimal interpolation. Both in-situ and satellite data are then 'projected' onto 'standard' sections at a uniform along-track spacing. Over 20 realisations of each data type are available over the common period (Oct 1992 - 1999).
The surface height anomalies from each data type are in good agreement (~3-5 cm rms) down to spatial scales of 300 km. Below this length scale, the in-situ data resolves small changes which are beyond the capability of the interpolated altimeter fields. We also investigate the relative proportions of baroclinic to barotropic variability in the altimeter fields. The deeper reference level is needed to resolve the baroclinic flow associated with the EAC and its eddies within the coastal region. Away from this highly energetic region, the 800 db level is generally sufficient to capture the main baroclinic variability. In the north Tasman Sea we observe a region where the T/P variability is significantly less than that of the in-situ data. This would appear to be related to unresolved barotropic flow. The ability of each data type to resolve both spatial and temporal signals of interest is studied using regression methods, spectral analysis and wavelet techniques. The results provide a basis for designing future monitoring programs which utilise these data techniques in an efficient manner.
Finally, we present results documenting the mean flow and variability of the EAC from the combined dataset. We observe interannual fluctuations in the EAC transport of up to 10 Sverdrups.

JSM41/W/09-B4 1515

VARIATIONS OF GLOBAL MEAN SEA LEVEL OBSERVED DURING THE TOPEX / POSEIDON MISSION

R. S. NEREM, D. P. Chambers, E. W. Leuliette, (all at the Center for Space Research, The University of Texas at Austin, Austin, TX, 78712, email:nerem@csr.utexas.edu) G. T. Mitchum (Dept. of Marine Sciences, University of South Florida, 140 Seventh Ave. South, St. Petersburg, FL, 33701, USA, email: mitchum@seas.marine.usf.edu) B. S. Giese (Dept of Oceanography, Texas A&M University, College Station, Texas, 77843, USA, email: giese@sweeney.tamu.edu)

The TOPEX/POSEIDON (T/P) satellite altimeter mission has been mapping global sea level every 10 days since its launch in August 1992. One of the objectives of climate change research is to establish the rate at which global mean sea level is increasing, so that it can be compared to similar predictions from global climate models. For this application, interannual variations can be quite troublesome, as they tend to mask the longer-term variations due to climate change. Using the T/P altimeter data, we observed a sharp rise in global mean sea level (~2 cm) during the 1997-1998 ENSO event, followed by a fall in sea level. We find these variations can be reproduced with GFDL's MOM2 ocean model, allowing us to determine the signal is confined to the upper 300 m of the water column. The sea level observations appear to match similar variations observed in satellite measurements of sea surface temperature over the same time period. In addition, they can be represented by the "ENSO modes" of an EOF analysis of the T/P sea level observations. Finally, comparison of the T/P measurements with tide gauge measurements appears to rule out the observed change being caused by an instrumental effect. These ENSO variations have important implications for using altimeter data to detect climate change, the most notable of which is that a time series of several decades in length may be required unless a technique can be found to remove the ENSO variations from the T/P observations. We are experimenting with several statistical/modelling techniques to accomplish this, and will discuss the progress of these efforts. In addition, we will discuss a physical explanation for why ENSO is changing global mean sea level.

JSM41/W/34-B4 1530

ALTIMETRIC SEA SURFACE HEIGHT (SSH), RELATIVE TO THE ELLIPSOID

Dr John Blaha (Institution: Naval Oceanographic Office Email: lahaj@navo.navy.mil)

Altimetric sea surface height (SSH), relative to the ellipsoid, is produced routinely with sub-5 cm accuracy. Global ocean circulation monitoring that would exploit this precision, will require, in addition, determination of the difference of satellite SSH from the geoid. We show comparisons of two methods to remove the effect of the geoid on SSH over the western North Atlantic. The first method fits the time mean of the SSH record on individual satellite groundtracks to a climatological mean of dynamic height. The second method specifies dynamic height by taking in situ observations along selected groundtracks at the times of altimeter overflights. We show the comparisons on 19 TOPEX/POSEIDON groundtracks sampled by aircraft-deployed bathythermographs in the region 25N-40N, 75W-50W. Temperature profiles, from the surface to 800 m, were taken 15-20 km apart (in the along-track sense) within 24 hr of the altimeter measurements. Steric sea level estimates relative to 2000 dbar were computed from these observations. For comparison purposes, differences were computed between the aircraft dynamic heights and the mean-adjusted altimeter heights. This distribution (along tracks crossing the features of the subtropical gyre) shows the competing effects of measurement error in the bathythermograph data and sampling error in the climatological means.

JSM41/W/06-B4 1545

MONITORING ANTARCTIC ICE SHEET WITH SATELLITE RADAR ALTIMETER DATA

V. Nuth (Dept. of Geological Sciences and the Center for Space Research, The University of Texas at Austin, Austin, TX 78712, email: van@csr.utexas.edu), C. R. Wilson (NASA HQ, Geodynamics and Geopotential Fields Code YS, Washington, DC 20546, email: cwilson@hq.nasa.gov) M. K. Cheng (Center for Space Research, email: cheng@csr.utexas.edu) C. K. Shum (Dept.of Civil and Evironmental Eng. and Geodetic Science, Ohio State University, email: ckshum@osu.edu)

Since the launch of Seasat, radar altimeter data have contributed enormously to the study of glaciology. Until the launch of ICESAT, spaceborn radar altimeter data remain the only means to monitor ice mass balance on a global scale. However, the rugged ice surface topography has meant that this data set cannot be used readily without significant on-ground reprocessing. We use retracked pairs of altimeter measurements at the satellite cross-over points along with a waveform cross-correlation method to compute the estimate of ice sheet elevation changes over time. We report here results obtained from analysis of ERS-1 data over the Antarctic Ice Sheet. Our elevation time series show that while Antarctica as a whole exhibits a reasonable seasonal signal both in amplitude and phase, selected regions in West Antarctica appear to have undergone large elevation changes which are speculated to be associated with seasonal snowfall and other effects.

ESTIMATION OF GLOBAL AIR-SEA TRANSFER OF CO2 USING TOPEX/POSEIDON DUAL-FREQUENCY BACKSCATTER

Nelson FREW, David Glover, Erik Bock, Catherine Goyet, Scott McCue and Richard Healy (Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, 360 Woods Hole Rd., Woods Hole, MA 02543 USA, e-mail: nfrew@whoi.edu)

Global and regional estimates of ocean-atmosphere gas fluxes are limited by the uncertainties in current gas transfer velocity parameterizations. These model functions use wind as the sole controlling parameter. However, many other factors, including boundary layer stability, wave age, and surface films strongly affect gas exchange rates.
We outline a new method for estimation of transfer velocity using altimeter backscatter as a more direct measure of sea surface roughness and, therefore, transfer velocity. The algorithm assumes a linear relationship between mean square wave slope and gas transfer velocity for wavenumbers >50 rad/m. Estimates of mean square wave slope from the nadir-looking C- and Ku-band microwave altimeters aboard TOPEX/Poseidon are used to derive monthly global maps of transfer velocity. The monthly maps show a strong correlation with NCEP and FNMOC global winds for the same periods. The transfer velocity fields, combined with in situ observations and ocean colour estimates of biological productivity, are applied in a 3-D ocean GCM to estimate global seasonal and annual CO2 fluxes. The theoretical background and empirical observations underlying the new algorithm will be presented.

A STUDY OF THE ARCTIC SNOWPACK BY USE OF SYNTHETIC APERTURE RADAR (SAR) IMAGERY

M Johansson and I A BROWN Climate Impacts Research Centre, Björkplan 6A, S-981 42 Kiruna, Sweden email: maria.johansson@natgeo.su.se, iabrown@natgeo.su.se

The extent and properties of the snow cover in polar regions is of great importance to the earth's radiation balance which is influencing the global climate. Therefore snow in the polar regions is an important study object when discussing climate change. A technique using satellite imagery in order to survey and describe the Arctic snowpack would be an important tool in the future, especially as input to global climate models (GCM) and for runoff forecasts made by hydropower companies. The synthetic aperture radar (SAR) is very suitable for operating in polar regions since it is independent of polar nights and cloudy skies. An additional advantage of the SAR-sensor is it's use of microwaves and the microwaves capability to penetrate the surface, i.e. the snowpack and it's substrata, which theoretically gives access to a three dimensional view of the snowpack.
The objective of this work is to investigate the use of SAR-imagery to study snow and snow melt in polar regions. The study focuses on the change in snow distribution and snow composition displayed through backscatter in SAR imagery during one spring season. Field data are collected at two filed sites in northern Sweden and Norway at 3-4 occasions at each field site during spring coincident with the acquired satellite imagery. The vertical variation in the snowpack is described by snow depth, dielectric constant, density and temperature measurements at selected profiles distributed over the field sites. The grain size and the stratigraphy of these profiles are ocularly described as well as the surface roughness of the snow cover. Analyses of ERS-1 and Radarsat-1 imagery are compared with the field observations. The field measurements will give a three-dimensional view of the snow cover which will be the background for a discussion highlighting the possibilities to calculate the snow pack status, i.e. liquid water content, density etc. to predict penetration depths, scattering and absorption of the microwaves at the time of satellite overpass. We will also discuss the need of multi-polarisation SAR-data, here HH and VV, within short time spans and the possibilities to follow the change in the snowpack through SAR-backscatter during spring.

VOLCANIC SO2 EMISSIONS - A 20-YEAR SATELLITE RECORD

Gregg Bluth (Department of Geological Engineeringand Sciences, Michigan Technological University,Houghton, MI 49931, USA, email: gbluth@mtu.edu); Arlin Krueger (Atmospheric Chemistry and Dynamics,NASA/Goddard Space Flight Center, Greenbelt, MD 20771, USA, email: krueger@chapman.gsfc.nasa.gov)

Data from the Total Ozone Mapping Spectrometer (TOMS) instruments have enabled us to develop a near-continuous record of worldwide explosive volcanism since 1978. While the original volcanogenic data product was sulphur dioxide, more recent advances have enabled the detection of ash clouds. In addition to the study of individual eruptions, these data have been used to place constraints on global volcanic SO2 emissions by explosive-type eruptions, both by infrequent, large eruptions and lower level, but more frequent events.
The current TOMS database includes well over 100 eruptions, including multiple eruptions during a continuous episode of activity. The magnitude of SO2 clouds range from >10 million tonnes (Mt) to as little as a few kilotonnes (kt). The longevity, and thereby long-term hazards, of the clouds likewise cover a wide range with Pinatubo removal occurring at a rate of 35 days (e-folding time), most mid-sized (200-5000 kt) eruptions from 2 - 10 days, and most small eruptions decaying within 1-2 days. Previous work estimates that explosive volcanic activity emits on the order of 4 Mt SO2/yr. However, new work suggests this estimate of annual flux may increase due to more intensive examination of the database focusing on smaller events, such as the prolific Nyamuragira volcano, Zaire. We report on some of the longer term (e.g., multiyear to decadal) trends in global volcanic activity observed through satellite observation, and how these trends may affect hazard planning and mitigation efforts. We also update the progress on a new NASA mission in hazard mitigation, VOLCAM, featuring a TOMS instrument upon a geostationary platform.

SATELLITE REMOTE SENSING OF GLOBAL SNOW COVER – A BRIEF HISTORY

R.L. Armstrong, (National Snow and Ice Data Center (NSIDC), Cooperative Institute for Research in Environmental Sciences (CIRES), University of Colorado, Boulder, CO, USA,
email: rlax@kryos.colorado.edu)

Snow cover is an important variable for climate and hydrologic processes due to its effect on energy and moisture budgets. In terms of spatial extent, snow cover is the largest single component of the cryosphere with a mean maximum areal extent of 47 million km2, about 98% of which is located in the Northern Hemisphere. During the past three decades much important information on Northern Hemisphere snow extent has been provided by the NOAA weekly snow extent charts derived from visible-band satellite imagery (e.g. NOAA/AVHRR, GOES, METEOSAT, GMS). This product represents the longest single time series of any geophysical product obtained from satellite. Beginning in 1997 the spatial and temporal resolution of the original analysis (approx. 190 km and 7 days respectively) was improved to become a daily product with a spatial resolution of 25 km. Limitations associated with visible wavelength data include the inability to acquire information below clouds or during darkness and the fact that data are limited to snow extent only. Because of the ability to penetrate clouds, provide data during darkness and the potential to provide an index of snow depth or water equivalent, passive microwave satellite remote sensing can greatly enhance snow measurements based on visible data alone. It is now possible to monitor the global fluctuation of snow cover over a 20 year period using passive microwave data (Scanning Multichannel Microwave Radiometer (SMMR) 1978-1987 and Special Sensor Microwave/Imager (SSM/I), 1987-present). A comparison of the visible and passive microwave time-series shows the visible data to have higher variability but trends are similar showing a decrease of approximately 0.4 % per year. The passive microwave data indicate less snow-covered area than the visible data throughout the year with the greatest differences in the fall and early winter when the snow cover is shallow. Results from new algorithms designed to reduce this error are presented.

JSM41/E/07-B4 **1705**

TOWARDS AUTOMATED MULTISPECTRAL SNOW MAPPING

PETER ROMANOV, Ivan Csiszar, and Garik Gutman NOAA/NESDIS, Office of Research and Applications, Camp Springs, MD

Current daily and weekly snow products at NOAA are generated by analysts, who use visible imagery from geostationary and polar orbiting satellites. There is no automated satellite-derived product based on the visible and/or infrared data, however. The automated satellite-derived snow product based on SSMI and/or AMSU microwave observations is used by the analysts only for verification because of the coarse resolution and remaining ambiguities. The present study is based on GOES Imager, NOAA AVHRR and DMSP SSM/I data over North America during the 1998-1999 snow season. The data from all channels on two GOES imagers (East and West) were intercalibrated with NOAA-14 corresponding channels and updated on a bi-monthly basis. The synergy between SSM/I, GOES Imager, and NOAA AVHRR observations has been utilized by taking advantage of the ability to observe ground surface through clouds by SSM/I, frequent views from GOES throughout the day, and the high resolution full coverage of northern latitudes by AVHRR. The SSM/I daily 30-km spatial resolution automated snow maps are produced routinely at NESDIS. They have been used as the primary source for a daily snow map. The shortcomings of the SSM/I-derived maps, such as spatial resolution and snow detection over forests, have been alleviated by a combined use of visible, mid-IR and IR from GOES and AVHRR. Daily composites based on the maximum brightness temperature have been constructed from GOES and AVHRR. All pixels in a daily composite are then classified into snow, snow-free and cloudy. The visible (0.6 5m) reflectances are corrected for angular effects with a semi-empirical kernel driven model. The mid-infrared reflectances were derived from GOES (3.9 5m) and NOAA (3.7 5m) data by subtracting the thermal component from observed radiances. The mid-IR reflectances did not exhibit any significant angular variability. They are then combined with the visible reflectances to form a snow index that is resistant to data contamination by most cloud types. Daily composites of this index are produced over North America from the combined data of the two GOES Imagers and NOAA-14 AVHRR. To produce weekly snow maps, 7-day composites have been formed based on the maximum snow index, reducing cloud contamination even further and filling the data gaps in the daily composites. We conducted validation and comparison of the derived snow maps with reports from ground stations and the current operational snow analysis at NOAA.

CRYSYS: COLLABORATIVE APPROACH TO MONITORING AND MODELLING THE CRYOSPHERE IN CANADA

BARRY E. GOODISON, Climate Research Branch, Atmospheric Environment Service, 4905 Dufferin Street, Downsview, Ontario, M3H 5T4 Ross D. Brown, Atmospheric Environment Service, 2121 Trans-Canada Highway, Dorval, Québec, H9P 1J3. Claude R. Duguay, Centre d'études nordiques, Université Laval, Sainte-Foy, Québec, G1K 7P4 Gregory M. Flato, Canadian Centre for Climate Modelling and Analysis, Atmospheric Environment Service, P.O. Box 1700, Victoria, British Columbia, V8W 2Y2 Roy M. Koerner, Glaciology, Terrain Sciences Division, Geological Survey of Canada, 601 Booth St., Ottawa, Ontario K1A 0E8 Ellsworth F. LeDrew, Department of Geography, University of Waterloo, Waterloo, Ontario, N2L 3G1 Anne E. Walker, Climate Research Branch, Atmospheric Environment Service, 4905 Dufferin Street, Downsview, Ontario, M3H 5T4

CRYSYS (Use of the Cryospheric System to Monitor Global Change in Canada) is a Canadian collaborative research effort involving 14 universities, four federal institutions, and one non-profit organization, established originally as an Interdisciplinary Science Investigation (IDS) in NASA's Earth Observing System (EOS) Program. Recognizing the importance of the cryosphere in both the global and regional climate system, CRYSYS has evolved to bring together a wide range of Canadian cryospheric expertise in remote sensing, modelling, field investigations, data integration and data management to provide improved capabilities for monitoring the state of the cryosphere, and a greater understanding of cryospheric processes and variability. The main scientific goals of CRYSYS are: (1) to develop capabilities for monitoring and understanding regional and larger-scale variations in cryospheric variables; (2) to contribute to the development and validation of local, regional and global models of climate/cryospheric processes and dynamics, and to improve understanding of the role of the cryosphere in the climate system; and (3) to assemble, maintain and analyze key historical, operational and research cryospheric data sets to support climate monitoring and model validation. These goals are addressed through the cryospheric components especially important within Canada (sea ice, snow, lake ice, glaciers and ice caps, and permafrost/frozen ground), but recognizing their application in a global context. The team's field expertise and on-going intensive field investigations throughout Canada are key elements in the development and validation of new remote sensing algorithms and techniques (e.g. snow water equivalent, lake ice freeze-up/break-up, sea ice motion, freeze/thaw of frozen ground, growth of glaciers and ice caps), the use of these data for improved model development (e.g. Canadian GCM, CLASS), and the creation of reliable time series for climatological and hydrological analyses.

CRYSYS, through its focus on climate/global change in Canada, will continue to contribute to international programs, including EOS, WMO/GCOS through the Canadian cryospheric GCOS activities, and to WMO/WCRP through GEWEX, ACSYS and the new CLIC initiative. This presentation will provide a summary of significant CRYSYS-supported research on monitoring and modelling the cryosphere with remotely sensed and in situ data, will highlight CRYSYS contributions to GCOS objectives, and will provide an assessment of the current state of the cryosphere in Canada.

JSM41/W/21-B4 1735

COMPLEMENTARY USE OF SATELLITE AND IN SITU DATA FOR MONITORING SPATIAL AND TEMPORAL CHARACTERISTICS OF SNOW COVER IN CANADA

BARRY GOODISON, Ross Brown and Anne Walker: (Climate Processes and Earth Observation Division, Atmospheric Environment Service, Downsview, Ontario, CANADA, M3H 5T4.
E-mail: ross.brown@ec.gc.ca)

Satellite observations are an indispensable component for mapping and monitoring of the cryosphere over large, high latitude land masses, such as Canada, where in-situ data are limited. Satellite sensing of snow cover has been found to be especially important for hydrological and climatological analyses and the assessment of variability and change over a range of spatial and temporal scales including monthly-seasonal and annual-decadal time scales. The CRYSYS project (Use of the Cryospheric System for Monitoring Global Change), a Canadian-led interdisciplinary science project in the NASA/EOS program, supports two important areas of research related to snow that are contributing to an enhanced ability to document spatial and temporal variations in snow cover: (1) the development, validation and refinement of empirical and theoretical algorithms for snow cover properties (extent, water equivalent, wet/dry state) in varying landscapes using passive and active microwave data, and (2) the merging of satellite and in-situ data to extend the satellite record and provide compatible and consistent information for climate variability studies, change detection, and validation of GCM transient climate simulations. This paper will present the results of new research on developing passive microwave SWE algorithms for forested areas, and the development of a satellite-derived SWE time-series (1988/89-1997/98) and climatology for the Prairie region of Canada taking account of the effects of wet snow. The paper will also present results from the merging of in-situ and satellite information that yielded monthly time series of snow cover extent information over North America and Eurasia from 1915. The reconstructed snow cover series show evidence of a significant 20th Century decrease in spring snow cover extent over Eurasia that corresponds with enhanced 20th Century spring warming over this continent. The problem will conclude with recommendations on requirements for monitoring snow cover for the Canadian GCOS program.

JSM41/E/19-B4 1750

PASSIVE MICROWAVE REMOTE SENSING OF FROZEN SOILS

T. Zhang, R. ARMSTRONG, and J. Smith, (all at the National Snow and Ice Data Center and Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, CO 80309-0449, USA, email: tzhang@kryos.colorado.edu and rlax@kryos.colorado.edu)

The timing, duration, areal extent, and depth of near-surface soil freezing and thawing are important parameters for regional climatic and hydrologic studies, and changes in these parameters are important climatic indicators and integrators. Conventional point measurements of surface soil freezing and thawing provide information for process studies in local areas. It is impractical to conduct large- or regional-scale investigations of surface soil freezing and thawing by using the point measurement method. In this study, onset, duration and areal extent of near-surface soil freezing and thawing were investigated using passive microwave remote sensing data in North America (30N and 130W to 60N and 50W) during the winter of 1997-1998. The criteria used to detect onset, duration, and areal extent of surface soil freezing include (i) a negative spectral gradient between Tb(37V) and Tb(19V), (ii) a cutoff Tb(37V). The algorithm was partly validated against field measurements in northern Plains of the United States. The primary results obtained indicate that frozen soil extent was generally in good agreement with zero degree Celius isotherm of air temperature. The boundary of frozen soil extent moved southward as the cold air was invading from north in northern Plains during the early winter. The onset of surface soil freezing ranged from September in northern and mountainous regions to December/January in southern regions. The duration of surface soil freezing varied from a few days in the south to about six months in the north and mountains. Surface soils were generally frozen before snow cover developed. Snow cover extent was also included for comparison. We will discuss the progress and problems concerning the application of pasive microwave remote sensing data to study of frozen soils.

Friday 30 July AM

TERRESTRIAL MONITORING

JSM41/W/19-B5 Invited 0900

SATELLITE REMOTE SENSING OF SOIL MOISTURE-THE MAXIMUM POTENTIAL OF PAST, CURRENT AND FUTURE SYSTEMS

Thomas J. Jackson, U.S. Department of Agriculture, Agricultural Research Service, Hydrology Lab, 104 Bldg. 007 BARC-West, Beltsville, MD 20705, USA email: jackson@hydrolab.arsusda.gov

The role of surface soil moisture in hydrology and climate has been defined over the past decade. A lack of a physically based soil moisture element and an observational data base for validating such models are recognized as critical sources of uncertainty in simulations and forecasts. Long term spatial soil moisture data have never been available. Although many technologies have been utilized and evaluated, none have been able to provide reliable in-situ measurements in a cost-effective manner. Satellite based microwave remote sensing is an ideal source of surface soil moisture information. Microwave sensors are sensitive to the water content of the soil and satellite sensors can provide updated image (map) products. The geographic domain for soil moisture retrieval is limited by vegetation. Vegetation reduces the sensitivity of the measurement to soil moisture changes. The reduction in sensitivity increases as frequency increases. Satellite agencies have not placed a high priority on providing instruments that are optimized for soil moisture measurement. SSM/I frequencies can only provide information for a few regions with minimal vegetation. There is a better outlook for soil moisture when the AMSR instruments are launched in the year 2000 by the U.S. and Japan. It is possible that by conducting the right kind of calibration activities with these instruments, that the data collected during the nearly ten years of SMMR observations can be more effectively utilized for long term studies. However, the greatest potential for soil moisture remote sensing is at lower frequencies, in particular L band. With current technologies it is possible to implement a spaceborne L band system with a spatial resolution that is compatible with large-scale hydrology and climate. With this system it would be possible to provide soil moisture information for 70% of the Earth's land surfaces.

JSM41/W/27-B5 0930

THE SOIL MOISTURE AND OCEAN SALINITY (SMOS) MISSION: AN OVERVIEW

Y.H. Kerr (CESBIO, 18 av E. Belin, 31401 Toulouse cedex, France, email: Yann.Kerr@cesbio.cnes.fr), P. Waldteufel (IPSL , 10-12 av de l'Europe, 78140 Vélizy, France) ; G.S.E. LAGERLOEF (Earth and Space Research, 1910 Fairview Ave E, Suite 102 Seattle WA 98102-3620, USA, email: lagerloef@esr.org) ; J.-P. Wigneron (INRA Bioclimatologie , Agroparc 84914 Avignon Cedex 9, France) J. Font (Dept. of Marine Geology and Physical Oceanography, Institut de Ciències del Mar - CSIC, P. Joan de Borbó s/n, 08039 Barcelona, Spain); J.-M. Martinuzzi (CNES, 18 Avenue Edouard Belin 31401 Toulouse cedex 4, France)

The goal of this paper is to present a space mission aimed at the retrieval of soil moisture and ocean salinity from space. It is now being proposed to the Earth Explorer Opportunity Programme, under the name of SMOS. The sensor is an L-band interferometer based on an innovative concept of bi- dimensional aperture synthesis method. The instrument is a Y shaped structure consisting of 3 co- planar arms consisting of an elongated array of elements operating in H and V polarization and incidence angles ranging from about 0 to 55 . The sensor has new and very significant capabilities especially in terms of multi-angular view configuration. The main goals of this mission are: (i) to provide fields of surface soil moisture and potentially of root zone soil moisture, all over the globe and every 2 to 3 days, (ii) to measure seasonal to interannual variations of sea surface salinity, (iii) to be used over ice and ice caps for research purposes. The ultimate goal is to provide global information on such key parameters (moisture and salinity) for models in the fields of oceanography, meteorology, hydrology and climate. This paper will give an overview of the SMOS Mission objectives and the main mission characteristics together with some of the technical features.

JSM41/W/02-B5 0945

DEVELOPMENT OF A SATELLITE SYSTEMS FOR MEASURING SOIL MOISTURE AND SEA SURFACE SALINITY

Edwin T. ENGMAN (Code 974, Hydrological Sciences Branch, Laboratory for Hydrospheric ProcessesNASA, Goddard Space Flight Center, Greenbelt, MD 20771, USA,
Email: tengman@neptune.gsfc.nasa.gov)

The science need for remotely sensed soil moisture and sea surface salinity has been well established in the hydrologic, oceanographic, climate change and weather forecasting communities. In spite of this well documented science need there are currently no satellite missions flying or funded to make these very important geophysical measurements. There have been a number of experimental programs that have demonstrated the feasibility of using long wave microwave sensors for estimating soil moisture and also a few that have shown the promise for measuring salinity. The principal sensor to accomplish both the soil moisture and salinity measurements is an L-band passive microwave radiometer. Unfortunately, each science driver, soil moisture sand salinity, impose quite different technical requirements on the sensor system. Soil moisture is driven by a spatial resolution on the order of 20 to 30 km and achieving this requires a very large antenna. Spatial resolution is not a driver for salinity except for possibly in the littoral zone, however the salinity measurement requires an extremely sensitive radiometer. This paper describes the several alternatives to solve the very large antenna challenge and still meet the radiometer sensitivity requirement for salinity. The paper also discusses the alternatives considered to obtain the necessary ancillary data for characterizing the surface roughness, the surface (land and ocean) temperature and the attenuation affects of vegetation needed to derive the geophysical parameters. Finally, the paper discusses proposed missions and how well they will meet the science requirements.

JSM41/W/16-B5 1000

SATELLITE MICROWAVE REMOTE SENSING OF LAND SURFACE HYDROLOGY

Toshio Koike (Nagaoka University of Technology, Nagaoka, 940-2188, Japan,
email: tkoike@nagaokaut.ac.jp)

Microwave remote sensing has high potential of measurement of land surface hydrological parameters quantitatively. Their diurnal cycles and heterogeneity also can be measured by non-sunsynchronous satellites and the combination of passive and active sensors, respectively. New algorithms for snow, soil moisture, surface temperature and rain by using passive microwave sensors are developed based on microwave radiative transfer theory. They are applied to the satellite data form the TRMM Microwave Imager (TMI) and the Special Sensor of Microwave Imager (SSM/I) and evaluated by using the ground-based data through the GTS and/or obtained during the GAME-Tibet Intensive Observing Period (IOP) in 1998. The estimated hydrological parameters, snow temperature, surface soil moisture, soil surface temperature and rainfall, show good correspondence to the observed data. An algorithm for soil moisture mapping in permafrost regions is introduced by using two images of L-band Synthetic Aperture Radar (SAR), one in winter and the other in summer. The algorithm is based on a relationship between two surface roughness parameters, r.m.s. height and correlation length, and the scattering model composed by the Integral Equation Method (IEM) and formulation of volume scattering from inhomogeneous medium. This algorithm is applied to the JERS-1 SAR data in the Tibetan Plateau in 1993. The estimated soil moisture shows in good agreement with the observed one obtained during the GAME-Tibet IOP in 1998. Provide fields of surface soil moisture and potentially of root zone soil moisture, all over the globe and every 2 to 3 days, (ii) to provide decadal values of sea surface salinity, (iii) to be used over ice and ice caps for research purposes. The goal is to provide information globally on key parameters (moisture and salinity) for models in the fields of oceanography, meteorology, hydrology to name the main ones. This paper will give an overview of the SMOS Mission objectives and the main mission characteristics together with some of the technical features.

JSM41/W/22-B5 1015

ENVIRONMENTAL SIGNALS IN LAND ALTIMETER DATA: POTENTIAL FOR SOIL MOISTURE MEASUREMENT

BERRY, P.A.M., Pinnock, R.A. & Hoogerboord, J.E. Geomatics Unit, De Montfort University, Leicester LE1 9BH, UK, e-mail: pamb@dmu.ac.uk

The development of an expert system for recovery of orthometric heights from land radar altimeter waveforms has now enabled the detection of environmental signals in the altimeter dataset from ERS-1 and ERS-2.
This paper presents initial results from an ongoing research project evaluating the potential for recovery of surface soil moisture from altimeter echoes. With measurements from ERS-1/2 missions now covering almost ten years, and the planned continuation of this datastream with Envisat, radar altimetry presents a unique time series with near global sampling when in ice mode. One focus of the work presented here is on semi-arid areas such as desert margins, where results using the expert system already confirm the presence of quantifiable environmental signals in the individual waveforms

JSM41/E/24–B5 1030

A STUDY ON SOIL EROSION IN SOUTH CHINA USING REMOTE SENSING AND GIS TECHNIQUE

ZHANG, Jiahua (Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing,100029, P.R.China email: zhangjh@ast590.tea.ac.cn)

Soil erosion seriously impact on global nature resources and ecological environment, in China the total soil erosion area covers 38.26% of total China's area, of which water erosion is 48.77%, and wind erosion accounts 51.22%, the total soil erosion amount annual year is five billion ton, accounting for 10% of the whole world. In the paper hilly land soil erosion condition in Southern China is severe, surface soil has been eroded away, soil fertility drop down, particularly in red earth and granite area, the resistance of erosion is low. Soil erosion and disasters caused by floods, windstorm, landform, slope, soil erodible character and landuse type, among this the human activities including cut down tree and excavate land is main factor. Using study methods of remote sensing and geo-information system can investigate and monitor the degree and of soil erosion, in the meantime dynamic of soil erosion can been analysis by different period investigate data. The result of investigation based on remote sensing and GIS to Xingguo country show the soil erosion area and annual soil erosion amount decreased 19.09% and 43.05% respectively from 1958's to 1988's. The gray forecast state that without soil erosion area increasing from 818.04 km2 in 1988 to 1276.69 km2 in 1995, in the meantime total soil erosion amount decreased from 607.21!A104 t/a in 1988 yr. to 472.12 !A104 t/a in 1995. By comparison to different landuse types, the sediment modulus of woodland is lowest with 177.16~187.75t / km2 !$a, on the contrary the bare land is highest with 10626.76~11265.48 t /km2 a, so high vegetation coverage planting can decrease the soil and water loss. In the end some methods including conservation farming and engineer measures control soil erosion are suggested, by these can control soil erosion, and ecological cycle may take a turn for the better.

JSM41/E/03-B5 Invited 1105

LAND SURFACE RESPONSE TO HYDROLOGICAL FORCING USING TIME SERIES OF AVHRR AND SMMR 37 GHZ OBSERVATIONS

Massimo MENENTI1, S. Azzali, G. Roerink, W. Verhoef2 and S. Leguizamon3 The Winand Staring Centre (SC-DLO), P.O.B.125, 6700 AC Wageningen, The Netherlands (1) Universite Louis Pasteur-LSIIT, 5 Blvd. S. Brant, 67400, Illkirch, France; e-mail: menenti@sepia.u-strasbg.fr (2)National Aerospace Laboratory (NLR), P.O.B. 153, 8300 AD Emmeloord, The Netherlands (3)Universidad de Mendoza/ CIS, Aristide Villanueva 776,5500 Mendoza, Argentina

In the last few years global satellite data sets have become available to provide observations of changes of land surface conditions over significant periods of time. Although instrument- and orbit-related artefacts still affect the precision of the observations, analyses of time series of satellite observations provide new insights on the response of heterogeneous land surfaces to hydrological forcing. The paper presents highlights of studies on land surface changes in arid (Africa), semi-arid (Mediterranean) and humid (South America) climates. To extract effectively information from such large data sets three algorithms have been developed and applied: Fast Fourier Transform (FFT), Harmonic Analysis of NDVI Time Series (HANTS) and wavelets transform. The analysis (FFT) of 10 years monthly NDVI time series of Africa and South America led to a continental map of vegetation-soil-climate complexes and to document their phenology. The HANTS algorithm was also used to improve the quality of the data sets by removing cloud- contaminated observations still present in the monthly composites. Vegetation type was strongly related to the Budyko aridity index. A detailed change analysis of 10 days 1 km data of the Mediterranean basin led to identify areas most sensitive to drought. Anomalous events in the time series were best detected using the wavelets transform. Notwithstanding the low spatial resolution, the SMMR 37 GHz observations were used to monitor flooding and recession in the Pantanal, a large natural reservoir in Brazil and Paraguay.

JSM41/E/18-B5 1135

INTERANNUAL CHANGES IN GLOBAL VEGETATION ACTIVITY: COMPARING SATELLITE OBSERVATIONS AND VEGETATION MODELLING

WOLFGANG KNORR (Max-Planck-Institut fuer Meteorologie, Bundesstrasse 55, D-20146 Hamburg, Germany; Tel. : +49-40-41173-282, Fax : +49-40-41173-298, Email: knorr@dkrz.de) and Garik Gutman (NOAA/NESDIS/ERA12, WWB 712, 5200 Auth Road, Camp Springs, Maryland 20746-4304, U.S.A.)

Remote sensing from satellites offers unique opportunities to monitor the state and evolution of global land vegetation. This is important, because land plants are considered to be of major importance for interannual changes in the global carbon cycle. It is particularly interesting to use remotely sensed imagery to test global models of vegetation activity. In this contribution, we compare interannual changes in vegetation cover inferred from NOAA-AVHRR data over the 1990s with the same changes simulated by the global Biosphere Energy-Transfer and Hydrology model (BETHY). We discuss the implications of differences and agreement between the two fields for the simulated carbon fluxes with BETHY. We find a pronounced impact of the El-Nino/Southern Oscillation phenomenon in both. Comparison with atmospheric CO2 data also suggests such a link, as it stresses the dominant impact of land vegetation on this time scale. The results suggest that satellite monitoring of vegetation activity could significantly enhance our understanding of the present global carbon cycle.

JSM41/E/14-B5 1150

THE RESPONSE OF SATELLITE-DERIVED NDVI TO LOCAL CLIMATE VARIATION IN SIBERIA

Rikie SUZUKI (Frontier Research System for Global Change, c/o NIED, Tsukuba, Ibaraki 305-0006, Japan, email: suzuki@frontier.bosai.go.jp)

The response of the satellite-derived Normalized Difference Vegetation Index (NDVI) to the climate (precipitation and temperature) regionality was investigated in Siberia. The NDVI was obtained from Gallo's monthly Global Vegetation Index (GVI) which is a coarse NDVI data set covering the globe. Since the vegetation in Siberia shows meridional (south-north) transitions corresponding to the climate, two meridional transects were established from arid to taiga (along 75E) and from taiga to tundra (along 110E) vegetation transitions. Using surface station temperature and precipitation data in the CD-ROM `Global Daily Summary', the profiles of NDVI, temperature, and precipitation in the two transects were compared in conjunction with the elevation of each station through 1987 to 1990. As for the temperature, WI(0) which is an annually accumulated monthly mean temperature above 0C was used. In the arid-taiga transect, it was revealed that the NDVI tends to be large at high precipitation stations (the correlation coefficient (r) between the NDVI and precipitation deviations is 0.66). This result shows that the NDVI sensitively fluctuates due to the station-to-station precipitation variation. It was illustrated that the crucial factor in the arid-taiga vegetation transect is precipitation.In taiga-tundra transect, the NDVI tends to be large at high WI(0) stations (r = 0.43 between NDVI and WI(0)), at the same time, a negative correlation between WI(0) and station elevation was found (r = -0.46). This fact means that the NDVI tends to be larger/smaller corresponding to the higher/lower WI(0) due to several hundreds meters lower/higher elevation of the station. These relationships may be an indication that the temperature factor is critical for the vegetation in taiga-tundra transect.

JSM41/W/18-B5 1205

MONITORING PHYSICAL AND BIOLOGICAL STATES OF DESERT GRASSLANDS USING REMOTE SENSING

Jerry C. RITCHIE, Albert Rango, Thomas J. Schmugge, and William P. Kustas (all at USDA ARS Hydrology Laboratory, Beltsville, MD 20705, USA, Email: jritchie@hydrolab.arsusda.gov) Frank R. Schiebe (SST Development Group Inc., 824 North Country Club Road, Stillwater, OK 74075, USA, Email: franksch@isc-durant.com)

In 1995 the USDA Agriculture Research Service Hydrology Laboratory began collecting remotely sensed data from ground, aircraft and satellite platforms to provide spatial and temporal data on physical and biological states of desert grasslands in the southwestern United States. Thesemeasurements are being used to quantify hydrologic budgets and plant responses to changes in components in the water and energy balance at the Jornada Experimental Range and the Sevilleta Long-Term Ecological Research (LTER) in New Mexico. A range of ground, aircraft, and satellite data have been collected on the physical, vegetative, thermal, and radiometric properties of two ecosystems (grass and shrub) typical of desert grassland in this area. Remote sensing campaigns have been made in dry (May/June) and wet (September/October) periods each year. Data from different platforms will allow the evaluation of landscape properties at a range of scales from meters to kilometers. Radiances measured at ground and aircraft platforms were found to be 3 to 5 % higher for a 30-m2 area at shrub sites when compared with the grass site. Landscape surface temperatures which were similar in the morning (9 am local time) showed 3 to 5 C higher temperatures at shrub sites when compared with grass sites by 1 pm local time. These differences in albedo and temperature could have significant effects on the energy and water balances of desert grasslands as shrubs continue to expand at the expense of the grass. Landsat and EOS satellite data will be used to extend these data to larger scales. These sites have been selected for EOS validation because of their long history of ground-based studies and ongoing repetitive remote sensing missions.

JSM41/W/20-B5 1220

COMPARISON OF REMOTE SENSING, MODEL AND FIELD ESTIMATES OF ACTUAL EVAPOTRANSPIRATION

GEOFF KITE and Peter Droogers, International; Water Management Institute, 35660 Menemen Izmir, Turkey. E-mail: g.kite@cgiar.org

Traditionally, actual evapotranspiration has been computed as a residual in water balance equations, from estimates of potential evapotranspiration or from field measurements by meteorological equipment. Recently, however, researchers have begun using remotely sensed data to estimate regional actual evapotranspiration. A field experiment was carried out in western Turkey over the summer of 1998 to compare the latest methods of estimating areal evapotranspiration using remotely sensed data from NOAA AVHRR and Landsat TM sensors, hydrological models at basin and point scales and field measurements, including scintillometers and net radiometer. This paper introduces the experiment, describes the data set and summarises the different estimation techniques. The results of the different methods are reviewed and compared and recommendations are made as to the suitability of the different methods for different circumstances.

JSM41/E/30-B5 1400

USING NOAA AVHRR PRODUCTS FOR THE GLOBAL MONITORING OF EL NIQO IMPACTS

Garik Gutman, Ivan Csiszar, PETER ROMANOV and Larry Stowe NOAA/NESDIS, Office of Research and Applications, Washington, D.C. 20233, USA

The development of the El Niqo Southern Oscillation (ENSO) in 1997-1998, the most intense in this century, has been monitored by space- and ground-based observations. This study discusses the potential of the current products, routinely derived at NOAA from measurements by the Advanced Very High Resolution Radiometer (AVHRR) onboard NOAA polar orbiting satellites, to monitor diverse ENSO impacts over the globe. Generally, ENSO impacts are manifested by droughts, excessive rain, or lack of snow cover, all affecting the agricultural production and often producing natural hazards, such as floods. We analyzed the month-to-month changes in surface-atmosphere conditions in several regions of the world, strongly affected by the 1997-1998 ENSO, using NOAA AVHRR products generated in near-real time, comprising surface and atmospheric variables, such as reflectances, temperatures, vegetation and fire indices, aerosol optical depths over ocean, fractional cloud amount, precipitation, and top-of-the-atmosphere outgoing longwave and absorbed shortwave radiation fluxes. The synergy of many variables allows us to better understand the big picture characterizing the state of the surface-atmosphere system and the relationship between different components of that system. This study demonstrates how the suite of the current NOAA satellite products derived from a single instrument in space can be used to detect ENSO-induced anomalies and to monitor the onset, extent, intensity and duration of ENSO impact on the surface-atmosphere system for diverse regions of the globe. We will discuss also some NOAA AVHRR products that are planned to be included into the suite of products for monitoring ENSO in the near future.

JSM 41/E/31-B5 1415

MONITORING LAKE LEVEL CHANGES USING TOPEX/POSEIDON AND ERS-1 ALTIMETRIC DATA. COMPARISON WITH REGIONAL HYDROLOGY

Franck MERCIER and Anny Cazenave (both at Laboratoire d'Etudes en Geophysique et Oceanographie Spatiales, 18 avenue Edouard Belin, 31401 TOULOUSE CEDEX 4, France, email: mercier@boreal-ci.cst.cnes.fr)

Topex/Poseidon and ERS-1 altimeters were primarily designed to measure height of the sea surface. Nevertheless, we can also use satellite altimetry to investigate level changes of continental lakes. We use 6 years of Topex/Poseidon altimetry data to study level changes of African Lakes (lake Malawi, lake Tanganyka, lake Victoria, lake Turkana, lake Tchad and additional smaller lakes). We also analyse the ERS-1 Waveform Altimeter Product raw data set to produce lake level time series. Due to its shorter intertrack spacing, ERS-1 provides a much

denser coverage of lakes than Topex/Poseidon. When available, in situ lake level measurements are compared with altimetric time series. In this analysis, we focus on the seasonal and interannual fluctuations of lake levels. Using available regional hydrometeorological data, we further study the water balance over each lake catchment basin. On the annual time-scale, we show a clear correlation between lake level and precipitation fluctuations while on the interannual time-scale, regional as well as global climatic changes are invoked.

JSM41/W/17–B5 1430

MODELING SUSPENDED SEDIMENT TRANSPORT BY INTERNAL TIDES

LI, Jiren (Remote Sensing Technology Application Center, Ministry of Water Resources, 20 West Chegongzhuang Road, Bejiing, China 100044, e-mail: ljr@mx.cei.gov.cn)

A sediment transport model was incorporated into an internal tide model to investigate the ability of internal waves to resuspend and advect sediment over continental shelfs and slope regions. Internal tides may play a dominant role in controlling the distribution of sediment where the water depth is large enough to attenuate any direct impact upon sediment distributions by wind generated surface waves and currents. A number of numerical experiments were carried out for various idealized slopes and the model was applied to an observed section of the Australian North West Shelf. In all experiments, simulated bottom layer shear stresses were large enough to resuspend sediment. During this talk, the consequences of the non-linearity and asymmetry associated with the internal wave velocity field upon resuspension, deposition, and net sediment fluxes will be discussed.

JSM41/E/11-B5 1445

IMPACT OF CO2 MULTIPLICATION ON CROP YIELD OF NORTH CHINA PLAIN BASED ON REMOTE SENSING DATA AND PLANT PHOTOSYHTHESIS MODEL

ZHANG Jiahua (Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing,100029, P.R.China email: zhangjh@ast590.tea.ac.cn)

In the paper, first considering remote sensing information and crop ecophysiological characteristics, the crop yield estimation model was set up based on NOAA-AVHRR derived variables and plant photosynthesis. Among them, photosynthetic active radiation (PAR) , CPAP (Crop Photosynthetic Assimilation Potential, reflects crop photosynthetic time and area), and photosynthetic rate were calculated by remote sensing information and meteorological data. The developed model has been applied to winter wheat yield distributions in North China plain area, shows the model has better precision. Second, taking into account the impact of CO2 doubling to agro-ecosystem and its influence on winter wheat, the model further developed and the regional crop yield was estimated owe to CO2 doubled. The further changes of agricultural NPP distributions in North China plain were given using the developed model.

JSM41/L/01-B5 1500

LANDUSE/LAND COVER CHANGE AND ITS IMPLICATIONS FOR DEFORESTATION IN THE HUMID TROPICAL RAINFOREST OF WEST AFRICA: THE EXPERIENCE OF THE LAGOS REGION (NIGERIA)

Simon. O. OJO (Department of Geography, University of Lagos, NIGERIA ,
e-mail: niomr@linkserve.com.ng)

Using Remote sensing technique, a land use/land cover change study of parts of the tropical rainforest region of West Africa, with emphasis on the Ikorodu area of the Lagos region (Nigeria) is discussed. The main categories of the land uses identified include the built-up areas, agricultural lands, wetlands (vegetated and unvegetated) and the water bodies in addition to barren lands. In addition to these main categories, 5, 2, 3 and 2 sub categories were also identified for the built-up areas, agricultural lands, wetlands and the water bodies respectively. In addition, the barren lands were also identified. Data generated using the 1962 and 1983 photographs were used for the study.
The study showed that between 1962 and 1983, the built-up areas increased by more than 600% from about 82 ha. to about 573 ha. Farmlands also increased by about 13% from about 1419 ha to about 1597 ha while wetlands decreased by about 13% from 2882 ha to about 2514 ha. Water bodies also decreased by about 19% from about 27 ha to about 22 ha. Barren lands also decreased by more than 90% from about 19 ha to about 2 ha. The implications of the results for deforestation in the area in particular, and the tropical rainforest region of West Africa is discussed.

JSM41/W/05-B5 1515

COMPARATIVE ANALYSIS OF GROUND-BASED AND SATELLITE-DERIVED SHORTWAVE SURFACE IRRADIANCE MEASUREMENTS OVER RUSSIA

POKROVSKY O.M.., Dalyuk I.V.(both at Main Geophysical Observatory,Karbyshev str.7, St.Petersburg, 194021, Russia, e-mail: pokrov@main.mgo.rssi.ru)

The subject of the study is incoming shortwave surface irradiance, main goal - to increase accuracy of satellite-derived surface radiative budget (SRB) estimates. The study concerns comparison of two types of data: results of retrieval from satellite data performed in the frame of ISCCP/SRB and ground-based measurements for the period 1985-1988 over Russia. In contrast to previous studies the biases between two types of data sets were studied at high temporal resolution - 3-hourly time step. Radiative transfer model exploiting delta-Eddington approximation was used to adopt ground-based data to solar zenith angles corresponding to satellite-derived data. Systematic and random errors for 27 most representative stations from all climatic zones of Russia were analyzed. It was shown that systematic error of monthly mean deviations is 7-10 times lower than standard deviations characterizing variations of instantaneous values of incoming shortwave irradiance. The most attention was paid to the statistical analysis of 2 months having extremal variations, July and March. In July mean deviations of monthly mean values were about 25 wt/m-2, in March they were about 34 wt/m-2. The coherence of both types of data is described by mean values of correlation coefficients: 0.74 in July and 0.66 in March. The intra-diurnal deviations of ground and satellite-retrieved data are, too, characterized by systematic and random components. Systematic component changes during the day from 15 to 90 wt/m-2. Random component has significantly greater amplitude: ±50-150 wt/m-2. Satellite-derived data values in comparison with ground-based measurements appeared to be overestimated for small values of radiation fluxes (50-200 wt/m-2) and underestimated for high values of radiation fluxes (700-900 wt/m-2). Within the interval 400-500 wt/m-2 the biases were minimal.

JSM41/E/05-B5 1530

DEVELOPMENT OF RUSSIA SMALL-SATELLITE SET FOR MONITORING OF GEODYNAMICAL PROCESSES

Vladimir A. ALEKSEEV and Victor N. Oraevsky (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation, Russian Academy of Sciences (IZMIRAN), Troitsk, Moscow region, 142092 Russia, email: ogm@fly.triniti.troitsk.ru)

To study the Earth and near-Earth space environment and to increase the capabilities of global monitoring, our Institute (IZMIRAN) develops Russia multi-purpose broad small-satellites set together with ground based infrastructure related. In particular, the makes it possible "to see" tectonic faults due to their influence to the ionosphere state by change of an atmospheric electrical field at the degasation of radioactive gases and aerosols in the fault zone. Thus, the whole system of tectonic faults can be fast and effectively mapped, including covert faults. This results in improvement of planning the search of mineral wealths. Changing atmospheric electrical field over faults is a dynamical process. Therefore, with the small-satellites set facilities it is for the first time possible to make monitoring of tectonic activity, using a short sampling interval. This information can help to strike out a new strategy of earthquakes forecasting. Also, (since the small-satellites set considered is a communication satellites system on the basis of high-grade space technologies) the project is aimed at improving the quality of public medicine by promoting the methods of remote consultations, the offered medical aid being able to envelop at once large number of sufferers in the region of a catastrophe.

JSS42/W/27-B4 0940

CONTRIBUTION TO THE IDNDR: TSUNAMI FLOODING MAPS

E.N. Bernard, Tsunami Commission

Since 1989, the IUGG Tsunami Commission has facilitated the dedicated efforts of tsunami scientists to produce over 30 tsunami inundation maps for mitigating the effects of tsunamis in 17 threatened countries. Through a process of planning, proposal acceptance, tsunami data collection, and numerical model development, an internationally accepted methodology for preparing tsunami flooding maps has been created as the tsunami community's contribution to the International Decade of Natural Disaster Reduction. More importantly, scientists in 17 nations were trained to use of this methodology enabling those countries to produce more maps in the future. The value of such maps is that they identify coastal areas that could be flooded by future tsunamis that require some evacuation procedure to remove people from tsunami danger. To accomplish this goal, the tsunami scientific community had to carefully measure the effects of tsunamis and use these data to construct numerical models that could realistically simulate tsunami dynamics. In the past decade 9 destructive tsunamis have killed over 3,200 coastal residents in 7 countries. Each of these tsunamis were surveyed by teams of international tsunami scientists to collect measurements on the extent of flooding along affected coastlines. All surveying scientists generously shared their data with all tsunami scientists quickly and efficiently through internet technology. In addition to new data ,a focussed modeling effort was required to convert tsunami flooding data into useful emergency management information. A partnership between the the IUGG Tsunami Commission, the United Nation's Intergovernmental Oceanographic Commission, and Tohoku University in Sendai, Japan was created to support the Tsunami Inundation Modeling Exchange (TIME) project. TIME is a modeling center at Tohoku University, under the leadership of F.Imamura and N. Shutothat trains scientists from other countries to use numerical models to estimate the extent of potential tsunami flooding for any threatened community. So far, these models have been transferred to scientists in seventeen countries, including: Australia, Canada, Chile, Columbia, Costa Rica, Ecuador, Greece, Indonesia, Italy, Japan, Korea, Mexico, New Zealand, Peru, Puerto Rico, Turkey, and the United States who have produced more than 30 inundation maps for tsunami threatened coastal communities. The global emergency management community now has a better tool to mitigate the impact of tsunamis.

JSS42/E/15-B4 1000

TRAFFIC HINDRANCE AFTER TSUNAMI

Nobuo SHUTO(Faculty of Policy Studies, Iwate Prefectural University, Takizawa, Iwate 020-0173, Japan, email: shuto@iwate-pu.ac.jp)

It is important to open coastal traffic after a tsunami, in order to ensure a quick rescue operation within the "Golden 24" hours. Eighty five examples of coastal traffic hindrance were collected, classified and analyzed for 11 tsunamis in Japan.
First cause of the traffic hindrance is destruction of structures. (1)Destruction of embankment of roads and railways by overflowing sea water. Destruction might begin with the erosion of slopes of embankment. If an embankment is lower than 0.5 m, and if the thickness of overflowing water is smaller than 1 m, then the embankment is not damaged, wigh no regard that the road is paved or not paved. (2)Damage due to concentration of water flow. Erosion around a bridge abutment begins at the end of wing walls and develops to the complete destruction of embankment, even though the abutment can withstand. A bridge pier is tilted or turned due to erosion around it. (3)Damage caused by impact of floating materials. Concrete bridges can withstand. Wooden bridges and light steel plate girder bridges are destroyed.

Railways is twisted due to movement of railway bridge. (4)Damage caused by buoyancy. Rails are moved due to buoyancy of wooden sleepers. Second cause is hindrance of function. (1)Standing sea water in low land. (2)Sand and mud depostion on roads and railways. (3)Depositions of logs, ships, houses and debris on roads. (4)Fires on or along roads.

JSS42/E/19-B4 1020

MITIGATION STRATEGIES BASED ON LOCAL TSUNAMI EFFECTS

JANE PREUSS (Urban Regional Research, 1809 7th Avenue, Suite 1000, Seattle, Washington, 98101 USA, tel.: (206) 624-1669, fax: (206) 626-5324, email: jpreuss@nwlink.com); Razvan Bidoae and Peter E. Raad (Mechanical Engineering Department, Southern Methodist University, Dallas, Texas, 75275-0337 USA, tel.: (214) 768-3043, fax: (214) 768-1473, email: peter@seas.smu.edu

When the local effects imposed on structures are better understood, the knowledge constitutes an important tool that planners and regulators can use when making decisions with respect to land use practices in coastal areas. An initial field inventory defined key vulnerability issues for analysis through numerical simulation. Structures meeting the following three criteria presented the most significant risks: a) potentiality for significant damage, b) high disruption or loss of life, and c) potentiality for interactive damage. In this work, the impact of a water wave with a single, tall structure was numerically simulated and the forces and moments on the structure were calculated. To assess the effects of upstream conditions on the forces experienced by the main structure, four simulations were considered. In the first simulation, the flow path of the wave toward the structure was unobstructed. The results revealed the existence of two large peaks in the force and moment fields. The initial impact (and force peak) occurs at the base of the structure, as expected. The unexpected secondary impact occurs due to the collapse of the water column that ascended along the front face of the structure. In the second simulation, a short, wide obstacle was placed in front of the main structure. The obstacle (dike, shorter building, etc.) causes the initial impact to occur at a higher elevation, giving rise to a significant increase in the moment experienced by the structure. In the third simulation scenario, single and multiple pylons were placed in front of the structure. The results indicated a reduction in the amount of water impacting the structure, but the decreases in impact pressure, force, and moment were not significant. In the fourth simulation, a groove (or trough) was prescribed in front of the structure (the containment dike used around tank farms). This final simulation indicates a significant decrease in the forces and moments exerted on the structure. Land use implications, pertain to structures fronting the water, and also the second and third tiers of buildings, which often differ in building quality (e.g., hotels in front and behind older one or two-story homes). Site planning implications include the layout of structures, relationships of primary to accessory structures such as beach houses, parking lots, and open spaces.

A FRESH LOOK AT ELEMENTS OF THE TSUNAMI WARNING SYSTEM IN THE PACIFIC

Michael BLACKFORD (International Tsunami Information Center, US National Weather Service, 737 Bishop Street Suite 2200, Honolulu Hawaii 96813-3213, USA, email: michael.blackford@noaa.gov)

In the aftermath following the 1960 Chilean earthquake and tsunami the Tsunami Warning System in the Pacific, was established in 1968 under the auspices of the UNESCO Intergovernmental Oceanographic Commission. An event of similar magnitude has not recurred in the last 30 years, however, thousands of lives have been lost and millions of dollars of damage have been wrought since the System was established. These losses can largely be attributed to insufficient preparation in many areas for tsunami events on a regional or local scale. Although there are several exceptions, the Pacific States have generally moved slowly with regard to the development of adequate tsunami warning subsystems.
Are States overwhelmed by subsystem start up costs? Do they believe the centralized System fulfills their needs? This paper looks at recent advances in communications and data acquisition that can bring down dramatically the costs of operating a tsunami warning system. It proposes a fresh look at a System that emphasizes the development of distributed subsystems that can be much more responsive to the needs of those vulnerable to tsunamis.

U.S. TSUNAMI HAZARD MITIGATION PROGRAM

Bernard, E.N., NOAA/Pacific Marine Environmental Laboratory, email: bernard@pmel.noaa.gov

The National Tsunami Hazard Mitigation Program is a Federal/State partnership (National Oceanic and Atmospheric Administration, Federal Emergency Management Agency, United States Geologic Survey/ Alaska, California, Hawaii, Oregon, and Washington) committed to reducing the vulnerability of U.S.coastal communities to tsunami hazards. Through three interdependent activities of tsunami flooding mapping for coastal communities, tsunami warnings, and education, the program is making progress on a broad range of emergency planning practices to mitigate the effects of tsunamis. A summary of the program's activities for the past 3 years will be given with emphasis on reducing coastal community vulnerability to tsunami hazards. A description of the program can be found at http:/ /www.pmel.noaa.gov/tsunami-hazard/.

JSS42/W/25-B4 1140

EARLY DETECTION AND REAL-TIME REPORTING OF DEEP-OCEAN TSUNAMIS

F.I. GONZALEZ, E.N. Bernard, H.B. Milburn and H.O. Mofjeld, (all at NOAA's Pacific Marine Environmental Laboratory, 7600 Sand Point Way, NE, Seattle, WA, 98115)

Current tsunami warnings are based on seismic data and coastal tide gage observations. But neither provides direct measurement of tsunami energy propagating toward coastal communities. As a consequence, an understandably conservative tsunami warning philosophy has produced an unacceptably high false alarm rate -- approximately 75% since 1950. These false alarms are a serious problem because they are expensive, they undermine the credibility of the warning system, and they place citizens at physical risk of accidental injury or death during an evacuation. The speed and accuracy of tsunami warnings can be improved when real-time reports are made of deep ocean tsunami data collected near the source region within a few minutes of generation. Such data will enable a more direct and rapid assessment of the hazard and, when coupled with model forecasting tools, a more accurate prediction of the impact on specific coastal communities. Thus, destructive tsunamis will be identified more reliably and the number of false alarms will be reduced. An added benefit of the real-time data stream is continued offshore tsunami monitoring. Dangerous conditions can persist for several hours after the first wave strikes a community because very large tsunamis can have periods as long as an hour and the largest wave may arrive as late as the third or fourth in a series. So offshore tsunami monitoring will provide important guidance for decision- makers who must judge the risk of deploying rescue and recovery personnel and equipment and, when the area is safe for the return of residents, sound the "all clear." NOAA's Deep-ocean Assessment and Reporting of Tsunamis (DART) Project is an effort of the U.S. National Tsunami Hazard Mitigation Program to develop this early tsunami detection and real- time reporting capability -- a formidable technological and logistical challenge. DART systems utilize bottom pressure recorders (BPRs) that are capable of detecting and measuring tsunamis with amplitude as small as 1 cm in 6000 m of water. The data are transmitted by acoustic modem to a surface buoy, which then relays the information to a ground station via satellite telecommunications. This design has been tested and refined through several deep ocean deployments of prototype systems. The latest prototype DART system was deployed on September 30, 1998 at Ocean Weather Station PAPA (50 N, 145 W). If this prototype system survives the winter, three additional systems will be deployed in 1999 off Alaska and Oregon as part of a planned six-buoy network in the north Pacific and equatorial region. The network is designed to provide early detection and measurement of tsunamis generated in source regions that threaten U.S. coastal communities: the Alaska Aleutian Subduction Zone, the Cascadia Subduction Zone, and the South American Seismic Zone.

JSS42/W/23-B4 1200

ELEMENTS OF A TSUNAMI WARNING SYSTEM FOR THE INTRA-AMERICAS SEA

GEORGE A. MAUL, Florida Institute of Technology, 150 West University Boulevard, Melbourne FL 32901 USA, and Douglas M. Martin, NOAA National Ocean Survey, 1305 East-West Highway, Silver Spring MD 20910 USA

At a series of workshops (Barbados, 1995; St. John, 1996; Puerto Rico, 1997; Miami, 1998) the case has been made for significant tsunami hazards in the Intra-Americas Sea (Gulf of Mexico, Caribbean Sea, Bahamas, and Guianas). For example, since the great 1867 US Virgin Islands earthquake and 9 meter-high tsunami, the population density of the region has increased 10-fold, infrastructure development has progressed without a notable natural hazards component, and governments seem to be oblivious to the risk. Accordingly, four essentials comprise the proposed Intra-Americas Sea Tsunami Hazards System: Education, Warning, Management, and Research.The first order of business is to better educate the populace through public information, K-12 student indoctrination, video and other multi-media products, workshops, and popular press articles. The warning component should capitalize on the recently established CPACC (Caribbean Planning for Climate Change) sea-level/weather GOES-reporting network, on existing seismic and meteorological reporting and warning systems, and on active participation with the ICG/ITSU (International Co-ordination Group for the Tsunami Warning System in the Pacific). Management issues include: integration with other natural hazards warning systems; exploration for funds; local warning and evacuation; search and rescue; fire suppression; emergency medical services; damage assessment; inter- and intra-governmental coordination; and, damage and hazard analysis. Research needs are: improved resolution bottom relief data; travel time maps for population centers; earthquake magnitude / depth thresholds; tsunami wave arrival amplitude estimation; potential for Kick'em Jenny and Soufriere (Montserrat) eruption; tsunami and earthquake history improvements; fault locations, activity, and tsunamigenic mechanisms; inundation maps; GPS stations for crustal motion monitoring; and loss estimation studies, amongst others.

JSS42/E/16-B4 1220

CONTEMPORARY ASSESSMENT OF TSUNAMI RISK AND IMPLICATIONS FOR EARLY WARNINGS FOR AUSTRALIA AND ITS ISLAND TERRITORIES

Jack RYNN (Centre for Earthquake Research in Australia, PO Box 276, Indooroopilly, Queensland 4068 Australia, email: sally.brown@uq.net.au; Jim Davidson (Bureau of Meteorology, GPO Box 413, Brisbane, Queensland 4001, Australia, email: jdavidson@bom.gov.au)

The natural hazard of tsunami relative to Australia and its Island Territories is perceived to be of little or no consequence, hence a small risk, when compared to our other more frequent natural disasters. The historical record shows that tsunami damage, although rare, occurred along the eastern seaboard (1877 and 1960 Chile earthquakes), and northwest coast (1983 Krakatoa volcanic eruption and the 1977 and 1994 Indonesian earthquakes). Tsunami mitigation is a need because the island nations of Australia depend on its coastal facilities for sustainable development, with 90% of the population domiciled in this environment. One Australian IDNDR project assessed the tsunami risk to its shorelines and island Territories. A specific methodology invoking a multidisciplinary approach was developed. More than 350 earthquakes and specific submarine volcanoes and landslide were considered as possible tsunamigenic sources. In the period 1788 through 1995 more than 60 registrations on tide-gauge records were identified, together with anecdotal information. The outcomes have been presented as an "information resource" in terms of hazard, vulnerability and risk assessment maps and commentaries, tsunami data base, maps of potential tsunamigenic sources, tsunami travel time charts and relationships between relevant tsunami parameters. This provides practical applications to upgrade the Bureau's warning procedures and emergency services counter disaster planning, including development of a regional tsunami warning system.

TSUNAMI GENERATION AND SEISMOTECTONICS

JSS42/W/08-B4 1400

MODELING FOR TSUNAMI GENERATED BY LANDSLIDING

Fumihiko Imamura; Kazumasa Hashi, Tomohiro Matsumoto, Nobuo Shuto Disaster Control Research Center, School of Eng., Tohoku University, Aoba 06, Sendai 980-8579, Japan, email: imamura@tsunami2.civil.tohoku.ac.jp

The numerical model to simulate tsunami propagation and generation due to a marine as well as land sliding is developed by deriving the governing equation and boundary condition for two layer flows with different density. The governing equation is derived by integration of Euler equation with viscosity , and by using kinetic and dynamic boundary conditions at free surface, interface, and sea bottom. Numerical scheme and procedure is designed the same as the standard model ; TUNAMI code for applications. It is found that the front condition of the lower layer as landslide is very important for numerical stability. The form/drag force and interaction of momentum between two layers at the front are introduced to solve the unstability. The numerical model is applied to two tsunami cases; the 1741 Oshima-oshima tsunami caused by lansliding on the volcanic island and the 1998 Sissano tsunami in PNG which might be related with a marine landslide. Although a pyloprastic model by Aida could not reproduce the runup heights measured along the peninsula of Oshima, the present model assuming the volume of landslide estimated from the change before and after eruption well simulate the distribution which is energy concentration on Kumaishi in north and Era in south. In the another case for marine landslide, it is demonstrated the interaction between two tsunamis caused by fault motion and landslide, suggesting the energy focus on the Sissano lagoon.

JSS42/W/03-B4 1420

ENERGY BALANCE IN THE PROBLEM OF LANDSLIDE-INDUCED TSUNAMIS

StefanoTinti and Cinzia Chiavettieri (both at Dipartimento di Fisica, Settore di Geofisica, Università di Bologna, email: steve@ibogfs.df.unibo.it)

Tsunamis generated by the movement of submerged large masses of sediments accumulated on the sea bottom over long periods of time are not rare and can be even very severe. The body of water and the body of sediments can be physically seen as two interacting systems exchanging energy. The main interest is typically focused on the energy gained by the water and manifesting in form of gravity water waves (the tsunami), but in principle the two systems are fully coupled, with energy flowing in both directions: energy is transmitted by the moving mass to the water giving rise to waves and energy passes from the waves to the mass, which means that the motion of the landslide is influenced by the propagation of the waves. This two-way nonlinear exchange of energy is generally overlooked. Here it is explored and consequences on modeling of tsunamis induced by underwater landslides are discussed.

JSS42/E/06-B4 1440

LANDSLIDE TSUNAMI 'GENERATION MECHANISM AND ITS DETECTION FOR EARLY TSUNAMI WARNING ISSUE'

S.I.IWASAKI (email: cuh@ess.bosai.go.jp) and S.Sakata (both at the National Research Institute for Earth Science and Disaster Prevention, 3-1 Tennodai Tsukuba 305-0006, JAPAN)

The cause of the Papua New Guinea Tsunami was probably landslide triggered by the original earthquake. As this example shows, these kinds of tsunamis generated by non-seismic causes sometimes gave heavy damages. Many reasons can be cited, such as the natural precursor of tsunamis, that is "shaking", were weak or nothing, generation regions were located in near shore regions, almost tsunami warning systems issue the tsunami warnings based on the Magnitude of earthquakes, generation mechanisms are still not fully clear and so on. In this presentation, at first, the simple landslide tsunami generation model will be introduced. Then, using a simplified topography of the ocean off Papua New Guinea coast, differences of wave forms of tsunami generated by a landslide and an earthquake will be discussed. A method to distinguish tsunami generated by an earthquake or a landslide will be shown. Finally, application of newly invented laser tsunami meter will be presented. The main conclusions are as follows; 1. Tsunami generated by a landslide shows strong directivity compared with that generated by an earthquake. 2. For the early tsunami warning issue, detection of tsunami informations at on site is essential. 3. For this aim, the cheaper tsunami warning systems are necessary and the newly invented laser tsunami meter is one of these.

JSS42/E/12-B4 1500

NUMERICAL SIMULATION OF THE LANDSLIDE-GENERATED TSUNAMI OF NOVEMBER 3, 1994 IN SKAGWAY HARBOR, ALASKA

Evgueni A. Kulikov and Alexander B. RABINOVICH (both at Tsunami Center, Shirshov Institute of Oceanology, 36 Nakhimovsky Prosp., Moscow 117851, Russia, e-mail: abr@tsucen.msk.ru); Isaac V. Fine and Brian D. Bornhold (both at International Tsunami Research, Inc. 11321 Chalet Rd., Sidney, BC, V8L 5M1, e-mail: itri@ii.ca); Richard E. Thomson (Institute of Ocean Sciences, 9860 W.Saanich Rd., Sidney, BC, V8L 4B2, Canada, e-mail: thomsonr@dfo-mpo.gc.ca)

We examine the origin and behavior of the catastrophic tsunami that impacted Skagway Harbor, Alaska, on November 3, 1994. Geomorphic and tide gauge data, combined with a rigorous numerical modeling of the event, reveals that the tsunami was generated by an underwater landslide which also resulted in collapse of a cruise-ship dock undergoing construction. The three-dimensional shallow-water numerical model for a viscous landslide with full slide-wave interaction and subaerial slide was used to simulate tsunami waves in Skagway Harbor caused by the failure.The results of the numerical simulation closely agree with the NOAA tide gauge record and eyewitness observations. The landslide has been linked to critical overloading of the slope at a time of extreme low tide and is consistent with similar events in other coastal regions of the world. In general, we conclude that the numerical model of the submarine landslide associated with the dock failure in Skagway Harbor accounts for all aspects of the observed wave field.

JSS42/W/22-B4 1520

"RED", "GREEN" AND "BLUE" TSUNAMIGENIC EARTHQUAKES: DOES ANY PHYSICAL BASIS FOR THIS CLASSIFICATION EXIST?

V.K. GUSIAKOV (Institute of Computational Mathematics and Mathematical Geophysics, Siberian Division, Russian Academy of Sciences, Novosibirsk 630090, Russia, Email: gvk@omzg.sscc.ru)

In the paper (Chubarov, Gusiakov, 1985), the theoretical dependence of the tsunami intensity I (on the Soloviev-Imamura scale) on the moment-magnitude Mw of a submarine earthquake has been obtained (I = 3.55Mw - 27.1). This formula can be used for calculation of expected (on the basis of the "piston-like" model of the tsunami generation) tsunami intensity for a submarine earthquake with the known moment-magnitude. In this study, we introduce the formal classification of the Pacific tsunamigenic earthquakes on the basis of their dI parameter, that is the difference between the actually observed and the expected tsunami intensity (dI=Iobs-Iexp). Based on the dI value, we divide all tsunamigenic earthquakes with known I and Mw into the three groups: "red" (dI>1), "green" (-1<dI<1), and "blue" (dI<-1). From 293 tsunamigenic events that occurred in the Pacific from 1900 to 1998 and which have both I and Mw values, 90 events fall within the "red" group, 153 are within the "green" group and 50 events are within the "blue" group. The geographical distribution of these tsunamigenic events shows their clear correlation with the climatic and circumcontinetal zonation in the oceanic sedimentation as described in (Lisitzyn, 1996). Namely, two of the five major zones of the oceanic lithogenesis (northern humid zone and equatorial humid zone), that are characterized by the increased rates of the oceanic sedimentation, are clearly indicated by the increased number of the "red" tsunamigenic earthquakes (for instance, 6 of 7 events occurred within the Java trench are "red"). The circumcontinental zonation is clearly expressed by the fact that all the tsunamigenic events occurred in this century in the East China, the Yellow, the Japan, the Okhotsk and the Bering Seas are "red". On the other hand, all major submarine earthquakes that occurred in the remote (from continents) tsunamigenic zones like Guam, Tonga, New Zealand are "green" or "blue". Despite a considerable Mw value (greater than 7.5), many of these events have generated very minor tsunamis with the run-up heights less than 1 meter. The results of this study show that the earthquake-induced disturbance of the bottom sediments, resulted in submarine slumping, can be the leading factor controlling the tsunami generation mechanism, and these processes should be taken into account in the operational tsunami warning as well as in the coastal tsunamizoning.

JSS42/W/25-B4 1600

LIMITATIONS OF FAULT DISLOCATION MODELS FOR TSUNAMI SIMULATIONS ON THE CASCADIA SUBDUCTION ZONE, NORTHWEST COAST, NORTH AMERICA

GEORGE R. PRIEST (Oregon Department of Geology and Mineral Industries, Suite 965, 800 NE Oregon St., #28, Portland, OR 97232, email: george.priest@state.or.us) Edward Myers and António M. Baptista (both at Oregon Graduate Institute of Science and Technology, PO Box 91000, Portland, OR, 97291-91000, email: emyers@ccalmr.ogi.edu; baptista@ccalmr.ogi.edu); Paul Flück (Swiss Federal Institute of Technology, Zürich, Switzerland); Kelin Wang (Geological Survey of Canada, Pacific Geoscience Centre, P.O. Box 6000, Sidney, B.C. V8L4B2, Canada, email: wang@pgc.emr.ca); Curt D. Peterson (Department of Geology, Portland State University, Portland, OR, 97207-0751, email: curt@ch1.ch.pdx.edu)

Three dimensional fault dislocation models (Okada's (1985) point source solution for an elastic half space) are used here to simulate coseismic ruptures on the Cascadia subduction zone for tsunami simulations. Earthquake recurrence of ~450 years, slip of ~15-20 m, and rupture widths (140 km) extending well onshore fit paleoseismic data. Narrower ruptures (70 km) that occur mostly offshore in Oregon and northern California fit thermal and geodetic data. The wide ruptures produced tsunamis about 30 percent lower than narrow ruptures, all other factors equal. Tsunami height varied directly with total slip. A rupture 1,050 km long with 15-20 m slip produced 6-9 m tsunamis, about twice as high as tsunamis from segmented ruptures 450 km in length with 7-10 m slip. The latter ruptures are most consistent with coupling and aspect (length:width) ratios of world wide analogues to Cascadia. Distribution of paleotsunami deposits appears to favor the 6-9 m tsunamis, but uncertainties in the fault dislocation models preclude assuming that lower slip (450 km) ruptures are not reasonable sources. None of the fault dislocation scenarios accurately depict possible inelastic deformation in the accretionary wedge or deformation from local faults, asperities, and submarine landslides, any of which could strongly modify deformation (and tsunamis) relative to the simulations.
Simulation of inelastic deformation in the rheologically weak leading edge of the accretionary wedge was attempted by decreasing slip there. Simulations produced anomalous "spikes" of uplift, because the elastic model treats the area of decreased slip as a strong barrier rather than (as intended) a weak mass. Slip was thus deflected upward at this "barrier," effectively reproducing the same total uplift as full slip, but with a different shape. Tsunami run-up therefore did not decrease as expected.

JSS42/W/18-B4 1620

THE DESTRUCTIVE SEISMIC ACTIVITY OF 1303 IN THE EASTERN MEDITERRANEAN: A POSSIBLE INTERPRETATION BASED ON REALISTIC SYNTHETIC WAVEFORMS

El-Sayed Attya (Geological Department Mansoura University, Mansoura, Egypt, The Abdus Salam International Center for Theoretical Physics, SAND group, Trieste, Italy and Dipartimento di Scienze della Terra – Università di Trieste, Via Weiss, 4 34127 Trieste,
email: elsayeda@geosun0.univ.trieste.it)Fabio Romanelli (Gruppo Nazionale per la Difesa dai Terremoti - CNR, Rome, Italy and Dipartimento di Scienze della Terra – Università di Trieste, Via Weiss, 4 34127 Trieste, Italy, email: romanel@geosun0.univ.trieste.it) Giuliano F. PANZA (Dipartimento di Scienze della Terra – Università di Trieste, Via Weiss, 4 34127 Trieste, Italy and The Abdus Salam International Center for Theoretical Physics, Miramar, Italy, email: panza@geosun0.univ.trieste.it)

The Hellenic Arc is located about 500 km away from the Egyptian border, but earthquakes generated in this area can cause severe effects in Egypt. The observed shaking duration in Lower Egypt due to an event located in the Hellenic Arc is, on average, 3 minutes long. The seismic activity of 8th of August 1303 seems an exception to this pattern in terms of damage and duration of shaking. It was strongly felt in Lower Egypt for about 15 minutes and caused a widespread damage in Crete, Egypt, Rhodes, Jordan, Syria, Palestine, Turkey and Cyprus. The location of the seismic source(s) is ambiguous. Recent seismic activity, synthetic tsunami and ground motion modeling are used to infer the parameters of the possible source(s) from the available historical records. Using as constraint the available macroseismic and tsunami information we propose that two events occurred on the 8th of August of 1303. One earthquake is a shallow event with small to moderate size, located in Egypt, probably to the south of Cairo. This event can be the source of the extensive damage in the Nile Delta, Cairo and Upper Egypt. The other suggested event has a relatively larger size and is situated in the Hellenic Arc at shallow depth. This second event can explain the observed tsunami in the Eastern Mediterranean, the minor to moderate macroseismic effects in a wide area, including sites in, Jordan, Palestine, Syria and Turkey, and the extensive damage in Crete and Alexandria of Egypt.

JSS42/W/10-B4 1640

NUMERICAL STUDY OF THE SOURCE OF THE JULY 17, 1998 PNG TSUNAMI

Vasily TITOV (NOAA/PMEL, JISAO, 7600 Sand Point Way NE, Seattle WA, 98115; email: titov@pmel.noaa.gov) and Frank Gonzalez (NOAA/PMEL, 7600 Sand Point Way NE, Seattle WA, 98115; email: gonzalez@pmel.noaa.gov)

The July 17, 1998 Papua New Guinea earthquake produced a tsunami with very high amplitudes, localized in a small area near the earthquake source. The relatively small earthquake magnitude and the concentration of the tsunami impact have prompted questions about the tsunami source mechanism. Possible source scenarios are landslide, bottom deformation, or a combination of the two. A numerical study of the July 17, 1998 Papua New Guinea tsunami is conducted to estimate discrepancies between different source mechanisms. Several source scenarios are simulated using the MOST numerical model, including a landslide source modeled as a viscous sediment flow and a co-seismic bottom deformation. Sources of various sizes at different locations are tested. Computed runup estimates are compared with measurements obtained by the International Tsunami Survey Team. It is found that several computed scenarios produce the runup distributions along the PNG coast which are reasonably close to the observed runup heights. Both pure landslide and bottom deformation are among these possible generation mechanisms, so it is difficult to distinguish between them on the basis of the runup comparison only. Distinctions in the tsunami runup dynamics for different tsunami sources are discussed. In the case of the PNG tsunami, as well as for many other events, runup values alone present too little information to distinguish between different tsunami source mechanisms. Any additional information about tsunamis, such as current velocities, sediments, number of waves and direct measurements in the possible source area, can provide crucial additional information for the tsunami source determination.

JSS42/W/20-B4 1700

GENERATION OF GRAVITO-ACOUSTICAL WAVES BY BOTTOM DISPLACEMENTS OF FINITE DURATION

M.A. NOSOV, Moscow State University, Faculty of Physics , Russia

The linear potential theory was used for the sake of a comparative study of waves generation by bottom displacements of finite duration in the layer of an ideal incompressible and compressible homogeneous fluid of constant depth in the field of gravity (3-D problem). The analysis of exact analytical solutions to the problem has shown that a substantial difference exists between the behaviour of compressible and incompressible fluids under typical tsunami source conditions. In particular the results of this study indicate that the compressibility of water can not be neglected, if one pretends to give an adequate description of the tsunami generation by bottom displacements of a duration less than 10 H/c, where H is ocean depth in the source region, c is the sound velocity in water. Tsunami source radiates not pure gravitational but a system of gravito- acoustical waves. The further study of the features of this waves could be of interest for tsunami forecasting in terms of tsunami forerunners.

STUDY OF TSUNAMI DEPOSITS IN HOKKAIDO, JAPAN: A PROGRESS REPORT

Kenji SATAKE, Futoshi Nanayama, Koichi Shimokawa (all at Earthquake Research Dept., Geological Survey of Japan, Tsukuba, 305-8567 JAPAN, email: satake@gsj.go.jp); K. Shigeno (Meiji consultant co., ltd.)

We are studying tsunami deposits on both the Japan Sea and Pacific coasts of Hokkaido, Japan, to better understand the sedimentology and the history of earthquakes and volcanic eruptions in the region. Our sites include: Taisei town across from Okushiri Island, where we identified tsunami deposits from the 1993 Southwest Hokkaido (Okushiri) earthquake as well as sand deposited by a 1959 typhoon; Ayukawa coast, where we identified tsunami deposits from the 1741 Oshima-oshima eruption; Kiritappu marsh and Bettoga coast, where we found sand layers from at least six tsunamis. The 1993 tsunami deposited four layers at Taisei. We correlate these layers with landward and seaward flows from the two main tsunami waves; the flow directions are shown by imbrication of gravel, current ripples, and the remains of knocked-down plants. On the other hand, the typhoon deposit forms only one layer and its cross bedding records only landward flow. The tsunami's landward-flow layers are mostly marine sand, whereas the seaward flow layers are composed of non-marine sand and a mixture of soil, gravel, and plant remains. The typhoon deposit is composed of mostly marine sand. The 1741 tsunami was associated with the eruption of Oshima-oshima volcano, but the generation mechanism has not been known. We found several cobbles in the tsunami-sand layer in our trench. The Pacific coast of Hokkaido has been affected by tsunamis from subduction-zone earthquakes both nearby and across the Pacific. We found multiple sand layers interbedded with tephra layers: two sand layers above a 1739 tephra, three sand layers between 1694 and the 10th century, and a few more sand layers below the 10th century tephra.

JSS42/W/01-B5 0850

THE GEOMORPHOLOGY AND SKDIMENTOLOGY OF THE JULY 9TH 1956 AEGEAN SEA TSUNAMI, ASTYPALAEA ISLAND, GREECE

Dale Dominey-Howes (Coventry Centre for Disaster Management, School of the Built Environment, Coventry University, Coventry, CV1 5FB, UK, email: apx124@coventry.ac.uk)

Sediments are described from Livadia aad Stavros, Astypalaea Island, Greece and are interpreted to be associated with the Aegean tsunami of9th July 1956. At Livadia, the marine provenance of the tsunami unit is inferred from two observations. Firstly, the similarity between the clasts comprising the tsunami unit and the contemporary beach sediments from which the sediments are derived, and secondly the inclusion of foraminiferal tests within the sediment matrix. Derivation from the 1956 tsunami, rather than from storm surge is inferred from the uniqueness of the deposits within the sedimentary record, their distinct imbrication and orientation, and 137Cs and 210Pb dating of overlying and underlying colluvium. The top of the tsunami sediment layer occurs at+2.00 meters above sea level indicating minimum flood level. At Stavros, the marine provenance of the tsunami sediments is demonstrated by the inclusion of marine mollusca, while the sediments here occur up to an elevation of+10.00 meters above sea level. The minimum flood levels indicated by these deposits are significantly lower than values previously reported. The results presented here represent the first systematic investigation into the geomorphology and sedimentology of modern Aegean tsunami, and, when combined with geomorphological evidence, indicate that previous reports of flooding from the 1956 tsunami were significantly over-estimated. Such over-estimation of flood levels may have important implications for tsunami hazard risk assessment and emergency pre-planning.

JSS42/P/02-B5 0910

GLOBAL DISTRIBUTIONS OF PEAK FREQUENCY AND THE AMPLITUDE TO THE BIGGEST THREE PACIFIC TSUNAMIS IN THIS CENTURY

Kuniaki Abe (Niigata Junior College, Nippon Dental University, Hamauracho 1-8, Niigata City, 951-8580, JAPAN, email: abeku@ngt.ndu.ac.jp)

Amplitude spectra were obtained for tide-gage records of the 1952 Kamchatka, 106 Chilean and 1964 Alaska tsunamis in all over the Pacific. Number of used stations are 38 (1952), 42 (1960) and 61(1964). The spectrum was calculated using Goertzel method for 6 hour's time history including the initial arrival from which tidal level was reduced and plotted for the frequency range from 0 to 2mHz(8.3min in period) at the interval of 0.0l mHz. In the spectrum we noticed a peak frequency and the amplitude. They were discussed in relation to the epicentral distance, which is approximately propagation distance, and azimuth angle of the station to the epicentre.
Average peak frequencies obtained are 0.46 (1952), 0.34 (1960) and 0.36 (1964) in mHz. The difference is mainly attributed to sea-depth at the source because of the proportionality to long wave velocity. The approximate average sea-depths are 2000m, 650m and 150m, respectively. In the amplitude-distance curve amplitude increased or kept a constant value for the distance larger than 10000km. The increase is noticeable for the azimuth direction normal to trench axis. This fact suggests a geometrical contraction of tsunami after passing the critical distance of a quarter of global circumference. The remarkable tendency in the 1952 Kamchatka tsunami is related to station distribution. Azimuth dependences of peak frequency and the amplitude were also observed and support a directivity of wave radiation from the source. Particularly, the largest value in all the peak frequencies for each tsunami is found in the direction approximately normal to the trench axis. If taking into consideration of curving wave ray, we conclude that tsunami including the highest frequency is radiated to the direction normal to the trench axis.

JSS42/E/05-B5 0930

DISTRIBUTION FUNCTIONS OF RUNUP HEIGHTS FOR RECENT TSUNAMIS BASED ON OBSERVED DATA

Efim PELINOVSKY (Laboratory of Hydrophysics and Nonlinear Acoustics, Institute of Applied Physics, 46 Uljanov Str., Nizny Novgorod, 603600, Russia, email: enpeli@appl.sci-nnov.ru); Igor Ryabov (Department of Applied Mathematics, Nizhny Novgorod Technical State University, 24 Minin Str., Nizhny Novgorod, 603600, Russia, email: igor@cced.kis.ru)

Studying the characteristics of the runup heights for several historic tsunamis, Van Dorn, Kajiura and Go have found that the distribution functions of the tsunami heights are described by the log-normal distribution. The aim of this paper is to obtain the distribution functions of the runup heights for recent tsunamis. The observed data of following tsunamis were analysed: Flores (12.12.92); Japan Sea (12.07.93); Java (02.06.94), Shikotan (04.10.94); Mindoro (14.11.94); Sulawesi (01.01.96); Irian Java (17.02.96), Peru (21.02.1996), Papua New Guinea (17.08.98). It is confirmed that the log-normal distribution describes the observed data well, and parameters of this distribution are found. An important problem of the quality of the prognostic characteristics of the tsunami distribution is discussed taking into account different numbers of the observed points.

JSS42/W/21-B5 0950

IMPACT OF LARGE TSUNAMIS IN THE MESSINA STRAITS, ITALY

Stefano Tinti, Alberto Armigliato and Francesca Fiorini (all at Dipartimento di Fisica, Settore di Geofisica, Università di Bologna, e-mail: steve@ibogfs.df.unibo.it, armigliato@ibogfs.df.unibo.it)

Among the Italian coasts, Messina Straits are one of the most exposed to tsunami attacks. Several historical events are reported for this region, generated both locally and in the surrounding regions, in particular in Thyrrenian Calabria to the north (the 1783 event) and in eastern Sicily to the south (1693). The 28 December 1908 earthquake generated tsunami was the last catastrophic event affecting this region: a large body of documents and reports exists for such event, as well as some tide-gauge records some hundred km away from the source. Nowadays, the Messina Straits coasts are characterised by a large number of urban, industrial and touristic settlements: in addition, towns like Messina and Reggio Calabria represent fundamental nodes for transports. The tsunami hazard assessment for the Messina Straits is then a very relevant problem, which may be faced on the basis of documents available for historical events, of the available geological and seismotectonic information and of numerical modelling and simulations.

JSS42/E/18-B5 1010

TSUNAMIS IN CENTRAL AMERICA

Mario Fernandez Acre, (Escuela Centroamericana de Geologia, Universidad de Costa Rica, San Jose, Costa Rica) Enrique Molina, (Instituto de Sismologia, Volcanologia, Hidrologia y Meteorologia de Guatemala, Guatemala) Jens HAVSKOV and Kuvvet Atakan (both at Institute of Solid Earth Physics, University of Bergen, Allegaten 41, 5007 Bergen, Norway, email: jens@ifij.uib.no)

A catalog of tsunamis has been compiled for Central America containing 49 tsunamis for the time period 1539 to 1996. This is believed to be the most complete catalog made so far. Most of the information (43 events) is reported after 1850. 12 of the tsunamis occurred on the Caribbean side and 37 on the Pacific side. 47 tsunamis were related to local earthquakes while 2 were caused by earthquakes outside the region. On the Caribbean side, there only seem to be a tsunami risk due to local earthquakes in the north and the south while on the Pacific side, the whole coast can experience tsunamis. Here the highest risk is along the costs from Guatemala to Nicaragua and outside Central Costa Rica. About 500 persons are known to have been killed by tsunamis and the largest known tsunami occurred in Nicaragua in 1992 killing 170 persons. On the Caribbean side, all earthquakes near the coast and larger then Ms have generated a significant tsunami while on the Pacific side only 43% of coastal earthquakes larger then 7 have generated significant tsunamis. These facts will be used as criteria for the new tsunami warning center to be set up in Central America.

JSS42/E/17-B5 1030

DEVELOPMENT OF LASER TSUNAMIMETER

Shoji SAKATA and Shin'ichi Iwasaki (both at National Research Institute for Earth Science and Disaster Prevention, Ten'nodai 3-1, Tsukuba-shi, Ibaraki-ken, 305-0006, Japan, email: sakata@geo.bosai.go.jp)

Direct observation of tsunami heights in off-shore areas by tsunamimeters installed on the sea bottom is very effective for mitigation of tsunami disasters. We have been developing a new laser tsunamimeter based on the invention by Sakata. The inspilation for this tsunamimeter came from the concept of the borehole laser strainmeter, of which development Sakata has been engaged in. Later Sakata invented an ingenious device for cancellation of effects of temperature change of the sea water around the vessel. By adding this device to the original laser strainmeter the concept of the laser tsunamimeter is completed. This laser tsunamimeter has many advantages over the conventional tsunamimeter of the quartz oscillator type. The change of the diameter of the vessel of the undersea part caused by pressure change due to the tsunami propagation is detected as the change of resonance frequency of the Fabry-Perot interferometer. Due to the simple design of the undersea part, in which neither IC nor mechanically movable part is included, possibility of trouble will besmall. Electricity supply to the undersea part is not necessary since it is connected to the land part by only optical fibers. The slender cable needs smaller amount of cost for production and installation. Expectedresolution is between 0.1-1cm. Recently we completed the production of the undersea part .

JSS42/W/02-B5 1110

RECENT TSUNAMIS OF 1990-1998 IN THE PACIFIC: GENERAL OVERVIEW

V.K. GUSIAKOV (Institute of Computational Mathematics and Mathematical Geophysics, Siberian Division, Russian Academy of Sciences, Novosibirsk 630090, Russia, Email: gvk@omzg.sscc.ru); J.F.Lander (National Geophysical Data Center, Boulder, CO 90309, USA, Email: jfl@ngdc.noaa.gov)

A comprehensive list of recent tsunamis occurred in the Pacific during the last nine years has been compiled as part of the joint IUGG Tsunami Commission and ICG/ITSU Project "Basic Pacific Tsunami Catalog and Database, 47 B.C. - 2000 A.D." The list contains 77 tsunamigenic events occurred in the Pacific from 01.01.1990 to 31.12. 1998. From these events, 60 have validity 4 (definite tsunami), 10 - validity 3 (probable tsunami) and 7 events still have validity 2

(questionable tsunami). For all the events, having at least one run-up measurement, the tsunami intensity I (on the Soloviev - Imamura scale) has been calculated. In terms of this parameter, the smallest but still detectable event was the February 9, 1991 Solomon Islands tsunami (I=-4.5) with the reported maximum wave height of only 3 cm. The three strongest events within this period were the July 12, 1993 Okushiri tsunami (I=3.1) with the highest run-up of 30.6 m, the July 17, 1998 New Guinea tsunami (I=3.1) and the September 2, 1992, Nicaragua (I=2.8). Several major submarine earthquakes having Ms or Mw value greater than 7.6 generated very minor tsunamis (with the wave height less that 0.5 meter). During this period, 30 regional and 1 Pacificwide warnings were issued by the national and the regional tsunami warning centers. Among them, only 10 warnings can be considered as justified, in other cases the maximum run-up height observed at the coast was less than 1 meter. By different reasons, for 3 damaging tsunamis warnings were not issued in time. They are the September 2, 1992, Nicaragua, the December 12, 1992, Flores and the January 1, 1996 Sulawesi tsunamis. Analysis of historical tsunami occurrence in the Pacific in this century shows that the last nine years had the slightly increased level of perceptible (I=1) as well as damaging (I=2) tsunamis as compared to the long-term average. Their annual rates of occurrence in 1990-98 were 2.2 and 1.1 against 1.7and 0.75 in 1900-98, respectively.

JSS42/E/18-B5 1130

A NEW TSUNAMI CATALOGUE FOR EASTERN MEDITERRANEAN SEA

G. A. PAPADOPOULOS (Institute of Geodynamics, National Observatory of Athens, 118 10 Athens, Greece, email: g.papad@egelados.gein.noa.gr)

A new catalogue of tsunamis occurring in the area of Eastern Mediterranean Sea from the antiquity to 1998 has been compiled on the basis of original historical documents, previous catalogues, scientific papers as well as of geological and archaeological evidence. The format of the catalogue is similar to that arranged by the GITEC group for the new European Tsunami Catalogue. The data incorporated in the new catalogue have been elaborated as for their completeness and reliability described as a function of time and of the particular geographic regions covered.

JSS42/E/20-B5 1150

OFFSHORE GEOLOGICAL ASPECTS OF THE SISSANO TSUNAMI PAPUA NEW GUINEA

DAVID R TAPPIN, British Geological Survey, Keyworth, Nottingham, NG12 5GG UK Takeshi Matsomotu, Japan Marine Science and Technology Centre, Natsushima-Cho, Yokosuka, 237-0061, Japan and shipboard scientific party.

A survey to investigate the offshore aspects of the July 1998 Sissano tsunami was carried out in January 1999 by the Research Vessel Kairei. It was coordinated by the Japan Marine Science and Technology Centre and the South Pacific Applied Geoscience Commission and acquired multibeam bathymetry, seabed sonar, sub-bottom profiles and piston cores. Models of the tsunami event have so far been based upon a fault solution. However, other evidence suggests that seabed faulting may be only part of the cause.
The survey results reveal a complex seabed morphology that is attributable to subduction of the Pacific Plate southwards beneath PNG along the New Guinea Trench. A narrow shelf 10 kilometres wide lies offshore of Sissano and passes seaward into an inner trench slope dissected by submarine canyons. Sediment transported from the land mainly bypasses the upper inner trench slope and is transported out into lower slope basins, into the trench and out onto the Pacific Plate. Sediments on the inner trench wall are cohesive clays, whereas in the lower slope basins and the trench they are interbedded fine clays (hemipelagites) and silts (turbidites). The inner trench slope is faulted and bears large arcuate scars interpreted as signs of slope failure. This failure is interpreted as taking place through rotational faulting rather than as debris flows. Nearshore bathymetry off of Sissano suggests a subsided delta front that may provide a focusing mechanism for the Sissano tsunami.

JSS42/P/01-B5 1210

FLOWS STRENGTH ON LAND OF THE 1998 PAPUA NEW GUINEA TSUNAMI

Hideo MATSUTOMI (Dept. of Civil and Environmental Eng., Akita Univ., Akita, 010-0852, Japan, email: matsu@ipc.akita-u.ac.jp); Yoshiaki Kawata, Yoshinobu Tsuji, Koji Fujima, Fumihiko Imamura, Masashi Matsuyama, Tomoyuki Takahashi, Norio Maki and Seh-Sub Han (Members of 1st and 2nd International Tsunami Survey Team); Nobuo Shuto (Faculty of Policy Studies, Iwate Prefectural Univ., Iwate, 020-0173, Japan, email: shuto@iwate-pu.ac.jp)

Field survey was conducted two times: during August 3 to 6 and September 30 to October 3, 1998. Main items of the survey were: (1) spatial distribution of both tsunami height and inundation depth in Sissano, Wapapu, Arop 2, Arop 1 and Malol regions, (2) dimension of houses and their floor height, (3) degree of damage to houses and (4) sand erosion depth and sand grain size on the sand spits of Sissano lagoon. Based on these data, (1) current velocities on flat land and on the sand spits, (2) relation between inundation depth and degree of damage to houses, (3) dependency of sand erosion depth on current velocity and so on are discussed. Laboratory experiments were also carried out to confirm the state of flow on the sand spits.
Results indicate that: (1) the largest inundation depth of 10m was found at Arop 2, and the current velocity was estimated greater than 10 m/s, (2) current velocities on flat land had the same tendency as that in past tsunamis, (3) wooden houses which are church were destroyed when the inundation depth exceeded 1 m. This critical depth is very small compared with that in other places and (4) the dependency of sand erosion depth on current velocities on flat land is the same as that in past tsunamis. But, that on the sand spits was different. As a reason, it is considered that undulate jumps would be formed on the lagoon side.

JSS42/W/15-B5 1230

CLUSTER ANALYSIS OF TSUNAMI MARIGRAMS

Gerald T. Hebenstreit (SAIC, Ocean Systems Group,1710 Goodridge Drive, McLean, Virginia, USA, 22102,703-827-4975, email: gerald.t.hebenstreit@cpmx.saic.com)

Teletsunamis and some local tsunamis on long coastlines are often marked by surprising differences in the intensity of tsunamis seen in marigrams. One section of a coastline may receive clearly apparent waves, while another section close by may recieve much less apparent effects. Cluster analysis is a tool which uses the characteristics of the data to delineate patterns that may not be apparent to visual observation. The analysis makes no assumptions about the data other than that the various pieces can be directly compared. Marigrams from two tsunamis - Chile 1985 and Andreanof Islands 1996 - were examined to identify possible systematic (as opposed to local) patterns in the dispersion of tsunami intensity on coastlines.

PHYSICAL AND NUMERICAL MODELLING

JSS42/W/06-B5 1400

TSUNAMI RUNUP INTERACTIONS WITH A TEST STRUCTURE

Harry YEH, Halldor Arnarson, and Catherine Petroff (all at Department of Civil & Environmental Engineering, University of Washington, Seattle, WA 98195-2700, USA, email: harryeh@u.washington.edu); Razvan Bidoae and Peter Raad (both at Department of Mechanical Engineering, Southern Methodist University , Dallas, TX 75275-0337, USA, email: peter@seas.smu.edu)

The hydrodynamics of local tsunami runup interactions with a structure were investigated both experimentally and numerically. A tall, vertical column with a square footprint was used as a model of the structure, and the tsunami runup was assumed to take the form of a uniform turbulent bore. In the laboratory, the impact and transient load forces on the column were measured with a load cell, while detailed temporal and spatial variations of the tsunami runup profiles were obtained with a laser-induced fluorescent technique. Furthermore, water velocities at various locations around the column were measured with a laser Doppler anemometer. The numerical simulations were obtained by the use of the recently developed three-dimensional surface marker and micro cell (3DSMMC) technique, which is a fully three-dimensional finite-volume approach that treats the free-surface dynamics by the use of Lagrangian surface markers defined in more highly resolved surface cells. The transient numerical results are in good agreement with the laboratory results in terms of the net force exerted on the column, the water-surface variations, and the flow velocities around the column. The favorable agreement of the numerical model with the laboratory data demonstrates that the numerical capability can be used with confidence in practical field applications to assess local effects of tsunami runup.

JSS42/E/21-B5 1420

CHARACTERISTICS OF ON-SHELF TSUNAMIS AND THE ACCURACY OF THE NUMERICAL SIMULATION

Shun-ichi KOSHIMURA (DCRC, School of engineering, Tohoku University, Aoba 06, Sendai 980-8579, JAPAN, email: kossy@tsunami2.civil.tohoku.ac.jp), Fumihiko Imamura (DCRC, School of engineering, Tohoku University, Aoba 06, Sendai 980-8579, JAPAN,
(email: imamura@tsunami2.civil.tohoku.ac.jp), Nobuo Shuto (Faculty of Policy Studies, Iwate Prefectural University, Morioka, Japan, (email: shuto@poly.iwate-pu.ac.jp)

The waveform and amplitude of obliquely incident tsunamis on a slope such as a continental shelf vary according to the conditions of incidence. However, there are cases that numerical simulation can not predict the characteristics of these on-shelf tsunamis with sufficient accuracy. Especially, if the tsunami is incident almost parallel to the slope, numerical result differ significantly depending on the grid size because of the error associated with the refraction of shallow water waves. So far, there is no criterion for the option of appropriate grid size for the numerical computation except for the specific case such as tsunamis around islands proposed by Fujima et al. (1998).
In the present study,the condition to obtain the accurate result in the numerical simulation of on-shelf tsunamis are discussed by taking the following procedure.
(1) We derive the analytical solutions of on-shelf tsunamis which is obliquely incident on a constant slope with arbitrary waveform.
(2) Based on the solutions obtained,the fundamental characteristics of on-shelf tsunamis are discussed for various types of incident waves.
(3) The numerical solutions of on-shelf tsunamis by the Leap-Frog finite difference method with a variety of grid sizes are compared with the analytical ones obtained by the present study,and the magnitudes of the errors are examined.
(4) The criterion of the grid size to obtain the sufficiently accurate result in the numerical simulation of on-shelf tsunamis is proposed.

JSS42/W/26-B5 1440

THE TSUNAMI COMMUNITY MODELING ACTIVITY (TCMA)

F.I. GONZALEZ, E.N. Bernard and S. Hankin (all at NOAA's Pacific Marine Environmental Laboratory, 7600 Sand Point Way, NE, Seattle, WA, 98115)

Tsunami modeling is a critical community activity that contributes to the overriding goal of saving lives and property. In particular, our community conducts R&D that is focused on model improvement and the development of effective tools for hazard mitigation. A Tsunami Community Modeling Activity (TCMA) is a way to facilitate this R&D process. Community models are well-established as valuable tools in other scientific communities. Good examples are the ocean circulation models maintained at the Institute of Marine and Coastal Sciences at Rutgers University, the Princeton Ocean Model (POM) maintained by Princeton's Program in Atmospheric & Oceanic Sciences, and the Australian Community Ocean Model (ACOM) maintained by the CSIRO Division of Marine Research in Hobart, Tasmania. The value of a community model rests on the following assumption. If easier and more widespread access to models and associated databases is provided, then the R&D to improve model science and develop more effective applications will be accelerated by broadening the user base and providing a mechanism to incorporate and document subsequent innovations and advances. The TCMA will provide a much-needed focal point for the tsunami research community to improve model physics and numerical techniques. Multiple users of the same model and databases will create regular, systematic, and invaluable feedback that will be exploited to improve the models and provide a high degree of quality control on both the model and related databases. A "community memory" will be created and institutionalized, so that important advances are not lost, redundancy and "re-inventing the wheel" is minimized, and the next generation of tsunami modelers will not be obliged to "start from scratch." Finally, and perhaps most importantly from a practical point of view, an optimal environment will be created for the systematic development and improvement of hazard mitigation products. A first step in developing an effective TCMA and enhancing the tsunami modeling R&D environment is the implementation of a distributed facility for the analysis and comparison of tsunami simulations (FACTS) that will allow global, transparent sharing of databases and model results that are resident on servers of participating institutions. FACTS will exploit the World Wide Web and additional existing technologies: Live Access Server software to seamlessly link each server; the FERRET applications package for manipulation, comparison, and analysis capabilities; the NSF/NASA supported Distributed Ocean Data System (DODS) from the University of Rhode Island for networked scientific data communications …

JSS42/W/07-B5 1500

OFFSHORE FORECASTING OF ALASKIAN TSUNAMIS IN HAWAII

V.V. TITOV, H.O. Mofjeld, F.I. Gonzalez and J.C. Newman (all at NOAA/PMEL, JISAO/UW, 7600 Sand Point Way NE, Bldg.3, Seattle, WA, 98115, USA, e-mail: titov@pmel.noaa.gov)

This study is an R&D activity conducted in an effort to develop tsunami forecasting tools for the Pacific Disaster Center (PDC). The research includes analytical and numerical sensitivity studies of tsunami wave characteristics offshore of Hawaii, for ranges of earthquake source parameters in the Alaska-Aleutian Subduction Zone (AASZ). The results demonstrate that, for a fixed location and magnitude, there is very weak dependence of the offshore tsunami characteristics on a reasonable range of other AASZ earthquake parameters. This sensitivity study provided guidance for the construction of a database consisting of pre-computed tsunami scenarios. The simulation results are stored as an online database with a WWW interface. A database user can very quickly obtain a model prediction of the tsunami offshore wave heights at chosen locations, for a wide variety of AASZ earthquake scenarios. Direct tsunami observations can be combined with the forecast database to improve the accuracy of the tsunami forecast methodology.Potentially, the best approach to forecasting the impact of a particular tsunami event on a specific coastal site is to perform real-time tsunami model simulations that include real-time data assimilation. As a community, we should work toward this difficult "Holy Grail" of tsunami forecasting. However insufficient real-time earthquake data and a lack of confidence in tsunami generation and inundation modeling, presently render the implementation of such an operational capability imprudent.Fortunately, however, existing numerical models are good enough to provide useful guidance, if exercised with care by an experienced tsunami modeler. Event- and site-specific inundation estimates can be computed far in advance of the earthquake, thoroughly tested and scrutinized for reasonableness and sensitivity to errors, then stored as a database. When an event occurs, the appropriate pre-computed results can be recalled, modified by data assimilation schemes that utilize a user-friendly interface to incorporate real-time tsunami measurements, and then made available to aid hazard assessment and evacuation decision-making.

JSS42/W/09-B5 1520

TSUNAMI SCOUR MECHANISMS AROUND A CYLINDER

Harry YEH (Department of Civil & Environmental Engineering, University of Washington, Seattle, WA 98195-2700, USA, email: harryeh@u.washington.edu); nji Sato and Norifumi Kato (both at Public Works Research Institute, 1 Asahi, Tsukuba, Japan, email: sato@pwri.go.jp)

It is known that tsunamis cause substantial erosion and scours on shore. The scour mechanisms around on-shore structures are expected to be different from the present understanding of bridge or pier type scour processes in a river or coastal environment. Flows associated with tsunami runup are not steady nor uniform, and the scouring occurs in a short duration, less than half an hour. In order to understand fundamental mechanisms of the scouring, a series of experiments was performed in a 135 m long, 2 m wide, 5 m deep sediment tank; this large facility is necessary because the substantial scale effects are anticipated for the sediment motions. The maximum stroke of the wave paddle is 2.4 m and it was tested and proven to generate, at least, a clean solitary wave of 40 cm high in 3 m deep of water. The circular column is used as a structure model, and is placed upright at three different locations: 1) 4m on-shore from the shoreline, 2) at the shoreline, and 3) 4 m offshore from the shoreline. The cylinder is 50 cm in diameter, made of 1 cm thick Plexiglas. Because of its transparent cylinder wall, the scouring process is conveniently recorded with three miniature CCD video cameras equipped inside of the cylinder, which cover more than 180 degrees of the circumference view. Pore pressure transducers are placed at four locations around the cylinder in the sediment depths of 10 cm, 20 cm and 30 cm. Also placed are the capacitance type wave gages and an electromagnetic flow meter. It was found that the maximum scour occurs during the tsunami drawdown stage and is approximately twice the depth of the final scour configuration. Based on the pore pressure data as well as the video images, sediments around the cylinder appear to become liquefied during the drawdown process.

JSS42/W/17-B5 1600

NUMERICAL SIMULATION OF 1998 PNG TSUNAMI ON A NEW BATHMETRY BY KAIREI

Masafumi MATSUYAMA, Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-shi, Chiba-ken, Japan.

The 1998 Papua New Guinea (PNG) tsunami caused devastating damage and casualty along the north coast of PNG, in particular near Sissano lagoon. Surveyed tsunami effects were much greater than the estimated based on the available seismic and bathymetry data. The similar discrepancy is often attributed to the phenomenon so called "the tsunami earthquake." This PNG event does not fit to the characteristics of the tsunami earthquake. The survey also found that only narrow coastal area, approximately 30 km long, around Sissano lagoon was significantly affected by the tsunami; the tsunami effects drastically decrease away from the region. In order to explain the discrepancies, Japan Marine Science and Technology Center(JAMSTEC) and South Pacific Applied Geo-Science Commission(SOPEC) conducted the marine geophysics survey in January, 1999. During the cruise, detailed bathymetry data and sub-bottom profiles are obtained in the offshore area adjacent to Sissano lagoon. With the obtained bathymetry data and the newly discovered fault location, Numerical simulations for the PNG tsunami were performed using the standard seismic model. It was found that significant tsunami-energy focusing toward Sissano lagoon is caused by the bathymetry effects. Furthermore, a possible submarine landslide site was identified, and the initial condition for the landslide generated tsunami is estimated. Even the landslide source area is small (5 km x 7 km), the computed runup heights around Sissano lagoon is significant (approximately one half the measured values). More importantly, the runup height distribution along the shore is qualitatively in good agreement with the simulation. The results demonstrate that the acurate bathymetry and the source location are critical for the predictions for tsumani runup.

JSS42/W/01-B5 1620

NON-REFLECTIVE OPEN BOUNDARY CONDITION FOR TSUNAMI NUMERICAL SIMULATION

Tomoyuki Takahashi (DRS, DPRI, Kyoto University, Uji, Kyoto 611-0011, Japan, email: tomo@drs.dpri.kyoto-u.ac.jp)Hiroya Ishihara (Fac. of Engineering, Kansai University, Suita, Osaka 564-8680, Japan, email: gj50010@edu.kansai-u.ac.jp)Yoshiaki Kawata (DRS, DPRI, Kyoto University, Uji, Kyoto 611-0011, Japan, email: kawata@drs.dpri.kyoto-u.ac.jp)

In order to carry out numerical simulation stably and with high precision, the setup of suitable boundary condition is indispensable. The boundary condition in tsunami numerical simulation is divided into the land side and the offing side. As for the boundary condition on the land side, there are a vertical wall condition and a runup condition, and a lot of studies about it have been made so far. Especially, much knowledge about the runup condition has been obtained theoretically and experimentally. On the other hand, as for the boundary condition on the offing side, the method of the long wave approximation, the characteristics method and the method of the virtual non-reflecting plane boundary are used well. However, they have been used without sufficient examination about their accuracy and stability. Although the free penetration of the progressive wave generated inside the computational area needs to be carried out, it turns out that a reflected wave occurs according to open boundary conditions. The reflected wave returns to the computational area and will cause instability and lower accuracy. Especially, the reflected wave occurs mostly by the case when the progressive wave diagonally approach to the boundary and the case where depth is shallow or bottom slope is large in the vicinity of the boundary. To reduce the influence of the reflected wave, the computational area is taken widely. But this makes a problem that the amount of the computation and the computation time become large.Moreover, it is abundant to compute without investigating what reflected wave has occurred at the open boundary. Then, by this research, each non-reflected open boundary condition was compared about the various depth, bottom slope and incident angle, and the applicable condition in tsunami numerical simulation was examined.

JSS42/E/09-B5 1640

COMPUTATIONAL EXPERIMENTS FOR SIMULATION OF TSUNAMI EFFECTS NEAR SOUTH KURIL ISLANDS

TATYANA IVELSKAYA, Sakhalin Tsunami Warning Center, 78, Zapadnaya str., Yuzhno-Sakhalinsk, 693000, Russia, email: TWC@Sakhalin.ru. Vasily hramushin, Special Research Bureau for Automation of Marine Researches, Far East Branch of Russian Academy of Sciences, 25 Gorky str., Yuzhno-Sakhalinsk, 693013, Russia, email: Khram@Sakhalin.ru;

The tsunamis and storm surges are dangerous sea phenomena, however, these admits the possibilities to organize the actions for the evacuation of peoples, will have earliness from a few minutes or a next hours.
The decision of a problem of numerical simulation with the purpose of operative forecasting of wave processes in a coastal zone for specific tsunami is described in this work.
As initial data for modeling a tsunami parameters of earthquakes, and also the information on displays a tsunami on coast are used the experience of work on realization of similar computational experiments at modeling of real tsunami has shown good results, which give sufficient conformity with records a tsunami.

TSUNAMIS BY VOLCANIC EXPLOSIONS: DEPOSITS AND RUNUP DATA FROM THE 1996 ERUPTION IN KARYMSKOYE LAKE, KAMCHATKA, RUSSIA

Alexander BELOUSOV and Marina Belousova (Institute of Volcanic Geology and Geochemistry, Petropavlovsk-Kamchatsky, Russia, email: Belousov@g23.relcom.ru) Barry Voight (The Pennsylvania State University, USA, email: voight@ems.psu.edu)

The 1996 subaquatic explosive eruption in Karymskoye lake (4 km across, maximal depth 70 m) generated multiple tsunamis. The steep northern shore of the lake adjacent to the crater was violently eroded by the tsunamis, with all plants and soil more than 1.5 m thick stripped off, and poorly consolidated bedrock exposed. Along the rest of the shoreline, more than 1.3 km from the crater, the tsunamis carved new cliffs up to 2 - 3 m high, eroded the upper layer of frozen soil up to 50 cm thick, and inundated adjacent areas as shown by vegetation removal, or destruction of alder bushes. In the band of devastation the tsunamis deposited several discontinuous, finely laminated layers of sand and gravel up to 35 cm thick, with scattered pebbles, fragments of plants and clots of soil. The distinctive band of devastation, and the tsunami deposits, allowed us to measure the runup height of the tsunamis at 24 points around the lake. These data enable determination of a law of attenuation of runup (wave) height for "explosive" tsunamis, which is compared with theoretical modelling. For the proximal zone, to radial distances (r) up to 1.3 km, the runup height (R) shows rapid attenuation (from >30m to 8 m) with distance as log R = -0.56 log[r] + 5.8. For the distal zone, r > 1.3 km, R decays more slowly (from 8m to 3m) as log R= -1.98 log[r] + 16.3. Rapid decay in proximal zone suggests that in the near field of the explosion the tsunami propagate as a collapsing wave with discontinuous change in height. The break-in-slope of the runup plot at 1.3 km suggests that the tsunami propagate further as a decaying one-dimensional wave in a channel of approximately constant width.

JSS42/W/13-B5 Poster 1700-02

LOCAL TSUNAMIS GENERATED BY STORM WAVES

GERARD J. FRYER (Hawaii Institute of Geophysics & Planetology, University of Hawaii at Manoa, 2525 Correa Rd, Honolulu, HI 96822, USA, email: gerard@hawaii.edu)

Many orphan tsunamis (events without identifiable sources) have occurred in the two centuries of recorded Hawaiian history. Such "tsunamis" have been commoner in the winter months, when surf can reach 10 m, so they are dismissed in the catalogs as "waves of meteorological origin." Unexplained, however, is occasional inundation far larger than expected even from 10-m surf. Inundation and damage have been so extensive that a true tsunami is the only possible explanation. Without a local earthquake, such an event is assumed to be "a tsunami from a distant but unknown source." The assumption is reasonable: flooding reports are typically from north-facing coastlines, and to the north lie the sparsely-populated Aleutian Islands, where tsunamigenic earthquakes (until the modern era of worldwide instrumentation) might pass unreported. It is now clear, however, that at least three events (in 1860, 1878, and 1903) were not from distant sources. Each of the major Hawaiian Islands has a broad, north-facing bay prone to extreme tsunami runup: Hilo on the Big Island, Kahului on Maui, Waialua on Oahu, and Hanalei on Kauai. A teletsunami producing high runup in one of these bays invariably produces high runup in all. The orphan events, however, affect only Kahului and Waialua Bays, the adjacent coastlines of Maui and Oahu, and the north coast of Molokai. Since the orphans occur only when surf is exceptionally high, it seems probable that by pumping up pore pressures, storm-generated waves drive bottom sediments to failure. The resulting landslide generates a tsunami whose effects are added to the already-large waves. The limited geographic extent of the anomalous flooding clearly identifies the locus of the landslides: the north slope of Molokai.

PALEO-TSUNAMIS NOVEL FINDINGS FROM NORTHWESTERN EUROPE

Nils-Axel Mörner Paleogeophysics & Geodynamics, S-10691 Stockholm, Sweden, email: morner@pog.su.se

Tsunamis are able to cause disasterous damage to coasts and coastal habitation. They are generated by coastal and submarine vertical fault movements or huge submarine slides. It is a well known phenomenon in the Pacific region. The Lisbon 1755 event is classic. In recent years we have also started to appriciate their imprints in our paleorecords. Past events are documented in the Mediterranian region. More surprising are the records from NW Europe. First we learned about the tsunami of the 7200 BP Storegga submarine slide outside Norway and its effect along the coasts of Norway and Scotland. The latest news come from Sweden where we have been able to document a major earthquake (generating liquefactoin over 320 km) occurring in the autumn of varve 10,430 BP and a subsequent event occurring in varve 9663 BP (generating seismites over 210 km). Both events generated tsunamis; the first one washed the strait between the Baltic and the North Sea free of ice so that marine water suddenly could invade the Baltic basin (by this creating the Yoldia Sea stage sensu stricto). The second event set up a wave recorded in the sea bed sedimentology and ice marginal shore morphology. A triple sedimentary sequence was recorded indicating sucking motions towards the epicenter, a deformational wave away from the epicenter, and a strong back-swash wave depositing high energy accumulations, deforming beds underneath and setting up a turbidite which is recorded in the varve chronology over an area of 210 km (in varve -424 = varve 9663 BP). Other deglacial events are under investigation. An event of more local character has been recorded in a lake system and dated at about 3500 BP. This gives a totally new picture of the long-term seismic hazard and actual occurrence of tsunami events in Sweden and surrounding regions.

IDENTIFICATION OF TSUNAMI DEPOSIT AND ITS APPLICATION FOR EVALUATING HISTORIC TSUNAMI HAZARDS IN HOKKAIDO, NORTHERN JAPAN: A REVIEW

YUICHI NISHIMURA (Institute of Seismology and Volcanology, Hokkaido University, Sobetsu 59, Usu-gun, Hokkaido 052-0103, Japan, email: nishi@eos.hokudai.ac.jp) Naomichi Miyaji (Shizuoka Prefectural Agricultural Experiment Station, Godo, Hamaoka-cho, Ogasa-gun, Shizuoka 437-1613, Japan, email: miyaji@ss.sand.agri-exp.pref.shizuoka.jp)

We have studied geological evidence for recent and historic tsunamis which a ttacked Hokkaido, northern Japan. At various kind of land beside the beach, we made pits to take core samples or excavated trenches, and identified tsunami deposits overlies volcanic ash soil, old dune and peat. These tsunami deposits are found to show some common features: (1) Deposit thickness and mean grain sizes decrease with distance from the sea. (2) The thickness and lithofacies vary according to the original surface undulation. (3) Graded bedding reflecting tsunami runup and backwash is present in thick deposits. It was possible to find coarse tsunami deposits sandwiched by fine dune sands, but hard to specify the original tsunami event except that known volcanic tephra lies closely. On the other hand, the age could be estimated for tsunami deposits in homogeneous peat deposit based on growth rate of the peat. When the upper boundary of a tsunami deposit is traced, we can estimate the minimum height of its corresponding tsunami runup. For the 1640 tsunami caused by an eruption of Hokkaido Komagatake, which killed more than 700 people around Uchiura Bay, we examined documentary descriptions, made numerical computations and traced tsunami deposits. It is useful to combine these independently obtained data to estimate height distribution of a historic tsunami and evaluate its disaster.

1952 NORTH KURIL TSUNAMI: A NEW DATA FROM ARCHIVES

Victor KAISTRENKO and Valentina Sedaeva (both at Institute of Marine Geology and Geophysics, Far Eastern Division of the Russian Academy of Sciences; Nauki St., Yuzhno-Sakhalinsk, 693002 Russia, email: tsunami@sakhmail.sakhalin.ru)

During the long time until 1990th most of data related to the catastrophic 1952 tsunami were secret and last years these data can be investigated. Most essential information is contained in the survey report made by Hydrographic Service of the Russian Navy. Several reports of different commissions were found in Sakhalin archives. Interesting information was received from eye-witness of this event.
Navy's survey team started to work in Severo-Kurilsk next day after the tsunami. Their report contains 10 maps of flooding areas around the settlements on North Kuril Islands and good description of damages due to tsunami and many photos.
The reports in Sakhalin archives give many descriptions of tsunami behavior and contain the lists of damages and lost persons. So, the Okeanskaya settlement was destroyed almost fully by 20-meter tsunami and 460 persons were lost, i.e. about 50 % of population, and 1753 persons were killed by tsunami in this region.
Several descriptions and photos were given by eye-witness. All these data are planned to publish as a book.

RUNUP OF TSUNAMI WAVES ON A VERTICAL WALL AND GENTLE BEACH IN A BASIN OF COMPLEX TOPOGRAPHY

Efim PELINOVSKY (Laboratory of Hydrophysics and Nonlinear Acoustics, Institute of Applied Physics, 46 Uljanov Str., Nizhny Novgorod, 603600, Russia, email: enpeli@appl.sci-nnov.ru) Elena Troshina (Geophysical Institute, University of Alaska Fairbanks, Fairbanks, AK 99775, USA, email: etroshin@images.alaska.edu) Vladimir Golinko and Nataly Osipenko (both at Department of Applied Mathematics, Nizhny Novgorod Technical University, 24 Minin Str., Nizhny Novgorod, 603600, Russia)

Being able to estimate the flooding area of the coastal zone caused by the tsunami waves is essential for tsunami hazard mitigation. Much progress has been made in applying the one-dimensional nonlinear shallow water theory to the runup height calculation. It was based on the analytical results of the well-known paper by Carrier and Greenspan. This method has been used by many authors to calculate the tsunami wave runup. The exact estimation of the size of the area flooded by tsunami waves requires the solution of two-dimensional shallow-water equations, taking into account the geometry of the coastal line (bays, straits, estuaries, etc.). We study runup of tsunami waves on a vertical wall and gentle beach in a bay of different cross-section using shallow water equations. The characteristics of the nonlinear deformed waves in bays of different cross-section are investigated. The nonlinearity causes the runup height to increase. Several examples of beach topography are considered. The criteria of the wave breaking are discussed.

NUMERICAL SIMULATION OF POTENTIAL SUBMARINE SLOPE FAILURES AND ASSOCIATED TSUNAMIS ALONG THE COAST OF BRITISH COLUMBIA

Alexander B. RABINOVICH, Evgueni A. Kulikov (both at Tsunami Center, Shirshov Institute of Oceanology, 36 Nakhimovsky Prosp., Moscow 117851, Russia, e-mail: abr@tsucen.msk.ru) Richard E. Thomson (Institute of Ocean Sciences, 9860 W.Saanich Rd., Sidney, BC, V8L 4B2, Canada, e-mail: thomsonr@dfo-mpo.gc.ca) Brian D. Bornhold, and Isaac V. Fine (both at International Tsunami Research, Inc. 11321 Chalet Rd., Sidney, BC, V8L 5M1, e-mail: itri@ii.ca)

Studies in coastal areas of British Columbia indicate the high instability of deltaic and nearshore sediments in many areas. Buildings, coastal facilities, pipelines, telecommunication and electrical transmission cable lines are at significant risk of direct damage from subaerial and submarine landslides. Tsunamis generated by these events probably pose an even greater threat in terms of damage and loss of life. We concentrate our attention on two areas of potentially high risk of slope failure: (1) Malaspina Strait, a narrow (5 to 10 km) channel separating Texada Island from the mainland of British Columbia; and (2) the Fraser River delta front in the southern portion of the Strait of Georgia. The main reasons for our interest in these areas are: (1) large volumes of unconsolidated sediments, accumulated there; (2) high risk of instability of these sediments; and (3) location of significant coastal infrastructure, which would be at risk should a failure and tsunami occur. We have developed two types of numerical model to simulate landslide-generated tsunamis: (1) viscous flow, and (2) rigid body. These models bracket the true response of the sea surface to the landslide, with the viscous slide model underestimating the wave response and the rigid body model overestimating the response. Parameters of slide bodies were defined from existing geological and geophysical investigations, and direct video observations. In the case of Malaspina Strait, the failure of the northern lobe of a perched sediment mass on the slope off eastern Texada Island, yielded trough-to-crest waves from 7 to 9 m. Two cases were…

ANALYSIS OF THE ALGERIAN TSUNAMIS ON THE MEDITERANEAN COAST OF SPAIN

Alexander B. Rabinovich (IOS, Sidney BC, Canada, Email: RabinovichA@pac.dfo-mpo.gc.ca), Sebastian MONSERRAT (CSIC-UIB, Palma de Malorca, Spain, Email: dfssmt4@clust.uib.es)

Although tsunamis in the Mediterranean are not so frequent and powerful as in the Pacific, they still present serious threat for the coastal areas. The major risk for the coast of Spain is related to the earthquakes in the northern part of Algeria. The Orleansville Earthquake (1954) with magnitude M = 6.6 and El Asnam Earthquake (1980) with M = 7.3 generated significant tsunamis observed all along the Mediterranean coast of Spain and in the Balearic Islands. These tsunamis were recorded by several tide gauges (Malaga, Ceuta, Alicante, Almeria, Algeciras, etc.). The number of tsunami records in the Mediterranean basin is extremely limited, so examination of these two tsunamis simultaneously measured by the instruments situated in various sites of the Western Mediterranean is of high scientific and applied interest. The method recently proposed by Rabinovich (1997) to separate the influence of source and topography in tsunami spectra was to analyze the data. The main attention was paid to Alicante records, which were of high quality, especially to the 1980 case when the corresponding tsunami was recorded by two gauges (inside and outside of the harbor). The response characteristics of the harbors were constructed. Several cases of atmospherically generated seiches have been also examined and the results have been compared with results of tsunami analysis.

THE AD1650 MT. COLUMBO (THERA ISLAND) ERUPTION AND TSUNAMI, AEGEAN SEA, GREKCE

Dale Dominey-Howes (Coventry Centre for Disaster Management, School of the Built Environment, Coventry University, Coventry, CV1 5FB, UK, Kmail:apx124(R)coventry.ac.uk)

This presentation reviews evidence for the eruption and tsunami reported to have occurred in AD1650 in the area of Mt. Columbo, Thera Island, Greece. The tsunami is believed to have been generated as consequence of the eruption of Mt. Columbo 6.5 km NE of Thera Island. Historical documents state that the tsunami flooded up to 2 miles inland and destroyed many engineered structures. Lithostratigraphic evidence from one abandoned trench and two trench excavations close to sea level in the villages of Kamari and Perissa respectively, which lie well within the reported inundation zone of the tsunami. The results presented show that _® marine- (tsunami) sediments were deposited at these locations. Alternative hypotheses of discontinuous sediment deposition and overestimation of the event magnitude are considered to explain the observations presented here. The data may have important implications for the development of hazard zone maps, risk assessment, vulnerability reduction and for emergency management officials.

MITIGATION OF TSUNAMI RISK FOR THE CITY OF SUVA, FIJI

Jack RYNN (Centre for Earthquake Research in Australia, PO Box 276, Indooroopilly, Brisbane, Queensland 4068 Australia, email: sally.brown@uq.net.au) Gajendra Prasad (Mineral Resources Department, Government of the Republic of Fiji, Private Mail Bag, Suva, Fiji, email: gajen@mrd.gov.fj); Atu Kaloumaira (Mitigation Advisor, South Pacific Disaster Reduction Management Office, c/o UNDP, Private Mail Bag, Suva, Fiji, email: atu@sopac.com.org)

As part of the UNDHA - South Pacific Programme Office "South Pacific Disaster Reduction Programme", within the auspices of Pacific Region IDNDR and the 1994 Yokohama Statement, the "Suva Earthquake Risk Management Scenario Pilot Project" (SERMP) was facilitated for the Government of the Republic of Fiji. SERMP considered mitigation measures for both earthquake and tsunami impacting upon the City of Suva, with the scenario event based on the real experience of the 1953 Suva earthquake (ML 6.5) and tsunami, which devastated the city, its industrial and harbour facilities. A specific methodology was developed involving a multidisciplinary approach with multi-agency cooperation to address, in both quantitative and qualitative terms, the premise RISK = HAZARD X VULNERABILITY and then integrate the assessments in terms of Fiji's emergency management requirements. The outcomes include hazard, vulnerability and risk zonation maps with commentaries, tsunami parameters and possible damage situations. It was concluded that a significant risk of local tsunami does exist for the City of Suva and its harbour environs. Practical applications of these results, in terms of community vulnerability and reduction of potential losses, and including a simulated tsunami exercise, have been a major element in this project. Fiji is now developing a regional tsunami warning system.

TSUNAMI WAVE SCATTERING IN THE NORTH PACIFIC

H.O. Mofjeld, V.V. Titov, F.I. González and J.C. Newman NOAA/Pacific Marine Environmental Laboratory Seattle, WA, USA

A theoretical study is being carried out to understand how escarpments, ridges and seamounts affect deep-water tsunami propagation in the Pacific Ocean. The study is also designed to determine the accuracy and resolution of bottom topography that are needed in numerical models to accurately simulate the effects of small-scale (*100 km) topographic features on tsunami propagation. The initial focus of the work is on tsunamis that are generated in the Alaska/Aleutian Subduction Zone (AASZ) and propagate southward to Hawaii. Analytic theory shows that main effects of these features is to scatter energy from the tsunami waves. The amount of scattering depends on the heights of the features relative to the total depth, their spatial extent compared with tsunami wavelengths, and their orientation relative to the direction of wave propagation. 2-D wavelet analyses of the Sandwell/Smith topography (Topo 6.2) are used to identify the spatial scales and locations of scattering features in the North Pacific. Numerical simulations based on the MOST model (with and without small-scale topography) show that deep-water scattering produces only a small amplitude decrease in the first waves of AASZ tsunamis propagating to Hawaii (a few percent in energy). This is compared with the geometric spreading and broad-scale refraction that occurs when the tsunami waves propagate southward from their sources. The primary reason for relatively little deep-water scattering is that the tsunami-scale topographic features between Alaska and Hawaii do not extend vertically over a substantial fraction of the total water depth. However, significant focusing of tsunami waves does occur near Hawaii; this is due to the seamount field north of Kauai, the Emperor Seamount Chain and the Hawaiian Ridge. While deep-water scattering has only a minor influence on the first waves in AASZ tsunamis, it does contribute to the complicated temporal patterns of the waves that occur later in Pacific-wide tsunamis. Scattering processes are much stronger on the upper continental slope and shelf; hence there is a need for accurate topography in these regions. Future work will extend the analysis to shallower water, to other source regions (e.g., Kamchatka, Kuril/Japan and Cascadia) and to other impact regions, especially the U.S. West Coast.

THE TSUNAMI OF 1722.12.27, ALGARVE–PORTUGAL

M.A. Baptista (Instituto Superior de Engenharia de Lisboa, Lisboa Portugal, email: mariaana@fc.ul.pt, fax + 3511 3953327) C.Lemos (Instituto Hidrográfico – Portugal) J.M.Miranda (Centro de Geofísica da Universidade de Lisboa)

The earthquake of 1772.12.27 generated a tsunami that affect the southern coast of Portugal, mainly in the area of Tavira. The maximum earthquake intensity was X and the magnitude 7.5 (given by Instituto Geografico Nacional, Madrid Spain). The historical data on this event is rather scarce. However, the earthquake was felt along the whole south Portuguese coast and in Faro and Tavira a rather strong river withdrawal were observed (Mendonça, 1758). The epicentre of the earthquake was located, from isoseismal analysis offshore the south coast of Portugal but the precise location is largely unknown. The aim of this work is the compilation of all geophysical data, and the use of tsunami hydrodynamic modeling to evaluate among a set of fault candidates which is the most probable source of the Tavira earthquake.
This work was financially supported by project RIMAR.

JSS42/E/07-B5 Poster **1700-13**

TSUNAMI RUN-UP

C. CORELA and L.A. Mendes Victor(both at ICTE, Instituto de Ciências da Terra e do Espaço, Rua da Escola Politécnica 58, 1200 Lisboa, Portugal, email: ccorela@ correio.fc.ul.pt)

The description of the Tsunami run-up is of greastest importance for Tsunami zonation and evaluation of Tsunami Hazard.The difficulties arising here are evident: the complexity of coastal zone morphology and the variety of underlying surfaces changing due to their interaction with the water flows caused by Tsunamis, the possibility of waves breaking and competition of nonlinear and disperson effects. A numerical method based on the upstream formulation for the advective term is applied to compute the run-up.

THE EXPERIMENTAL ITALIAN TSUNAMI WARNING SYSTEM AT AUGUSTA (EASTERN SICILY)

Alessandra Maramai, Alessandro Piscini and Giuseppe D Anna (Istituto Nazionale di Geofisica (ING), Via di Vigna Murata 605, Rome - Italy

In the frame of the GITEC-TWO (Genesis and Impact of Tsunamis on the European Coasts) project, in the Eastern Sicily coasts a "pilot" station of the first Italian Tsunami Warning System (TWS) has been installed. Most of the tsunamis affecting the Italian coasts are generated by local earthquakes with focal region close to the coast, both in land or in the sea. As regards the Eastern Sicily coast, usually the historical tsunamis are characterized by a first withdrawal of the sea, followed within a few minutes by a more or less violent flooding. Taking into account this characteristics, the experimental TWS is conceived for the coastlines affected by tsunamis locally generated, where the waves invest the coast just a few minutes after the earthquake occurrence, so what is needed is an immediate detection of the generated tsunamis. In this context, the Italian TWS is an integrated system designed for the simultaneous acquisition of the seismic signal and the sea level oscillations, for processing both signals, for detecting dangerous conditions and for issuing an alarm message to specific units of the local Civil Protection service. As regards the sea level data, a pressure gauge has been installed in a suitable wharf close to the Augusta harbour. The water level sensor is connected to an automatic station to collect and process the sea level data and many other intersting parameters and to send the data (via radio link) to a TWS "control center". As for the seismic data, the three components (S-13) Augusta seismic station is used and a spectral analysis of the background seismic noise has been done. The TWS control center is equipped with two PC units, connected in LAN network, to collect and process in real time the seismic and the sea level data and to identify anomalous conditions in the two signals, in order to send a useful alarm message. One PC unit is responsible for the seismic signal acquisition and processing, working in a Windows NT environment. The second unit, in UNIX environment, is for both the seismic and the sea level data and it contains specific routines for the detection of sea level anomalous oscillation and for the alarm message transmission code. This unit is also equipped with a specific software for the data management, that is data automatic acquisition, real time data validation, data collection displaying, monitoring of the station activity, etc. The station has been working since July 1998 and at present some preliminary analysis of the registered data sets has been done.

TSUNAMI INUNDATION MODELING FOR SELECTED COMMUNITIES IN KODIAK ISLAND, ALASKA

Elena N. Suleimani and Roger Hansen (both at Geophysical Institute, University of Alaska Fairbanks, Fairbanks, AK 99775-7320, USA, email: etroshin@images.alaska.edu)

The 28 March 1964 earthquake produced a destructive tsunami in Alaska and on the West Coast of the United States. The event showed avulnerability of Kodiak, a region with a number of relatively high populated communities and significant fishing resources. Over the last ten years there had been substantial growth of Kodiak City and other island communities, a number of engineering projects, and significant changes to the harbor. As part of an ongoing component of the National Tsunami Hazard Mitigation Program and the Alaska Science and Technology Foundation we are providing assistance to threatened communities with potential tsunami inundation assessment. Three of the Kodiak communities were identified as high-priority zones for inundation mapping.
The numerical model is based on the nonlinear shallow-water equations which are solved by a finite-difference method. The historically documented wave runup, mainly from the 1964 Alaska earthquake, is used to calibrate the model. First, the actual ground displacement of the 1964 earthquake is assumed, then, the hypothetical sources are modeled. The results will be presented using a web-based interface. They will allow us to evaluate the potential tsunami hazard for the Kodiak communities and to provide them with the tsunami inundation maps for emergency planning of evacuation routes. Finally, about 10 additional communities are planned for evaluation over the next four years as part of the federal/state mitigation program.

DISPERSIVE TSUNAMI GENERATION BY BOTTOM DISPLACEMENTS WITH COMPLICATED TIME-SPATIAL HISTORY

M.A. NOSOV, S.V. Mironyuk

The linear potential theory was used to obtain the exact analytical solution of the 3-D problem of gravitational waves generation by bottom displacements of finite duration as double Fourier integrals over components of the wave vector. The integrals were evaluated numerically. In particular it was demonstrated that the bottom displacement should be considered as a process of a finite duration, not as an impulse one. Using some models of bottom displacements of finite duration (piston, membrane-like, traveling, with alternating signs) a certain influence of bottom displacements time-spatial history on amplitude, energy and directivity of tsunami radiation from asymmetric source was revealed. It was also established that as the distance from the source increases, the directivity of energy radiation is preserved, whereas the distribution of wave amplitude characteristics in the azimuthal angle becomes isotropic.

SPECTRAL ANALYZIS OF OCTOBER 5, 1994 SHIKOTAN TSUNAMI RECORDS

TATYANA IVELSKAYA, Sakhalin Tsunami Warning Center, 78, Zapadnaya St. Youzno-Sakhalinsk, 693000, Russia, George Shevchenko, Institute of Marine Geology and Geophysics, Far East Branch of Russian Academy of Sciences, Nauky str., Yuzhno-Sakhalinsk, 693002, Russia, email: Tsunami@Sakhalin.ru

Spectral characteristics of wave field after strong earthquake that occurred at the October 5, 1994 in the region of Shikotan Island were analyzed. It was shown that main energy of tsunami at the South Kuril stations was concentrated in the relatively high frequency band (with periods about 21 min). Probably, it was induced by the particularities of the seismic processes in the epicentral area of underwater earthquake.
At the same time the energy of tsunami on the coast of Japan was concentrated in the relatively low frequency band (with periods about 28, 36, 48, 60 min). Probably, it was connected not only with particularities of tsunami source, but with the influence of sea bottom topography in this region.
Calculation of spectral-time diagrams shows the complicated structure of wave records that includes five splashes of intensity on the main part of stations. Very likely that these splashes were induced by aftershocks in the epicentral area of underwater earthquake. Spectral-time diagrams detected the early wave groups with wide spectra, and resonance particularities of basins selectively amplify some spectral components.

A FAST AND SIMPLE DIAGNOSTIC METHOD FOR IDENTIFYING TSUNAMIGENIC EARTHQUAKES

Nikolai. M. SHAPIRO, Shri Krishna Singh, and Javier Pacheco (all at Instituto de Geofisica, Universidad National, Autonoma de Mexico, Mexico D.F., Mexico, e-mail: shapiro@ollin.igeofcu.unam.mx)

An analysis of regional broadband seismograms of moderate and large subduction-zone earthquakes of Mexico shows that the earthquakes which occur near the trench are abnormally depleted in high-frequency radiation. This observation leads to a simple and fast method to assess regional tsunami potential from earthquakes which occur along the Pacific coast of Mexico. A significant advantage of the method is that a single broadband seismograph is sufficient for the purpose. The method is based on the ratio of the total energy to the high-frequency energy (between 1 and 5 Hz), ER, computed from the seismograms. For earthquakes of same seismic moment, ER is an order of magnitude greater for a source area near the trench as compared to that for areas near the coast. The same seismograms are used to compute energy magnitude, Me, which is tied to the moment magnitude, Mw. A regional tsunami may be expected along the coast if Me > 6.5 and ER corresponds to a source near the trench. If, however, ER corresponds to a near-coast source, then Me may have to be greater than about 7.3 for a tsunami of similar size to occur along the coast. The method holds promise for a fast regional tsunami warning in many Pacific basin countries which lack an adequate seismic network.

FUNDAMENTAL STUDY ON TSUNAMIS GENERATED ON A SHELF

Koji FUJIMA (Department of Civil Engineering, National Defense Academy, Yokosuka 239-8686, Japan, email: fujima@cc.nda.ac.jp)

Based on the linear long wave theory, theoretical solution is obtained for the tsunami propagation >from an arbitral tsunami source generated on a straight beach with an uniform slope. The solution indicates that the behaviors of tsunami generated on a shelf is governed by the conditions of initial tsunami profile. The edge wave is generated considerably in the

case when a tsunami source locates near a coastline. On the contrary, in the case when a tsunami source is generated in a region far from a coastline, the edge wave is not generated and tsunami energy is concentrated in a narrow area. The empirical formulas are derived which evaluate the characteristics of tsunami by those of tsunami source such as the lengths of long-axis and short-axis, the position and direction of tsunami source, and so on. Further, effect of the Colioris force is also discussed.

THE THREE-DIMENSIONAL TSUNAMI NUMERICAL ANALYSIS WITHOUT ASSUMING THE STEP-TYPE BOTTOM BOUNDARY

Kenji MASAMURA and Koji Fujima (both at Department of Civil Engineering, National Defense Academy, 1-10-20 Hashirimizu, Yokosuka 239-8686, Japan, email: kenji@cc.nda.ac.jp, fujima@cc.nda.ac.jp) Chiaki Goto (Department of Civil Engineering, Tokai University, 1117 Kitakaname, Hiratsuka 259-1292, Japan, email: goto@keyaki.cc.u-tokai.ac.jp)

The conventional numerical analysis of Tsunami based on the shallow water theory cannot reproduce three-dimensional flow. To improve this deficiency, three-dimensional numerical model without using the long wave approximation was developed. This model can compute the propagation of non-linear dispersive waves, because the hydrostatic pressure distribution is not assumed in the model. However, when the complicated geographical features are adopted for the calculation, submarine bottom boundaries are approximated as the stair-shaped step. Therefore, accuracy of calculation tends to become worse at the tip of runup. Thus, in this study, a "permeation rate" is introduced as a new parameter in each surface of the cell. The "permeation rate" is defined by he ratio of the section area of the portion where a water particle can pass through and the area of the surface of the cell. Therefore, the bottom boundary is approximated by a slope crossing the inside of the cell. As the result, runup height can be reproduced with good precision by the present model.

COMBINATION OF BATHYMETRY AND TOPOGRAPHY DATA FOR TSUNAMI MODELING

R.A. KAMPHAUS (NOAA/PMEL, TIME, 2115 SE OSU Drive, Newport, OR 97365, USA; e-mail: kamphaus@pmel.noaa.gov), D. Divins (NOAA/ NGDC, CIRES, 325 Broadway, Boulder, CO 80303, USA; e-mail: ddivins@ngdc.noaa.gov) and F.I. Gonzalez (NOAA/PMEL, 7600 Sand Point Way NE, Bldg.3, Seattle, WA, 98115, USA, e-mail: gonzalez@pmel.noaa.gov)

Grids that integrate bathymetric and topographic data are needed for effective tsunami inundation modeling. Topographic data in the form of Digital Elevation Models (DEMs) have been available for the majority of the United States for several years from the US Geological Survey (USGS). Bathymetric data, on the other hand, has been more sparse and not available digitally for all areas. As more digital data becomes available through the efforts of data centers-such as NOAA's National Geophysical Data Center (NGDC) -- techniques for efficiently incorporating these data into numerical grids are being developed. Using techniques and databases developed at NGDC, the Center for Tsunami Inundation Mapping Efforts (TIME) has created several high quality gridded data sets for tsunami inundation modeling along the coast of California. The grids are assembled by gridding the NOS Hydrogaphic Database soundings, and supplemental soundings, to the same 3 arc-second (~90 m) resolution and registration as the USGS's 3-arc-second DEMs. In the United States the topographic and bathymetric data are collected in different reference datums; therefore, the data are adjusted to a common datum and a correction for tides is calculated. By adjusting the data to a common vertical datum, and gridding across the shoreline, a smooth transition from ocean bottom to land surface is achieved. The two data sets are then spliced at the NOS medium-resolution vector shoreline. The result is a 3-arc-second elevation grid in which elevations are resolved to 1/10 of a meter. Similar techniques can be used by researchers for different resolution grids and in different areas depending on the availability of data.

INFLUENCES ON ATMOSPHERIC BOUNDARY LAYER STRUCTURE IN THE NEW ZEALAND SOUTHERN ALPS

Andrew STURMAN (Department of Geography, University of Canterbury, Private Bag 4800, Christchurch, New Zealand, email: a.sturman@geog.canterbury.ac.nz); Hamish McGowan (School of Earth Sciences, Victoria University of Wellington, P.O. Box 600, Wellington, New Zealand, email: Hamish.McGowan@vuw.ac.nz)

The Southern Alps of New Zealand provide an interesting and challenging environment in which to undertake atmospheric boundary layer research, as heterogeneous surface characteristics and mountainous terrain strongly influence the structure of the lower atmosphere. Research has been conducted in the Lake Tekapo region of the South Island since 1991, initially identifying the complexity of the local wind regime in this region with regard to dust dispersion. This complexity results from local and regional variation in surface sensible heat flux, including the effect of Lake Tekapo. In particular, the effects of different scales of motion were noted including the interaction of mountain/valley, land/lake and land/sea breeze systems, as well as with broader scale airflows such as the topographically modified foehn nor'wester. A more comprehensive research programme is under way to understand in greater detail the nature of the wind systems and thermal structures that develop in this region. The current research involves the analysis of data collected using a network of automatic weather stations, surface energy flux measurement systems, pilot balloons, free-flying and tethered sondes, SODAR, and an instrumented light aircraft. Computer simulations using two different mesoscale modelling systems complement the field programme. Some initial results are presented of the interaction of synoptic airflow with locally developed wind systems resulting from slope heating and thermal discontinuities at the surface.

JSM43/E/01-B4 **1050**

FLOW OVER THE NEBRASKA SANDHILLS - ANALYSIS OF AIRCRAFT AND TOPOGRAPHIC DATA

Yoseph Mengesha, Peter A. TAYLOR (Dept. of Earth and Atmospheric Sciences, York University, 4700 Keele Street, Toronto, Canada, M3J 1P3, Email: pat@yorku.ca); Donald Lenschow (NCAR, Boulder, Colorado, USA)

In a preliminary investigation of topographic parameters appropriate for drag parametrization we have made a study of the Sand Hills area of Nebraska (USA). Digital topographic data (3 arc seconds, approx 90m) of the Sand Hills terrain were analyzed and parameters (K,L,M) suggested by Baines (1995) to characterize topography were calculated from the topographic data using various horizontal resolutions. Slope-related parameters are highly resolution dependent.
Data collected in Aug 1980 by the NCAR Queen Air during low level flights over parts of the region have also been studied. The area overflown has an extensive area of relatively regularly spaced, elongated ridges, of typical peak to trough height of order 75m and crest to crest separation of order 2km. Typical flight levels were about 100m above the terrain but no surface level data were available. We have however computed flight level turbulence statistics and drag coefficients for different sections of the flight and compared these with the mean square slope of the underlying terrain. These preliminary data indicate a potential for a significant increase in aircraft level drag coefficient with topographic slope, but stability effects are also an important factor. Horizontal turbulence values (sigma- u, sigma-v) were about 20-40% higher than one might expect over flat terrain, but vertical components, sigma-w, were not significantly affected. The data show a strong variation with static stability and u and v spectra have secondary peaks associated with topographic effects.

THE EFFECTS OF SALT FLATS AND ADJACENT COMPLEX TOPOGRAPHY ON PBL PROPERTIES

Thomas WARNER, Hsiao-Ming Hsu, Chris Davis (National Center for Atmospheric Research Boulder, Colorado, USA); Elford Astling (West Desert Test Center Dugway, Utah, USA)

Salt flats are common in deserts throughout the world and have a profound impact on the PBL thermal, moisture and wind-field properties because of their unique surface characteristics. The desert salt flats often occur near complex terrain, as in the western U.S., and thus the modulation of the PBL properties by the salt flats interacts with that associated with the nearby complex terrain.
In this study, a quadruply nested mesoscale model, with a 1 km grid increment on the finest mesh, is used to simulate the effects of desert salt flats and adjacent mountains on the PBL structure. The use of a complex land-surface model with multi-layer soil physics allows determination of how specific salt-flat characteristics, such as proximity of the water table to the surface, affect the PBL properties. Circulations that result from the thermal contrast between the salt flat and the surrounding desert, referred to as "salt breezes", are as strong as the mountain-valley breezes. Overall, PBL signatures that result from the salt flats are as large as those forced by the adjacent mountains.

JSM43/E/06-B4 **1130**

SPATIAL AND TEMPORAL VARIATION OF SOIL MOISTURE AND GROUND TEMPRETURE NEAR THE INTERFACE OF HIGH/LOW STANDS

Xinguo MO (Environment and Eco-technology Station, Institute of Geography, Chinese Academy of Sciences, beijing 100101, P.R.China, email: moxg@dls.iog.ac.cn); Suxia Liu (Department of Hydrology, Institute of Geography, Chinese Academy of Sciences, Beijing 100101, P.R.China, email: liusx@sun.ihep.ac.cn)

This paper presents an observational study of the variation of soil moisture and ground temperature with distance of an interface of alfalfa/winter wheat stand. Micro-meteorological elements were observed together. It was found that the influence of the interface on the soil moisture of both high stand (winter wheat) and low stand (alfalfa) is obvious. The difference of soil moisture of high stands and low stands generally increases with the observational sites closing to the interface. The horizontal influence scale is 4~16 meter to the interface. Precipitation and irrigation can fully change this pattern. Ground temperature beneath the surface decreases gradually from relatively hot alfalfa field to cold winter wheat without any influences from the interface. However at the surface, the difference of ground temperature of high and low stands increases with the observational sites closing to the interface, as what we found from the variation of soil moisture. The vertical influence scale is 5 cm. The influence of precipitation and irrigation is less than that of interface. The results of micro-meteorological can help to explain the bigger difference of temperature and soil moisture occurs at the place nearer the interface.

WIND TUNNEL MEASUREMENTS VS NUMERICAL SIMULATIONS IN COMPLEX TERRAIN

Maria ATHANASSIADOU, Nigel Wood (Met. Office, Bracknell, UK)

Wind tunnel measurements of neutral flow over a series of rough surfaced sinusoidal hills are presented and compared with numerical simulations. The experimental data were taken in the A - Tunnel (4.2m x 0.9m x 0.6m, L x W x H) of the EnFlo Lab at Surrey University as part of a collaborative research project between the UK Met Office and EnFlo. The numerical simulations were performed using BLASIUS, a numerical model designed to simulate turbulent flow over two and three dimensional hills. Issues addressed include the ability of numerical simulations to reliably reproduce turbulent flow over complex terrain, the influence of different boundary conditions employed as well as different turbulence closures. The problem of how to best compare data and results obtained using different methods is also examined.

MESOSCALE CIRCULATIONS IN SOUTHERN PORTUGAL: OBSERVATIONS AND NUMERICAL RESULTS

Pedro M. M. SOARES (email: psoares@fc.ul.pt), Carla S. F. Barroso (email: cbarroso@fc.ul.pt), Pedro M. A. Miranda (email: pmiranda@fc.ul.pt), André Barbosa (email: abarbosa@fc.ul.pt) (all at: Centro de Geofísica da Universidade de Lisboa, R. Escola Politecnica 58, 1250 Lisboa, Portugal)

In the last two years, two field experiments were made to better characterise the sea breeze circulation in the South Coast of Portugal, in the perspective of its impact in local meteorology. The campaigns included 2 weeks of measurements during the summer, with a number of surface stations and regular release of radiosondes. The analysis of the observational data also included information from all automatic weather stations in the area. The results showed the expected diurnal cycle of the sea breeze in stations where the near coast is linear, they have also revealed the importance of local orography and coastal irregularity in the shaping of the temporal hodograph of low level wind. Data from inland stations was used to compute the sea breeze penetration in land and the inland velocity. The principal goal of this study was to achieve an experimental confirmation of model predictions for this type of circulations, in the case of complex mesoscale interactions between the sea breeze, coast orography, lake breezes and finally in consequence of coast irregularity. Using the observed atmospheric profiles, a number of numerical simulations were performed, using the NH3D mesoscale model (Miranda and James 1992) coupled with the soil ISBA model (Noilhan and Planton 1989), which are used to perform a detailed analysis of the coastal circulation and to identify the main mechanisms involved in its forcing.

JSM43/W/13-B4 1420

OBSERVATIONS AND MODELING OF MESOSCALE CIRCULATIONS PRODUCED BY SURFACE HETEROGENEITIES

Pedro M. A. MIRANDA (Centro de Geofisica and Department of Physics, University of Lisbon, R. Escola Politecnica 58, 1250 Lisboa, Portugal, email: pmiranda@fc.ul.pt); Rui Salgado (Centro de Geofisica, University of Evora); Pedro M. M. Soares and Carla Cardoso (both at Centro de Geofisica, University of Lisbon)

The summer circulation over the Iberian Peninsula is largely dominated by the interaction between a strong sea-breeze effect and up-slope/downslope winds around mesoscale mountains. At the scale of the Peninsula, these effects produce a pulsating thermal low of great regional climatic importance. Locally, these thermal and orographic circulations may be rather distorted by local effects due to surface heterogeneities, in particular in cases where large horizontal gradients of water availability are produced by irrigation patches. Some of these effects are revealed in observations in southern Portugal, which have been organised in the two last years, including a network of continuous surface observations and some radiossonde observations in the summer period. A set of non-linear numerical experiments with a non-hydrostatic mesoscale model, coupled with a soil evolution model, are use to analyse the dynamics of the thermal circulations, including the diurnal evolution of the boundary layer development over land and the horizontal progression of the sea-breeze front.

JSM43/E/02-B4 1440

MODELLING LONGITUDINAL VORTICES IN BOUNDARY-LAYER AIRFLOW OVER 2D WAVY SURFACES

Peter A. TAYLOR, Wensong Weng (Dept. of Earth and Atmospheric Sciences, York University, 4700 Keele Street, Toronto, Canada, M3J 1P3, Email: pat@yorku.ca); Stefano Gallino (Department of Physics, University of Genova, Italy)

Gong et al (1996) reported observations of the development of longitudinal vortices in a wind tunnel study of turbulent boundary-layer flow over 2D sinusoidal waves. Large eddy simulations of the same flow showed somewhat similar features but they were less regular or organised. Using a time dependent version of the 3D non-linear mixed spectral finite difference code (NLMSFD) for boundary-layer flow over topography we can simulate the development of similar vortex structures, but their rate of development tends to be rather slower that was observed in the wind tunnel.
Results will be presented showing, amongst other things, a strong dependence of vortex growth rate on the steepness of the waves and on boundary-layer depth. So far these model predictions have not explained a significant disparity between wave crest velocity profile predictions with the 2D NLMSFD model and the profiles measured in the wind tunnel, or differences in the drag on the topography. Potential application of the results to airflow over water waves and to wind wave generation will be discussed.

JSM43/E/04-B4 1500

SUB-GRID SCALE TOPOGRAPHIC DRAG PARAMETRIZATION FOR LARGE SCALE MODELS - NEUTRAL AND STRATIFIED FLOW

Peter A. TAYLOR, Wensong Weng, Jingnan Zhou (Dept. of Earth and Atmospheric Sciences, York University, 4700 Keele Street, Toronto, Canada, M3J 1P3, Email: pat@yorku.ca)

At the present time models of neutrally-stratified boundary-layer flow over hills, with Reynolds-averaged flow equations and various turbulence closure schemes, can, in general, do quite well at predicting the "speed-up" of the wind at the summit of isolated low and moderate slope hills, and on the upwind slope. Predictions in the lee of hills with flow separation are more difficult but some progress has been made. It is however proving difficult to obtain reliable results for the form or pressure drag on topography, even in neutrally stratified flows. For stably stratified flow linear inviscid theory appears to provide a reasonable first estimate of the wave drag, at least in terms of comparisons with simplified boundary-layer models. In a boundary-layer context some model results on pressure and wave drag are discussed, and the link between pressure drag on the surface and wave drag aloft illustrated.

JSM43/W/04-B4 1600

A NUMERICAL STUDY OF TURBULENT BOUNDARY-LAYER FLOW OVER COMPLEX TERRAIN

Wensong WENG, Peter A. Taylor (Department of Earth and Atmospheric Science, York University, 4700 Keele Street, Toronto, Ontario, Canada M3J 1P3, Email: wweng@yorku.ca)

The Mixed-Spectral Finite Difference (MSFD) and its Non-Linear extension (NLMSFD) models are used to study neutrally-stratified turbulent boundary-layer flow over the real terrain --- Askervein Hill. Three different turbulence closures are used. The model results are compared with the field observations from the Askervein Hill Project of 1982 and 1983 which provided an extensive full-scale data set for studies of wind flow and turbulence over complex terrain. The linear limitation, non-linear effects and impact of different turbulence closures on the model prediction are discussed.

JSM43/E/12-B4 1620

SURFACE HEAT FLUX AVERAGING IN HETEROGENEOUS TERRAIN

Niels Otto JENSEN, Charlotte B. Hasager (Risoe National Laboratory, Wind Energy and Atmospheric Physics Dept., 4000 Roskilde, Denmark)

The paper considers the problem of estimating an areal average of the surface heat flux in a terrain consisting of patches in the landscape with different surface temperatures. It is demonstrated analytically as well as with a numerical model that the average stability is not neutral and the heat flux not zero even if the average temperature of the patches equals the air temperature. The numerical modelling focus on non-linear area-averaging of the atmospheric turbulent response between patches in the landscape with variable aerodynamic roughness and surface temperature.
Input to the model are maps of aerodynamic surface roughness and radiant surface temperatures from Landsat TM satellite scenes and meteorological observations of wind speed, wind direction and air temperatures. Aggregation of the heat flux in the landscape is based on a linearized flow equation solved by Fast Fourier Transforms. Stability correction is performed pixelwise. An output of the model is the areal average value of the temperature roughness of the particular terrain. The aggregation model is computationally fast and useful for grid averaging from scales of 30 m to 10-20 km grid cells.

JSM43/E/10-B4 1640

LARGE-EDDY SIMULATIONS IN COMPLEX TERRAIN

Nigel Wood, Mike HOBSON (The Meteorological Office, London Road, Bracknell, Berks, RG12 2SZ, UK)

A useful large-eddy simulation of flow over hills is non-trivial. Inevitably it requires a balance between what is desirable in terms of producing the most realistic results possible and what is feasible in terms of computing power. In designing a large-eddy simulation, or a wind tunnel simulation for comparison with one, a key component determining this balance is the ratio of the wavelength of the hill to the roughness length of the surface and much consideration needs to be given to specifying it. Whilst increasing this ratio requires a significant increase in the total number of grid points, decreasing leads to a reduction in resolution within the inner region. It the flow within this region, in particular, in which we are most interested. A consideration of all the factors determining this balance is both an interesting and valuable exercise.

JSM43/W/11-B4 1700

THE EFFECTS OF LANDSCAPE HETEROGENEITY AND COMPLEX TERRAIN ON THE CONVECTIVE BOUNDARY LAYER

Roni AVISSAR, S.G. Gopalakrishnan, Somnath Baidya Roy, Tanya Schmidt (Dept. of Environmental Sciences, Rutgers University, 14 College Farm Road, New Brunswick, New Jersey 08901-8551, USA, email: avissar@gaia.rutgers.edu)

The effects on the Convective Boundary Layer (CBL) of surface heterogeneities produced by various topographical features and sensible heat waves with different means, amplitudes, and wavelengths, were investigated with a Large-Eddy Simulation (LES) model. A wavelet analysis was performed on the model outputs to identify the scales of response of the CBL to these various forcing. The major objective of this study was to evaluate at which scale surface heterogeneity starts to significantly affect the heat and momentum fluxes in the CBL. We find that the impact of amplitude and wavelength of the surface heterogeneity is nonlinearly dependent upon the mean heating rate. The circulations (or rolls) resulting from surface heterogeneity are relatively strong when the amplitude and the wavelength of the surface heterogeneity are relatively large, especially at low mean heating rate. In that case the profiles of horizontally-averaged variables are quite strongly modified in the CBL. The potential temperature is not constant with elevation, and the sensible heat flux considerably departs from the linear variation with height obtained in a typical CBL that develop over an homogeneous domain. The mean turbulence kinetic energy (TKE) profile depicts two maxima, one near the ground surface and one near the top of the CBL, corresponding to the strong horizontal flow that develops near the ground surface and the return flow at the top of the CBL. In a dry atmosphere, a relatively weak background wind of 2.5 m/s is strong enough to considerably reduce the impact of ground surface heterogeneity on the CBL. A moderate background wind of 5 m/s virtually eliminates all impacts that could potentially be produced in realistic landscapes. From this study, it can be inferred that as long as the "patchiness" of the landscape has a characteristic length scale smaller than about 5-10 km (even without background wind), the "mosaic of tiles" type of land-surface scheme suggested by Avissar and Pielke (1989) can be applied to represent the land surface in atmospheric models. At larger scales, the impact of landscape heterogeneity may be significant, especially when the atmosphere is humid. Therefore, this study supports previous estimates, which were based on theoretical analyses.

JSM43/E/07-B4 1720

A TOWN ENERGY BUDGET SCHEME FOR ATMOSPHERIC MODELS SURFACE

Valery MASSON (CNRM, Meteo-France, 42 av Coriolis 31057 Toulouse, FRANCE,
email: valery.masson@meteo.fr)

An urban surface model for atmospheric meso-scale models is presented. A generalization of the local canyon geometry is defined instead of the usual bare soil formulation currently used to represent the cities in atmospheric models. This allows to improve the radiative budgets as well as momentum, heat and conduction fluxes. This scheme is aimed to be as general as possible, in order to represent any city in the world, for any time or weather condition (heat island cooling by night, urban wake, water evaporation after rainfall, snow effects). Sensitivity tests and comparison with vegetation schemes outputs on annual forcings (one representative of temperate region, one of continental climate) are discussed. Application in the MESO-NH model to the Paris area for an anticyclonic situation are shown.

JSM43/W/10-B5 0900

MEAN WIND AND TURBULENCE CHARACTERISTICS IN THE SURFACE LAYER OVER AN AGRICULTURAL FIELD

J. S. PILLAI, S. Sivaramakrishnan (Indian Institute of Tropical Meteorology, Pune, India 411008, email: pillai@tropmet.ernet.in)

Evolution of wind and turbulence in the surface layer depends on static stability of the atmosphere and surface cover over different terrains. In this paper we present the wind profile and turbulence measured at two different seasons near the surface of an agriculture field in Anand (22° 35' N, 72°35' E, 45.1 m MSL), India, using a fast response instrument (sonic anemometer at about 9.5 m AGL) and slow response instruments (cup anemometer at 1, 2, 4, 8 m AGL). The power index (a) used to describe the wind profile law has been computed between different levels during 1000 to 1600 hrs IST when the atmosphere was unstable/ near neutral at moderate wind speeds. It has been found that a varies between 0.1 in April to 0.14 in August 1997, agreeing with the rural terrain values. The ratio of vertical turbulence intensity (Iw) to longitudinal turbulence intensity(Iu) is found to be nearly equal to 0.5 and that of lateral (Iv) to longitudinal tubulence intensity(Iu) 0.75 - 1.0. The Reynols stress lies in the range of 0.001 to 0.007 in April and 0.001 to 0.06 in August 1997. The large values of Reynols stress at 8m AGL, has been observed at Kharagpur (0.005) and at 8m AGL, at Jodhpur(0.02) in India over a gently rolling terrain during the summer monsoon: June- August 1990. High Reynols stress is also attributed to a change in terrain roughness due to seasonal crops in the upwind sector of the site during April and August 1997.

JSM43/E/08-B5 0920

ANALYSIS RESULTS OF THE TURBULENCE CHARACTERISTICS AND SPECTRA DURING A COLD FRONT PASSAGE

Zhang AI-CHEN, Dept. of Geophysics, Peking University, Beijing 100871, China

Based on data from two levels of sonic anemometer/thermometer measurements at the heights of 47 m and 120 m of the IAP (Institute of Atmospheric Physics) meteorological tower, situated at the NW border district of Beijing City, the paper gives some results from calculated and analysed turbulence characteristics during a period where a cold front was passing through. The following interesting results have been shown:
1. The stability parameter Z/L showed slightly negative values over the whole process (including day and night).
2. The values of nondimensional turbulence energy dissipation were smaller than 1.0 during the process.
3. The low frequency portion of the spectrum of U and V wind conponents, with its energy containing subrange extending to the lower frequencies, covered a wide frequency range compared with the spectrum in calm weather situations.

JSM43/E/11-B5 0940

THE ANALYSES RESULTS OF THE SEA BREEZE OVER THE COAST REGION OF THE SOUTH CHINA SEA

Zhang HONG-SHEN, Zhang Ai-chen (Dept. of Geophysics, Beijing University, Beijing 100871, China)

In the winter and Summer 1988, a number of low level radiosondes, wind finding and turbulence instruments was set up in a network in a large area of the Zhu-jiang River Mouth Region, situated along the coast region of The South China Sea. It included one sounding station situated at a small island, seven coast and in-land sounding stations, and two turbulence exploring system. The results showed a set of very typical sea breeze situations, micro fronts and thermal internal boundary layer structures.Results from this exercise will be presented.

JSM43/W/01-B5 1000

MULTIFRACTAL TURBULENCE OF CHERNOBYL FALL-OUT: HOT SPOTS OF 137CS SOIL CONTAMINATION AND SELF-ORGANIZED CRITICALITY

I. TCHIGUIRINSKAIA (E.E.&S. Dept., Clemson University, 342 Computer Court, Anderson, SC29625, USA, email: iouliat@clemson.edu); D. Schertzer (L.M.M., Université Pierre et Marie Curie, 4 Place Jussieu F-75252 Paris Cedex 05, France); S. Lovejoy (Physics Dept., McGill University, 3600 University st., Montréal, Qué., H3A 2T8, Canada)

We estimated the average value of the 137Cs soil contamination during years 1986-1991 on 16384 pixels covering a 300 km radius around the Chernobyl area (Ukraine), using a subset of the data base published by the ex-Soviet Hydromet office. The rather complex structures of Chernobyl fall-out at all scales poses nontrivial difficulties for risk assessments since the risks will depend notably on measurements of local doses which have an extreme spatial variability. We consider a new atmospheric dispersion approach based on a multifractal cascade process which leads to an infinite hierarchy of singularities of the multifractal field. We made a special study of the important probability tails associated with the extreme 137Cs soil contamination events ("hot spots"), showing that they are associated with first order multifractal phase transitions and a non classical Self-Organized Criticality. The moment order for the first order phase transition to Self-Organized Criticality is qD=2.2. This confirms preliminary empirical studies using the "R.E.M. Chernobyl fall-out data base" covering about 4000 towns over western Europe.

DISPERSION

JSM43/W/07-B5 1100

MULTISCALE LOCAL FORCING OF THE ARABIAN DESERT DAYTIME BOUNDARY LAYER, AND IMPLICATIONS FOR THE DISPERSION OF SURFACE-RELEASED CONTAMINANTS

Thomas T. WARNER, Rong-Shyang Sheu (National Center for Atmospheric Research Boulder, Colorado, USA)

Four, six-day simulations were performed, using a mesoscale model run in a data- assimilation mode, of the atmospheric conditions over the Arabian Desert during the time of the 1991 detonation and release of toxic material at the Khamisyah, Iraq weapons depot. These atmospheric simulations are being employed in a forensic analysis of the potential contribution of the toxic material to the Gulf War illness. The transport and concentration of such surface-released contaminants is strongly related to the planetary boundary layer (PBL) depth and the horizontal wind speed in the PBL. The product of the PBL depth and the mean wind speed within it is referred to as the ventilation, and is used as a metric of the horizontal transport within the PBL. Thus, a corollary study to the larger forensic analysis involves employing the model solutions and available data in an analysis of the multiscale spatial variability of the daytime desert PBL depth and ventilation as they are affected by surface forcing from terrain-elevation variations, coastal circulations and contrasts in surface physical properties. The coarsest computational grid spanned the entire northern Arabian Desert and surrounding areas of the Middle East, and represented the large scale PBL modulation by the orography. The PBL depths were greatest over the high elevations of the western Arabian Peninsula and over the Zagros Mountains in western Iran, and depths were shallowest over water bodies and the lower elevations in the Tigris-Euphrates Valley. Higher resolution grids in the nest (the smallest grid increment being 3.3 km) showed that the PBL depth minimum in the Tigris-Euphrates Valley was likely a consequence of compensating subsidence associated with the thermally forced daytime upward motion over the Zagros Mountains to the east in Iran. Further local modulation of the daytime desert PBL occurred as a result of the inland penetration of the coastal sea-breeze circulation on the west side of the Persian Gulf, where BL depths were suppressed as far as 100 km inland. On the finest scales, significant PBL-depth variability resulted from surface thermal differences associated with contrasts between barren desert and partially vegetated desert. The average 1500 LT ventilation over the Arabian Desert for the six day period varied spatially from less than 4,000 to over 24,000. This represents over a factor-of-six average spatial variation in the ability of the atmosphere to transport contaminants away from a source region.

JSM43/W/12-B5 1120

SCALING OF BLOWING SNOW FLUXES OVER COMPLEX TERRAIN

Richard ESSERY (Hadley Centre, Bracknell, UK); John Pomeroy (National Hydrology Research Centre, Saskatoon, Canada), Long Li (Division of Hydrology, University of Saskatchewan, Saskatoon, Canada)

Transport and sublimation rates for wind-blown snow increase rapidly with increasing wind speed and so are highly sensitive to wind speed variations in response to changes in elevation and surface roughness over complex terrain. Sublimation of suspended snow returns moisture to the atmosphere, and redistribution by wind can generate large variations in snow depth which influence the depletion of snow during melt.
A model of windflow over complex terrain and a model of blowing snow over uniform terrain are coupled with a representation of downwind development in a distributed model of blowing snow over complex terrain. Applied to an arctic tundra basin with gentle topography and marked variations in vegetation height, the distributed model is found to give reasonable agreement with measured snow accumulations.
For large-scale modelling applications, scaling relationships are developed between modelled spatial distributions of wind speeds and statistical characteristics of the topography which can be obtained directly from a digital elevation model. These relationships are used to investigate the scaling of blowing snow fluxes over complex terrain.

JSM43/W/09-B5 1140

THE DISPERSION OF PARTICLES IN HETEROGENEOUS, COMPLEX TERRAIN

Roni AVISSAR, S.G. Gopalakrishnan (Department of Environmental Sciences, Rutgers University, 14 College Farm Road, New Brunswick, New Jersey 08901-8551, USA, email: avissar@gaia.rutgers.edu)

A systematic analysis of the impacts of heat patches and topographical features on the dispersion of passive materials in a shear-free convective boundary layer (CBL) was performed. A coupled large-eddy simulation (LES) and Lagrangian particle dispersion (LPD) model was used for that purpose. Over a homogeneous, flat terrain the dispersion statistics produced by the model is in excellent agreement with convection tank data and with other model results. Heat flux heterogeneity has a remarkable influence on particle dispersion in the CBL. The horizontal pressure gradients created by these heterogeneities impede vertical mixing. For a near surface release, the particles travel horizontally rather than "lifting-off," increasing the concentration near the ground surface. Particles released at higher elevations reach the surface much slowly than when released above a flat, homogeneous domain. Topography has very little impact on "lift-off," dimensionless crosswind integrated concentration, mean particle height, particle spread and ground level concentration of particles released near the ground surface. This is true even with hills as high as 25% the height of the CBL. However, it has a noticeable effect on the dispersion statistics of particles released from higher elevations. In particular, for a source height located about _ the height of the CBL, the locus of the maximum concentration in cross-wind integrated plume descends to the surface of a moderate hill noticeably slowly than above a flat, homogeneous domain.

JSM43/E/03-B5 1200

SOLID AEROSOLS DISPERSION IN URBAN AREA

K. V. Karelsky, V. V. Papkov, A. S. PETROSYAN (Space Research Institute of the Russian Academy of Sciences, Profsoyuznaya 84/32, Moscow 117810, Russia, email: apetrosy@iki.rssi.ru)

A new model of solid aerosols dispersion around buildings and street canyons is developed. This is initially based on the description of the multiphase flow problem using the well established non-viscous hydrodynamic equations with full account (in the equation of state) of the changed thermodynamics. The study of multiphase flows is performed using an original idea in which the multiphase flow is simulated by the above-mentioned ideal equations with a finite difference representation which incorporates an internal, i.e. numerical, viscosity. More specifically, the computer calculations are based on the Godunov method which is a first finite difference representation of the non-viscous (Euler) equations of hydrodynamics and has the great advantage of providing the numerical viscosity. This use of the Godunov method has been shown to be practically reliable in important situations when molecular viscosity effects are evidently important. One example is when the boundary layer is heavily loaded with solid particles. It was shown efficiency of developed method for important cases when vertical size of inhomogeneity is in excess of horizontal size and topological diffusion, wake/secondary flow effects and blocking effects exist on complex terrain.

JSM43/E/05-B5 1220

A NEW MODEL FOR DENSE GAS DISPERSION THROUGH GROUPS OF OBSTACLES

K. V. Karelsky, V. V. Papkov, A. S. PETROSYAN (Space Research Institute of the Russian Academy of Sciences, Profsoyuznaya 84/32, Moscow 117810, Russia, email: apetrosy@iki.rssi.ru)

A new model for dense gas dispersion in complex terrain including groups of obstacles is discussed. This model is based on shallow layer equations describing dense gas cloud. It is well known analogy between compressible gas equations and shallow layer equations. This

allows to apply for dense gas description generalised solutions of shallow layer equations which are best adapted for boundary layer including groups of obstacles. A full set of selfsimilar solutions of initial discontinuity decay problem for shallow layer equations will be provided and new computer model based on Godunov method has been shown to be practically useful to predict gas flows in important case when only two layer model is applicable. One example is when shallow dense gas cloud is located above step inhomogeneity and usual shallow layer equations are non-applicable in the vicinity of terrain discontinuity. Computations for different type of obstacles and terrain will be discussed.

THE THERMAL EVOLUTION OF THE SOUTHERN INDIAN SHIELD

R. N. SINGH (CSIR Centre for Mathematical Modelling and Computer Simulation, Bangalore, 560037, India, email: rnsingh@cmmacs.ernet.in); Jibamitra Ganguly (Dept. of Geosciences, University of Arizona, TUCSON, AZ 85721, USA, email: ganguly@geo.arizona.edu)

The southern Indian shield has been a major focus of research among Geoscientists due to its Archean granulite and granite terranes, mantle xenoliths transported by Proterozoic kimberlite eruptions, and intraplate seismicity. Heat flow, magnetic and seismological (tomographic, DSS and teleseismic receiver function) investigations have revealed the deep structure of the shield and the continental roots. The tectonic evolution of the shield has also been a subject of intensive investigation. A comprehensive summary of these studies will be presented in this paper, especially in the context of their importance in understanding the thermal evolution of the Indian shield. We have constructed steady state thermal models of the crust using the available crustal heat flow and heat generation data along with the P-T array of the Proterozoic mantle xenoliths, and accounting for the effect of erosion of the radiogenic layer (Singh, 1984). The latter effect was ignored in our earlier work (Ganguly et al., 1995). These thermal models have been extrapolated to the Archean time taking into consideration the cooling effect in a convecting mantle. A range of transient thermal perturbation models have been calculated to explain the P-T array of the Archean granulites, accounting for the effects of thrusting, CO2 flux, and irreversible adiabatic decompression of the fluid. As discussed in our earlier work (Ganguly et. al., 1995), geophysical data do not support significant magma underplating, whereas thrusting alone could not have produced the thermal perturbation necessary for the formation of granulites. In this work, the magnitude of the required CO2 flux has been re-evaluated by coupling it to thrusting, and using the revised calculation of steady state initial geotherm. Finally, we discuss the implications of the CO2 fluxing on the dehydration of crust/lithosphere, its viscosity structure and the stability of continental roots in the light of recent theoretical studies on the mantle convection coupled to moving plates and experimental work on rock rheology.

JSS44/E/09-B4 0950

ARCHAEAN DHARWAR CRATON, SOUTHERN INDIAN SHIELD: REGIONAL CRUSTAL THERMAL MODEL AND LOCAL DEPARTURES

Sukanta ROY, R.U.M. Rao (National Geophysical Research Institute, PO Bag 724, Uppal Road, Hyderabad 500007, India, email: postmast@csngri.ren.nic.in)

The Archaean Dharwar province in the southern India shield com-prises greenstone-granite belts and gneisses which give way to granulites further south. The heat flow regime is found to be low, spanning a range of 25 to 50 milliwatt/sq m. However, the radiogenic heat production of surface rocks is found to vary widely, from 0.2 to 8 microwatt/cu m. Based on considerations of regional geology and crustal sections constrained by deep seismic sounding and gravity data, five 1-D scenarios are envisaged for crustal heat production in the province. These are compatible with the range of the observed surface heat flow and represent the extremes possible in the crustal heat contribution, on a regional scale. A salient outcome is that all result in heat flow at the base of the crust in a very narrow range, 11.5 to 14.5 milliwatt/sq m. This range is about the same as those derived for the Archaean provinces in the Canadian shield and for the Kaapval craton southern Africa. There are locally anomalous areas departing from the regional heat flow - crustal heat production scenarios, where the surface heat flow is well within the regional variation but the surface rocks are incompatibly high in heat production. In such areas, heat flow data constrains the thickness of the high heat producing surfacial rocks to thin "veneers" at the top, and further below, the crustal scenario is one among the five envisaged. The regional crustal thermal model also places bounds for crustal temperatures in the province, 280 to 360 deg Celcius at the Moho.

JSS44/E/04-B4 1010

MAFIC DYKES AND GEOTECTONIC EVOLUTION OF THE PROTEROZOIC SOUTH INDIAN LITHOSPHERE

T. RADHAKRISHNA, G. Balasubramoniam (both at Centre for Earth Science Studies, Trivandrum, 695 031, India, email: coral@giasmd01.vsnl.net.in)

Proterozoic magmatism manifested as mafic dyke intrusions constitutes an important geological event of the Eon over the Indian shield. The mafic dykes across the South Indian Granulite Terrain (SIGT) and the northern Dharwar Craton (Granite-Greenstone terrain) share many similar geochemical characteristics. These dykes are classified as within plate Fe-rich tholeiites and they possess large ion lithophile and light rare earth element enrichments, depletion of Nb and Ta, high Sri (0.703-0.706) and low INd values (0 to –6). Their 40Ar/39Ar and K-Ar (limited Rb-Sr and Sm-Nd) isotope age data and the palaeomagnetic data group them into at least four discrete phases between c. 1.6 and 2.1 Ga, while 1.65 Ga episode is the most predominant and widespread. Comparison of palaeomagnetic directions from the dykes of these terrains shows a remarkable correlation for the 1.65 and 1.8 Ga period. Two important geotectonic implications are drawn here for the Proterozoic continental lithospheric configurations. Firstly, the northern Dharwar Craton and the southern SIGT amalgamated at least by mid- Palaeoproterozoic and thus do not support some of the interpretations extending the Pan-African orogenic belt within the late Proterozoic Gondwana reconstruction across the Indian shield. Secondly, the thermal anomalies associated with these magmatic episodes have initiated the formation of the largest Proterozoic sedimentary (Cuddapah) Basin in Indian shield, but its present large size is mainly related to the widespread 1.65 Ga igneous episode.

JSS44/E/10-B4 1030

COMPARISON OF LITHOSPHERIC STRUCTURE BELOW DIAMOND-FERTILE AND DIAMOND-BARREN FIELDS NEAR CUDDAPAH BASIN, INDIA, BASED ON INTEGRATED GEOPHYSICAL, GEOLOGICAL AND GEOCHEMICAL STUDIES

Saurabh K. VERMA (National Geophysical Research Institute, Uppal Road, Hyderabad-500 007, India, email: postmast@csngri.ren.nic.in)

Geophysical, geological, and geochemical characteristics of the lithosphere below two kimberlite fields in the vicinity of Cuddapah Basin, India, are analysed. In the Wajrakarur kimberlite field, located southwest of the basin, 21 pipes have been identified so far and most of them are found to be diamondiferous. On the other hand all the pipes studied so far from a cluster of 31 pipes in the Narayanpet kimberlite field, located north-west of the basin, are non-diamondiferous. While the geophysical data suggests different lithospheric structure below these two fields, the geochemical study provides supportive evidences in terms of pressure, degree of partial melt and oxygen fugacity. All these studies suggest that possibly the lithosphere-asthenosphere structures below the two fields are qualitatively different.

JSS44/W/10-B4 1110

SPATIAL AND TEMPORAL RATE VARIATIONS OF ONTINENTAL RIFT MARGIN UPLIFT AND EXHUMATION: THE ASATCH MOUNTAINS, UTAH (USA)

Phillip A. Armstrong, Todd A. EHLERS, David S. Chapman (Dept. of Geology and Geophysics, Univ. of Utah, Salt Lake City, UT 84112, USA, email: paarmstr@mines.utah.edu); Peter J.J. Kamp (Dept. of Earth Sciences, Univ. of Waikato, Hamilton, New Zealand)

The Wasatch Mountains mark the eastern extent of the Basin and Range province and reflect a major continental rift margin uplift. Holocene fault scarps along the range front correspond to apparently long-lived topographic salients and bedrock faults that extend into the range. GPS campaigns across ~N-striking Wasatch Fault segments indicate decadal displacement rates of 3.5 to 5mm/yr for a 55 degree dipping fault. Trenching studies indicate millennium-scale displacement rates of 1-2 mm/yr. (U-Th)/He ages range from 1.6 Ma at the range front to 4.9 Ma ~8 km eastward into the footwall. Helium ages indicate cooling from about 75 degrees C and give apparent exhumation rates of 1-2 mm/yr. at the range front for the last 2 My and 0.3-0.6 mm/yr. for the last 5 My east of the range front. AFT ages from samples that span the E-W extent of the central, pluton-cored section of the range are ~5 Ma adjacent to the range front but increase to ~35 Ma at 35 km eastward. Our preliminary interpretation is that the eastern rocks were rapidly exhumed between ~20 and 35 Ma with little exhumation since whereas the range front rocks were exhumed at 0.5-1.0 mm/yr. for the last ~10-17 My. If range front exhumation and fault displacement rates are assumed to be proxies for one another, then the exhumation and displacement rates have increased by a factor of 3 to 5 between the mid Miocene and present day. Exhumation rates have been relatively low farther east and into the footwall since the middle Miocene, reflecting eastward tilt of the range, which is in agreement with petrographic, fluid inclusion, and structural studies and probably reflects flexural tilt due to tectonic unloading.

JSS44/E/31-B4 1130

GEOPHYSICAL CONSEQUENCES OF THE CORDILLERA-CRATON THERMAL TRANSITION IN S. W. CANADA

R.D. Hyndman, Trevor LEWIS (Geological Survey of Canada, Pacific Geoscience Centre, Sidney, B.C. V8L 4B2, Canada)

There is a pronounced increase in heat flow and lithosphere temperatures across the transition from the stable North American Craton to the southeastern Canadian Cordillera. The heat flow increases from 40-60 mWm-2 in the Craton to 80-100 mWm-2 in the Cordillera. There are numerous reliable heat flow data in the Cordillera but measurements in the Western Canada Sedimentary Basin overlying the adjacent Craton are in petroleum exploration wells with inherent low accuracy and are affected by hydrological effects. However, the deep thermal boundary is well defined based upon contrasts in several other temperature sensitive geophysical parameters. The boundary is located 100 km west of the mountain front in the region of the Rocky Mountain Trench, and it must occur over a distance of less than 200 km. Temperatures in the deep crust and upper mantle are first computed from the heat flow and radioactive heat generation data. These temperatures are then compared to those estimated from the temperature dependence of uppermost mantle seismic velocity, Pn, and from xenoliths in kimberlites for the Craton, and in Tertiary volcanics for the Cordillera. Pn velocities decrease from about 8.2 km/s in the exposed Craton to 7.8 km/s in the Cordillera. The temperatures just below the Moho are 400-500C for the Craton and 900-1000C beneath the Cordillera based upon all three constraints. Two temperature sensitive changes across the thermal boundary are examined. There is a westward decrease in crustal thickness from 40-50 km for the Craton to 32-34 km for the Cordillera with no significant change in average elevation nor in gravity. Isostatic balance is maintained by thermal expansion and density reduction in the high temperature Cordillera lithosphere. The average temperature to a depth of 150 km is about 400C higher for the Cordillera compared to the Craton. There also is a pronounced westward decrease in lithosphere strength and thus deformation style. In the Craton, the crust and upper mantle are very strong to at least 100km depth. As a result, the foreland belt deep crust and upper mantle have remained undeformed during Late Mesozoic to Early Tertiary tectonics. Shortening occurred primarily in overlying sedimentary thrust sheets, mediated by high pore fluid pressures. In the Cordillera hinterland, the high temperatures result in the rheological lithosphere with significant strength being limited to the upper 10-15 km of the crust. Mesozoic-Cenozoic shortening deformation and subsequent extension included this whole thin lithosphere.

JSS44/L/03-B4 1150

ELECTROMAGNETIC IMAGES OF STRUCTURAL AND GEOCHEMICAL EVOLUTION OF OLD CONTINENTAL LITHOSPHERE

J.A. CRAVEN, D.E. Boerner, R.D. Kurtz, (Geological Survey of Canada, Ottawa, Canada, K1A 0E9); I.J. Ferguson (University of Manitoba, Winnipeg, Canada R3T 2N2); R.C. Bailey (University of Toronto, Dept. of Physics, Canada M5S 1A7)

Recent evidence suggests that the geophysical snapshot of the lithosphere is also a viable view into the ancient lithosphere. Deep electromagnetic probing based on the magnetotelluric (MT) method reveals a conductivity structure sensitive to the spatial distribution of minor constituents such as carbon and hydrogen. These elements are important geochemical

indicators of lithospheric reworking related to mantle devolitilization and to subduction-related metasomatism. MT surveys across the Archean Hearne and Superior Provinces of Canada contrast the nature of lithospheric reworking during the Proterozoic and Archean. The Archean Hearne Province beneath the Western Canada Sedimentary Basin was substantially weakened during at least three Proterozoic reworking events. One legacy of these events is a strong gradient in the deep electrical conductivity at the margin of the Hearne lithosphere, likely created by modal metasomatism. This view is contrasted by conductivity models of the lithosphere beneath the western Superior Province which is strongly conductive and almost one-dimensional (layered) within the North Caribou subcrustal lithosphere, but spatially juxtaposed against electrically two-dimensional subprovinces to the south. This electrical fabric argues for a stable (primary?) cratonic element in the North Caribou subprovince against which crustal blocks and their lithosphere were coherently accreted during Late Archean. Integration of laboratory and synthetic analyses of the deep conduction mechanisms is the key to unlocking the relationship between the deep electrical geophysics and the on-going evolution of the lithosphere.

JSS44/L/01-B4 1210

LITHOPROBE - REVEALING THE EVOLUTION OF A CONTINENT THROUGH MULTIDISCIPLINARY EARTH SCIENCE STUDIES: EXAMPLE FROM THE TRANS-HUDSON OROGEN, CENTRAL CANADA

Ron M. CLOWES (Lithoprobe and Department of Earth & Ocean Sciences, University of British Columbia, 6339 Stores Road, Vancouver, BC, V6T 1Z4, Canada; email: lowes@lithoprobe.ubc.ca) with contributions from many other LITHOPROBE scientists

LITHOPROBE, Canada's national earth science research project, was established in 1984 to develop a comprehensive understanding of the evolution of the northern North American continent. LITHOPROBE's 10 transects (study areas) span the country and 4 b.y. of geological time. A pan-LITHOPROBE synthesis will bring the project to a formal conclusion in 2003. Here we illustrate the multidisciplinary approach and preliminary results of transect synthesis for the Trans-Hudson Orogen Transect. Located in Saskatchewan and Manitoba, the Paleoproterozoic Trans-Hudson Orogen is the best exposed and most complete orogenic belt of a network of such belts formed by collision of older Archean microcontinents. Understanding of its 3D architecture and tectonic history has been changed fundamentally through integration of seismic reflection, seismic refraction, potential field, paleomagnetic, geochemical, geochronological and geological research. An ocean on the scale of the present Pacific Ocean separated Archean blocks that eventually collided. A previously unknown Archean microcontinent, the Sask craton, has been identified in the west central part of the orogen. Crustal thickness over the orogen varies from <40 km to >50 km. Below the central orogen, velocity anomalies in the mantle may represent a preserved mantle suture resulting from the collision of two Archean cratons. The economically important greenstone belt of the Saskatchewan-Manitoba borderland has been revealed to be a collage of oceanic/arc volcanic assemblages that were later intruded and overlain by volcanic, plutonic, and sedimentary rocks. This research has resulted in a new, chronologically well constrained, working model for the tectonic evolution of the orogen between 2.4 and 1.7 Ma, although some inconsistencies remain.

JSS44/W/03-B4 1400

THE 3-D STRUCTURES OF THE TORNGAT AND MAKKOVIK OROGENS AND NAIN PLUTONIC SUITE (LABRADOR) FROM JOINT ANALYSIS OF GEOPHYSICAL AND GEOLOGICAL DATA

Thomas Funck, Keith LOUDEN (both at: Dept. of Oceanography, Dalhousie Univ., Halifax, NS, Canada B3H 4J1, email: tfunck@is.dal.ca); Ian Reid (Danish Lithosphere Centre, Oster Voldgade 10, DK-1350 Copenhagen K, Denmark); Jeremy Hall (Dept. of Earth Sciences, Memorial Univ., St. John's, NF, A1B 3X5 Canada); Dick Wardle (Newfoundland Dept. of Mines and Energy, St. John's, NF, A1B 4J6 Canada)

New geological and geophysical data from the Canadian Lithoprobe's ECSOOT (Eastern Canadian Shield Onshore-Offshore Transect) Program indicate major differences in the deep structures of the Paleoproterozoic Torngat and Makkovik orogens and the Mesoproterozoic anorogenic Nain Plutonic Suite (NPS). These data include recent wide-angle seismic profiles, which allow us to extend interpretation of earlier marine deep MCS profiles onto land where extensive geological studies have been undertaken. For the Torngat Orogen, seismic tomographic inversion images a N-S trending crustal root with a relief of up to 15 km that decreases to the north. The shape of the root in E-W sections across the N-S striking collisional suture changes from asymmetric in the south to symmetric in the north, coincident with changes in the surface geology that indicate N-S variations in late stages of the orogenic development. Preservation of the crustal root and penetration of large-scale shear zones through the entire crust are consistent with an absence of post-orogenic magmatism. In contrast, profiles across the Makkovik orogen, south of the Nain Province, have no crustal root but show signs of significant tectonic modification of the lower crust and upper mantle. An S-shaped reflector separates reworked Archean crust to the north from juvenile Proterozoic crust to the south, but crustal velocities are the same. Finally, the later NPS anorthosites appear to be related to major velocity variations in the mid-to-lower crust.

JSS44/W/13-B4 1420

GEOPHYSICAL IMAGES OF THE SVECOFENNIAN OROGEN

Pekka HEIKKINEN, Annakaisa Korja (Institute of Seismology, P.O. Box 26, FIN-00014 University of Helsinki, Finland)

The Svecofennian orogeny took place, when the continental Karelian plate in the east collided with a newly formed Central Finland island arc plate in the west. Later Southern Finland Island Arc Complex amalgamated to this newly formed continent from the south. In the Subjotnian, 200 million years later, an aborted rift was formed within the Southern Finland Island Arc Complex. BABEL lines 1 and 6 image the architecture of the Southern Finland Arc Complex. When the reflection profile data are combined with lithological, new marine gravimetric and seismic wide angle data, the varying reflectivity patterns can be understood in relation to the major processes forming the Svecofennian crust in the region. The unusually thick crust (55-60 km) is cored by unreflective, high density gabbroic intrusions (200km x 50km x 20km), interpreted as a magmatic core of a primitive island arc complex. A highly reflective ramp anticline structure developed against the island arc in the south. The crust was thickened via a sequence of ramp anticlines comprised of the Southern Svecofennian migmatite, schist and volcanic belts. Mantle plume magmatism in the Subjotnian resulted in extensional environment that was expressed by crustal thinning via reflective listric shear zones, that most probably are inverted thrust faults, and via unreflective rapakivi granite magmatism. Shear zones and mafic dyke swarms related to Subjotnian magmatism can be identified from low altitude aeromagnetic maps and lithological maps. Crustal underplating and intraplating are seen as highly reflective, high velocity lower crust underlain by a 5 km thick, unreflective lower crust, which in turn is cut by a new sharply reflective Moho. BABEL lines 3&4 image reflective NE-dipping suture of the Southern Finland Island arc complex against the Central Finland Arc Complex and the collisional structures of the deformed supracrustal rocks. Ladoga- Bothnian Bay transform fault zone that developed at the Svecofennian Karelian boundary zone is imaged as a 30 km wide, subvertical unreflective band cutting through the crust.

JSS44/E/02-B4 1440

INTEGRATED LITHOSPHERIC MODELLING FOR THE STRUCTURE AND OROGENIC EVOLUTION OF THE WESTERN CARPATHIANS AND PANNONIAN BASIN

Miroslav BIELIK (Geophysical Institute, Slovak Academy of Sciences, Dubravska cesta 9, 842 28 Bratislava, Slovak Republic, email: geofmiro@savba.sk); Hermann Zeyen (Department of Earth Sciences, Universite de Paris-Sud, Bat. 504, F-91405 Orsay, France, email: zeyen@geol.u-psud.fr); Anco Lankreijer (Institute of Earth Sciences, Vrije Universiteit, 1081 HV Amsterdam, The Netherlands, email: lana@geo.vu.nl)

The contribution focuses on integrated lithospheric modelling for study of the structure and evolution of the continental lithosphere in the Western Carpathian-Pannonian basin region. The integrated 2D modelling algorithm that utilises gravity, local isostasy and thermal analyses is applied to determined lithospheric thermal structure. To improve the knowledge of the continental lithosphere, the rheology of the lithosphere based on extrapolation of failure criteria, lithology and temperature models is also studied. The results show a relatively thin lithosphere underneath the Polish foreland (100-120 km) with indications of a flexural forebulge of about 200 m height. Underneath the Pannonian basin, the lithospheric mantle has to be 5-10 kgm-3 denser than usual subcrustal mantle which may be explained by enrichment due to a plume. The Carpathians are characterized by a thickened lithosphere which is interpreted as remnants of a subducted slab. Rheological cross-sections show significant variations in rheology of the lithosphere in the Polish foreland, the Western Carpathians and the Pannonian basin with important implications for the tectonic scenarios.

JSS44/E/18-B4 1500

ALPINE POLY-STAGE TECTONO- METAMORPHIC EVOLUTION OF THE SOUTH CARPATHIANS AS A PRECURSOR HISTORY OF A YOUNG MOUNTAIN BELT

Viorica IANCU (Geological Institute of Romania, 1 Caransebes Street, Bucharest 32, ROMANIA, RO-78344, Email: viancu@ns.igr.ro); Antoneta Seghedi, Dumitru Ioane (both at Geological Institute of Romania, 1 Caransebes Street, Bucharest 32, Romania, RO-78344, email: geol@igr.sfos.ro)

The structural model of the South Carpathians is based on the ideea of a polystage tectono-metamorphic evolution and mountain building. The main tectogenetic events responsible for the compressional and crustal thickening processes are: Mid-Cretaceous ("austrian phase"; 117-118 Ma, by Ar/Ar, Dallmeyer et al., 1996) and Upper Cretaceous ("laramian phase"), the main nape piles including: Danubian, Arjana, Severin, Getic and Supragetic units. The younger history of the belt is dominated by the Miocene tectogenetic events, including thrust of the older nape stacks over Moesian platform, orogen parallel faulting and extension related sedimentation. These structural features of this branch of the Alpine Carpathian mountain belt are strongly supported by structural, petrological and geochronological constraints and are underlined by an integrated analysis of geophysical data: gravity, magnetics, seismics, tellurics. The special features of the alpine history can be underlined by: the succesive extensional to compressional tectogenetic events, affecting the same crustal domains, alternating from the Lower Jurassic to Upper Cretaceous, with a period of quiescence in Paleogene, the youngest FT ages beying around 30 Ma (Sanders, 1998). The main paroxismal compressional events alternated with longer periods of extension, magmatism, sedimentation or uplift-erosion; thus, the continent/ocean crust type collision on both sides of the belt, was followed by continent/continent type collision, the alpine mobile belt beying attached to the eastern european platforms by the "post-laramian" sedimentary cover during the Neogene.The metamorphic evolution of the alpine cycle has a polystage character in the units of the danubian domain (from chloritoid to prehnite-pumpellyite blastesis in mesozoic covers. In the upper nappes (Getic-Supragetic) the alpine metamorphic imprint is related to high thermal and low-pressure gradients spatially associated with magmatic-arc intrusions (banatitic magmatites) in two pulses: subsequent to late-Albian and intra-Senonian as suggested by U/Pb of 79-75 Ma (Nicolescu, 1998) and K/Ar data (81-68 and 62-45 Ma intervals, cf. Russo-Sandulescu et al., 1994).

JSS44/L/02-B4 1520

UPPER MANTLE DOMAINS BENEATH CENTRAL-SOUTHERN ITALY: PETROLOGICAL, GEOCHEMICAL AND GEOPHYSICAL CONSTRAINTS

A. PECCERILLO (Dipartimento di Scienze della Terra, Piazza Universit`, 06100 Perugia, Italy, e-mail: pecceang@unipg.it), G. F. Panza (Dipartimento di Scienze della Terra, Universit` di Trieste and the Abdus Salam ICTP, SAND Group, 34124 Trieste, Italy)

The Italian peninsula shows high complexity of the mantle-crust system and of the Plio-Quaternary magmatism. The lithospheric thickness shows remarkable lateral variations from about 110 km to a minimum of about 30 km. Intermediate and deep-focus earthquakes indicate the presence of a lithospheric slab under the Eolian-Calabrian area and at the southern end of Campania. Much less extensive and more shallow seismic activity characterizes the Roman-Tuscan region, where the existence of a relic slab has been hypothesized. The deep seismicity in the southern Tyrrhenian sea is associated with active calcalkaline to shoshonitic volcanism in the Aeolian arc. Alkaline potassic volcanism occurs in central Italy. Finally, potassic lamproitic magmatism coexist with crustal anatectic and various types of hybrid rocks in the Tuscany area. The parallelism between changing magmatism and variations of the structure of the crust-mantle system makes central-southern Italy a key place where petrological and geophysical data can be used to work out an integrated model of the structure and composition of the upper mantle. It is suggested that the upper mantle beneath Tuscany consists of a thick lithospheric lid that has been affected by intensive subduction-related metasomatism. This caused the formation of phlogopite-rich veins that cut through residual spinel-harzburgite and dunite. These veins, possibly partially molten, may be an explanation for the soft mechanical characteristics that are unusual for lithospheric mantle. In the Roman Province, the upper mantle is formed by a thinner lid and by metasomatic fertile peridotite, problably connected with the uprise of an asthenospheric mantle wedge situated above the Apennine subduction zone. Geochemical data indicate that metasomatism, though still related to subduction, had different characteristics and age than in Tuscany. Finally, the upper mantle in the eastern sector of the Aeolian arc and in the Neapolitan area appears to be distinct as in the Roman and Tuscan area and is problably represented by fertile peridotite contaminated by the presently active subduction of the Ionian sea floor. The overall picture of the mantle-crust system in Italy that unfolds from geophysical, petrological and geochemical data is that of a mosaic of various mantle domains that have undergone different evolutionary history in terms of both metasomatism and pre-metasomatic events. The coexistence side by side of these sectors is a key factor that has to be considered by models of the geodynamic evolution of the Central Mediterranean area.

JSS44/E/21-B4 1540

THE LITHOSPHERIC STRUCTURE OF SOUTHERN ITALY: A CONTRIBUTION FROM GEOCHEMICAL AND GEOPHYSICAL CONSTRAINTS

F. ITALIANO (Istituto di Geochimica dei Fluidi, C.N.R., via U. La Malfa 153, 90146 Palermo, Italy, email: italiano@igf.pa.cnr.it); M. MARTELLI, P.M. Nuccio (both at Dipartimento C.F.T.A., Università di Palermo, via Archirafi 36, 90123 Palermo, Italy, email: marte@neomedia.it); G. Martinelli (Regione Emilia Romagna, Serv. Cartogr. e Geologico, v.le Silvani 4/3,41100 Bologna, Italy, email: g.martinelli@mo.nettuno.it)

Many fluids emissions of the Southern Apennine sedimentary chain are characterised by geochemical features able to furnish new and useful information about the local lithospheric structure. The widespread CO2-rich gas emissions of this chain portion are the first geochemical evidence of the geodynamical activity of the area. These emissions display high 3He fluxes and a 3He/4He ratio as high as 2.84 times the air ratio, clearly testifying an appreciable-to-important contribution of mantle fluids. In particular sites, the presence of intracrustal melt intrusions has been inferred (Italiano et al., 1999). Furthermore, several geophysical data confirm the peculiarity of this crustal portion. Heat-flow displays anomalous values, as high as 215 mW/m2 (Mongelli et al., 1996); extremely low rock resistivity values beneath 15 km have been evidenced by Loddo et al. (1995), and a deepening of ipocentral depths toward South has been inferred (Doglioni et al., 1996). In relation with these geochemical and geophysical anomalies, we discuss the characteristics of the lithosphere in the investigated zone and its variations in both the apenninic and the antiapenninic directions.

JSS44/E/01-B4 1620

LITHOSPHERE STRUCTURE OF DEEP BASINS IN NORTHERN EURASIA AND ITS MARGINS

Nina PAVLENKOVA. (Institute for Physics of the Earth, B.Grusinskaja 10, 123810 Moscow, Russia, email: Ninel@Pavlenkova.msk.ru)

Several large and extremely deep basins are outlined in Northern Eurasia and its margins. They are basins formed on cratons and young platforms and in outer and inner seas. Some common features may be determined in their crustal structure and geological carbonate sediments are dominant. Flat bottoms and very steep sides formed by deep faults are typical for the basins. For deep structure the common features are: uplift of the Moho, decreasing of consolidated crust thickness, unusually high velocities (6.5 high seismic velocity intrusions in the lower crust. There is no evidence for large extension. Such basins seem to be formed by a similar process. At the first stage rifting helped to open a channel for transfer of mantle heat and material, starting a ience has been due to the crustal rock modification into more dense phases, to the load of sediments, to effects of thermal blanketing, to a metamorphism of the lower sediments, and to cooling of the formerly
intruded hot mantle material.

JSS44/L/04-B4 1640

INTEGRATED GEOPHYSICAL MODELS OF THE CRUST IN THE NORTH EURASIAN SHELF ON THE BASIS OF NEW COMPUTER DERIVED POTENTIAL FIELD MAPS AND GEOTRANSECTS

MASCHENKOV S.P., Astafurova E.G., Glebovsky V.Yu., Zayonchek A.V., Cherhych A.A. (All at VNIIOkeangeologia, 1, Angliysky pr., St.-Petersburg, 190121, Russia, e-mail: mascha@vniio.nw.ru)

The deep crustal structure of the North Eurasian shelf was studied on the basis of the integrated interpretation of potential field, seismic refraction and seismic reflection data. To improve the digital magnetic anomaly and gravity data bases in the area a team at VNIIOkeangeologia (St. Petersburg, Russia) has been assembling a bulk of original aeromagnetic profiles and free-air gravity observations. The available seismic cross sections were digitised and compiled. The magnetic and gravity anomaly maps and their derivatives provide with significant information for regional characterisation of major tectonic elements and the deep crustal structure. The basement topography was studied on the basis of comprehensive interpretation of seismic profiles and potential field maps, 2D- and 3-D gravity modelling, and the depth to magnetic source estimations. The position of the Moho evaluated from the gravity modelling along the geotransects was controlled by deep seismic refraction data where available. The integrated geophysical models allow to distinguish the large-scale structures of the North Eurasian shelf and develop a better understanding of their tectonic history.

MAPPING LITHOSPHERE-SCALE STRUCTURES IN THE EASTERN SIBERIAN PLATFORM

Yvette H. POUDJOM DJOMANI, William L. Griffin, Lev M. Natapov, Suzanne Y. O'Reilly (all at GEMOC ARC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia, email: ypoudjom@tilley.es.mq.edu.au); Yuriy Erincheck (VSEGEI, St. Petersburg, Russia 199026, email: erinch@mail.convey.ru)

The Siberian platform consists of several major Archean and Proterozoic basement terranes that have been mapped from regional magnetic data and basement exposures in the Anabar shield. Garnet and chromite concentrates from mantle xenoliths from a chain of Paleozoic to Mesozoic kimberlites across the platform have been used to construct mantle sections showing rock type distribution. These mantle sections reveal that the lithospheric mantle shows significant differences, corresponding to tectonic terranes mapped at the surface, and indicating that the terrane boundaries are translithospheric. Furthermore, the Archean terranes are underlain by typical depleted Archean lithosphere > 200 km thick, while the Proterozoic terranes are underlain by thinner and less depleted lithosphere. Enhancement of geophysical data shows more strongly negative Bouguer anomalies and a more noisy magnetic anomaly pattern over the Archean terranes than on the Proterozoic terranes. This reflects the difference in the mantle composition beneath the terranes as revealed by mantle-petrology studies. The elevation across the platform is not more than 900 meters. Gravity and topography data have been inverted to estimate the flexural strength, or elastic thickness (Te) of the plate. The results show that although the study area is a geologically stable Precambrian craton, Te is relatively low (< 30km) across most of the area suggesting a weak lithosphere comparable to that of tectonically much younger areas around the world. These results also show a major zone, ~ 150 km wide, of very weak lithosphere (Te < 10 km) running N-S across the western part of the study area which coincides with a zone of thicker lithosphere, lower surface heat flow and thicker lower crust, as well as abnormally high sub-Moho P-wave velocities suggesting an anisotropy in the upper mantle. The kimberlite fields in the Archean part of the platform are localised on the western flank of the zone of weak lithosphere. We suggest that the low Te zone is a mantle shear zone which has been a preferred conduit for magma into the lower crust, and has controlled the emplacement of kimberlites in the study area.

JSS44/E/20-B4 1720

SECULAR EVOLUTION OF SUBCONTINENTAL LITHOSPHERIC MANTLE

W.L. GRIFFIN, Suzanne Y. O'Reilly (GEMOC, Dept. of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia, Email: bill.griffin@mq.edu.au); C.G. Ryan ((and WLG) CSIRO EM, P.O. Box 136, N. Ryde, NSW 2113, Australia)

Chemical and petrographic observations on mantle-derived xenoliths and xenocrysts define a fundamental distinction between Archean cratonic mantle and Phanerozoic mantle. Archean xenoliths are more depleted on average, and have higher Si/Mg; subcalcic harzburgites are well-represented in Archean xenolith and xenocryst suites, but rare in younger ones. Analysis of >13,000 garnet xenocrysts from volcanic rocks worldwide shows a correlation of garnet composition with the tectonothermal age of the crust penetrated by the volcanic rocks. In xenoliths, the Cr content of garnet correlates well with the Al content of the rock, and Al is closely related to the contents of other major and minor elements. These correlations allow calculation of the mean composition of a mantle section, given the Cr content of garnet xenocrysts from that section. The calculated mean composition of SCLM beneath Archean, Proterozoic and Phanerozoic terrains shows a secular evolution in all measures of depletion, such as Al, Ca, mg#, and Fe/Al; Proterozoic SCLM is intermediate in composition between Archean and Phanerozoic SCLM. Cenozoic SCLM, exemplified by garnet peridotites from young extensional areas (China, Siberia, Australia) is only mildly depleted (_ 10% melt extraction) relative to Primitive Mantle. SCLM beneath some Phanerozoic terrains, especially in Europe, is more depleted and may represent reworked Proterozoic SCLM. Most Archean SCLM probably was derived by high-degree melting at depths „150 km. Comparison of xenolith suites with ophiolitic and abyssal peridotites suggests that subducted oceanic mantle is not a major component of Phanerozoic SCLM. Most existing Proterozoic and Phanerozoic SCLM probably has been generated in extensional post-orogenic environments. The broad correlation of SCLM composition with crustal age implies quasi-contemporaneous formation of crustal volumes and their underlying SCLM, and crust-mantle coupling over periods of aeons; it also requires an evolution in fundamental processes involved in the formation of continents and their roots.

JSS44/E/32-B4 1740

THE STRUCTURE OF THE ANABAR SHIELD CRUST

Svet MILANOVSKY, M.K. Kaban (both Institute of Physics of the Earth, Moscow, Russia, email: svet@uipe-ras.scgis.ru); A.V.Egorkin (GEONCenter, Moscow, Russia); O.M. Rosen (Institute of Lithosphere, Moscow, Russia)

For the area of Anabar Shield we investigated geology, seismic, gravity and thermal fields. The Earth crust of Anabar presents a relict of most ancient sialic cover of the Earth. From geological point of view the crustal complexes of Anabar Shield are identified and subdivided into passive (terranes) and active (collision zones) tectonic unites. Our interest for the study granulitic terranes is caused by the possibility to see the inner structure of the deep eroded crust from the surface geology and in the same time to study it with geophysical technology. Gravity field of the crust within Anabar is characterized by linear maxima which are oriented in NW- SE direction. These maxima coincide with zones of granulites. 3D analysis of gravity field gives the same direction of inclination of high density blocks in the crust that was found from surface geology and seismic model along DSS profile "Shpat". Thermal field of the Anabar Shield is characterized by very low heat flow. The average crustal heat generation was estimated to be 0.36 mkW/m3. Crustal petrology model was compared with heat generation values, seismic velocity (Vp,Vs) model and 2D density model Moho temperature is about 250-270 gradC on Anabar. We have "frozen" crust with eroded granite- gneiss layer. The present-day crust being a possible model for the consideration of the lower crust consisting of the blocks reflecting collision nature of the Anabar Shield granulites due to intense overthrust movements.

IS THICK-SKINNED TECTONICS DUE TO WEAK FAULTS?

M. Cristina Pomposiello (CIRGEO, Ramirez de Velasco 847,1414 Buenos Aires, Argentina, email: cpomposi@mail.retina.ar); John BOOKER, Shenghui Li (both at Geophysics Program, University of Washington, Seattle WA 98195 USA, email: booker@geophys.washington.edu, shenghui@geophys.washington.edu); Alicia Favetto, Ana Osella (both at Dpto. De Fisica, Univ. Buenos Aires, Ciudad Universitaria, Pabellon I, 1428 Buenos Aires, Argentina, e-mail: favetto@df.uba.ar, osella@df.uba.ar); Claudia Sainato (Catedra de Fisica, Fac.Agronomia, Univ. Buenos Aires, Av. San Martin 4453, 1417 Buenos Aires, Argentina, email: csainato@ciudad.com.ar)

The Sierras Pampeanas (SP) of Argentina are a region of active thick-skinned deformation between stable cratonic South America and the Andes. The Tucuman Plain (TP) lies at the northern end of the SP between the most easterly active reverse faults of the Andean deformation (which dip west) and the first high ridge (Aconquija) elevated by an eastward dipping reverse fault bounding it to the west. In October 1998, we collected 10 wideband magnetotelluric sites on a 165 km east-west transect of the TP. This transect coincides with industry seismic reflection data reprocessed to image structure to almost 40 km. We observe very low electric resistivity (below 1 Ohm-m) in the lower half of the crust under the western portion of the TP. To the east, the top of this conductor dips eastward roughly orthogonal to the dominant westward dip of the seismically imaged active faults. It continues horizontally eastward in a more subdued form in the mantle under the craton. The active faults bounding the TP and the adjacent Aconquija Ridge are rooted in the very low resistivity zone. Furthermore, the fault that has been traced at high angle to greatest depth (the Guasayan) has a reversely polarized bright reflection below 30 km. Both the low resistivity and reversed seismic reflection polarity lead us to suggest that the thick-skinned faulting beneath the TP is the result of low fault strength due to high fluid pressures. However, the unusually low resistivity under the TP may be due to precipitation of graphite or other very good conductor in the active faults rather than due to the fluid itself.

JSS44/W/08-B5 0850

ISOSTATIC STATE OF THE CENTRAL ANDES AND RIGIDITY OF ANDEAN LITHOSPHERE

H.-J. GOETZE, M. Koesters (both at FU Berlin, Institut fuer Geologie, Geophysik und Geoinformatik, Malteserstr. 74-100, D-12249 Berlin, Germany, email: hajo@geophysik.fu-berlin.de); A. Kirchner (Shell International Exploration and Production B.V., 2280 AB Rijswijk, Netherlands)

The gravity field of the southern Central Andes and their eastern foreland between 20° to 30°

S was investigated with regard to the isostatic state, the crustal density structure of the orogeny and the rigidity of the Andean Lithosphere. Gravity data-base came from recent field data acquisition in the Central Andes and covers both the area of northern steep subduction zone and the flat slab area in the South. All gravity data analysed in this paper were tied to the IGSN-71 gravity datum and terrain-corrected as well. Bouguer anomaly was evaluated using the sea level datum and a standard density of 2670 kg/m3 for mass correction. Analysis of Andean topography bases on the 1 km x 1 km mean elevation data grid of the USGS (Bliss and Olson, 1996) and other sources. The gravity effect of the downgoing Nazca Plate was removed from both Bouguer and isostatic residual anomalies (Airy and Vening-Meinesz type) and then correlated with mean topographic heights to identify areas of disturbed isostatic equilibrium. Additionally the balance of topographic surplus and deficit masses of the Andean root was estimated by applying Gauß´ theorem to the residual gravity field. As can be expected from the principle of isostasy, isostatic anomalies close to zero dominate, however, clearly shifted to a small positive mean values. Most of the morphological Andean units close to an isostatic equilibrium. Differences were obtained in the Argentine Puna, the south-eastern foreland and along a large NW to SE striking zone crossing the volcanic arc. This structure can be linked to high density crustal remnants of Mesozoic rifting. A novel methodology (Lowry and Smith, 1995) for 2D modelling of lithospheric rigidity which can account for surface and subsurface loads were applied to both topography and gravity field. Rather low values (10 E22 to 10 E23 Nm) were obtained for the area of the inner mountainous basins and 10 E23 to 5x10 E23 Nm were observed for the back arc region which corresponds with an effective elastic thickness of 35 to 45 km.

JSS 44/E/27-B5 0910

GEODYNAMICS AND STRESSES IN THE ANDEAN SUBDUCTION ZONE AT 21DEG S

Tanya ROMANYUK, Jury Rebetsky (both - Institute Physics of the Earth, B.Gruzinskaya 10, Moscow 123 810, Russia, email: t.romanyuk@relcom.ru, reb@uipe-ras.scgis.ru); Hans-Jorgen Goetze (Freie University, Malterstr. 74-100, N, 12249 Berlin, Germany, email: hajo@geophysik.fu-berlin.de)

The most sections of the convergent zones of the Earth are imaginated as underthrusting oceanic plates beneath immovable and stable continents. However, we believe that the Andean subduction zone is a region of a global sinking of material from the outer into the deep part of the Earth, with participation by both oceanic, and continental lithosphere. The movement of the material is strongly asymmetrical: the oceanic Nazca plate horizontally moves near trench at ~10cm/y, whereas the cratonic central part of the South America movement is indirectly estimated ~1cm/y. We tested this idea comparing the (1) results of 2D numerical modeling stresses and (2) parameters of present-day stress state. 1) To compile a 2D combining model we summarized information from the seismic refraction profiles, the gravity measurements, a seismic reflection profile of ANCORP group, electro-magnetic profiles and geological data. The densities and rheological properties of rocks, and velocities of the plates movements were used as the input data and boundary conditions for the task. 2) The principal stress axis directions, type of stress ellipsoid and ratio between isotropic pressure and maximum shear stresses were obtained from the earthquake focal mechanisms (CMT - Harvard catalog) with help of an original "cataclastic analysis" method based on the plasticity theory principles. The results of 2D numerical modeling are good agreed with the parameters of present-day tectonic stress state and allows: to allocate zones of tectonic overlithostatic compression and extension along subducting slab and maximum intensity areas of stress tensor.

JSS44/W/18-B5 0930

THE MAGNETIC, PETROMAGNETIC AND EVOLUTION MODELS OF THE CRUST FOR THE EAST EUROPEAN CRATON

M.I. ORLYUK (Institute of Geophysics National Academy of Sciences of the Ukraine, 32 Palladin Ave., 252142 Kiev, Ukraine)

The comprehensive of the interpretation near surface magnetic field, its regional component and MAGSAT anomalies were used for modelling. Petromagnetic data for the upper crust, the depths to the Pre-Riphean basement and to the Mohorovicic discontinuity, chronological and other geodata were used also as a priori information. 3D and 4D magnetic models of the crust have been compiled for the East European Craton (EEC). The EEC consists of the large-scale magnetic provinces with different mean magnetization which are fixed by T-Magsat anomalies. The magnetic provinces are located at the S-S-W and N-N-E margins of the Craton. Within of these provinces the sources of the regional magnetic anomalies of 60-120 km wide, with 1.0-4.0 A/m magnetization intencity of the crust are concentrated. They are presented mainly by femic (basaltoids, basic granulites) and sial-mafic (andesites, diorites) petromagnetic types. The low-magnetic central and S-E part of the EEC are presented by ultramafic-mafic (peridotites, granulites and eclogites) and sial (granitoids and their metamorfic analogues) types. According to 4D magnetic model the high-magnetic body are formed cyclicaly during the time intervals: 2,90-3,20; 2,25-2,55; 1,60-1,70; 0,90-0,95; 0,35-0,44 Ga.The high-magnetic blocks are related mainly to epochs of extension answering to the tectonic situations as rifts, basic granulite nuclears, subduction zone, while low-magnetic ones are associated with periods of constraction of the crust (collizional orogens and compression structures) and may serve as time-markers these stages. In the EEC high-magnetic, deep-seated blocks are indicators of Archean "protoriftoids", the Proterozoic and Phanerozoic riftogenetic structures etc.

JSS44/P/03-B5 0950

GEOPHYSICAL FIELDS AND DEEP STRUCTURE OF THE OKHOTSK SEA

Yuri Neprochnov, Gennady Semenov (both at Institute of Oceanology, Moscow 117585, Russia, email: ypn@geo.sio.rssi.ru); Liu Guangding, Hao TIANYAO (both at Institute of Geophysics, Chinese Academy of Sciences, Beijing, 100101, P.R. China, email: tyhao@mail.c-geos.ac.cn)

A review and integrated interpretation of existing geophysical data from the Okhotsk Sea region is presented. Three types of the earth's crust are revealed in the region: continental (western, northern and eastern marginal areas of the sea), subcontinental (central parts of the sea and the Kuril Island arc), and suboceanic (the Kuril Basin). The crustal thickness changes within the limits of 12-35 km. The central part of the Okhotsk Sea is characterised by rather small isometric anomalies of magnetic field, but positive anomalies of north-eastern direction have found in the Kuril Basin. The free-air gravity anomalies derived from shipboard measurements (25mgal interval) and from satellite altimetry (10mGal interval) were used for the comparative analysis. Mostly positive anomalies prevail in the northern in central parts of the sea, but negative anomalies down to -20 mGal occur in the Kuril Basin. The analysis of heat flow has shown a clear correlation with main tectonic structures: it is rather stable in central part of the sea, high on the rises in its western part and very high on the Kuril Basin. The gravity-seismic modeling was made for several seismic/geological profiles crossing the major tectonic structures of the Okhotsk Sea, and modified 2D and 3D geophysical models were constructed.

JSS44/E/24-B5 1010

STRUCTURE OF THE LITHOSPHERE IN CONTINENT OF CHINA AND ITS SURROUNDING MARGINAL SEA

Zhu JIESHOU, Yan Zhongqiong, Cao Jamin (Dept. of Geophysics, Chengdu University of Technology, Chengdu 610059, China, email: zhujs@cdit.edu.cn)

The continent of China and its marginal sea were formed by a series of rapid convergence of plates and blocks in the late Paleozoic (about 200-300 Ma). The Indian subcontinent collided with Eurasian continent, causing the crust to be shortened and uplifted in the late Mesozoic to Paleocene epoch, forming the highest plateau of Qinghai-Tibet and Pamir, and orogens of Himalayan and Hindu Kush. Based on the integrated geophysical and geological data, such as Global Geoscience Transects (GGT), the deep seismic refracted and reflected profiles, and the tomographic velocity imaging from seismic body wave and surface wave data, the three-dimensional structure of the lithosphere has been reconstructed for China and its surrounding marginal sea. The studied area ranges from 0o 0N to 60o 0N in latitude and from 60o 0E to 140o 0E in longitude. The Alpine-Himalayan belt throughout the Northern Pakistan (Hindu Kush and Pamir), Qinghai-Tibet plateau including Tarim basin and Tian-Shan mountain chain is characterized by the continent-continent collision zone with a thick crust (50-70 km) and lithosphere (120-250 km). The eastern part influenced by the motion of pacific plate and has a thin crust (28-40 km) and lithosphere (60-90 km). Several paleonuclei and paleolands, such as Tarim, Yangtze, Ordos and Indian shield, show a great thickness of lithosphere (about 130-250 km). The fold belts, such as Altai, Qinlin belt, North-South tectonic belt, southeast continental margin, and the marginal sea (South China Sea, East China Sea, Yellow Sea) have thin lithosphere (about 60-80 km). The central Asia, from Indian subcontinent to Tibet, Xinjiang, Mongolia and Baikal regions is the present largest convergence place in the world.

JSS44/P/04-B5 1050

CRUST AND UPPER MANTLE STRUCTURE IN THE WEST AND SOUTHWEST MARGIN OF ERDUOS, CHINA, FROM INTEGRATED GEOPHYSICAL, GEOLOGICAL AND GEOCHEMICAL STUDIES

Li QINGHE, Guo Shounian, Lu Dehui (Lanzhou Institute of Seismology, China Seismological Bureau, Lanzhou, Gansu, 730000, P. R. China, email: liqh@lzu.edu.cn)

Erduos Block is a stable platform but with active faults and violent earthquakes around it. The west and Southwest margin of Erduos are Qilian, Qinling folding system and located on the Northeast part of the Qinghai-Tibet Plateau. The crust and upper mantle structure in the west and Southwest margin of Erduos, China, were studied. The P- and S- velocity structure, Q-factors were got from Deep Seismic Sounding and seismic tomography. Bouguer anomaly, gravity inversion, density structure were analysed. Magnetic structure, deep faults and Curie isotherm were obtained from aeromagnetic data. The electric resistivity distribution with depth were interpreted from MT profiles. The heat flow and their distribution, thermal conductivity, deep temperature were got from geothermal measurements. The tectonic stress field image is clear from focus mechanism and others. The simultaneous inversion and interpretation for density and velocity, electric resistivity and temperature, electric resistivity and velocity were manipulated. The geophysical model of this field was established. The geotectonics, stratum, deep rock fabric, geochemical properties, basin and folding tectonics, fault tectonics, tectonics evolution and so on were studied. Based on the integrated interpretation of deep and shallow faults, geology, geochemistry and geophysics, the crust and upper mantle model was built up. The special geological, geophysical and seismicity features of this field are induced from the motion of Qinghai-Tibet Plateau toward north and north-east, as well as upheaval from the mantle.

JSS44/E/30-B5 1110

THERMO-TECTONIC MODELING OF P-T-T PATHS OF ULTRA HIGH PRESSURE METAMORPHISM IN THE DABIE MOUNTAIN, CHINA

Yaolin SHI, Taoyuan Fan (both at Graduate School, University of Science and Technology of China, Academia Sinica, Beijing 100039, China, email: shiyl@cc5.gsbustc.ac.cn)

Based on geological observations, we propose a three-stage process of ultra high pressure metamorphism (UHPM) in the Dabie Mountain, and calculate the dynamic and thermal processes by finite element method. In the first stage, the buoyant continental crust was hauled down to more than 100km depth by the subducting oceanic plate, producing a growing prism. In the second stage, continuing subduction of the plate drives a corner flow of low viscosity continental rocks in the prism. In the third stage, the oceanic plate is detached, and continental rocks in the prism is uplifted to lower crust level by buoyancy, and then further uplifted by crustal continental collision tectonics. A Newtonian viscous model is applied to calculate the motion within the prism at different stages. Advective heat transfer then can be included to calculate temperature evolution. P-T-t paths of various blocks can be traced in the modeling and compared with observations at different locations in the Dabie Mountain. It is found that in order to fit the observed P-T-t paths, for normal rate of subduction, frictional/dissipative heating due to rock deformation must be included. A rapid buoyant uplift of UHPM to lower crust level followed by a slow uplift due to collision tectonics are also required. The calculation can further explain the observed spatial distribution of "hot" and "cold" ecolgites, and reveal complexities in P-T-t path formation. The complexities indicate that care must be paid in interpretation of observed P-T-t paths.

JSS44/W/06-B5 1130

THERMAL AND STRENGTH STRUCTURE OF LITHOSPHERE IN QINLING OROGENIC BELT DERIVED FROM SURFACE HEAT FLUX AND GRAVITY OBSERVATIONS

Xiong XIONG, Houtze Hsu (Both at Institute of Geodesy and Geophysics, Chinese Academy of Science, 54 Xudong Road, Wuhan, Hubei 430077, China, email: xxiong@asch.whigg.ac.cn); Rongshan Fu (Department of Earth and Space Science, University of Science and Technology of China, Hefei, Anhui 230026, China, email: frs@ess.ustc.edu.cn)

Since the data of the surface heat flux is very limited, other geophysical observations must be used as constraints to determine the thermal structure of the lithosphere. A algorithm combining the thermal and gravity observations is employed to determine the steady state thermal structure of lithosphere of Qinling orogenic belt. Given the rheological parameters, the strength structure of the lithosphere is also derived. The computation is carried out by using the finite element method. The numerical results show that the thermal regime of Qinling orogenic belt is very inhomogeneous. It is shown that the Qinling orogenic belt can be divided into several blocks with distinct thermal features. The southern Qinling is the hot zone, while the northern Qinling is the cold one. The corresponding features are also shown in the strength structure. The strength of southern Qinling is much greater than that of northern Qinling. The strength structure of southern and northern Qinling indicates that the Yangzi and Huabei blocks might subduct beneath Qinling block. The numerical result fits well with the geological and geophysical observations.

JSS44/W/16-B5 **1150**

SEISMIC TOMOGRAPHY IMAGES OF THE QINLING-DABIE OROGENIC BELTS

Ruomei SUN, Futian Liu, Jianhua Liu, Peifen Xu (all at Institute of Geophysics, Science Academy of China, 100101 Beijing, CHINA, email: sunrm@sun.ihep.ac.cn)

The Qinling orogen of central China between the Sino-Korea craton and the Yangtze craton began in late Mesozoic. Ultra-High Pressure (UHP) metamorphic rock belt, found in Dabie mountain, is the largest one in the world. We did the P, S wave and Vp/Vs tomographic inversion of North China craton, Qinling-Dabie orogenic belt and Yangtze craton in central China. The results are as follows: 1. The image of the upper crust has a close correlation with surface geology. The North China basin shows obviously low velocity, whereas the orogenic belt expresses high velocity with E-W trend, reflecting old tectonism. However the velocity anomalies at depths 80-110km display a trend in N-S direction, a feature possibly controlled by recent tectonism. 2. The velocity image at depth of 40+ km beneath the Moho shows that the orogenic belt is divided into three sections. West of 108E, the West Qinling displays low velocity anomaly, the crust is thicker than 40km with indications of a mountain root. Between 108°E and 104°E, in the East Qinling, the velocities are high with no indication of mountain root, and the crustal thickness is less than 40km. East of 104°E in the Dabie Mountains, velocities are obviously low, the crustal thickness is not less than 40 km. 3.The image in a profile across the Dabie mountain shows a slab-like high velocity anomaly dipping from south to north, that may be remain of ancient subducted block, which break off around 130-170km. The slab breakoff seems the mechanism of recurvature of UHP metamorphic rock.

JSS44/P/02-B5 **1210**

THE QINLING-DABIE COLLISIONAL OROGENIC BELT AND THE EVOLUTION OF LITHOSPHERE IN EASTERN CHINA

Yuan XUECHENG (Chinese Academy of Geoexploration, 31 Xueyuan Road, Beijing, China)

The Qinling-Dabie orogenic belt is the boundary between North China craton and Yangzi craton, and is the largest among the seven UHP belts in the world. Since l992, the Qinling-Dabie orogenic belt was been integrated studying by geology, geophysics, and geochemistry. An integrated geophysical profile, involving seismic reflection, wide-angle seismic reflection, seismic tomography, magneto-telluric sounding, heat flow measurement, gravity, aeromagnetic survey, and petrophysical work was fulfilled across the East Qinling. Another integrated geophysical profile across the Dabie orogeny is undertaking. The geophysical profiling shows that the Qinling orogenic belt is a collisional orogeny, composed by a series of crocodile structures with their mouths towards the north. Seismic tomography in this area discovered that lithosphere in eastern China has been rifted in several places during Mesozoic-Cenozoic period when the Yangzi craton subducted to the North China craton, the hot mantle upwelled to the height near Moho along mantle rifts, overflew in all directions and formed the horizontally layering middle lithosphere, just like the mushroom cloud in a nuclear explosion. UHP metamorphic rocks carried by the upwelling mantle exhumated fast along the "mantle rift" to a height near Moho, and then thrusted and outcropped on the surface when the Yangzi craton collided with the North China craton.

JSS44/W/19-B4 Poster **0930-01**

DEEP STRUCTURE OF NORTHWESTERN SIERRAS PAMPEANAS (27° S.L. ARGENTINA)

Ernesto CRISTALLINI (Universidad de Buenos Aires, Department of Geological Sciences, Cornell University, Snee Hall, Ithaca NY 14853-1504; e-mail: ernesto@geology.cornell.edu); Alberto Cominguez and Diego Mercerat (CONICET, Departamento de Geofísica Aplicada, Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, Paseo del Bosque s/n, La Plata, Argentina; e-mail: coming@fcaglp.edu.ar); Victor Ramos (Laboratorio de Tectónica Andina, Departamento de Ciencias Geológicas, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria Pab.II, Cap.Fed., Argentina; e-mail: andes@gl.fcen.uba.ar)

Reprocessing of industrial seismic lines, in eastern and western foothills of Sierra de Aconquija, northwestern Sierras Pampeanas, Argentina, shows the deep structure of the range and the deep geometry of the Andean foreland basin. On the eastern side of Sierra de Aconquija, the structure is characterized by reverse faulting with eastward vergence, with the Guasayán and El Rosario faults exhibiting the most deformation. To the south, the Guasayán fault produces the uplift of the Guasayán basement range over Tertiary deposits, and can be identified in the seismic reflection record down to 40 km depth. On the western side of Sierra de Aconquija, the deep structure of Campo del Arenal is characterized by westward vergent structures controlled by the basement fabric of the Sierra de Aconquija basement. Further to the west, the deformation stile changes to eastward vergence. The cross-cutting relationships between the west and east vergent fault systems, as well as the geometry of the synorogenic deposits permit establishment of the uplift history of Sierra del Aconquija. The uplift started during the Late Miocene, after the Paranense sea transgression, and still continues, as demonstrated by neotectonic activity. Additionally conspicuous sub-horizontal acoustic-reflectors are present at about 18, 25, 30, 40 and 53 km depth, and interpreted as present or pass brittle-ductile transitions.

JSS44/W/05-B4 Poster **0930-02**

MODELING SURFACE WAVE TRAVELLING ACROSS SIERRAS PAMPEANAS, ARGENTINA.

Nora C. SABBIONE, María L. Rosa (both at Depto. de Sismología, Fac. de Cs. Ast. y Geofísicas, Universidad Nacional de La Plata, Paseo del bosque s/n, 1900, La Plata, Pcia de Buenos Aires, Argentina, email: nora@fcaglp.unlp.edu.ar); Ana M. Osella (Dpto. de Física, Fac. Cs. Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, Pab.1, 1428 Buenos Aires, Argentina, email: osella@df.uba.ar)

Surface-waves group velocity dispersion curves were analyzed from digital data obtained in LPA seismological station (La Plata, Provincia de Buenos Aires), Argentina, using WWSSNLP instruments. The earthquakes chosen since 1995, come from focus such that in their way to the station go through the Sierras Pampeanas province, northwest of Argentina. This mountain block lies over a continental active margin between the Nazca plate and the South American continental plate, constituing a moderate topography system where the foreland deformation structural characteristic coincide with a subductive angle variation from 30° to less than 10°. The applied method is based on the Multiple Filter Technique and on the latter application of an inversion process to the resulting velocities, to obtain finally a lithosphere model of the region being analyzed.

TECTONIC PATTERN OF SOUTH AMERICA INFERRED FROM TIDAL GRAVITY ANOMALIES

Marta S. M. MANTOVANI (Instituto Astronômico e Geofísico, Universidade de São Paulo, Rua do Matão, 1226 CEP 05505-900 São Paulo, S.P., Brazil, email: marta@iag.usp.br); Vladimir Shukowsky (Instituto Astronômico e Geofísico, Universidade de São Paulo, Rua do Matão, 1226 CEP 05505-900 São Paulo, S.P., Brazil, email: wladimir@iag.usp.br); Silvio R. C. de Freitas (CPGCG - Centro Politécnico, Universidade Federal do Paraná, PR, Brazil, email: sfreitas@cce.ufpr.br)

The knowledge of several physical parameters that characterize a tectonic unit is important to evaluate its dynamic evolution and, therefore, its role in the continental evolution. Several methodologies have been used to measure the elastic properties of tectonic units using: seimic waves, the level of coherence between the wavelength pattern of the topography and gravity fields, borehole deformation rate, mineral fabric, etc. In this study, the Earth´s dynamic elastic response to gravity tides is applied for measuring the lithosphere effective elastic thickness. This methodology proved to be a good alternative to the conventional coherence method. It was applied over the continent, taking into account the poor gravity coverage in South America and the restricted area of some tectonic units. Results are presented as lateral distribution of the effective elastic thickness in South America.

INFORMATIONS FROM AEROMAGNETIC AND RADIOMETRIC DATA IN GUYANE FRANCAISE

P. SAILHAC (IPGP, Laboratoire de GuomagnUtisme,Institut de Physique du Globe de Paris, 4 Place Jussieu, 75252 PARIS Cedex 05, FRANCE e-mail: sailhac@ipgp.jussieu.fr); A. Galdeano (IPGP), C. Delor BRGM); D. Gibert (Geosciences Rennes); F. Moreau (Geosciences Rennes)

Guyane Franpaise is part of the Guyana Shield (South America), a former part of a main relief of Gondwana. This includes paleoproterozoic rocks, and the nature of the orogen is not yet resolved. A high resolution aeromagnetic survey including radiometric measures has been done during automn 1996. This provided very precise data reflecting the near underground average properties in U, Th and K on the one hand (radiometry). On the other hand, aeromagnetic data have been analysed via a continuous wavelet transform giving information on the inclination of the magnetization of sources and on their depths. A few additional paleomagnetic data from the ground has completed the survey and helped the analysis of aeromagnetics. These informations have been compared to the Geology and are discussed in term of the ages and positions of structures.

SEISMICITY AND 3-D VELOCITY STRUCTURE OF THE INTRA-ISLAND-ARC CRUST FROM TRAVEL TIME ANALYSIS OF THE DATA OF THE JOINT SEISMIC OBSERVATION IN THE TOHOKU DISTRICT, THE NORTHEASTERN AREA OF JAPAN

Makoto MATSUBARA, Naoshi Hirata, Shin'ichi Sakai (Earthquake Research Institute, the University of Tokyo, 1-1-1 Yayoi Bunkyo-ku, Tokyo, JAPAN, email: mak@eri.u-tokyo.ac.jp)

To get a new insight of the island-arc crustal dynamics with a relation between seismicity and lateral heterogeneity, we are conducting seismic experiments in the Tohoku area, northeastern Japan, since 1997. One is the Joint Seismic Observation (JSO) since October 1997, and the other is seismic array observation (SAO) of micro-earthquakes in the Kitakami and Sen'ya Faults area in 1998. The SAO was conducted in the area where the JSO is carried out. We need combine the 3-D velocity structures of regional (150 km x 150 km) and local (30 km x 40 km) areas around 39.5 N. We performed the inversion for velocity structure of regional area. We used 412 events comprising 18,475 P- and 8,937 S-wave arrivals. From July 14 to August 20 in 1998, at KK22 (Shiriaigawa) in the Kitakami array, we detected 2,359 events, which include natural earthquakes, 13 explosions and earthquake swarm beneath Mt. Iwate. During the same period 3,310 earthquakes were observed by the regional network of the JSO. The number of local events with a S-P time less than 3 s is 577. This seismicity may be related to the fault zone activities, which will be clarified in detail.

CRUSTAL SECTION ACROSS THE NORTHERN HONSHU ARC, JAPAN, AS REVEALED FROM WIDE-ANGLE SEISMIC DATA

Takaya IWASAKI (Earthquake Research Institute, the Univ. of Tokyo, Tokyo, 113-0032, JAPAN, Email: iwasaki@eri.u-tokyo.ac.jp); W. Kato, T. Takeda, S. Sekine (ERI, the Univ. of Tokyo, Tokyo, JAPAN); T. Moriya (Hokkaido Univ., Sapporo, JAPAN); N. Umino, T. Okada (Tohoku Univ., Sendai, JAPAN); A. Hasemi (Yamagata Univ., Yamagata, JAPAN); K. Miyashita, T. Mizogami (Ibaraki Univ., Mito, JAPAN); T. Matsushima (Kyushu Univ., Shimabara, JAPAN); K. Tashiro (Kyushu Univ., Fukuoka, JAPAN); H. Miyamachi (Kagoshima Univ., Kagoshima, JAPAN)

An extensive wide-angle seismic experiment across the Northern Honshu Island, Japan, in October 1997 provided a new image on the detailed crustal structure of the volcanic arc. Seismic data collected on an E-W profile line of 150-km length indicate remarkable lateral structural changes. The uppermost crust of the eastern (forearc) side of the profile shows a rather simple structure consisting of 0.3~1-km thick surface layer with a velocity of 4.0~5.4 km/s and 5.9~6.1-km/s crystalline basement. These layers were underlain by the 15~20-km thick reflective lower crust. The uppermost crust of western (backarc) side of the profile characterized by thick (3~5 km) sedimentary layers of 2.0~5.4 km/s is severely deformed owning to the process of the back-arc spreading and the following compressional stress regime in this region. The velocity of the basement is relatively low (5.8 km/s) as compared with that in the eastern part. The total crustal thickness in northern Honshu is 35-40 km. The wide-angle reflection from the Moho is very weak which may indicate the existence of structural transition zone from lower crust to mantle. The Pn velocity in the western part of the profile is 7.7-7.8 km/s, approximately 0.2-0.3 km/s lower than that beneath the Sea of Japan.

DEEP CRUSTAL STRUCTURE OF LARGE-SCALE INTRA-ARC FAILED RIFT, CENTRAL JAPAN

Tetsuya TAKEDA, Takaya Iwasaki, Hiroshi Sato, Shin'ichi Sakai (Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi, Bunkyo-ku, Tokyo, Japan, 113-0032,
email: takeda@eri.u-tokyo.ac.jp, iwasaki@eri.u-tokyo.ac.jp, satow@eri.u- tokyo.ac.jp, coco@eri.u-tokyo.ac.jp)

The Itoigawa-Shizuoka Tectonic Line (ISTL) is a major structural boundary, which divides SW and NE Japan. It was formed as a normal fault under the tensional stress regime associated with the Miocene opening of the Sea of Japan, but has reactivated as a reverse fault owing to

subsequent crustal shortening. Reanalysis for three wide-angle reflection data sets provided a new image of the crustal structure around the ISTL. The upper crustal structure was mainly determined from travel time analysis including an inversion method. Deeper part of the crust, on the other hand, was modelled using both travel time and amplitude information. The obtained profiles clearly demonstrate that the northern part of ISTL is characterized by an eastward dipping reverse fault. Tertiary sedimentary rocks with velocity of 3.0-4.0 km/s accumulated along the ISTL at depth of 2-km, suggesting the existence of the Miocene graben. All profiles indicate reflective lower crust, however its depth range shows a clear change across the ISTL. The change was probably caused by the differential tectonic movements of NE and SW Japan blocks and the subsequent different thermal history due to back-arc spreading. Clear Moho is not recognized in all profiles. Highly laminated structure is well developed below 30-40 km depth including the uppermost mantle. It may represent the nature of upper mantle beneath volcanic arc.

INTEGRATED SEISMIC EXPERIMENT IN THE NORTH-EASTERN HONSHU ARC, JAPAN

Naoshi HIRATA, Hiroshi Sato, Takaya Iwasaki (Earthquake Research Institute, The University of Tokyo, Tokyo 113-0032, Japan, e-mail: hirata@eri.u-tokyo.ac.jp, satow@eri.u-tokyo.ac.jp, iwasaki@eri.u-tokyo.ac.jp); Akira Hasegawa, Norihito Umino (Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University, Sendai 980-8578, Japan, e-mail: hasegawa@aob.geophys.tohoku.ac.jp, umino@aob.geophys.tohoku.ac.jp); Masanao Shinohara (Department of Earth Sciences, Faculty of Science, Chiba University, Chiba 263, Japan, e-mail: mshino@earth.s.chiba-u.ac.jp)

To understand the mechanism of earthquake occurrence in an intra-island-arc crust with its deformation process, we are conducting a large-scale integrated seismic experiment across the North eastern part of Honshu arc at about 40 degree N, Japan, since October 1997, including both passive and active sources, in land and at sea. The target of the experiment is to image the whole crustal section with a special attention to deep structure of active fault systems. The study is also intended to understand the formation process of the island-arc as a part of the continental growth process. We have deployed 50 3-component temporary seismic stations, from which data are transmitted through a satellite communication system. The active experiment includes a 150-km-long refraction profiling on land and 220-km in the Japan Sea. Three 15-km-long reflection surveys were also carried out in the central part of the Tohoku arc. The preliminary results of the seismic profiling indicate that an active fault continues to a detachment fault at a depth of about 15km in the island-arc crust. We found a reflective lower crust in the arc area, which is sometimes detected in a continental crust. The tomography study indicates a correlation with a low velocity area and an active fault area, suggesting a concentration of crustal deformation near the active fault areas.

STRUCTURE OF THE CRUST IN VIETNAM FROM MAGNETIC AND GRAVITY DATA

Cao Dinh TRIEU (Institute of Geophysics, VNCST, Box 411 Buu Dien Bo Ho, Hanoi, Vietnam, email: trieu@igp.ac.vn)

Aeromagnetic and 2d gravity modeling enable the interpretation of the depth to the Moho and crystalline basement. The data used in this study comprise the following: a/ Aeromagnetic anomaly map of the territory of Vietnam at the 1: 500, 000 scale. b/ Bouguer gravity anomaly map of the territory of Vietnam at the 1: 500, 000 scale. e/ Geological map of the territory of Vietnam at the 1:500, 000 scale. The depth of the Moho varies from 30 km to 38 km, the deepest part occurring in Northwest Vietnam. The structure of the basement is fairly similar to that of the dominant geostructural zones. In the Dong Bac zone, the crystalline basement outcrops in positive areas with NW-SE direction. The basement in the Red River depression lies at a depth of about 8-10 km in its central part. In the Tay Bac zone, Fansipan represents the exposed basement. In the Muong Te zone, the depth to the basement varies from 3 up to 5-6 km. In the Truong Son zone, the depth to the basement varies from 1 to 4-5 km and is exposed in the Phu Hoat geoblock. The basement in the Kon Tum zone is exposed over a large area and lies at 1-3 km. The Da Lat zone is characterized by a large negative structure of the basement. In the Cuu Long basin, the depth to the basement varies from 1 to 5 km, and the basement in the Minh Hai-Kien Giang zone lies at a depth of about 3-5 km.

A STUDY ON THE ELECTRICAL CONDUCTIVITY DISTRIBUTION BENEATH AN AREA OF ACTIV E VOLCANISM IN THE NORTHEASTERN PART OF CHINA

Hisashi UTADA, Makoto Uyeshima (both at Earthquake Research Institute, Univ. Tokyo, Tokyo 113-0032, Japan; email: utada@utada-sun.eri.u-tokyo.ac.jp, uyeshima@utada-sun.eri.u-tokyo.ac.jp), Zhao Guoze, Tang Ji (both at Institute of Geology, Seismological Bureau of China, Beijing, China; email: zhaogz@public.bta.net.cn); Ma Mingzhi (Seismological Bureau of Jilin Province, Changchun, China)

Seismic tomography gave us an image of a "stagnant slab" around the depth of 660 discontinuity in various zones of plate subduction in the world (e.g., Fukao et al, 1992). One of the clear examples can be found beneath the North eastern district of China where active Quaternary continental volcanism is widely seen. The cause of this continental volcanism is still controversial, though there have been suggested several models such as hot region (Miyashiro, 1982) or wet region (Iwamori, 1992) in the upper mantle. A study of large- scale deep electrical conductivity structure in this region will give import ant information for investigating the cause of the volcanism and the lithospheric evolution, as well as their possible relation to the presence of a stagnant slab. For this purpose, a Network-MT experiment was carried out in Jilin Province, NE China, as a collaborative project between China and Japan. This experiment consists of mobile electric field measurements by using telephone lines with typical line length of 30 km and a reference geomagnetic field measurement. This paper presents a preliminary result of this project.

PRE-ALPIAN STRUCTURE OF ZERAVSHAN-HISSAR FOLDED REGION (SOUTH TIEN SHAN) BASED ON THE FREQUENCY ANALYSIS OF PALEOZOIC THRUST PACKETS

Yu. S. RZHEVSKY (Centre for Advanced Professional Education, St.-Petersburg State University; Office 135, 14th line 29, St.-Petersburg, 199178, Russia, email: yurkov@cape.nw.ru)

Southern Tien-Shan as a link of West Ural-Mongolian fold belt emerged after collision of Kirgiz-Kazakh (to North), Karakum-Tajik and Tarim (to South) continents, formerly separated with Turkestan paleo-ocean (a part of the vast Paleo-Tethys Ocean). Relicts of the oceanic crust, mainly sedimentary and igneous rocks that had accumulated on the sea-floor of the Paleo-Tethys, crop out in many places and appear to be largely allochtonous. Complicated tectonic design of accretion wedges is an object of hot discussion. It concerns especially the question is thrusting of tectonic units in early study of accretion really took place. We used frequency analysis of thrust sheet packets in the Paleozoic of Zeravshan-Hissar region to solve the problem. Results of such an analysis for Zeravshan-Hissar fold belt are done in the paper demonstrated that stratigraphic section had been corrupted by sheet thrusts before folding.

THE POSITION OF NORTH CHINA IN THE GRENVILLE AND CALEDONIAN OROGENIES FROM ND-SR ISOTOPIC STUDIES IN THE QILIAN FOLD BELT

A.D. SMITH, C.-H. Chung, D.-J. Wen, K.-A. Tung, L.-Y. Huang (Department of Earth Sciences, National Cheng Kung University, Tainan, Taiwan; email: mochinm@mail.ncku.edu.tw)

Late Proterozoic plate reconstructions depend heavily on the SWEAT model in which the continental blocks of Asia such as North China and Siberia are placed along the northern margin of North America. Such models require long migration paths for North China to reach the Caledonian position off eastern Gondwana suggested by identical Late Ordovician Rb-Sr isochrons and Middle Proterozoic Sm-Nd TDM model ages for metasediments in the Qilian belt and central Transantarctic Mountains of Antarctica. Rather, the position of North China in the Early Paleozoic suggests it formed part of the megacontinent Laurentia along with North America, the southern tip of South America, and Siberia. Within this continental mass, North China lay in approximately the same position as Mexico today relative to North America with the Qilian-Qinling belts of China continuing into the Famatinian fold belt of South America and the Appalachian fold belt of North America. The Taconic, Famatinian, Qilian and Ross orogenies of the Caledonian stage are thus equivalent. Amphibolite and hornblende-plagioclase gneisses yield common TDM=1.8 to 2.4 Ga Sm-Nd model ages for the basement of the North and Central Qilian terranes with the implication that the latter is a fragment of North China rather than Gondwana. In conjunction with previous geochronological data, a Sm-Nd isochron of 1060+/-39 Ma with epsilon Nd=-1.2 for granitic gneisses delineates the Central Qilian terrane as a Sibaoan belt and suggests North China may have maintained its inferred position relative to North America since at least the end of the Middle Proterozoic, with the Sibaoan event in North China being equivalent to the Grenville event in North America.

GRAVITY ANOMALIES ACROSS THE NE MARGING OF THE INDIAN PLATE AND THEIR INTERPRETATION IN TERMS OF SURFACE AND SUBSURFACE FEATURES

Carla BRAITENBERG, Maria Zadro (Department of Earth Sciences, University of Trieste, Via Weiss 1, 34100 Trieste, Italy, email: berg@univ.trieste.it, zadro@univ.trieste.it)

The Kohistan-Ladakh Arc (NW-Pakistan) is set between the Northern border of the Indian plate and the Southern border of the Asian plate. The Kohistan sequence has been interpreted as the crust and mantle of an obducted island arc. We study existing, publicly accessible gravity data, extending from the Indian to the Eurasian plates, across the Arc. Apart from the long wavelength field tied to crustal thickening, the gravity anomalies show remarkable variation in the medium to short-wavelength component, which correlates with the major sutures. The features of the gravity values are not explained by the surface geology alone, but indicate the presence of mid crust anomalous masses, which can be interpreted in terms of the collisional process.

INTERPRETATION OF GROUND MAGNETIC DATA OF OIL BEARING CAUVERY BASIN, INDIA

Vinit C. ERRAM, S.P. Anand, Mita Rajaram (Indian Institute of Geomagnetism, Colaba, Mumbai-400 005, India)

The Cauvery basin along the Eastern Continental Margin of India is important from the point of view of oil exploration. Over 200 wells have been drilled, both onshore and offshore, by the Oil and Natural Gas Commission (ONGC) of India. A ground magnetic survey was carried out with readings at every 10km for the magnetic total field `F' and the vertical field `Z'. Four major magnetic anomaly trends N-S, E-W, NE-SW and the Cauvery shear trend are evident on the anomaly maps. The major anomalies are constrained within the Eastern Ghat Folding and the anomalies are smooth with very small variation in the region where marine transgression and regression occurred. It is evident from the anomaly maps that the shallow features are superposed on the long wavelength anomalies. The trend in the ground magnetic anomalies corroborates very well with the aeromagnetic maps. Comparison with the marine magnetic data shows that the anomalies continue into the offshore region. The ground and aeromagnetic data are transformed to get second vertical derivative, horizontal gradient of pseudogravity and reduced to pole. These maps distinctly isolate the shallow and deep sources. The ground and aeromagnetic anomalies are compared with gravity, marine magnetic and other available eophysical data and related to the surface geology and subsurface structures. Further, these constraints are used to develop an evolutionary model of the Cauvery basin lying on the rifted continental margin of India.

COMPARATIVE STUDY OF TWO SEDIMENTARY BASINS IN THE EASTERN CONTINENTAL MARGIN OF INDIA

Mita Rajaram, S.P. Anand, Vinit C. ERRAM (Indian Institute of Geomagnetism, Colaba, Mumbai-400005, India)

Krishna Godavari (KG) and Cauvery basins are typical, hydrocarbon bearing sedimentary basins along the Eastern Continental Margin of India (ECMI). The present paper deals with the coarse grid ground magnetic surveys conducted over these basins and the data analysis undertaken to study the tectonic elements of the basins constrained by gravity, magnetotellurics, DSS and borehole data. Available aeromagnetic maps are also analysed. The ground and aeromagnetic total field anomaly maps are transformed to delineate the deep and shallow features. In both the basins the shallow features are showing a NE-SW trend which is in conformity with the Eastern Ghat trend. The KG basin shows distinct NW-SE trends for deeper features which can be related to series of deep seated parallel faults. Along two such prominent faults the Godavari graben is found to extend offshore. On the other hand, the NW-SE trending deep seated fault is dominated by the NE-SW trends in the Cauvery basin. Thus Krishna Godavari basin is formed of two distinct structures while no distinction is seen in the Cauvery basin. The present paper compares these two basins lying on the rifted continental margin of India and relates it to the tectonics and evolution of these basins as the Indian subcontinent separated from Gondwana land in the Mesozoic.

GEOPHYSICAL STUDY OF THE AHNET BASIN (SW ALGERIA)

A. K. YELLES-CHAOUCHE, R. Ait Ouali, A. Abtout, M.E.M. Derder (Both at C.R.A.A.G., Algerian Research Center of Astronomy, Astrophysics and Geophysiscs, BP 63 Bouzarea, Algiers, Algeria, e-mail: geoph3@ist.cerist.dz); H. Ghandriche (Head of District 3 of SONATRACH, Algiers)

The Ahnet basin, one of the Algerian Saharan basins, is located at the boundary between the West African Craton and the Hoggar Shield. This particular location indicates that its evolution is influenced by history of the suture between the two main geological domains. During the last twenty years, several geophysical surveys were carried out in this basin due to its importance for the oil companies. Analysis of several seismic lines and others geophysical data (aeromagnetic, gravity...) reveals that: structuration of the basin started at the end of the panafricain orogeny. During the Paleozoic time, the basin was filled by thick sedimentary series. During the Hercynian orogeny the basin was affected by reactivation of the major N-S panafrican accidents with a shortening direction of about N030-040. This stress regime allowed creation of strikeslip faults with an E-W direction and leading to deformation of N-S anticlines. Later, at the Jurassic period and in relation with the opening of the Atlantic ocean, magmatic event affected the basin.

INTEGRATED USE OF AIRBORNE MAGNETIC, GEOLOGICAL AND SATELLITE IMAGERY DATA IN ELUCIDATING THE STRUCTURAL SETTING OF GABAL AMRIT-GABAL DIF AREA; A SAMPLE AREA FROM THE SOUTH EASTERN DESERT OF EGYPT

Abouelhoda M. ELSIRAFY, Magdy L. Meleik, Ahmed M. Sabri, Alaa Eldin A. Aref (Nuclear Materials Authority of Egypt, P.0 Box 530 Elmaadi, Cairo, Egypt)

The study area comprises a wide diversity of igneous, metamorphic and sedimentary rocks ranging in age from Precambrian to the Quaternary. Integration of results obtained from qualitative and quantitative interpretation of the aeromagnetic survey data with the geological and Satellite imagery data, has significantly contributed to the delineation of the regional structural framework of the area under consideration. Analysis of the aerial magnetic data involved the application of some selected 2D-frequency domain filtering operations. 3D-Euler deconvolution was applied to quantify the interpretation of the filtered magnetic anomalies. Furthermore application of standard digital image display and enhancement techniques to these non-imaged magnetic data offered much in terms of structural interpretation of these data.
The present study indicated that the study area has been affected by two sets of major deeply rooted faulting structures, trending mainly in the NNW to NW and NNE to NE directions. This faulting pattern is closely related to the development of the Red Sea rifting. The intersection of these two sets of linear tectonic zones has resulted in what is referred to as the block structures, consist mainly of highly magnetic rocks with basic or ultrabasic massif rocks cut by occasional granitic and pegmatitic bodies. Folding structures are dominant in the eastern part of the area. These have a general NW-SE trending direction, occasionally changed to the NNE-SSW due to faulting and rotation around the stable basic to ultrabasic intrusive rock masses. It was also evident from this study that the gross surface structural fabric of the study area provided a fair expression of the subsurface structures.

BASEMENT TRENDS AND LITHOSPHERE STRUCTURE IN EGYPT OBTAINED FROM GEOPOTENTIAL DATA

Hassan HOSNEY (Associate Professor, Geophysics Department, Cairo University, Egypt); Samir Riad (Professor of Geophysics, Geology Department, Assuit University, Egypt)

The Bouguer anomaly and RTP aeromagnetic maps of Egypt were utilized to delineate gravity and magnetic trends that are probably due to structures related to basement and deeper horizons within the upper lithosphere. Present trends show that old basement tectonics are controlling the tectonic pattern known to prevail in the whole country. The geophysical lineaments, presumably faults, show a pattern of normal and strike-slip faults that could be explained by either a pure or simple shear stress. In the first case, the acting principal stress is oriented in almost N-S direction, related to the drifting of the African continent and the interaction between the African and European plates. A secondary stress field related to the active Red Sea rift is acting, in addition to the previous one, since the Oligocene time. In the second case, the obtained trends are related to a simple shear stress associated with the transform faulting controlling the spreading of the southern Atlantic.

CRUSTAL STRUCTURE OF ERATOSTHENES SEAMOUNT (EASTERN MEDITERRANEAN COLLISION ZONE BETWEEN AFRICA AND EURASIA) FROM SEISMIC, PONETCIAL FIELDS AND GEOLOGICAL STUDIES

S.M.Zverev, D.A. ILINSKI (both at Schmidt Institute of the Earth Physics, 123810, Bol.Gruzinskaya 10, Moscow, Russia)

Crustal seismic wide-angle reflection refraction measurements were made across Eratosthenes seamount, during the Soviet research project "Tetis" in 1990. This seamount is located near the southern edge of collision zone between African and European plates. The nature (continental or oceanic) of major Eastern Mediterranean structures such as Eratosthenes seamount is still unclear and under discussion in geological literature. The P-wave velocity cross-section was obtained after evaluation of acquired seismic data. Ray-tracing and full-field acoustic response modeling proves the resulting section. Magnetic and gravity models were built from the basic seismic model. Data from new acquired gravity map of Eastern Mediterranean were used. Crystal rocks with P-wave velocities of 6.0-6.5 km/s uplift under Eratosthenes. Section of the fist 10km depth at the Southern part of Erastosthenes has alternation of thin high and thicker low velocity layers. High velocity layers have higher magnetization and density comparing with background structures and could be associated with ancient lava flows. Upper Cretaceous limestone from borehole 967 (DSDP Leg 160) recovered from 2900 meters under the water depth at the north part of Eratosthenes correspond to the same age limestone founded at the south part of the seamount during the dreging (1.3 km water depth). From this evidence we can conclude that northern part of Eratosthenes was lifted down and can explain why the higher velocity and density layers within upper 6 km of the section were not found under the Northern part of the seamount. We suppose that seamount was built in pre-Cretaceous time since limestone covered the Eratosthenes has Senomanian age.

THE CONTACT ZONE BETWEEN PALEOZONIC AND PRECAMBRIAN PLATFORMS IN ROMANIA IN THE LIGHT OF NEW GRAVITY AND MAGNETIC DATA

Ligia Narciza ATANASIU, Dumitru Ioane (both at Geological Institute of Romani, 1 Caransbebes Str., 78344 Bucharest-32, Romania, email: ligia@igr.sfos.ro); Marius Visarion (Romanian Academy, Calea Victroiei, Bucharest, Romania)

One of the major tectonic problems in Europe and in Romania too is the determination of the southwest margin of the East-European platform. A large lithospheric fracture zone, called Tornquist-Teisseyre zone, oriented NW-SE, represents this boundary from North Sea to the Black Sea. It represents the contact zone between East European Platform (Precambrian Platform) and Central European Platform (Paleozoic Platform).
In Romania the TTZ is overridden by the Carpathian front. It reappears in Dobrogea, a region between the Danube and Black Sea. The results of this study show that TTZ in Romania is situated between the crustal fault Siret in the eastern part and another crustal fault situated under Central East Carpathian Nappe System or inner nappes, in the Western part.
Near Bacau, the TTZ shows an important change in the east and Southeast direction being boarded by the crustal faults: Vaslui-Cetatea Alba Fault, Bistrita Fault and Pecenaega-Camena Fault. The Peceneaga-Camena Fault, which separates the North Dobrogea from the Moesian Platform, is the major fracture of TTZ.
The magnetic and gravity anomaly maps shows representative features on the anomalous magnetci and gravity fields in the region of both Paleozoic Platform and Precambrian Platform. The modelling of the gravity and magnetic anomalies which are performed on two regional geological sections offers some information about the geological units, their limits and the total thickness and the positions of the Conrad and Mohorovicic discontinuities.

JSS 44/E/08-B4 Poster **0930-21**

CRUSTAL STRUCTURE IMAGE BASED ON GEOPHYSICAL AND GEOLOGICAL DATA ALONG THE DEEP REFRACTION PROFILE BUCHAREST-BACAU (ROMANIA)

Andrei BALA, Victor Raileanu (both at National Institute for Earth Physics, P.O. Box MG-2, Bucharest, Magurele, Romania, email: bala@infp.ifa.ro)

The most important tectonic feature of Romania, the Carpathian Orogen, is bounded on the north and north - east by the East European Platform and on the east and south by the Moesian Platform; inside the Carpathian Orogen and westward are the Transylvanian Basin and Pannonian Basin separated by the Apuseni Mountains. Three main types of crustal structure have been identified in Romania and they cover the most part of the country: 1. Orogenic belt type: 40 -50 km depth, in Eastern and Southern Carpathians; 2. Platform type: 30 - 40 km depth in Moldavian and Moesian Platform; 3. Depression type: 26 - 30 km depth in Pannonian Depression.
A notable exception from this classification is the crust of the Carpathian Foredeep, especially in front of the Eastern Carpathians Arc Bend (with thickness of 43 - 45 km). This is the place with the most active tectonic and seismogenic forces in Romania. As a result, here are situated the hypocenters of the most numerous and strongest earthquakes in Romania, both at crustal and subcrustal level. A deep refraction profile will be carried out this year in an attempt to clarify the exact position of the most important boundaries of the crustal structure in the area. This profile will cover 200 km from Bacau to Bucharest and will be continued to south- west, until Danube river. The available geophysical and geological data are integrated and represented along path of the refraction profile, to create a state of the art image of the crustal structure as suggested by the present data.

JSS 44/E/23-B4 Poster **0930-22**

REGIONAL LITHOSPHERE STRUCTURE AS INFERRED FROM EARTHQUAKE DISTRIBUTION IN EASTERN ROMANIA

Andrei BALA, Mircea Radulian, Mircea Biter, Zina Malita (all at National Institute for Earth Physics, P.O. Box MG-2, Bucharest - Magurele, 76900 Romania, email: bala@infp.ifa.ro)

The Eastern Carpathian Arc Bend (ECAB) and the Carpathian Foredeep in front of it are the most distinctive tectonic features of Romania. Here is the collision region between at least three tectonic plates: East European plate, Intra-Moesian subplate and Intra-Alpine plate. Some researchers consider the eastern part of the Moesian Platform together with Central Dobrudja as representing the Black Sea subplate. Their assumptions are made mainly on the existence of the Intra-moesian Fault which is considered to be still active due to the crustal earthquakes produced on its northern end. This paper focuses the attention on Vrancea zone and the surrounding area, because this is the most active and intense seismogenic area. Here are situated the most numerous, strongest and still unforeseeable earthquakes from Romania. There were represented all the earthquake hypocenters from the period 1982 - 1997 situated in an area which covers Vrancea zone (25º - 28.5º E, 44.5º - 47º N). Because of the great number, they were found to describe well the limits of the tectonic plate (plate fragment?) which is supposed to be subducted in this region until 200km depth. These limits were put in direct relations with the known geology and tectonics of the area. Available fault plane solutions for the crustal earthquakes are analyzed in correlation with the orientation of the principal fault systems in the area.Principal stress vectors are represented as derived from the focal mechanisms of 69 crustal earthquakes. A structural model of this region was derived on the basis of seismological data and linked with fault system in the area as it was established from geological and geophysical researches.

GEOPHYSICAL MODEL OF THE URALS CRUST ACCORDING TO GEOMAGNETIC DATA

Vsevolod SHAPIRO, Natalia Fedorova, Alexander Chursin (Institute of Geophysics, 100 Amundsen str., Ekaterinburg, 620016, Russia, email: seva@maglab.mplik.ru)

The Urals orogenic belt is one of the greatest structural feature of the Eurasian continent. According to recent point of view Uralian crust was developed during the collision of island arc and micro continental fragments with the structures of East European Craton. The range of geomagnetic investigation of the lithosphere was carried out at the Urals during last two decade. One of the most important part of this research is precise aeromagnetic survey along the network of profiles with the length up to 1200 kms crossing the orogenic belt in latitudinal direction. Besides the airborne survey we used satellite magnetic data and investigated all spectrum of geomagnetic variations from short-period to secular and used new method for interpretation of experimental data. As a consequence of this research we construct the magnetic model of the crust along number of profiles. As a result of study we come to conclusion that the Urals has practically non-magnetic crust in comparison with the magnetisation of the crust of adjacent platforms.

A "HOT" MODEL OF LOW S VELOCITY ZONE BENEATH THE CENTRAL EUROPE AND AN ORIGIN OF ASTHENOLENSES

Ya. M. KHAZAN (Institute of Geophysics of Nat. Acad.Sci. Ukr. Palladin pr. 32, Kiev-142, 252680, Ukraine, email: earth@igph.kiev.ua)

Shear wave seismic tomograpy (Zielhuis and Nolet, 1994) revealed in the transition zone (depth 250æ450 km) beneath the central Europe an elongated low S velocity zone (LSVZ) about 500 km wide extending from the Bothnia Gulf to Asia Minor. Just above the LSVZ at subcrustal depths a number of high conductive objects (asthenolenses) with characteristic dimensions of 50æ100 km were found (Burakhovich et al., 1996). In some cases the asthenolenses correlate with positive heat flow anomalies and topographic uplifts of some hudreds meters amplitude. Thus it seems reasonable to treat them as hot and partially melted bodies. The present paper considers a "hot" model of LSVZ (heating from below) that is an alternative to the "cold" model of Nolet and Zielhuis [1994] and treats the asthenolenses as resulting from the thermal instability of the uppermost (lying above the meltæsolid density crossover) part of partially melted LSVZ.

3 D TOMOGRAPHY OF THE CRUST IN BELGIUM

Fabienne COLLIN (Royal Observatory of Belgium, av. Circulaire 3, 1180, Brussels, Belgium. e-mail: F.Collin@oma.be)

A new algorithm for 3D tomography has been build. It's an iterative method inserting Newton method, trust region method and LSQR algorithm. The choice of the parameters is done by an original way in order to limit errors on the travel time evaluation and to optimize the dimensions of the cells. Exemples in 2D with synthetic and reel data are given. Simulations in 3D are produced and first results are given for the South of Belgium. Comparisons with gravimetrical and geological results are done.

TOR: DEEP LITHOSPHERE VIA TELESEISMIC TOMOGRAPHY IN NORTHERN EUROPE

Tor Working Group, reporter Soren GREGERSEN (KMS, Rentemestervej 8, DK-2400 Copenhagen NV, Denmark, email: srg@kms.dk)

We do distinguish very significant deep lithosphere differences in the data of the Tor project, of the largest seismic antenna to this time in Europe. Field work was 1/2 year 1996-1997, data processing 1997-1999. And now preliminary interpretations are available of the project across Germany, Denmark and Sweden. The Tor project has a horizontal resolution of 20-30 km compared to more than 100 km in previous studies. It involves teleseismic tomography as well as studies of receiver functions, S-wave splitting, scattered waves and surface waves.The Tor line goes along a well studied crustal profile of an earlier project, so that the sediments and crustal structure are assumed known, and the inversion efforts are concentrated on the deep lithosphere and asthenosphere differences to depths around 300 km. The investigations can be called two-and-a-half dimensional, being a 900 km profile with 100 km width plus a few seismographs off the profile. The project has established several versions of a 3D crustal/upper mantle model based on existing data, and through ray tracing in the model a picture of the influence on the seismic rays of respectively the known crust and the unknown deep lithosphere/asthenosphere system is established. For several events of the large data base it is shown that the observed travel time anomalies of 1-2 seconds can be divided almost equally between known crustal effects and unknown lower lithosphere/asthenosphere differences. The latter transition is judged to be gradual across Denmark.

SEISMIC ANISOTROPY AND LARGE-SCALE FABRIC OF THE CONTINENTAL MANTLE LITHOSPHERE

V. BABUSKA, J. Plomerova (Geophysical Institute, Czech Acad. Sci., 14131 Praha 4, Czech Republic, email: v.babuska@ig.cas.cz)

Seismic anisotropy studies using both surface and body waves provide information on the olivine fabric within the subcrustal lithosphere and asthenosphere. A joint interpretation of P-residual spheres and shear-wave splitting at experimental and permanent seismic stations in the Variscan belt of central Europe and in southern Sweden enable us to model orientations of hexagonal or orthorhombic anisotropic structures within smaller-scale lithospheric blocks and to define first-order sutures separating blocks with different orientations of their fabric. The surface-wave anisotropy beneath the Precambrian shields and platforms world-wide exhibits its maxima at about 100 km depth with Vsv < Vsh signature, while beneath Phanerozoic regions it is characterized by Vsh>Vsv, with maximum at depths about 70 km. An interpretation of the observed seismic anisotropy by the preferred orientation of olivine crystals results in a model of the mantle lithosphere characterized by anisotropic structures plunging steeply beneath Precambrian shields and platforms, compared with less inclined anisotropies beneath Phanerozoic orogenic belts. The different olivine orientations can result from different processes that lead to the formation of the continental lithosphere in Precambrian, compared with the Phanerozoic, and that probably changed considerably during the Proterozoic.

INTEGRATED INTERPRETATION OF SEISMIC AND GRAVITY DATA USING A NON-LINEAR DENSITY-VELOCITY RELATIONSHIP

Elena KOZLOVSKAYA (Department of Geophysics, University of Oulu, POB 3000, FIN-90401 Oulu, Finland, e-mail: elena@babel.oulu.fi); Jukka Yliniemi (Sodankylä Geophysical Observatory, Oulu Unit, POB 3000, FIN-90401 Oulu, Finland, e-mail: jyl@babel.oulu.fi)

The fact that there exists a strong correlation between rock density and seismic waves velocity has been widely used in geophysics for many years for calculating density models from data about velocity of deep structures obtained from seismic investigations. It is a common practice to use for this purpose Birch equation or its modifications. The previous experience of combined interpretation of seismic and gravity data has shown that such equations do not allow to obtain density models that satisfy observed gravity data. To avoid this problem, we have developed a method of integrated interpretation of seismic and gravity data that allows not only to obtain density models of complicated 2-D and 3-D structures, but also to improve the quality of seismic data interpretation.
This method uses a more complicated non-linear relationship connecting density, compressional and shear seismic waves velocity. This equation is obtained as a solution of inverse gravity problem, and it is a very important difference of this technique from the traditional approach. The data on other geophysical and geological measurements are used as a-priory information necessary to find reliable solution. The equation is then used to calculate density model and its gravity field. The method has been applied to the interpretation of some DSS profile data including LT-7, TTZ profiles in Poland, SVEKA profile in Finland and EUROBRIDGE-95-96 profiles in Lithuania and Belarus. The results allow the conclusion that integrated interpretation of seismic and gravity data with the use of the above technique significantly improves the quality of seismic data interpretation.

OUTLINE OF PRECAMBRIAN STRUCTURE OF THE FENNOSCANDIAN SHIELD AS REFLECTED BY SOURCES OF POTENTIAL FIELD ANOMALIES

Juha V. KORHONEN, Tapio Koistinen, Seppo Elo, Heikki Seevuori (all at Geological Survey of Finland, P.O. Box 96, FIN-02151 Espoo, Finland, Email: juha.geofys@gsf.fi); Jussi Kriainen (Finnish Geodetic Institute); Sven Aaro (Geological Survey of Sweden); Larske Haller (National Land Survey of Sweden); Jan Reidar Skilbrei (Geological Survey of Norway); Hans Peter Plag, (Norwegian Mapping Authority); Anatoli Tchepik (Northwest Regional Geological Centre); Anatoli Kulinich (Petersburg Geophysical Expedition); Lioudmila Jdanova (State Company "Mineral"); Rein Vaher (GeologicalInstitute of Tallinn)

One of the goals of the joint Fennoscandian map project is to find geophysical characteristics, that distinguish exposed Precambrian rocks (Fennoscandian Shield) from the surrounding rocks of the same age, covered by Phanerozoic sediments (East European Platform). The boundary of the shield is not shown in the magnetic, pseudogravimetric or Bouguer anomaly signatures. Instead these anomalies are all low in the central part of the shield and roughly concentric with the Fennoscandian land uplift area. Radially averaged magnetic anomaly field increases from the central part (-120 nT) to +120 nT at a distance of 500 km, steeply decreasing near zero outside. The positive magnetic anomaly ring is associated with Neoarchaean-Mesoproterozoic igneous rocks, mainly acid in composition. Correlation with petrophysical properties reveals that the anomalies are partly caused by unexposed sources. Study is going on concerning the geological nature of the structure and its possible connections to other lithospheric characteristics of the shield. The shield outside the structure consists of accreted Precambrian terrain of Kola, Svekonorwegian orogeny and Lofoten area. These terrain are characterized by higher magnetization in their central parts, than in the border areas, thus differing in nature of the central geophysical ring structure of the…

CHARACTERIZATION OF CATACLASTIC FAULT ZONES BY PETROPHYSICAL AND GEOCHEMICAL PROPERTIES APPLYING MULTIVARIATE STATISTICAL METHODS

Helmuth WINTER (Institut fuer Allgemeine und Angewandte Geophysik der Universitaet Muenchen, Theresienstrasse 41, D-80333 Muenchen, Germany, email: winter@geoelek.geophysik.uni-muenchen.de); Helmut Kuechenhoff (Institut fuer Statistik der Universitaet Muenchen, Akademiestrasse 1, D-80799 Muenchen, Germany, email: helmut@stat.uni-muenchen.de); Heinrich C. Soffel (Institut fuer Allgemeine und Angewandte Geophysik der Universitaet Muenchen, Theresienstrasse 41, D-80333 Muenchen, Germany,
email: soffel@magbakt.geophysik.uni-muenchen.de)

Cataclastic fault zones are important structures in the Earth's crust: they provide paths of migrating fluids, represent seismic reflectors and zones of high electrical conductivity. Analyses of particular samples from scientific drill holes show that composition and physical properties of cataclastic fault zones are different compared to the surrounding not distorted rocks. Direct probing is difficult due to the low strength of the material and, therefore, drill cores from cataclastic fault zones are rare. Data from drill cuttings and borehole measurements are available more easily and in a higher density. They give the basis for our investigation.
Multivariate statistical methods are applied to characterize the cataclastic fault zones by petrophysical and geochemical properties. The data sets of the German Continental Deep Drilling Project (KTB) are used which represent a 9-km-deep profile of crystalline rocks, mainly consisting of gneiss and amphibolite, intersected by various cataclastic fault zones in different depth. The calculations lead to a model with characteristic changes in cataclastic fault zones.

THERMAL EVOLUTION AND EXHUMATION HISTORY OF THE WASATCH NORMAL FAULT, UTAH, USA: RESULTS FROM THERMAL MODELING

Todd A. EHLERS, Phillip A. Armstrong, David S. Chapman (Dept. of Geology and Geophysics, University of Utah, Salt Lake City, UT, USA 84112: email: taehlers@mines.utah.edu); Thomas Kohl (Institute for Geophysics, ETH Honggerberg, CH-8093 Zurich)

The thermal regime surrounding an active normal fault is important for the interpretation of thermochronometric data but is complicated by tectonic and topographic processes. The footwall thermal gradient is affected by rates of uplift, erosion, and flexure, whereas the hanging wall gradient is affected by sedimentation and burial. If the exhumation and fault displacement rate are fast enough, an enhanced thermal regime in the footwall is juxtaposed against a depressed regime in the hanging wall, causing lateral heat flow and curved isotherms in the subsurface. Topography causes 3-D variations in isotherms that mimic the topography and are damped in amplitude at several kilometers depth. Exhumation rates calculated from apatite fission track (AFT) and (U-Th)/He analysis are sensitive to the thermal regime surrounding the fault. Our multidimensional thermal models suggest that above a threshold displacement rate isotherms are curved and not horizontal. The depth to the closure temperatures varies with distance from the fault, exhumation duration and rate, and topographic wavelength. Hence, interpretation of fission track data in tectonically active regions necessitates the use of multidimensional thermal models. We interpret spatial variations in exhumation rates from published and new AFT and (U-Th)/He ages using 2-D and 3-D numerical simulations of the Wasatch Mountains. Simulations were run with variable flexural displacement profiles and exhumation rates varying from 0.1 to 5 mm/yr for up to 20 My. Results suggest predicted exhumation rates from multidimensional thermal models differ from commonly used 1-D models by ~40% or more when applied to thermochronologic data.

DIFFERENCE IN THE THERMOMECHANICAL RESPONSES OF CRATONIC AND MOBILE LITHOSPHERES AND INTEGRATION OF GEODATA SETS

U. RAVAL, K. Veeraswamy National Geophysical Research Institute, Hyderabad, India

By grouping, the continental lithospheric (CL) region into cratonic and mobile (MBs) domains, large geophysical, geological and geochemical data over the Indian subcontinent could be integrated in a bimodal geodynamical framework consisting of Plate- and Plume-tectonics. The study examines the Meso-Cenozoic tectonothermal development of the Indian CL which exhibits: occurrence of three CFB's over 70 my duration, three breakups (at ~125, 90 & 64 Ma); high plate velocity (up to 16-19 cm/yr during 80-50 Ma), and a continent-continent collision. It is shown that a major thermomechanical difference existing across a -50 mgal

contour could be understood in terms of interaction between cratons/MBs and hotspots. This difference is characterised by high gravity, high heat flow and presence of MBs north of the contour and a relatively low gravity and low heat flow to its south, which does not posses any major mobile zone, because in the southern region major MBs have already participated in the continental break-ups aided by plume activity. The combination of plume & MBs hence appears to be 'fatal' for the continental stability. Concepts of deep rooted (thick), cold, rigid and dry cratonic and relatively thin, warm, weak and wet mobile lithospheres thus allows integration of different data sets and better understanding for the Indian CL.

THERMAL INSTABILITY IN THE UPPER MANTLE: EFFECT OF THE MELT-SOLID DENSITY CROSSOVER

Ya. M. KHAZAN (Institute of Geophysics of Nat. Acad. Sci. Ukr. Palladin pr., 32, Kiev-142, 252680, Ukraine, email: earth@igph.kiev.ua)

The existence of the melt-solid density crossover (MSDC) at pressure 8-10 GPa (250-300 km) [Rigden et al., 1984; Agee and Walker, 1993] should strongly influence the style of thermal instability in the upper mantle. Below the MSDC the melt is denser than the solid. This implies that partially melted layer heated from below remains stable until the solidus isotherm rises above the MSDC. To estimate scales and increments of the instability of an unstable layer lying in the vicinity of the MSDC the problem is treated as a Rayleigh-Taylor one with additional constraints accounting for a thermal relaxation. It is shown that the instability develops when the unstable layer thickness reaches 10-15 km.. Linear stability time (some Myears) and diameter of a body arising from the layer (some tens of km) depend on temperature at the layer bottom and viscosity contrast between undisturbed mantle, unstable layer and intermediate layer. While rising up, the velocity of the body increases about ten times due to both the decompression melting and the increase of the solid _ melt density difference away from the MSDC.

THERMAL HISTORY OF THE EARTH MANTLE AND GLOBAL ASTHENOSPHERE

Vadim GORDIENKO (Institute of Geophysics of Nat. Acad. Sci. Ukr., Palladin pr., 32, Kiev-142, 252680, Ukraine, email: tectonos@igph.kiev.ua).

Thermal history of the Earth mantle has been analyzed. After the Earth core and crust separation the temperature (25800C at 500km depth and 28600C at 1100 km) exceeded solidus down to 1100km depth and liquidus down to 500km depth. The subsequent evolution included the influence of the radioactive decay, conductive cooling through the Earth surface, advective heat transfer that periodically resumed in activation. By the present a partial melting zone at 800-1000km depth must have remained under the continents and oceans. Its existence is confirmed by geoelectrical data (specific resistance reduced from 5-100Hom*m to 0.5-50Hom*m) and does not contradict the seismological data (dV/dZ reduced from 3-5*10-3s-1 to 1.5-2*10-3s-1, Vp/Vs reduced from 1.81-1.82 to 1.78-1.79).

REALIZATION OF A TERRESTRIAL REFERENCE FRAME FOR LARGE-SCALE GPS NETWORKS

Detlef ANGERMANN, Juergen Klotz, Christoph Reigber (GeoForschungsZentrum Potsdam, Telegrafenberg C2, 14473 Potsdam, email: dang@gfz-potsdam.de)

The GFZ Potsdam established GPS networks for geodynamic studies in South America (SAGA), Central Asia (CATS) and South-East Asia (GEODYSSEA), in cooperation with various organizations in the host countries, as well as in Europe and North America. This presentation concentrates on the datum definition of these networks.
The GPS data of the large-scale networks were processed simultaneously with data of the IGS station network using the GFZ software EPOS. The mean station coordinate residuals between our global network solutions and the ITRF96 coordinates are 1cm horizontally and 1-2 cm vertically. With respect to a regional reference frame the mean station coordinates residuals are in the range of 2-5 mm horizontally and below 1 cm for the height. For the interpretation of our network results we focus on regional tectonics and relative plate motions. To achieve this goal we define the datum of the station velocities in a regional frame. We present results for the datum definition of the SAGA and CATS network.

THE ULTIMATE WIDTHS OF THE 3 OCEANS WHEN CONTINENTAL DRIFT CEASES

Yi ZHENG (7 Hickling House, Slippers Place, Rotherhithe, London SE16 2ER, UK, email: justicezy@hotmail.com)

Continental drift has been lasting since late Jurassic about 150 Ma ago. However what is the basic cause that makes the continents drift is a quandary in earth science which has been perplexing earth scientists for more than 80 years. Our planet can be taken as a quasi-rigid body rotating around an axis. Its total resultant moment is zero. Thus its angular momentum is conservation. The continental lithospheres as the solid surface layer possessing the maximum distance from the axis play main role in the process of global plate movement because there exists an altitude difference of about 5 km between the average height of continents and the average depth of ocean floors. The rheological asthenospere is deformable which makes the movement of continental lithospheres over it facilitated. The movement of the continental lithospheres can be divided into longitude drift and latitude drift. The former is that the continental mass tends to move towards equator and is the response of continental mass versus the slowing down of the rotation of the earth. Its results is that the Mediterranean is being squeezed to shrink gradually. The latter is the even distribution of continental mass along latitude and is the response of continental mass versus that the earth's rotation tends to dynamic equilibrium. Its result is that the Pacific Ocean is being squeezed to shrink gradually and with a tendency to break continents. With the aid of oceanic palaeomagnetic data upon which oceanic lithospheric age map can be created, quantitative analyses and calculations indicate that the global continental drift will not continue indefinitely. In about 83 Ma the dynamic equilibrium of the earth's rotation will greatly achieve and the large scale continental drift will turn to cease and the widths of the Pacific, Atlantic and Indian Ocean basins at equator then will be 12,889km, 11,550km and 6,790km respectively.

LARGE TIME ASYMPTOTIC SOLUTION FOR POROUS MEDIA WITH MOVING BOUNDARY

E. Suetnova (United Institute of the Physics of the Earth of RAS, Moscow, 123810, Russia, email: elena@uipe-ras.scgis.ru); V. CHERNIAVSKI (Paleogeodynamics, Institute of Oceanology of RAS, Moscow, 117851, Russia, email: cherniav@chip.sio.rssi.ru)

It is investigated the dynamics of evolution of two phase porous layer subject to vertical compaction to simulate large time evolution of low-temperature system where a viscous fluid saturates a viscous matrix under the influence of gravity force. The thickness of the layer is growing with a specific velocity, which is determined by boundary condition (sedimentation rate, for example). It is supposed non-linear dependence of permeability and viscosity on the porosity. It is suggested that impermeable bottom boundary moves downward with constant velocity. Upper boundary is at rest and it is supposed two boundary conditions of constant pressure and definite porosity are posed on it. Numerical modeling shows that the solution of boundary value problem strongly depends on initial conditions at the short and intermediate time level. With the increasing of time, this dependence is decreasing. Analytical modeling has been done to study large time asymptotic solution. Because of investigating evolution when non-dimensional time tends to infinity initial conditions of porosity are not discussed. The width of the region tends to infinity with the same order of rate as time. It is found an exact solution which is valid in a wide region near upper boundary of order of the whole width and can be used in the near bottom region of order unity as a weak solution satisfying integral mass conservation law. The solution is useful to analyze compaction of sedimentary basins and evolution of metamorphic terrains on the geological time scale.

PHYSICAL EXPERIMENTS OF DYNAMIC PROCESSES ON CONTINENT-CONTINENT COLLISION

Jiazeng Shan(Institute of Geology, Academia Sinica, P. 0. Box 9825, Beijing, China, email: JZ Shan@ ihw. cow. cn)

Physical experiments of continent-continent collision is performed with a new apparatus. The apparatus used in the experimentation consists of large box(100cm long, 70cm high and 12cm wide) with two motors-drive. It is possible that rotational speed of motor-drive changes in 1-2800r/min to simulate drive forces of the mantle convection. Experimental results have indicated that continent- continent collision is one of the principal mechanism leading to lithosphere/crust thickening and mountain building. The models shortened and thickened about 45% and 85% respectively under combined actions by the viscous drag exerted on the base of the lithosphere by lateral motion of the top mantle convection cells from deep mantle and compressive forces from plate movement in the experimental conditions. An evolutionary relationship between napping/mountain building and subducting can be observed from photograph of experimental model.

COUPLED KINEMATIC AND RHEOLOGIC MODEL FOR THE EVOLUTION OF RIFT BASINS

He LI-JUAN, Xiong Liangping, Wang Jiyang (all at Institute of Geology, Chinese Academy of Sciences, Beijing 100029, China; Email: dsdpc@sdb.csdi.ac.cn)

Coupled kinematic and rheologic model lies between the traditional kinematic model and geodynamic model. It incorporates the advantages of both models, considering simultaneously the effects of heat, stress and rheology on the tectono-thermal evolution of rift basins. On the assumption that the motion of the lithosphere is already known (just like the kinematic model), the model studies the tectono-thermal evolution history of the rheologic lithosphere (just like the geodynamic model). Using this model, we can simulate the multi-phase evolution of the rift basins more flexibly than the geodynamic model by comparison with observed tectonic subsidence values. Much attention must be paid on the consistence of isostatic theory in the coupled kinematic and rheologic forward model and in the backstripping inverse model. Since the flexural isostasy is included in the forward model, tectonic subsidence should be calculated by flexural back stripping too. The effective elastic thickness of the lithosphere, which is affected by the thermal structure of the lithosphere, the sediment loads and the state of stress and strain, may link the forward model with the inverse model. The value of the effective elastic thickness of the lithosphere and its changes with time and space obtained from the forward model, can be used in the inverse flexural back stripping model. We simulated the tectono-thermal evolution history of the Yinggehai basin, South China Sea, which had experienced three phases of extension during the Cenozoic, and satisfied results were obtained should be launched on near polar orbits to pass whole range of local time.

SPATIAL VARIABILITY OF TIDAL GRAVITY ANOMALIES AND ITS CORRELATION WITH THE EFFECTIVE ELASTIC THICKNESS OF THE LITHOSPHERE

Wladimir SHUKOWSKY (Instituto Astronômico e Geofísico, Universidade de São Paulo, Rua do Matão, 1226 CEP 05505-900 São Paulo, S.P., Brazil, email: wladimir@iag.usp.br) Marta S. M. Mantovani (Instituto Astronômico e Geofísico, Universidade de São Paulo, Rua do Matão, 1226 CEP 05505-900 São Paulo, S.P., Brazil, email: marta@iag.usp.br)

Associations of the Earth tidal gravity response to physical properties of the lithosphere have been attempted at least for the last four decades. Although experimental data suggest this association, rigorous models have not yet been proposed. In this work statistical tests are performed on the available World Gravity Earth Tides data set. Auto-correlation analysis shows that the M2 tidal gravity anomalies are significantly correlated up to a distance of about 500km, with an approximately exponential correlation decay. The analysis of the latitudinal

dependence of the anomalies shows that the anomaly variance, estimated inside of different latitude bands, follows a curve within the latitude interval and defines the noise level for the M2 gravity anomaly data set. The regression analysis between M2 tidal gravity anomaly and the lithosphere Effective Elastic Thickness estimates shows that these quantities are significantly correlated, with a correlation coefficient of -0.82. The wide range of tidal gravity anomaly and effective elastic thickness values, combined with a good global distribution of the data used in the regression analysis, makes the regression equation suitable to be used as a predictor for effective elastic thickness values in areas where M2 tidal gravity anomaly data exist and meet the required quality criteria.

SEISMIC REFLECTION RESEARCH ON THE FAULTS IN THE OFFSHORE AREAS TO THE SOUTH OF HAINAN ISLAND CHINA

Saijun LIU (Seismological Bureau of Hainan Province, Bailong Road 42, Haikou 570203. China, email: zhengli@pub1.fz.fj.cn); Jinhai Chen (Seismological Bureau of Fujian Province, Hualin Road 203, Fuzhou 350003, China, email: ap35@sdb.csdi.ac.cn)

In the paper, the activities of the large fault in the offshore areas to the South of Hainan Island China were studied in detail by using the data of oil reflection survey. As the boundary fault between the Yingehai and the Southeast Hainan Basin, the No 1. Fault strike NW is more than 200 km. It is a normal fault dip SW. It stretches to the northwest and connects with the Honghe faults at the north of Vietnam. As an old basement fault, there were movements till the Cenozoic era. Near the point (Long. 1080E, Lat. 190N), it is divided into 2 parts by a pair of faults (NE). And, we find that the fault No.1 is more active in the southeast than the northwest part. Also, there is a gradually strengthening tendency towards SE of Gancheng. The geophysics survey data of the profiles shows that the faults are not any movements in the NW section of Gancheng since the Quaternary period. It shows that in the SE section of Yingehai, however, they had been moving till the early period of the Quaternary Period. And to the south east of the point (1090E, 17.50N) it shows the reduced activities that there were no signs of inheritances in the layer of the Quaternary System. According to the survey data, the fault can be separated into four sections in general. Among them the fault in the Yingehai-Meishan section is more active. In the areas around Gancheng-Lingtou nearby the NE section of the No.1 fault, the earthquake swarm (M=3~4) have occurred since Jan. 1992. The largest one is the earthquake with the Magnitude of 4.5. And the after-earthquakes are lasting till now. The large fault in the offshore areas to the SE Hainan Island was NE-NNE. It turns to the NEE and nearly EW in the waters to the south of Sanya, which is consistent with the gravity and magnetic anomaly belt, the Moho depression and the Arched contact belt. In the NE section, the earthquake (M=6.8) occurred in the 1931. Two earthquakes (M_i_5.0) took place in the waters around Lingshui in Dec. 1969. The profiles show that from the waters of Yalong Bay of Sanya to the east of the fault, activities are very apparent in the early Quaternary Period still.

WIDE-ANGLE SEISMIC PROFILING: ASEISMIC MODEL OF THE CRUST THROUGH THE BROKEN HILL BLOCK

J. H. Leven, D. M. FINLAYSON, A. J. Owen, D. W. Johnstone, B.J. Drummond (Australian Geodynamics Cooperative Research Centre, Canberra, Australia, email: jleven@agso.gov.au, dfinlays@agso.gov.au)

The Broken Hill Block, Australia, hosts one of the world's major mineral deposits. It lies just inboard of the Tasman Line, which in this region is coincident with the late Neoproterozoic continental rift margin. In 1997, the Australian Geodynamics Cooperative Research Centre undertook wide-angle seismic profiling across the Broken Hill Block and Tasman Line to investigate the crustal structure beneath and to the east of the Broken Hill Block. Results from this survey indicate:
• Two layer crust: upper layer 5.9 km s-1 to 6.4 km s-1 with variablethickness ranging between 20 and 30 km, lower layer 6.8 km s-1 to 7.2 km s-1 of relatively constant thickness of around 14 km.
• Moho depth ranges from 35 km on either side of the Broken Hill Block to 43 km beneath it.
• A sub-Moho P-wavespeed of 8.1 km s-1.
• Low seismic wavespeeds in the upper crust associated with the region of the Tasman Line.
• Relatively low crustal P-wavespeeds compared with those of eastern Australia, and no evidence of a massive underplated lower crustal layer with P wavespeeds around 7.7 km s-1.
The structure of the remnant troughs of the Darling Basin which lie to the east of the Broken Hill Block, and the crustal structure as determined from the wide-angle survey suggest that the Broken Hill Block resulted from crustal thickening. The low P-wavespeed upper crustal zone east of the Broken Hill Block is interpreted as a near-surface thrust splay zone, with the leading edge of the thrust sheet defined by the inflection in the Bouguer gravity gradient Southeast of Broken Hill.
