SOURCE PARAMETERS BY SPECTRAL ANALYSIS OF OCEANIC EARTHQUAKES RECORDED AT GAURIBIDANUR SEISMIC ARRAY, INDIA

Imtiyaz A. PARVEZ (Department of Geology, Kumaun University, Nainital, INDIA. Presently at the Department of Earth Sciences, University of Trieste, ITALY, email: parvez@geosun0.univ.trietse.it); Avadh Ram (Department of Geophysics, Banaras Hindu University, Varanasi - 221 005, INDIA)

A study of source parameters from the Andaman Sea and Carlsberg Ridge earthquakes in a narrow azimuthal range using the Gauribidanur Seismic Array (GBA) data in southern India has been carried out. Nine earthquakes from Andaman sea and eight from Carlsberg Ridge in the magnitude range of 4.5<Mb<5.4 recorded by the short-period digital seismometers of 1 sec period at the rate of 20 samples/s have been used. The earthquakes from both regions are at an epicentral distance of about 17 degree from GBA. The Fourier displacement spectra of P-waves are estimated for 512 samples in time domain to the frequency domain and analysed with respect to Brune's model. A systematic and uniform approach to the problem of determining the corner frequency (fc) and low frequency spectral level has been used by computing theoretical spectra in frequency domain and compared with observed one. It is interesting to note the characteristic of the seismic sources of two different oceanic regions having the identical distances and similar path with recording instrument alike. The seismic moment and stress drop for the Andaman sea earthquakes are estimated as 4.6E+22 to 4.8E+23 dyne-cm and 14-78 bars, respectively. The source radius, apparent stress and energy released are estimated as 1.10-1.41 km, 1.49-8.04 bars and 2.5E+17 to 1.3E+19 ergs, respectively. For the Carlsberg Ridge, seismic moment and stress drop are estimated as 4.8E+23 to 8.3E+23 dyne-cm and 81-116 bars, respectively. The source radius, apparent stress and energy released are estimated as 1.36-1.47 km, 8.38-11.88 bars and 1.3E+19 to 3.2E+19 ergs, respectively. The source parameters versus magnitude have also been plotted to find out the empirical relationships and compared for the two regions. It has been observed that all the source parameters of the Carlsberg Ridge are showing higher stress drop as compared to the Andaman regions may be because the two areas have evolved from different geological and tectonic processes.

ACOUSTIC AND ELECTROMAGNETIC DISTURBANCES DURING VIBROSEISMIC SOUNDING

V.V. Kuznetsov, V.V. Plotkin, S.Y. KHOMUTOV, O.E. Grekhov, A.F. Pavlov, A.N. Fedorov (Institute of Geophysics SB RAS, Koptyug av., 3, Novosibirsk 630090, Russia; e-mail: hom@uiggm.nsc.ru)

The powerful seismovibrators can be considered as controlled sources of the seismic energy. They can be used for the researches of the mechanisms of the earthquake precursors. The observations of a disturbances of the acoustic, electric and magnetic fields at various distances from a source during the operating of the seismovibrators in a sweep-mode (the frequency range is 6-11 Hz) are performed. The used seismovibrators are the centrifugal vibrosources with the sinusoidal vibrational action onto the ground of 100 and 40 tons. The signal in the vertical component of the atmospheric electric field at the distances up to 2 km is detected. This signal has near zero delay with respect to session beginning and advances beyond the acoustic and seismic signals. It can specify an electromagnetic nature of disturbances of the electric field. The infrasonic signal is reliably registered on distances up to 50 kms. In some cases depending on acoustic signal magnitude the seismic signal with the same arrival times is registered. The amplitude of infrasonic signals depends on the meteorological conditions along a path of its propagation. The measurements with the remote infrasonic sensors have allowed to determine a path of the acoustic wave from vibrosource to sensors. The disturbances caused by the seismovibrators were also registered in a telluric field at distance up to 2 km from source.

FRACTAL DISTRIBUTIONS OF THE EARTHQUAKE SEQUENCES IN BANAT AND CAMPULUNG-FAGARAS SEISMIC REGIONS (ROMANIA)

Emilia Popescu (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: epopescu@infp.ifa.ro); Mircea RADULIAN (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: mircea@infp.ifa.ro); Ana Utale (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania)

Fractal characteristics of time, space and size distributions of earthquake sequences in two regions of increased seismic activity, located at the eastern and western extremities of the Southern Carpathians (Romania) - Campulung-Fagaras and Banat - are analyzed. Campulung-Fagaras area is situated close to Vrancea subduction region. Here the largest shallow earthquakes on the Romanian territory are observed (MW = 6.5). The last large shock was recorded on January 26, 1916 (MW = 6.5). Banat area is situated at the contact of the Pannonian basin and Carpathians orogen and is characterized by a relatively high seismicity in the upper crust (h < 10 km; MW < 6). Two important earthquake sequences occurred between July 1991 and June 1992 in Banat region and between May and June 1993 in Campulung-Fagaras are considered. A number of 1134 events with 1.5 < MW < 5.8 are identified in the first case, and 318 with 1.2 < MW < 5.2 in the second. Fractal properties of the time, space and size distributions are outlined and compared for the two seismic processes. The fractal dimension of the temporal distribution is in the range 0.14 < D < 0.25 in both cases. The fractal dimension of the epicenter distribution and the b-slope of the frequency-magnitude distribution, as functions of time, are positively correlated for the Banat sequence and negatively for the Câmpulung-Fagaras sequence.

REGISTERED TWO DISTINCT WAYS OF RELEASING ACCUMULATED POTENTIAL ENERGY: SEISMICITY AND "FAULT SUPERINTENSIVE MOVEMENTS"

CHURIKOV V.A., Kuzmin Yu.O. (both at United Institute of Physics of the Earth, Recent Geodynamic Lab., B. Gruzinskaya Str. 10, Moscow, Russia, email: vt.churik@relcom.ru)

Data obtained in the geodynamic polygon of Kamchatka (Russia) by multiple repeated high-precision vertical geodetic observations with great detail in time and space in fault active zone are discussed. The data processing, measurements and analytical methods that were originally used for small local levelling profile in fault zones have been elaborated. As a result of analysis are be found very localized superintensive deformations of the ground surface in fault zones with amplitude approximately 5 - 10 cm per year. Accurately located superintensive movements correspond to extension fracture local fault zones has been identified along the profile. Correlation between the deformation rate and seismic activity allowed us to distinguish direct and inverse correlation types. In the direct correlation, the main deformational event precedes the seismic event (deformation forerunner of an earthquake, in our case M 7.1, 1992 March 2, 82 km from the profile), while in the inverse type the redistribution of accumulated energy is expressed by both the seismic process and the fault superintensive movement. Hence, while executing observations for predicting destructive earthquakes, one should take into consideration the correlation character between seismic activity and contemporaneous superintensive movements in the fault zones.

IDENTIFY THE CHANGE OF SHEAR-WAVE SPLITTING ON MARBLES WITH LOADING IN LABORATORY

Yuan GAO (Center for Analysis and Prediction, China Seismological Bureau, 100036 Beijing, China/Graduate School, University of Science and Technology of China, Email: geo_yuan@yahoo.com /ygao@tomo.ig.erdw.ethz.ch); Shi-yu Li (Institute of Geophysics, China Seismological Bureau, 100083 Beijing, China) Hui-lan Zhou (Graduate School, University of Science and Technology of China, 100039 Beijing, China)

We have done a laboratory test on measuring shear-wave splitting change with loading pressure on marbles. The data acquisition is performed by a triggering digital waveform acquisitor of frequency of 20 million Hz. Using the probes of three components, the signal source of shear wave could be changed in frequency, the waves which propagate through the sample rock could be received well by probes at three channels.
This experiment is focused on the change of pattern of shear-wave splitting when the loading presure is changed. We selected two groups of marbles. One of groups is composed of intact marble samples which just show original paralell structure, without original cracks. With the increment of pressure from free status, the shear-wave shows the splitting and incresment. When near to the critical state in which samples will be destroyed, the time delays of shear-wave splitting do not change regularly incresing with loading. Those changes for samples are different with each other. The pattern is characterized as more complexity. Another groups of marble samples are composed of those with original paralell cracks. No loading, we directly detect the shear-wave splitting. Results show obvious azimuthal anisotropy. Splitting phenomena of shear-wave were also observed.
Although we did this experiment in single-axis loading, not in condition of a triaxial stress cell. The critical patterns of marbles are very complicated. The results suggest that the critical change of shear-wave splitting could be observed. However, it is possible to identify the change before a large event with the observation on shear-wave splitting.

SOURCE COMPLEXITY OF THE CAP - ROUGE EARTHQUAKE – MODERATE EARTHQUAKES YIELD THEIR SECRETS

John ADAMS (Geological Survey of Canada, 7 Observatory Crescent, Ottawa K1A 0Y3 Canada, email: adams@seismo.nrcan.gc.ca) and R.A.W. Haddon (32 Mahuta Road, Five Mile Bay, RD2, Taupo, New Zealand)

The mbLg 5.1 Cap-Rouge earthquake is the largest well-instrumented earthquake in southeastern Canada since the (similar-sized) 1990 Mont-Laurier earthquake. It occurred on 971106 at 0234, 22 km under the western suburbs of Quebec City (46.80N, 71.42W, see www.seismo.nrcan.gc.ca). The mainshock (Mw ca. 4 1/2) was well recorded by seismographs at >100 km, and by the Quebec City analog strong motion instrument (11 km). The network recorded 15 aftershocks of magnitude 2.9 - 1.3 and field instruments recorded 20 smaller aftershocks, the tight cluster of the latter establishing the hypocentre. A P-nodal mechanism (by A. Bent) indicates primarily reverse faulting, from geological arguments likely on a plane dipping 70 degrees southeast and striking N50E. We have interpreted spectral ratios and forward modelled the source (compare Haddon and Adams, GJI 129:235). Derived source spectra vary for various azimuths and show spectral scalloping, a source interference effect implying a double event. Spectral modeling indicates a pair of sources with the second about 1.0km southwest of the first and delayed by 0.6 sec. The strong motion time history supports a double source. Consequences of the interference for moment determination and Q determination will be presented. The spectral characteristics of this model are fully consistent with the Haddon 1996 (BSSA 86:1300) source scaling model. Complexity like this makes simplistic interpretations of "the" source in terms of Brune-type models extremely misleading. Taken with the results of the Mont-Laurier mainshock, Saguenay mainshock, Saguenay foreshock (also a double event), and other mbLg>4.5 earthquakes studied, we find this complexity pervasive for eastern Canada. If such complexity exists for many Mw 4.5 earthquakes in other areas, conclusions about average rupture velocities as inferred from the size and duration of rupture will be inaccurate and may account for the unusual properties claimed for the "nucleation zones" of M>6 earthquakes.

GROUND MOTION COMPUTATION AND MODELLING OF CONTROLLED AND NATURAL SOURCES

Soma Chatterjee; Avadh RAM (Both at Department of Geophysics, Banaras Hindu University, Varanasi-221005, India; tel: +91 542 317123; fax: +91 542 317074; email: aram@banaras.ernet.in)

Physics of earthquake processes and crustal stresses and its mechanism may be investigated in fomulating any programme towards earthquake hazard and risk estimation or for earthquake prediction. In order to assess the quantum of strain energy released during an earthquake, the nucleation process of the fault and the final rupture must be given due consideration. The seismodynamics and numerical earthquake prediction methodologies are being contemplated. The problem of source characterization and theoretical estimation of ground motion in the vicinity of the source under controlled media have also been considered. The spherical cavity model emplaced in a homogeneous, ideally elastic and infinite medium, has been chosen to compute the elastic wave motion. A modified pressure function has been used for computation of ground motion. The effect of transmission path and some other factors have also been considered. The analytical expressions for reduced displacement potential as source function, radial displacement and velocity for any yield in a given medium have been derived using the Duhamel's integral. The results are compared with observed data. Further earthquake source modelling and computation of relevant ground motion using body wave waveform modelling technique has also been carried out. Two different fault systems i.e. the one associated with Bihar earthquake of January 15, 1934 and the other with the recent event of Jabalpur earthquake of May 22, 1997, have been mapped in detail. These fault systems have also been simulated. A comparison of the model parameters for two different source processes has yielded very interesting results which may provide a clue in solving the

enigmatic problem of earthquake prediction.

SEISMIC MOMENT TENSORS ISOMETRIC HYPER-SPHERICAL REPRESENTATION

YUNGA, S. (Institute of physics of the Earth, Moscow, 123810, B.Gruzinskaya, 10, Email: syunga@uipe-ras.scgis.ru)

A new system of parameters describing seismic moment tensors is suggested. Classification of seismic moment tensors is considered on this basis. Typical geometrical configurations are constructed, from one side, with the help of the set of synthetic planar faults: a horizontal fault, a vertical fault, an oblique fault, and, from the other side, using the synthetic slip vectors of horizontal, vertical or oblique orientations. Parametrization of normalized deviatoric moment tensor is obtained by specific spectral decomposition, in terminology of Trusdell. Parametric representation is calculated through angular parameters. It is found that in application to the problem of classification the results of parametrization are geometrically obvious. The suggested set of angles may be considered as spherical coordinates of unit radius-vector in the 4D space. Thus, a parametric representation of seismic moment tensor in spherical coordinates as a point of a 3D surface of a hyper-sphere in 4D space, preserving scalar product is established. Optimum graphic representation of initial data on seismic moment tensors, as well as results of its summation, is obtained. This can be used effectively in seismotectonic deformation study, as well as in statistical analysis of moment tensors. This research was partly supported by R.F.B.R., grant N 98-05-65159.

STRESS REDISTRIBUTION IN A SCALING ORGANIZATION OF FRACTURE TECTONICS (S.O.F.T.)

Clement Narteau (1), Peter SHEBALIN (2), Mathias Holshneider (1), Jean-Louis Le Mouël (1) Claude Allègre (1); (1)Institut de Physique du Globe de Paris, IPGP, B.P.89, 4 Place Jussieu, 75552 Paris Cedex 5, France, e-mail: narteau@ipgp.jussieu.fr; (2) International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, 79/2, Varshavskoye shosse, 113556 Moscow, Russia, e-mail: shebalin@mitp.ru

We consider here simple case of friction in a pre-fractured medium between two tectonic plates which move in horizontal plain with a constant relative velocity. Sliding can occur in a system of many parallel plains. We model this system (its horizontal plain) with a 2-D hierarchical system composed of embedded cells.
Nucleation of sliding occurs in the lowest level cells with a probability depending on the local stress. Each fracture propagates through the hierarchical system according to the S.O.F.T rule (Allègre et al. 1995) applied now in a time interval defined according to the cell size and the fracturing velocity. Sliding of different sizes introduces a self similar stress redistribution in adjacent cells with the scaling of absolute values according to the intensity stress factor. In this simple model with few parameters, we obtain an inverse power-law cascade of fracturing which gives foreshocks before strong earthquakes, power-law post-seismic decay of aftershocks and seismic cycle. In our system the aftershock sequences are obtained without any supplementary artifice; they are due to stress relaxation of non-broken parts in the main shock fault and also due to stress maximums formed by the fault on a distance.

SOURCE RUPTURE PROCESS IN THE DIFFERENT FREQUENCY RANGES FOR THE 1997 YAMAGUCHI, JAPAN, EARTHQUAKE (MW 6.0)

Satoshi IDE (Earthquake Research Institute, Univ. of Tokyo, 1-1-1, Yayoi, Bunkyo, Tokyo, 113-0032, JAPAN, email: ide@eri.u-tokyo.ac.jp)

It is sometimes claimed that an earthquake rupture process looks different depending on analyzed frequency ranges. To investigate the kinematics and dynamics of the earthquake source, I made the analyses of spatio-temporal distribution of earthquake rupture in the different frequency ranges using the same waveform inversion method except for Green's functions. In the relatively high frequency range more than about 1 Hz, it is difficult to calculate accurate Green's function using layered structure. Therefore, for the analysis in high frequency range (0.5 - 2.0 Hz) the empirical Green's functions (EGF) are used, while the theoretical ones are used for low frequency (0.1 - 0.5 Hz) analysis. The studied event is the 1997 Yamaguchi earthquake occurred in western Japan. The data is the strong motion records of Kyoshin-NET, National Research Institute for Earth Science and Disaster Prevention, Japan. The spatio-temporal slip distribution on an assumed fault plane is determined by waveform inversion method of Ide and Takeo (1997). In different frequency ranges and different EGF events, five solutions are obtained. All results have three distinct subevents. Spatially, the slip in the high frequency solution locates near the edge of the slip region of low frequency result. The slip-rate time function at each point on the fault plane in high frequency result tends to have narrow peak at the rupture initiation, while that in low frequency result has smoothed shape and long duration. These suggest that wecan see the migration of rupture front using high frequency waveform. Dynamic behavior is also studied using finite difference method for each result. In this calculation, slip and stress relations show larger slip-weakening rate, d(stress)/d(slip), in the high frequency result.

ESTIMATES OF FAULT GEOMETORIES AND RUPTURE VELOCITIES FOR SMALL EARTHQUAKES USING STOPPING PHASES

Kazutoshi IMANISHI and Minoru Takeo (both at Earthquake Research Institute, University of Tokyo, 1-1-1, Yayoi, Bunkyo, Tokyo, JAPAN, Email: imani@eri.u-tokyo.ac.jp; takeo@eri.u-tokyo.ac.jp)

Dimensions of small earthquakes have been investigated based on corner frequencies of source spectra or pulse widths of waveforms assuming a rupture velocity, a specific shape of fault surface and orientation of fault plane. Since these assumptions can lead to large errors, most previous estimates of the fault dimensions of small earthquakes are unreliable. In this study, we propose a method to estimate fault geometries (dimensions, shapes and orientations of fault plane) and rupture velocities for small earthquakes using stopping phases. We assume that the fault surface is bounded by an ellipse and that rupture initiates at one focus of the ellipse. In this model, we found that there exist two high-frequency stopping phases whose difference of the arrival times are dependent on rupture velocity, the radius of major semi-axes of ellipse and its ellipticity. These parameters are estimated by nonlinear least-square inversion method. We also determine the fault plane from two nodal planes by comparing the residual at each nodal plane. We apply this method for several small earthquakes occurred around the source area of 1984 Western Nagano earthquake (M=6.8). The result indicates that rupture velocities and rupture propagation of small earthquakes have large variation as like as large earthquakes.

MEDIUM-VELOCITY IMPACTS ON GRANITE: GENERATION OF HIGHLY MOBILE POSITIVE HOLE CHARGE CARRIERS

Friedemann FREUND and Alexander S Bradley, (NASA Ames Research Center, Moffett Field, CA 94035-100 USA)

Impact experiments were conducted on a 25x25x20 cm block of granite from Barre, Vermont, USA, using the NASA Ames Vertical Gun Range (AVGR) with 6.3 mm Al spheres, in the 1.4-1.6 km/sec range plus two shots at 4.45and 5.64 km/sec which led to disintegration of the block. The granite block, sitting on a grounded Al metal plate, was equipped with (i) three magnetic pick up coils, a first on 10 cm above the plane of impact to measure the electromagnetic (EM) emissions from the plasma plume, a second one at mid-height and third one at the bottom to measure the EM emission from within the block, (ii) three capacitive sensors in the plane of imapct, at mid-height and at the bottom, and (iii) two contact electrodes, one at the top in the plane of impact and another one at the bottom, both connected to gound through 2.4 Mohm resistances. After impact the on-set of the EM emission from within the block propagated at the speed of sound, ringing at distinct frequencies in the 10-30 KHz range, decaying within less than 1 msec. The capacitive sensors recorded trains of 20 micro seconds long voltage pulses travelling down the block at the speeds of P wave (6 km/sec) and S wave (3.4 km/sec) and up again with the reflected waves, due to piezoelectic signals from quartz crystals. At the same time the capacitive sensors registered a positive voltage building from within the rock over 600-800 micro seconds and decaying over 2-3 msec. The contact electrodes recorded a current flowing into the rock and decaying over a similar time interval. The current drawn by the bottom contact electrode was modulated by wide amplitude variations, also seen in the response from the capacitive sensors, in particular at mid-height and at the bottom. These observations are consistent with shock-activation of highly mobile positive hole charge carriers h., e.g. defer electons in the O 2- sub latice (O-) from pre-existing electically inactive dormant precursors, presumably preoxy links (O- -O-), in the constituent minerals. Activated by the shockwave throughout the volume, the insulating granite becomes momentarily semiconducting. As the h. charges spread to the surface and the resulting positive voltage exceeds the potential barrier at the metal-to-semiconductior contact, the Al metal ground plate acts as a gate injecting bursts of electrons across the interface of the rock.

NEW TECHNIQUE FOR ANALYSING STRESS-STRAIN STATE OF THE EARTH AS A UNIFORM SYSTEM

Anatoly DYCHENKO, (Department of Mechanical Engineering, Ukrainian State University of Food technologies, Volodymyrska St., 68, Kyiv, 252610, Ukraine, tel.: 380 (44) 558 8313, fax.: 380 (44) 212 4267, E-mail: dychenko@uduft.niiit.kiev.ua)

Principally new technique for determining analytically the distribution of values of physical parameters in real bodies depending on geometric properties of a body's shape and on the physical factor acting on the shape has been developed. The new technique excludes static uncertainty of existing mathematical models. This allows to receive analytical results of a high exactitude, adequate to an initial problem, and also to analyse the stress-strain state of systems of various geometry and to investigate both elastic systems, and systems which do not possess elastic properties.The new technique allows to analyse the stress-strain state of the Earth as a uniform system and can become the basis for creating new methods for long-term prediction of the stress-strain state of the Earth's crust, dynamics of atmosphere and hydrosphere.
The application of the given technique when studying physical state of the Earth allows to use in the most comprehensive way the information contained in processed input data and to reduce largely unproductive expenditures of material tools, expended for their deriving. The new technique is an effective analytical tool for the deepening of existing and deriving of new knowledge about the real physical world.

SOURCE PARAMETERS OF THE TWO RECENT SCR EARTHQUAKES IN THE INDIAN SUBCONTINENT

M. RAVI KUMAR, D. Sarkar (both at National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India, email: postmast@ csngri.ren.nic.in) and S. J. Duda (Institute of Geophysics, University of Hamburg, Bundestrasse 55, 20146, Hamburg, Germany, email: duda@dkrz.de)

The Latur earthquake of 29 September, 1993 with an Mw of 6.2 and the Jabalpur earthquake of 21 May, 1997 with an Mw of 5.8 are two examples of the recent SCR earthquakes in the Indian subcontinent. From the P- wave portions of the broad-band data from several stations of the IRIS and GEOSCOPE networks, we derive the parameters like corner frequency, seismic moment, energy, fault length, stress drop and apparent stress, of these earthquakes using the concept of magnitude spectrum (Duda and Yanovskaya 1993, 1994). This study reveals that for each of these earthquakes, the corner frequency estimates from different stations are relatively consistent. While the fault length for the Latur earthquake is found to be 4.8 km, a larger fault length of about 5.7 km is estimated for the Jabalpur earthquake, although the moment magnitude of the latter is smaller. Also, the Latur earthquake indicates a stress drop and apparent stress, which are 5 times higher, compared to the Jabalpur earthquake.
These observations support the view that the Latur earthquake could have occurred due to a relatively new fault in the Deccan traps, while reactivation of a pre-existing fault in the Narmada-Son lineament zone is responsible for the Jabalpur earthquake.

EARTHQUAKE AS A FINAL STAGE OF CREEP

Vitali A.MORGOUNOV (Institute of Physics of the Earth, Moscow 123810, B.Grusinskaya 10, Russia, email: vam@uipe-ras.scgis.ru)

Critical stresses in the interior before the shock are favorable for development of the last, accelerated stage of creep. Creep process, being the more general phenomenon do not always ends with seismic event, that is the physical basis of occurrence of false alarm. Thus, earthquakes can be considered as a display of the general creep motions in the Earth crust, which is important for estimations of reliability of the short-term forecast of earthquakes. Great variety of the earthquake precursor's signature is one of the obstacles to understand the mechanism of its generation. The results of experimental study of short-term precursors carried out in different seismic regions during earthquakes of various energy, depths and at epicentral distances are discussed. The comparison of the records of different geophysical parameters showed that the upper layers of the Earth crust follow after the dynamic of stress-strained state in the focal zone. Consideration of the process of tertiary creep under relaxing load makes possible to explain in the term of Relaxation Creep Model different images of the registered pre-seismic short/immediate-term anomalies in geophysical fields like abnormal electromagnetic and acoustic emission, atmospheric-electric and geochemical parameters at the period just before the earthquake. The experimental estimations of the prognosis probability of the time of impending earthquake in a short-term scale are submitted.

AN ANALYSIS OF THE STAGES OF ACOUSTIC ACTIVITY IN THE LABORATORY EXPERIMENT

SOBOLEV G.A., Ponomarev A.V. (United Institute of Physics of the Earth, Russian Academy of Sciences, Moscow, 123810, B.Gruzinskaya, 10, Russia, email: sobolev@uipe-ras.scgis.ru)

The distribution of hypocenters of acoustic signals of the different energy classes was studied in the course of artificially restrained formation of a macrodestruction source in a granite sample deformed under triaxial compression. The formation of the source is followed by a sudden rise in acoustic activity and by reduction of the external load. The relative frequency of appearance of signals of low energy classes is concurrently reduced, whereas that of higher energy classes increases. The change in this parameter is observed prior to reduction of the outer load, i.e., it represents the prognostic indicator. The distribution of acoustic signals within the zone of the forming source and outside it is different. Inside the source zone, the relative frequency of the appearance of signals of low energy classes is reduced and, consequently, it increases in the outer zone. The signals of high energy classes are characterised by inverse relation. The formation of the source, therefore, takes place during transition of cracking from the lesser to the larger scale level. The development of the source has the stage of acoustic quiescence, during which again occurs the relative increase in the frequency of appearance of signals of low energy classes. The chains of clusters of acoustic signals of different energy classes were investigated. Their appearance precedes both the formation of the zone of the source on the whole and the separate large events within the source. This approach allows to indicate the deterministic part of acoustic activity and thus create the more predictable model of process. The distribution of hypocenters of clusters indicates the area of the future source. It is presumed that the effects and stages of acoustic activity recorded in the course of the analysis of data of the laboratory experiment can be applied to reveal the earthquake sources and to keep track of their development. The work is supported partly by RFBR grants.

EFFECTS OF LARGE SHEAR LOAD PERTURBATIONS ON FRICTION AND HEALING IN SIMULATED FAULT GOUGE

Stephen KARNER and Chris Marone (both at Dept. Earth, Atmospheric and Planetary Sciences, MIT, 77 Massachusetts Ave, Cambridge, MA, USA, Email: slk@berea.mit.edu)

Many characteristics of faulting can be described by the laboratory based rate and state friction laws. However, few laboratory studies have investigated the frictional response to large, rapid loading variations likely to occur in the spatio-temporal vicinity of dynamic rupture. To explore the effects of large loading perturbations on fault restrengthening, we have performed experiments on layers of quartz fault gouge in a biaxial testing apparatus at room-temperature and humidity. We modified the conventional slide-hold-slide (SHS) technique by rapidly reducing shear load prior to holds, and we vary shear load for holds (thold), hold time (th), loading rate, and initial layer thickness (T0). Healing (Dm) is defined as the difference between reload peak friction and pre-hold sliding friction. For all tests, gouge layers dilate during reloading and the amount of dilatancy is greater for larger Dm. With decreasing thold, we observe a systematic increase in Dm and layer compaction. For increasing T0, we observe a similar increase in Dm and layer compaction. For zero-load SHS tests we observe decreasing Dm and increasing layer compaction for longer th. This time-dependent weakening is a consistent feature of our zero-load SHS data, independent of loading rate and T0. Direct measurement across gouge layers show a reversal of slip direction as shear load is reduced (10's _m). This observation, coupled with our compaction data, suggest that gouge deformation during hold cycles occurs in two stages: 1. during unloading, considerable gouge compaction and some slip reversal promotes large initial restrengthening dependent only on _hold and T0; 2. during holds, time-dependent gouge compaction is associated with processes that counteract the initial restrengthening, resulting in time-dependent weakening. We have performed numerical simulations using the Dieterich (1979) and Ruina (1983) rate and state friction laws and find that healing predictions do not match the systematic observations from our data. The Dieterich law underpredicts the observed _hold dependence of healing, while the Ruina law fails to match the trend. Neither law predict the healing levels nor the time-dependent weakening shown by our data.

SOURCE PARAMETERS OF WEAK CRUSTAL EARTHQUAKES OF VRANCEA (ROMANIA) INFERRED BY WAVEFORM INVERSION

Luminita ARDELEANU and Mircea Radulian (both at National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: ardel@infp.ifa.ro) Jan Sileny (Geophysical Institute, Acad. Sci. Czech Republic, Prague, Czech Republic, email: jsi@blboun.ig.cas.cz) Giuliano Francesco Panza (Department of Earth Sciences, University of Trieste, 34127 Trieste, Italy, email: panza@geosun0.univ.trieste.it)

The inversion of high-frequency waveform data is used to determine the source parameters (seismic moment tensor, hypocenter depth, source time function) and their reliability, for 14 shallow, weak events, distributed in the crustal seismogenic zone, located at the major bending of the Carpathians Mountains. The source is described by the unconstrained moment tensor, which is subsequently decomposed in a volumetric (V) component, a compensated linear vector dipole (CLVD) and a double couple (DC). The Green's functions needed to extract the moment tensor rate functions from the observed seismograms are computed using the multimodal summation method in layered anelastic media. The observed data are digital waveforms recorded by the Romanian telemetered network (epicentral distances up to 150 km). Using four-station configurations the method allows to get the focal mechanism of small events, for which the standard procedures, based on amplitudes of first arrivals, are not providing reliable determinations. To diminish the effects of the inexact structural modelling, consequence of the few available data, an averaging procedure is used to constrain reasonably the source mechanism and the source time function.

A NEW LIGHT ON ARRESTING MECHANISM OF DYNAMIC EARTHQUAKE FAULTING

Nobuki KAME (Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, 6-10-1 Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan, Email: kame@geo.kyushu-u.ac.jp) and Teruo Yamashita (Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi, Bunkyo-ku, Tokyo 113-0032, Japan, Email: tyama@eri.u-tokyo.ac.jp)

Classic analyses have shown that dynamic growth of a shear crack cannot be arrested in a uniformly stressed elastic medium with homogeneously distributed fracture strengths. This leads to a general supposition that earthquake rupture growth is arrested by inhomogeneities in the distributions of strengths or stresses. We propose a novel idea for arresting mechanism of dynamic crack growth in the simulation with no constraints on the crack geometry. Our analysis shows that the arresting occurs spontaneously soon after crack bending even in the homogeneous medium and that inhomogeneities are indispensable not for stopping crack growth, but for its promotion.

PERIOD DOUBLING OF STICK SLIP CAUSED BY HETEROGENEITY IN FRICTION

SHENGLI MA and Changrong He (both at Institute of Geology, China Seismological Bureau, Beijing 100029, China, email: tplabssb@public.bta.net.cn)

Period doubling bifurcation of stress drop is one of nonlinear dynamic phenomena in transition from stable sliding to stick-slip of rock friction. It has been suggested that the onset of period doubling is dependent on stiffness, constitutive parameters and load point velocity.
We find in our frictional experiment on medium-scale samples that period doubling bifurcation of stick-slip occurs due to macroscopic heterogeneity of the sliding surface under conditions for typical stick-slip. The strain measurement shows that the period doubling bifurcation of stress drop results from the alternate occurrence of strain release along whole fault and that along parts of fault, i.e. strong patches of fault.
To better understanding the physics of period doubling as a possible phenomenon in a fault system with two strong patches as has been simulated by the experiment, we conduct numerical analysis using a two- block model based on the rate- and state- dependent friction law. We get a result that is the most analogous to the experimental result. The simulation result indicates that strong block is active in producing stress drop and weak block only triggers stress drop. Based on detailed analysis of the simulation result, the interaction between two blocks and the mechanism of period doubling of stick- slip are discussed.

STATISTICS OF APPARENT STRESS VALUES AND THE EARTHQUAKES GENERATION MODEL

M.V.RODKIN (Geophysical Centre, Russ. Ac. Sci., 117296 Moscow, Molodezhnaya 3, email: rodkin@wdcb.rssi.ru)

Seismic stresses (apparent stress values, stress-drops) have typically unexpected low values and change in a very wide bounds. This poses a problem do these characteristics have a real physical meaning. The problem was examined using the apparent stress values calculated from the Harvard CMT catalogue and from the regional Russian network. Firstly, the tendency of change of typical stress values was examined. It was shown that despite of a very high variability of apparent stress values the typical stress values display a close correlation with the fluid regime as it is suggested for the Earth's crust and subduction zones. Thus, it is reasonably that variations in stress values have a physical sense also. Distribution of apparent stress values obey the lognormal law. This distribution was imitated by the cascade scheme similar to multifractal approach. Difference in strength of rigid asperities and soft zones was modelled this way. It was shown that the used model describes a few empirical relations between earthquake size and apparent stress value. Thus the used model seams reasonable and thus strength of earthquake source zone is a multifractal. Physical models that could explain the multifractal strength distribution and the revealed tendency in change of typical appartent stress values are discussed.

STUDY OF LONG-RANGE INTERACTION BETWEEN SYNTHETIC EARTHQUAKES IN THE MODEL OF BLOCK STRUCTURE DYNAMICS

Alexandre SOLOVIEV and Inessa Vorobieva (International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Warshavskoye sh. 79, kor. 2, Moscow, 113556 Russia, email: soloviev@mitp.ru, vorobiev@mitp.ru)

The phenomenon of long-range interaction between earthquakes is studied by means of modeling of block structure dynamics. Absolutely rigid blocks separated by thin plane faults are considered in the model. The interaction of the blocks along the fault planes and with the underlying medium is viscous-elastic. The velocity vectors, which define the motion of the structure boundaries and of the medium underlying the blocks are, input model parameters. When for some part of a fault plane the ratio of the stress to the pressure exceeds a certain strength level a stress-drop ("a failure") occurs in accordance with the laws of dry friction; it can cause failures in other parts of the same fault or within other faults. In the model the failures represent earthquakes, so a synthetic earthquake catalog is produced. Numerical experiments with simple block structures show that there is the long-range interaction between synthetic earthquakes. This is detected by statistical analysis of the synthetic earthquake catalogs obtained. At the same time increasing the strength level for individual faults to prevent earthquake occurrence on them affect pronouncedly earthquake flows on other faults. This means that the long-range interaction found in the observed seismicity could be explained by considering lithosphere blocks being absolutely rigid in comparison with fault zones, separating them, and the underlying medium.

NEW MECHANISM OF GENERATION OF LOW FREQUENCY VIBRATIONS DURING THE SEISMIC RUPTURE PROCESS IS PREZENTED AS THE MOVING DEFORMATION WAVE

V.V. AKSENOV (1), V. Rudajev (2) and J. Kozak (3) United Institute of Physics of the Earth, Russian Academy of Sciences, 10 B. Gruzinskaya, Moscow, 123810, Russia (2) Institute of Rock Structure and Mechanics, Academy of Sciences of the Czech Republic, V Holesovickach 41, 182 09 Prague 8, Czech Republic

The long period waves, preliminaring stress drop were registrated by laser velocimeter method in shear-slip modeling experiments. Single polar wave profile were always observed after integration. The wave amplitude is reduced with distance from fault zone and became zero. Spectral structure of acoustic signal is changed from anomaly low frequency at fault to standard high frequency with distance from foci. These phenomena were observed while carrying out field experiments (rock burst). The observed long period waves in fault zone is interpreted like moving deformation waves. It is represented a contact interaction of two solid bodies at their relative motion by the scheme of contact interaction of mass having slender deforming lines. Relationships between relative velocity and motion value of a contact surface arbitrary point and geometrical form of deformation transverse and longitudinal waves, their velocities and contact lengths are reported. Forms of longitudinal and transverse waves at displacement motion are observed on different models. Deformation wave velocity; velocity and value of displacement of a contact surface of arbitrary point in the course of moving wave of deformation are determined experimentally. Theoretically estimated and experimentally observed spectra of oscillations have been presented. Physical interpretation of observed (laboratory experiments, rock bursts, aftershocks) modulated oscillations, in the shape of interaction of elastic waves and deformation ones is given.

ON THE 3-D FRACTURE AND ITS IMPLICATION TO EARTHQUAKE NUCLEATION

Li SHI-YU, Yin Xiang-chu and Liu Qi-liang (Institute of Geophysics, China Seismological Bureau, 5 Minzuxueyuan Nanlu, Haidian District, Beijing 100081, China, email: lisy@cdsndmc.css.gov); Teng Chun-kai(Institute of Geophysics, Chinese Academy of Science, Beijing 100101, China)

The three-dimensional fracture of rock and other material was investigated. Series of fracture experiments on the extension of oblique non-penetrating cracks in plate specimens of rocks and other brittle solids under uniaxial compression was carried out. These cracks are in the category of compound mode ¢ò-¢ó. The main feature of extension is that a set of non-coplanar double-curvature sub-cracks and a couple of main crack occur along the crack front. The shape of fracture is asymmetric, which is different from mode ¢ó and mode¢ñ-¢ó.
The normal stress criterion of a 3-D brittle fracture of continuum is developed based on the Griffith-Irwin theory. As the results of new method, the shapes of the initial fracture surfaces are described as wide-angle cone with its initial point as its apex. These cones straddle the crack front, and their outline is quasi-helical. Every generatrix of the cone is normal to the maximal principle stress at that point. These results are in good agreement with all the previous experimental results.
There are several characteristics of 3-D fracture, e.g., the initial fractures distribute closely with similar shape. They form self-similar construction, and the number of fractual is about 1.0. In the dynamic process (video recording), the fractures grow one and another but not simultaneously. These characteristics may be significant to the nucleation of the earthquake to interpret the distribution shape of faults (e.g., appearing as en-echelon in the surface of the ground in earthquake center) and the non-coplanar of multiple shocks.

STRAIN FIELD CHANGES DURING FAULT FORMATION, GROWTH, AND SLIP PROCESSES - AN EXPERIMENTAL STUDY

Hironori KAWAKATA (Disaster Prevention Research Institute, Kyoto University, Gokasho Uji, Kyoto, 611-0011, Japan, email: kawakata@rcep.dpri.kyoto-u.ac.jp); Akio Cho (Geological Survey of Japan, Tsukuba, Ibaraki, 305-8567, Japan, email: cho@gsj.go.jp); Takashi Yanagidani and Mitsuhiko Shimada (both at Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto, 611-0011, Japan, email: yasan@rcep.dpri.kyoto-u.ac.jp, shimada@rcep.dpri.kyoto-u.ac.jp)

We analyzed the tangential strain of fault in granite samples, and the onset of relative displacement on experimentally formed faults during triaxial compression tests. We obtained samples having experimentally-formed faults produced by fault-formation processes in a laboratory. The samples were recovered after the peak stress level had been reached, but before the samples were bisected in the triaxial compression tests. After attaching strain gauges around the fault trace on the sample surface, parallel to the fault trace or transversely across it, the samples were compressed again in the same way as previously. Tangential strain localized around fault tips in accord with the static strain deviation due to slip on a fault in an elastic medium. Localization near the fault nucleation region preceded peak stress. Tangential strain never localized at a point which had previously experienced localization, when the sample was again loaded. Our results also show that the onsets of relative displacement (slip) were behind the fault tips.

PORE CREATION DUE TO FAULT SLIP IN A FLUID-PERMEATED FAULT ZONE AND ITS EFFECT ON SEISMICITY - GENERATION MECHANISM OF EARTHQUAKES

Teruo YAMASHITA (Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi, Bunkyo-ku, Tokyo, Japan, email: tyama@eri.u-tokyo.ac.jp)

Spatio-temporal variation of rupture activity is modeled assuming fluid migration in a narrow porous fault zone formed along a vertical strike-slip fault in a semi-infinite elastic medium. Pores are assumed to be created in the fault zone by fault slip. Principle of the effective stress coupled to the Coulomb failure criterion introduces mechanical coupling between fault slip and pore fluid. The fluid is assumed to flow out of a localized high-pressure fluid compartment in the fault with the onset of earthquake rupture. The duration of earthquake sequence is assumed to be muchshorter than the recurrence period of characteristic events on the fault. The rupture process is shown to be significantly dependent on the rate of pore creation. If the rate is large enough, a foreshock-main shock sequence is never observed. When an inhomogeneity is introduced in the spatial distribution of permeability, high complexity is observed in the spatio-temporal variation of rupture activity. For example, frequency-magnitude statistics of intermediate-size events is shown to obey the Gutenberg-Richter relation. Rupture sequences with features of earthquake swarmcan be simulated well when the rate of pore creation is relatively large. For example, such sequences generally start and end gradually, and no single event dominates in size in each sequence. In addition, the b values are shown to be unusually large. These are consistent with seismological observations on earthquake swarms.

A MECHANICAL MODEL FOR EARTHQUAKE NUCLEATION

F. Fattori SPERANZA, V. Sgrigna (both at Dipartimento di Fisica, Universita' Roma Tre, Via della Vasca Navale 84, 00146 Roma, Italy, email: SPERANZA@amaldi.fis.uniroma3.it, Sgrigna@amaldi.uniroma3,it); M. Caputo (Dipartimento di Fisica, Universita' degli Studi "La Sapienza", P.le Aldo Moro 2, 00185 Roma, Italy); R. Console (Istituto Nazionale di Geofisica, Via di Vigna Murata 605, 00143 Roma, Italy)

A 3-D model is developed in order to simulate the occurrence of earthquakes in a seismogenic region characterised by a domain of both parallel and collinear interacting faults, spatially non-homogeneous. The Amonton's law with non-constant friction coefficient is applied to the fault domain. Each fault is supposed to be constituted by a matrix of n*m square elements of equal dimensions. Both cohesion and friction coefficient increase with depth up to 20 km, which is a good representation of the observed seismogenic layer. At greater depths, it is supposed that many earthquakes with very small magnitude are nucleated with the condition that cohesion and friction values are much smaller than those assumed for the upper layer. In this way, the a-seismic creep is simulated. Every fault surface element is supposed to be locked until the occurrence of a seismic event (e.g. non seismic slip takes place in the seismogenic layer). We assume that the friction coefficient is not slip- and rate- dependent, but that it is time-dependent. The time intervals corresponding to the variation of friction are chosen randomly in the range 10-100 year, which is the period necessary to allow the stress to reach the fault strength. Empirical features as the Gutenberg-Richter's relationship and the Omori's Law are expected to be fit by our model. Further refinement of the model is obtained by applications to experimental data.

MEDIUM TERM FORECAST ON NOVEMBER 18, 1997, M=6.7 EARTHQUAKE IN GREECE

ZAVYALOV A.D. (United Institute of Physics of the Earth, Russian Academy of Sciences, str.B.Gruzinskaya, 10, 123810 Moscow, Russia, tel. +7(095)254-2478, fax +7(095)254-2478, email: zavyalov@uipe-ras.scgis.ru.

In the beginning of 1997 the MEE algorithm (Map of Expected Earthquakes), based on physics of a seismic source, results of physical modelling and research of a seismic regime, was used for maps of expected earthquakes computation for Greece. The informational basis of work was the catalogue of earthquakes for 1964-1995 (about 55 thousands of events), kindly given by the Greek colleagues from the Geophysical Laboratory Aristotel University of Thessaloniki. The algorithm allows calculating the maps of spatial distributions of conditional probability of strong earthquake appearance with use of a complex of geology-geophysical prognostic indicators, each of which has the certain physical sense. Two types of indicators are used: dynamic, fast varying on the time intervals, that are essentially smaller as compared with time preparation of strong earthquake, and quasi-stationary, slowly changing its values. As dynamic prognostic parameters b-value, density of seismogenic ruptures Ksr, number of weak earthquakes, released seismic energy of weak events E**2/3 were selected. A role of a quasi-stationary indicator performed the map of seismotectonic faults of Greece. The retrospective analysis of maps of expected earthquakes has shown, that 48% of target earthquakes with Ml>=5.5 happen in areas with conditional probability P(D1|K)>70%. The square of these zones does not exceed 20% from total square of observation area. On the last map of expected earthquakes with the prognostic period 1996-2002 a number of zones with increased probability of target earthquake appearance in them are revealed. The obtained results were presented on the S7 symposium on 29-th General Assembly of IASPEI in August 1997 (Greece, Thessaloniki). In one of zones located in 200 km to a southwest from Athens, on November 18, 1997 has taken place earthquake with M=6.7. The work has been executed under financial support of RFBR, project 94-05- 16114.

THE USE OF AN OUTLIER DETECTING METHOD IN TIME SERIES OF CONTINOOUS DAILY MEASUREMENTS OF UNDERGROUND WATER LEVEL AND TEMPERATURE IN EARTHQUAKE PREDICTION INVESTIGATION

D. Arabelos, G. ASTERIADIS, M. Contadakis (all at Department of Geodesy and Surveying, Aristotle University of Thessaloniki, Univ. Box 444, GR-540 06 Thessaloniki, Greece,
email: aster@eng.auth.gr); G. Zioutas (Division of Computational Methods and Programming, General Departmrent, Faculty of Technology, University of Thessaloniki, Greece); Xu Daoyi, Zhang Cunde, Zheng Binghua (Department of Geology, State Seismological Bureau, 100029 Beijing, China)

Two years continuous daily measurements of underground water level and temperarure have been performed in four selected shallow wells in a seismic area close to Thessaloniki, Greece. A graphical method has been applied for the analysis of these water level and temperature time series in order to detect outliers. The magnitude of the changes of the underground water level, characterized as outliers, varies from 3 to 10 cm, and the corresponding changes of the temperature varies from 0.3 to 0.8 degree centigrade. Combining the resulting outliers with the seismic activity observed in the same time period and in the same area, a high correlation was found in the case od the water level time series. In the case of the water temperarure time series the correlation was lower. Most of the outliers were detected in a time interval which varies from 1 to 7 days before or after the earthquakes. The strongest outliers found, correspond to earthquakes with M > 3.0. The software developed is able to detect outliers, in the time series of continuous daily measurements, at the time of their occurrence, using only the previous observations. This is very important in studying precursory phenomena of forthcoming earthquakes.

AN ANALYSIS OF LONG-TERM SEISMIC QUIESCENCE BEFORE THE GREAT HYOGO-KEN NANBU, JAPAN, EARTHQUAKE ON JANUARY 17, 1995

FU ZHENGXIANG and Liu Geiping (Center for Analysis and Prediction, China Seismological Bureau,63 Fuxing Avenue, Beijing, 100036, China. Email: fzx@ip.cap.ac.cn); Ando Masataka, (Research Center for Earthquake Prediction, DPRI, Kyoto University, Japan)

The great Hyogo-ken Nanbu, Japan, earthquake 7.2 on January 17, 1995 was located at 34.595 N, 135.036 E. The aftershock area of about 25km x 70km trended northeast to southwest. The aftershock area is considered to the source area of the mainshock, where the temporal variation of seismicity before the mainshock has been studied here. The earthquake data (1976.1 to 1995.1) used come from the seismic data-base compiled by DPRI, Kyoto University, Japan. The minimum magnitude of completeness was considered as 2.0 by the magnitude -- frequency relation. The research show that there was a period of about 6.5 years of seismic quiescence from July 25, 1988 to January 16, 1995, the seismic rate in the period decreased by 34 percent comparing to a background seismicity rate from January 1, 1976 to July 24, 1988; the difference between the rates in two periods is obviously at the significant level 90 -- 95 % by statistically Z--test method, the calculated Z value is equal to 1.78. The seismicity had an increase in a short-term of several days prior to the mainshock occurrence.

PREDICTION MODELS OF THE TIEN-SHAN SOURCE ZONES LOCATION

Elena MUSIENKO (Institute Of Seismology, Nas Kyrgyz Republic, Asanbai 52/1, 720060 Bishkek, Kyrgyzstan, email: kis@imfiko.bishkek.su; itmc@imfiko.bishkek.su); Alexander Lobanchenko (Institute of Geology NAS Kyrgyz Republic, Erkindik avenue 30, 720000 Bishkek, Kyrgyzstan)

The approch to modeling mathematicaly the source zones location was applied at the Tien-Shan region. We used method of purposeful classification and objectives ordering to calculate possible Mmax through polymeasured linear correlation between geological and geophysical parameters and the strongest earthqauke sources (M >6.0) space distribution. 24 primary parameters were selected to characterize the deep structure, recent tectonics and seismicity at the region. We chose four reference patters at the three main Tien-Shan tectonic areas which are significantly different. The estimation of correlations between parameters mentioned above and strongest earthquake sources space distribution has shown that number of parameters and their informative weights are not the same for different reference patterns. However following four parameters: small earthquakes density on 100 sq.km; summary velocities of the vertical tectonic motions for Recent period; transformed gravity field and Vp velocities for the upper

crust (depth is about 30 km) remained among informative ones invariably. Quality of recognition of the source zones location depended on choice reference pattern. From 55% to 77% strong events (M>6.0) occured in past were discerned by 4 prediction models. Numerical models included past and new sources zones that are similar in general.

PHYSICS OF THE SEISMIC SOURCE AND EARTHQUAKES PREDICTION

Ponomarev A.V., Sobolev G.A., Tyupkin Yu.S., ZAVYALOV A.D. (all from United Institute of Physics of the Earth, Russian Academy of Sciences, str.B.Gruzinskaya, 10, 123810 Moscow, Russia, tel. +7(095)254-2478, fax +7(095)254-2478, email: zavyalov@uipe-ras.scgis.ru.)

The complex of laboratory and field researches of physical substantiation of new methods of seismic hazard evaluation and prognosis of earthquakes was carried out.
It was established as result of laboratory experiments, that the model of a seismic source passes some main stages during its development: accumulation of small-sized ruptures up to a critical level; association of cracks with formation larger and localization of this process in a zone of an unstable strain. These stages are accompanied by prognostic effects of clusterization of acoustic emission, quiescence and forshocks activation.
On a basis of the physical modelling regularities the algorithms were offered and the programs for revealing places of the developing sources, time and magnitude of appropriate earthquakes were compiled. The medium term forecasts in real time of two earthquakes with M=7.0 (June 21, 1996) and M=7.7 (December 5, 1997) on Kamchatka are carried out. The information basis of work was the regional catalogue of earthquakes (more than 60 thousands of events) and laboratory catalog of acoustic emission (more than 100 thousands of events). The suggested approach is shown to be effective for using in real time warning systems.
The work has been executed under financial support of RFBR, projects 96-05-65439, 97-05-65906 and 99-05-65447.

PREDICTION OF THE LARGEST EARTHQUAKES WORLDWIDE SINCE 1985

Vladimir KOSSOBOKOV, Leontina Romashkova (both at International Institute for Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, 79-2 Warshavskoye Shosse, Moscow 113556, Russia, E-mail: volodya@mitp.ru)

The hierarchical approach to earthquake prediction has been statistically verified at the 99% confidence level recently. In became possible due to the on-going systematic real-time testing in the Pacific Rim and to abnormal rise of global seismic energy release during 1993-1996 that produced enough magnitude 8 events for the conclusion. Statistical validity of predictions by the reproducible algorithms M8 and MSc confirms the underlying paradigms: existence of robust premonitory seismic patterns, large size fault system involved in formation of the phenomena at the scale of years, their partial similarity in a wide range of tectonic environment, and their certain universality. We have analyzed in detail case histories of all the recent great earthquakes (with magnitudes 8 or above) within space-time of intermediate-term predictions in attempt to find short-term rise of seismic activity close to the epicenter of approaching large earthquake. This phenomenon is observed before some of the great earthquakes (e.g. 4 October 1994, Shikotan Island, M=8.2 event), but in some cases it is hard to reveal due to evident incompleteness at small magnitudes of the global data bases available. Thus, in such regions better catalogs of earthquakes are needed for next refinement of intermediate-term predictions on a regular basis. On the background of intermediate-term prediction the short-term precursors could become distinguished. Without the intermediate-term stage they could be lost easily in the seismic static.

EARTHQUAKE PREDICTION CASE HISTORIES IN VRANCEA (ROMANIA) AREA

V. MARZA (Seismological Obs., Univ. of Brasilia, Brasilia-DF, Brazil, email: marza@unb.br); V. Burlacu (Center for Monitoring Research, Arlington, VA 22209, email: burlacu@cmr.gov); H. Sandi (INCERC, Bucharest, Romania, email: sandi@cons.incerc.ro); H. Shimamura (Lab. for OBS, Hokkaido Univ., Sapporo, Japan, email: shima@lobs.sci.hokudai.ac.jp); A. Pantea (Seismological Lab., NI[R&D]EP, Bucharest, Romania, email: pantea@infp.ifa.ro)

Vrancea Seismogenic Zone [VSZ] is a conspicuous active area in terms of its: (A) extraordinary seismotectonic characteristics (extremely compact subcrustal source, impressive seismic energy release rate or a rare 'event' in terms of hypothesis of a terminal phase of detachment of a subducting slab), (B) outstanding persistent and highly recurrent seismicity [SE] displaying a remarkable regularity in occurrence of large events and manifestation of a plethora of (geo)physical precursors [PRs]; (C) severe socio-economic impact (i.e., 4-5 damaging events a century) with huge felt and meizoseismal areas. During the 1985-1989 period a joint Japanese-Romanian earthquake prediction [EqP] program was underway in VSZ and along the time EqP and hazard evaluations were carried by various teams as well.
The last two major VSZ events, i.e., the 1977 (Mw=7.4) and 1986 (Mw=7.2) were successfully forecasted and respectively anticipated. The forecasting (long term EqP) of the 1977 event was based on salient regularity patterns in long-term strong SE (cyclicity and paired occurrences) displayed by all large events (Mw ≥7) during a time span more than a millennium. The anticipation (medium term EqP) of the 1986 event was based on a variety of precursory SE patterns including: preseismic quiescence, hypocentral migration, b-slope change etc ('a priori' reported), but also other PRs: seismic (e.g., foreshocks), geophysical (an underground microtemperature anomaly or a telluric current observation) and biological ones, or parameterized EqP algorithms were observed.
Currently a forecast for the next major (Mw ≥7) VSZ event is attempted with the approximate time window: 2006 ± 7 yr and magnitude range Mw=7.3 ± 0.3 unit; obviously the space interval is not crucial as the spatial extent of the VSZ is only 80x35 km2 (certainly the depth range should be of more interest, but this parameter could be inferred when some physical PRs, e.g., seismic quiescence, would be detected). All the above case histories are presented, discussed, refined and evaluated for their causal, informational and predictive potential.
Finally we like to emphasize (based on past history) the good prospects and likeliness for observation of PRs and predictability of VSZ major events and in turn we advance/contemplate the following…

STUDY ON THE QUASI DYNAMIC FACTORS IN THE APPLICATION OF EARTHQUAKE PREDICTION

Wang LINYING, Zhu Chuangzhen and An Zenwen (Institute of Geophysics, China Seismological Bureau.Beijing, 100081,China. email: Zhucz@ihw.com.cn)

Earthquake process consists of a complex macro-system, based on the concept of modem physics, there are two fundamental features of macro-system: dissipation and catastrophe. Dissipative function is illustrated by invariability of time-inversion during the violating rule of macroscopic movement, while, catastrophe means that a series of instability corresponding to the violation of symmetry in time. Thus, it is essential in earthquake prediction research, to probe the dissipative function in the preparatory process of earthquake and instability of temporal evolution. It is reasonable to assume that the earthquake preparatory system develops into a self-organized critical state just prior to the occurrence of large earthquake than the characteristics of system should be indicated by special dynamic patterns. In the paper we pay more attention to the selection of relatively independent predicting factors from non-linear dynamics point of view, as well as to the efficiency of prediction through strict stochastic test. Considering the clustering, orderliness and instability shown in the precursory seismic pattern, seismic entropy, multi-fractal dimensions, algorithmic complexity and Hurst index are selected as predicting factors. By use of scanning analysis, more than hundred earthquake cases in Chinese Continent have been studied from 1970 to 1998 and rigorous statistical test is carried out to estimate the efficiency of earthquake prediction. The results indicate that the factors selected above exhibits a certain efficiency of prediction than the random forecast, and false alarm can be greatly reduced by using multi-factor comprehensive prediction method.

THE EARTH TIDE OBSERVATION IN CHINA AND ITS APPLICATION STUDIES ON PRIDICTION OF EARTHQUAKE

Yaibin ZHANG , Jun Jiang, Shengle Li, and Daihong Yan(all at Institute of Seismology, China Seismological Bureau, Wuhan, 430071, China)

There are more than 100 observation stations of the earth tide(tilt, strain and gravity) in China, they belong to the Seismological Bureau of China and about 40 stations are in good working. Their main purpose is for monitoring and observing of the seismic precursor and predicting of earthquake. In this paper, the progressive development of studies how to use the earth tide observation on earthquake prediction in China is introduced systematically in several aspects as below:
(1).The analysis of the earth-tide observation data and study on catch information of precursor abnormal. The main methods are: (a).The characteristic parameters that relate to the elasticity of crust media are analyzed based on the tide theory. The results can show the effect of elasticity change in the seismic process. (b).By using of some mathematical methods such as fit-testing, filtering, testing, spectral analysis etc, to catch the interference information in observation by that seismic effect. c.The application of the theory of response ratio by tidal load and unload. (2).The statistical analysis results of the scope of monitor ability of the earth tide observation. (3).The testing evaluates of the various precursory parameters. (4).The synthetic analysis method of the precursors information. (a).To get physical characteristic parameters synthetically from earth tides observations considering its physical properties. (b).Synthesis many different observational anomalous information in some spots or area. (5).The study on some examples of earthquake. (a).The analysis on precursors of the Ms 7.0 Lijiang earthquake took place in Feb, 1996 is carried on by using the earth-tide observations in Yunnan and Sichuan area, China. (b).To show the analysis results of precursory anomalous of Ms 6.2 earthquake happened in Zhangbei, Hebei province, China in 1,1998.

RELIABILITY OF FORECAST AND LUNAR HYPOTHESIS OF EARTHQUAKES

Yury A. BRAGIN, Oleg A. Bragin (both at Novosibirsk State University, 630090 Novosibirsk, Russia, email: obragin@phys.nsu.ru); Vasily Yu. Bragin (United Institute of Geology, Geophysics and Mineralogy, Ac. Koptyug prospekt, 3, 630090 Novosibirsk, Russia)

It is established that the global component of a geoelectrical field contains electrical precursors of earthquakes. We isolated these precursors and observed that they arise in some tens hours before the earthquakes manifest itself on a surface of the Earth. The comparison of time when a precursor appears and the real earthquake occurs revealed the following experimental facts. (1) If during the forecasted period no electrical precursors of the large amplitude appeared, then no strong earthquakes occurred on the Earth at this time. There were no exceptions from this statement for four years of permanent monitoring. (2) Time interval between the moment of registration of an electrical precursor and the moment of appropriate earthquake is approximately constant. (3) As a first approximation, the magnitude of an electrical precursor is proportional the earthquake magnitude expressed in Mb. The last two statements allow forecasting the time and magnitude of earthquakes with reliability 60-70%. The unreliability arises mainly due to lacking of global information about powerful earthquakes. On the basis of prevailing positive experience of the forecast one can make the conclusion about presence of a periodic factor, that influences substantially on the earthquake dynamics. We believe the lunar influence is this factor. At the certain stage of formation of earthquake the processes in seismically stressed points become especially sensitive to periodic change of gravitational influence of the Moon.

THE PREDICTION OF EARTHQUAKES (PE) AND EM PARAMETERS OF SEISMIC SOURCES (SS)

A. P. NAUMOV (D.I. Mendeleyev Institute for Metrology, St. Petersburg, 198005, Russia, email: slovo@mail.line.ru)

Many field observations of electromagnetic (EM) tectonic signals, which researchers realized for last 20 years in different regions, have shown a direct relation of these signals with the possibility of PE. We shall select only some observations as undoubted possibility short-term PE on EM and magnetic signals within the range of frequencies from 0 to 10 Hz, when high-speed magnetometers with the optical pumping (MOP) can be applying. The installation of the vector MOP in the corners of equilateral triangles with sides 20-50km gives the possibility to define power, time and coordinates of the sources of expecting earthquakes on results of components measurements in the zone of coherent EM signals. This measurements made with MOP allows to cover seismic hazards area using a small number of instruments. Nature of SS can be better understood, if we produce the physical models of SS and process of earthquake. This model-process consist of several stages: the first - accumulation of tectonic energy (months, years); the second - preseismic preparation, when all precursors are registered (hours, weeks); etc. Specific sequence of the EM tectonic signals corresponds to each stage. We considered different aspects of both models, made quantitative estimates some EM parameters of SS in all stages. Differences between EM tectonic signals and signals of ionosphere are discussed.

A POSSIBILITY OF SHORT-TERM PREDICTION OF ORIGIN TIME FOR DISASTROUS EARTHQUAKE IN SOUTHERN KURIL ARC

Ivan Tikhonov (Institute of Marine Geology and Geophysics, Far East Branch of RAS, Yuzhno-Sakhalinsk, Nauka street, 693002 Russia, email: tsunami@sakhmail.sakhalin.ru); Alexander MALYSHEV (Institute of Geology and Geochemistry, Urals Branch of RAS, Pochtovy per 7, Ekaterinburg, SU-620151, Russia, email: root@igg.e-burg.su)

Satisfactory origin time estimations for disastrous earthquakes with M>=7.5 were obtained from a retrospective short-term prediction in the studied region on the basis of mathematical modeling. The following parameters of seismic process were investigated: a cumulative sum of the number of shocks, the similar sum for energy of earthquakes and square root from the energy. We analyzed the total seismic events flux within the region for magnitude M>=4.0 since 1962. The algorithm was designed to imitate real time processing. The average relative prediction error is within the interval 18-49 %. The first satisfactory results are gained not earlier than 100 days before the main shock, however, in one anomalous case - 2.7 days before. This technique has been tested for more than 10 years and now is fit for experimental predictions of Kuril earthquakes. We plan to combine it with intermediate-term prediction algorithms (first of all with the M8 algorithm), that gives a significant reduction of failures-to-predict. We have now good possibilities to realize a prediction scheme in two steps: intermediate first and then short-term. Thus, the alarm is declared by the M8 algorithm since 1996 to 2001 within the studied region for earthquakes with M=7.5-7.9. Trial calculations show, that our prediction methods, probably, will be perspective for using in other regions.

FORESHOCK ACTIVITY BEFORE THE STRONG EARTHQUAKE AS A PRECURSOR FOR LONG TERM EARTHQUAKE PREDICTION

PHAM DINH NGUYEN, Pham Quang Hung, Nguyen Dinh Xuyen, Institute of Geophysics Vietnam National Center for Natural Science and Technology, Cau Giay - Hanoi - Vietnam.

Using the seismological data of ISC in the period 1965-1993 the authors have studied the variation of seismic activity in the focal area of earthquakes (Mb >= 5.0) in the region limited by 20N =< lat. =< 30N and 95E =< long. =< 105E. Seismic activity is characterized by total of number N of earthquakes in interval of time dt = 5 years and its variation is expressed in the graphs (N , t), where t is observation time. We can see on the graphs that the foreshock activity is clearly observed in many cases, among them are all the cases of earthquakes of magnitude Mb >= 6.0. This activity may be begun about 10 or 15 years before the main shock. In this period the seismic activity is gradually increased. The observed fact indicates that the foreshock activity is a precursor for long term earthquake prediction.

ST1/E/42-A3 Poster **0900-14**

SUCCESSFUL PREDICTIONS FOR THE KRONOTSKY EARTHQUAKE DECEMBER 5, 1997, M=7.9, KAMCHATKA, AND FOR ITS STRONG AFTERSHOCKS M_6.

Sergei A. FEDOTOV, Sergei D. Chernyshev, Jury D. Matvienko, and Nikolai A. Zharinov (Institute of Volcanology, Far East Division, Russian Academy of Sciences, Petropavlovsk-Kamchatsky, 683006 Russia, email: volcan@svyaz.kamchatka.su)

Successful long-term and mean-term seismic prediction for the Kronotsky earthquake December 5, 1997, M=7.9, occured in subduction zone near the Kronotsky peninsula, Kamchatka and for its strong aftershocks, M_6 has been made by four different methods at the Institute of Volcanology, FED RAS. Their combination includes next ones: long-term seismic prediction based on features of seismic gaps and seismic cycle, algorithm M8, repeated geodetic measurements, application of the found average sequence of aftershocks M_6 which follow Pacific earthquakes M~8.
Regular long-term seismic prediction for Kamchatka made in June, 1997 has shown that the area of the Kronotsky peninsula has become one among two most probable places of earthquakes M>7.7 in Kamchatkan seismic zone for the next 5 years. This result was reported on June 19, 1997.
Algorithm M8 was used to determine mainly probable time intervals for events M_7.5 near Kamchatka. It was reported in April 1996 that such interval for the area of the Kronotsky peninsula is between July 1, 1993 and June 30 1998.
Different geodetic observations were repeated since 1971 at the Ust-Kamchatsk geodetic poligon at distance 100km from the epicenter of the Kronotsky earthquake. Contraction of all measured lines (4_10-6) was detected here at the end of November 1997. Conclusion was made and reported on December 4 1997 one day before the Kronotsky earthquake that earthquake M>7.0 is preparing in its area.
Expected number and magnitudes of strong aftershocks M_6 were predicted correctly after the main shock of the Kronotsky earthquake for the first days, weeks, months and year of aftershocks.

A METHOD TO EXPRESS THE PATTERN OF SEISMICITY ANOMALY BEFORE STRONG EARTHQUAKES AND ITS PREDICTIVE VALUE

Hong CHEN (Institute of Crustal Dynamics, China Seismological Bureau, Beijing, 100085, China; E-mail: hongchen@sdb.csdi.ac.cn, tel: 0086-010-62913865-2107)

Seismic quiescence and seismic clusters within the preparation area of earthquakes are one of the anomalies before strong earthquakes. Here we proposed a method to express seismic quiescence and seismic clusters on a map at the same time and we hope that would be useful to determine the future earthquake position. Two parameters were defined as:;
Here Nij is the number of earthquake with magnitude M≥m in i-th space and j-th time interval, and is the average earthquake number of many years in the same space grid. Eij is the equivalent magnitude of seismic strain release in i-th space and j-th time interval, and is the average equivalent magnitude of many years in the same space grid. China was divided into three seismic areas according to its seismicity level and detection level. Each seismic area was divided into a 1˚x1˚ grid, _N and _E were calculated for each grid using seismic data from 1970 to 1998 (M≥2.5), and the contour maps of _N and _E were got for each time interval (one year). The results show that from 1970 to 1998 there were 68 earthquakes magnitude greater than 5.0 occurred in North part of China, values of _N and _E within the preparation area of 48 earthquakes are great or low obviously. We also calculated another two siesmic area of China. We analysed if it is possible to use those patterns of seismicity anomaly to determine future earthquake position.

SOME EVIDENCE FOR PREMONITORY CHANGES IN SEISMICITY FOR THE 1995 HYOGO-KEN NAMBU EARTHQUAKE: (2) FRACTAL DIMENSION AND ITS CORRELATION WITH B-VALUE

Bogdan ENESCU (National Institute for Earth Physics, Bucharest, Magurele, P.O. Box MG-2, Romania, e-mail: benescu@infp.ifa.ro)Kiyoshi Ito (Disaster Prevention Research Institute, Kyoto University, Gokanosho Uji, Kyoto, 611-0011, Japan, e-mail: ito@rcep.dpri.kyoto-u.ac.jp)

Using the same catalogue as in the first part of our study (but without declustering), we continue our search for possible precursory changes associated with Hyogo-ken Nambu Earthquake. This time we focus our attention on fractal dimension (correlation dimension, D2) evolution in time and the correlation between D2 and b-value and its evolution in time. We use for the computation of D2 the sphere counting method and for b-value determination we use the maximum likelihood approach. In order to see reliability and robustness change of the results, we compute the above functions using different initial inputs; time windows of 100, 200 and 400 events and different minimum magnitudes. The obtained results show that the time evolution pattern of the computed parameters is changing before the Hyogo-ken Nambu Earthquake. We observe also that, for all the period considered, the change of D2 and b-value in time correlates quite well with seismicity evolution (occurrence of events of magnitude bigger than 4, aftershocks and preshocks, earthquake swarms). Approximately 7 years before the Hyogo-ken Nambu Earthquake the correlation between D2 and b value is changed from weak negative to moderate positive. We propose some possible physical explanations for this new earthquake precursor : the correlation between D2 and b.

LOCAL PROBABILITY OF A MAJOR EARTHQUAKE: AN ALTERNATIVE METHOD TO ESTIMATE LOCAL SEISMIC HAZARD, THE EXAMPLE OF GREECE

G.CHOULIARAS (Institute of Geodynamics, National Observatory of Athens, 118 10 Greece, Email: gchoul@mail.otenet.gr);, M. Wyss (Geophysical Institute, University of Alaska, Fairbanks, USA), S.Wiemer (Meteorological Research Institute, JMA, Tsukuba, Japan); George Stavrakakis and G.Drakatos (both at Institute of Geodynamics, National Observatory of Athens, 118 10 Greece)

We assume that the frequency-magnitude relationship contains information about the probability of occurrence of main shocks, P(M), in the volume for which it is valid and that in some areas one can estimate from its parameters a and b the probability for a main shock. If small volumes, comparable in size to crustal asperities, are studied separately, one finds that a- and b-values vary strongly over distances of just a few kilometers. That means that P(M) must vary locally also strongly and we introduce the notion of PL(M), the local probability of a main shock. It is this variation that we intend to map, and we explore its potential for better estimating the local probability for a main shock for the Greek area. The local probability of a main shocks that we estimate may be useful for identifying locations where major earthquakes are most likely, and from where ruptures of large earthquakes may emanate. We don't argue that the standard engineering approach of estimating accelerations should be replaced by estimating PL(M). Instead, we propose that PL(M) gives a complimentary estimate of seismic hazard, and that in the future the standard engineering approach may be improved by using local a- and b-values within the seismic source volumes, instead of bulk values.

THE SEISMIC RISK MAP OF VIETNAM USING THE GUMBEL'S THEORY

PHAM QUANG HUNG Nguyen Ngoc Thuy Institute of Geophysics Vietnam National Center for Natural Science and Technology, Cau Giay,Hanoi, Vietnam.

In this work, a seismic risk map of Vietnam is constructed using the modified first asymptopic distribution of the extreme values theory. On the basis of the earthquake catalogue of Vietnam the earthquakes with M > 4 of the studied territory was obtained and analyzed. The maximum potential earthquakes that are expected to occur with a 10% exceeding probability within 50 years are estimated in eight seismic provinces. Finite seismic sources of maximum expected potential earthquakes are assumed as seismogenic faults or points located randomly within the meizoseismal areas in each seismic province. Maximum ground acceleration for all points on a grid: 0.16 degree X 0.16 degree (geographical coordinate) are computed by using Boore's attenuation equation and the results are contoured on the seismic risk map of Vietnam.

EARTHQUAKE PREDICTION: PROBLEMS AND RESULTS

Oleg KHAVROSHKIN, Vladislav Tsyplakov and Natalia Vidmont (United Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya 10, 123810 Moscow D242 Russia, Email: khavole@uipe-ras.scgis.ru)

The history of the problem mentioned in the head is full of dramatic collisions. Methods of many branches of modern science are applied for its solving. Thus, we shall invent general aspects of this problem without detail: 1. The monitoring of the energetic state of investigated region. 2. Physical models. 3. The paradigm of the prediction and courses of its deadlock. 4. Nets of seismic stations. 5. What to do: abandonment of the old paradigm, the prediction in the open non-linear system, etc.
The analysis based on the scheme proposed leads to sad prognosis on complete decision of the problem in nearest 10-20 years. The only way is to abandon on the existing paradigm and development of the scheme of operative prediction of individual using (OPIU). We propose the scheme of OPIU that can be realized just now. It is based on the analysis of the emission seismic response of geophysical media in the region learned by the user, to local variations of strained state. We suppose that the great part of seismological information is contained in the emission seismic noise. Thus, this noise must be recorded in dangerous areas permanently.

SEISMIC SEQUENCES IN RILA MOUNTAIN

Blagovesta Babachkova, Tatiana TOTEVA, Snezina Rizikova (Department of Seismology, Geophysical Institute, Ak.G.Bonchev Str., Block 3, 1113 Sofia, Bulgaria, email: toteva@nlcv.net)

This study aims to investigate the sequences in Rila mountain region. The area mentioned above is interesting for some reasons: the lack of strong earthquakes, but this region is closed to active areas especially Kresna seismic zone - the most active region in Bulgaria (Rila region is included in Knopoff space window for 1904 earthquake, M=7.8). Another reason for investigating the Rila Mountain is the observed seismic sequences there. The last seismic swarm occured in 1997. More than 170 events were located in a very narrow area. The waveforms and earthquake recurrence graph were investigated. Great similarity exists in the waveforms for most of the swarm events. Nevertheless, the old sequences in this region were reviewed and an attempt to find a probable relation between them and the strong events was made.

MODEL FREE SEISMIC HAZARD EVALUATION AND ITS APPLICATIONS IN MINING INDUCED SEISMICITY

Stanislaw LASOCKI Andrzej Kijko.

Statistical procedures which are used for the evaluation of seismic hazard assume that the analytical forms of the distribution functions of seismic event magnitude are known. The distribution functions are usually derived from the Gutenberg-Richter relation or its modifications. In most cases, for magnitudes in the middle of the range of distribution, the choice of the model is not crucial, however, it can have a significant effect on estimates related to the upper tail of the distribution which determine the values of seismic hazard parameters. Hence, for example, the occurrence of so called "characteristic" events can drastically change the tail of the magnitude distribution and influences the values of hazard.
The presently used models of magnitude distribution are unable to account for these and other non-linear effects in frequency-magnitude relations, well documented in both natural and mine induced seismicity. It was therefore decided to replace analytical models of the magnitude distribution by kernel-based distributions, which are data-based and non-parametric. To describe the probability density function (PDF) of seismic event magnitudes we chose the Gaussian kernel function and the smoothing factor estimated by means of the least-square minimization of the mean integrated square error. An analysis of several cases of seismicity induced by mining in South African gold mines and Polish copper mines showed that the model-free approach provides much better fit of the estimated PDF of magnitudes to observations and significantly changes the hazard estimates. In some cases the largest event probability obtained from the non-parametric considerations turned out to be changed by several dozens times with respect to its estimate achieved from the Gutenberg-Richter relation based approach.

TOWARDS AN AUTOMATIC APPROACH FOR SEISMIC MOMENT TENSOR INVERSION OF MINE-INDUCED MICROSEISMIC EVENTS

Douglas ANGUS (Queen's University, Kingston, Ontario, Canada, K7L 3N6,
Email: angus@geol.queensu.ca);. C.-I.Trifu and V. Shumila (both at E.S.G. Canada Inc., Kingston, Ontario, Canada, K7K 7G3)

The seismic moment tensor is a valuable tool in the evaluation of seismic source mechanisms because it is the most general representation of any indigenous source. For that reason a seismic moment-tensor inversion approach has been developed by E.S.G. Canada Inc. for retrieval of source mechanisms of mine-induced microseismic data. This method is unique because it is based on a time-domain calculation/evaluation of the seismic moment-tensor components.
The limitations and applicability of this moment-tensor inversion method is tested using a waveform simulation program. This waveform simulation algorithm is sophisticated enough to test the inversion approach for the retrieval of geometrical as well as shear and non-shear components of failure. The results from the waveform simulation tests indicate that the seismic moment-tensor inversion approach is reliable so far as retrieving the geometrical aspects of the seismic source are concerned. Inversions for the double-couple and so-called general mechanism are shown to be robust for the various wavetype solutions, under reduced array coverage, hypocentral mislocation and the addition of Gaussian-normally distributed noise. Errors in first-arrival polarities and low-frequency displacement amplitude are very influencial, though. Although for manually processed data these effects can be significantly reduced, it is anticipated that for automatically processed data that they become quite problematic.
The tests conducted with simulated waveforms indicate that the inversion approach is valid in principle. These tests, however, are only preliminary and more work is needed to completely sanction this method as a standard technique in microseismic source analysis. This is not to suggest that doubt exists about the principles and direction of the method, but simply is a reflection of the sophistication and intricacy of the algorithms and software.

STATISTICAL EVALUATION OF POTENTIAL FOR PREDICTION: THE CASE OF A PARAMETRIZATION OF EPICENTER DISTRIBUTION OF MINING INDUCED SEISMIC EVENTS

Anna LASKOWNICKA and Stanislaw Lasocki (both at Department of Geophysics, Univeristy of Mining and Metallurgy, al. Mickiewicza 30, 30-059 Krakow, Poland, email: anial@geol.agh.edu.pl, lasocki@geol.agh.edu.pl)

Candidates for precursors to targets of prediction are mostly inferred from the knowledge about a physical process controlling the studied phenomena. Before, however, such a candidate is introduced to the prediction system it is reasonable to test its potential for prediction - a step which is often omitted but which can both save further efforts in case of rejection and provide hints on construction of a prediction algorithm in case of acceptation. In our opinion a parameter can be regarded as having the potential for prediction if its values prior to the occurrences of targets of prediction differ statistically significantly from its values at random moments. In many instances simple statistical procedures can determine whether the parameters has a feature like that.
It is expected that an occurrence of a strong event in the local mining induced seismicity is preceded by certain alterations of epicenter distribution of smaller events. Three parameters defined on series of epicenters of successive events were selected as candidates for precursors to strong tremors: the directional coefficient of the temporary linear trend of epicenter distribution, the root-mean-square dispersion around the trend and the statistical coefficient of seismic diffusion. Seismic series connected with individual mining stopes were used to build appropriate experimental and control groups of the parameter values. The study of potential for prediction of every parameter involved comparing locations of the parameter distribution in experimental and control groups by means of the Wilcoxon matched-pair test. If the locations did not differ the Shapiro-Wilk's and Kolmogorov-Smirnov tests were used to check overall differences in the distributions. All three parameters turned out to change significantly before strong event occurrence.

EARTHQUAKE PRECURSORY MODEL FOR KOYNA RESERVOIR, INDIA

H.N. SRIVASTAVA and S.N. Bhattacharya (both at India Meteorological Department, New Delhi-110003, India, e-mail: snb@imd.emet.in)

Koyna region continues to be seismically active with the recurrence of earthquakes of magnitude 5.0 from time to time, which may cause some damage. Based on 12 parameters for 10 months prior to the occurrence of the largest magnitude earthquakes namely number of microearthquakes at Koyna observatory, earthquakes of magnitude 2.0 to 2.9, earthquakes of magnitude ≥ 3.0, total number of epicentres, sense of first motion C, D and percentage ratio C/D at Koyna, and Dilatation at Pune, largest magnitude earthquake, total seismic energy released, reservoir height and change of level per month, a predictive model has been developed using Principal Component Analysis for Koyna reservoir and neighbourhood. This technique has provided deeper insight about the role of different parameters preceding earthquakes of same magnitude in different years. It is shown that the methodology provides an operational model for prediction of earthquakes in Koyna region similar to that used in long range weather forecasting before the southwest monsoon.

SOME ASPECTS OF RESERVOIR INDUCED SEISMICITY IN BRAZIL WITH EMPHASIS ON RECENT CASE HISTORIES

Vasile MARZA, Lucas Barros, Jose Eduardo Soares & Juraci Carvalho (all at Seismological Obs., University of Brasilia, Brasilia-DF, Brazil, e-mail: marza@unb.br or obsis@unb.br); Marcelo Assunpção (Geophysical Department, IAG, University of São Paulo, São Paulo, SP, email: marcelo@iag.usp.br)

The realm of the reservoirs induced seismicity [RIS], has started to mature after more than a half century of investigation and with the increase of both the number and size of reservoirs worldwide RIS turned in a serious issue for its environmental, societal and economic impact. By the other hand, the phenomenology of RIS process is considered a bridge between the laboratory scale and the natural extreme scale in modelling the seismogenesis. In Brazil the matters of RIS have been approached during the decade of '70s when the seismographic monitoring of reservoirs has begun, but during the '80s the interest became greater.
The paper attempts to accomplish a synopsis of the main 15 case histories of RIS in Brazil, to discuss its features (with a taxonomic goal) and to analyze the most recent RIS cases observed in Brazil during 1998, i. e., the principal events at Tucuruí (PA) on March 02 (magnitude 3.6) and and Nova Ponte (MG) May 22 (magnitude 4.0). The main findings of the our work should be: (1) manifestation of a particular category of RIS at some Brazilian reservoirs, i.e., repetition of the mainshocks at a specific reservoir, which we coin it as "repetitive cycle"; (2) a conspicuous time-space precursory seismicity pattern, associated to the 1998 Nova Ponte mainshock, displaying the following stages: early foreshocks - seismic quiescence - immediate foreshocks - mainshock - aftershocks, and a nonrandom spatial configuration of the event population.

ST1/E/16-A4 Poster **0930-05**

INDUCED SEISMICITY AS MANIFESTATION OF FINE STRUCTURE OF GEODYNAMIC PROCESSES

Alexei NIKOLAEV and Vsevolod Nikolaev (both at Joint Institute of Physics of the Earth, Bolshaya Gruzinskaya 10, 123810 Moscow, Russia, email: alex@nikavs.msk.su))

Weak natural and man-made impacts on the Earth's crust - the Earth tide, changes of the Earth rotation velocity, variations of atmospheric pressure, filling of reservoirs, oil, gas and minerals extraction, water pumping in and out, strong earthquakes and underground nuclear explosions - display in their influence upon seismicity.
Sensitivity of seismicity towards inner actions and its response to it - the induced seismicity - has pronounced non-linear character, and is dependent upon fine structure of medium, its stress condition and mechanical instability.
Typical of this reaction is its time changing sensitivity to the outer processes conditioned by temporal changes of stress field in lithosphere; sequence of periods of organised and chaotic behaviour; pronounced connection with separate periodic components of the Earth tide. These qualities allow to reveal typical features of time-spatial dynamics of the stress field, the rate and direction of creep, movement of crustal blocks.
The induced seismicity caused by the Earth tide shows that gravitational action of the Sun and the Moon is one of the causes of tectonic movements performed by wave mistransfer of substance. The fine structure of these movements has the same character as that of the induced seismicity: frequency-selective response to weak inner impacts, spatial mosaic, time instability.

STUDY OF SEISMIC EFFECTS OF MINE BLASTING ON STRUCTURES AT GOL-E-GOHAR IRON ORE MINE S. E. IRAN

Ahmad Sadidkhoi and Abdolrahim JAVAHERIAN (both at Institute of Geophysics, Tehran University, P. O. Box 14155-6466, Tehran, I. R. Iran, email: javaheri@chamran.ut.ac.ir)

In most open pit mines, explosives are used for crushing materials. The seismic waves generated by these explosions can cause damage to near structures, especilly in large mines with great blastings. In Gol-e-Gohar iron ore mine, almost 26000 kg of explosives is used for each blasting. To investigate the effect of blasting on the structures, we recorded seismic signals of two normal explosions by several digital recording systems. Each recording system consisted for a digital data acquisition part and a three component seismometer. The three component of each seismometer were aligned in vertial, radial (towards the blasting location) and tangential directions. For the first explosion, we used a dispersed array of seismometers to find 2-D model of peak particle velocity (horizontal model), which led us to radiation pattern of explosion. This pattern was determined for each component of particle velocity. For the

second blasting, seismometers were aligned in a line to study the effect of distance on the particle velocity. So we enabled to draw the variations of peak particle velocity versus distance. This study showed that normal explosions in Gol-e-Gohar iron ore mine have no destructive effect on near structures due to safety standards.

CHARACTERIZING HYDRAULIC FRACTURE BEHAVIOUR USING MICROSEISMICITY

T.I. URBANCIC, C-I. Trifu, V. Shumila, (Engineering Seismology Group Canada Inc., 1 Hyperion Court, Kingston, ON, Canada, K7K 7G3, email: urbancic@esg.ca) J.T. Rutledge (Los Alamos National Laboratory, Earth and Environmental Sciences Division, Los Alamas, N.M., USA, 87545, email: rutledge@seismo5.lanl.gov) R.J. Zinno (Union Pacific Resources Co., 777 Main St., Fort Worth, Texas, USA, 76102-5398, email: DickZinno@upr.com)

Temporal-spatial variations in event locations, source parameters, and in frequency-magnitude parameters (occurrence rate of seismic activity and b-value) are evaluated for a catalogue of 994 microseismic events (-2.0 # M # -0.5) associated with the Cotton Valley (East Texas, USA) fracture treatment of May 14, 1997. The treatment was carried out between 2756 and 2838 m depth and consisted of three separate injection phases. Event locations were obtained based on P- and/or S-wave arrivals and direction vectors, to an accuracy of 14 to 24 m. Spatially, the event locations were contained within the perforation interval, and outlined a hydraulic fracture 560 m in length and 60 m in width, that was symmetric about the treatment well (TW), and followed the predicted N70E trend. Nearly 50% of the events occurred over the short interval 90m to 120m east of TW. Over this interval, b-values were above 1 during the initial two injections, S- to P-wave energy release values (Es/Ep) were small (<10), and occurrence rates increased relative to other parts of the fracture. During the third injection, the fracture growth eastwards was accompanied by b-values above 1 and Es/Ep values ranging from 20 to 30, suggesting that the failures within the treatment contained non-shear components near TW and were more shear-like with distance east of TW. To the west of TW, b-values ranged from 0.5 to 1 for all three injections, however, the third injection was accompanied by an increase in occurrence rate. Based on these observations, we suggest that microseismic event locations can be used to define the overall dimensions of the hydraulic fracture, and that source and frequency-magnitude parameters can potentially be used to identify differences in fracture growth and failure mechanisms.

EARTHQUAKES TRIGGERING OTHER EARTHQUAKES AS A PRECURSORY PROCESS

G. A. PAPADOPOULOS (Institute of Geodynamics, National Observatory of Athens, 118 10 Athens, Greece, email: g.papad@egelados.gein.noa.gr)

Observations made in California, Greece and elsewhere about earthquake clusterings occurring beyond chance in adjacent or spatially isolated seismic zones, at distances ranging usually between 200 km and 900 km, indicate that some earthquakes are triggered by other earthquakes. When this domino-like phenomenon takes place as a synchronization between two particular zones, then the triggering earthquake is bearing a precursory nature to the triggered one. A geophysical mechanism has been developed to explain (1) how after some initiation the process is accelerating leading to the clustering by rupturing a number of near to failure prestrained regions, and (2) why a preferential correspondance occurs in the case of synchronization. The value of the above observations and modelling for earthquake prediction is discussed on the basis of earthquake triggering examples from Greece. This is a contribution of the ASPELEA Project supported by EU-DGXII - Inco Copernicus, Contract n. IC-15CT-97-0200.

MAN-MADE RISE OF THE LAKE BAIKAL WATER LEVEL AND THE M=6.8 BAIKAL'S EARTHQUAKE OF AUGUST 29, 1959 : COINCIDENCE OR REGULARITY ?

Pyotr DJADKOV (Institute of Geophysics, av. Acad. Koptyug, 3, Novosibirsk, 630090, Russia, E-mail: djad@uiggm.nsc.ru)

The M=6.8 earthquake of August 29, 1959 occurred in the central part of Lake Baikal near the Selenga river delta at depth of 18 km during the initial period of man-made rise of Lake Baikal water level under filling of reservoir of the Irkutsk water-power station. Selenga delta has high level of seismic activity which is developed during the periods of increase of seismic activity in the all Baikal rift zone as a rule. It was showed earlier that the influence of the water level variations on seismicity of this region occurred exactly during the such seismic active periods [Djadkov, 1997]. The M=6.8 earthquake of 1959 took place in time of high seismic activity (1957-1962) in Baikal rift zone and the main energy source of this event was caused by the crustal stress redistribution in this period. However the time of this earthquake fell on the first stage finish of quick rise of the Baikal water level in period of May to September 1959. The quick water level rise was caused summation of the man-made rise and the natural season rise of water level. So far as the induced or triggered seismicity depend clearly on the rate of water load in this place [Djadkov, 1997] the moment of the 1959 earthquake had the close connection with one. So although the energy source of the 1959 earthquake was caused mainly by the high regional seismic activity in 1957-1959 the man-made rise of the Lake Baikal water level could initiate this earthquake and besides the such rise could increase its magnitude.

REGIONAL SEISMICITY TRIGGERED BY THE GREAT HYOGO-KEN NANBU, JAPAN, EARTHQUAKE, ON JANUARY 17, 1995

Fu ZHENGXIANG and Liu Geiping(Center for Analysis and Prediction, China Seismological Bureau, 63 Fuxing Avenue, Beijing, 100036, China. Email: fzx@ip.cap.ac.cn)

The great Hyogo-Ken Nanbu, Japan, earthquake with magnitude 7.2 on January 17, 1995 was located at 34.595 N, 135.036 E. The focal mechanism of the mainshock is a right-lateral strike-slip faulting with trend of N40E. The aftershock area extended about 70km trending northeast to southwest. The regional seismicity triggered by the mainshock is studied here. The studied region is defined as an area of 33 – 37 N, 133 – 138 E around the mainshock epicenter and divided into 16 sub-regions. The earthquake data (1976.1 to 1996.6) used come from the seismic data bank compiled by Disaster Prevention Research Institute, Kyoto University, Japan. The minimum magnitudes of completeness ranging from 1.0 to 3.5 for the different sub-regions are determined by using the earthquake magnitude – frequency relation. The research results show that (1) the high seismicity triggered by the mainshock were observed in 10 sub-regions, where the differences on seismicity rates before and after the triggering time are obviously at the significant level 95% or more by using statistically Z - test method, the maximum of rate changes occurred in the sub-regions near to the aftershock area, the sub-regions of triggered seismicity go as far as about 250 – 280 km from the mainshock epicenter; (2) the high triggered seismicity happened respectively in the first, second and fifth day after the mainshock for 3 sub-regions adjacent to the aftershock area, the triggered seismicity delayed several ten days for other sub-regions far an away; (3) the magnitudes of triggered events are not more than 5.4. The triggering mechanisms are also discussed.

INDUCED EARTHQUAKES ACCOMPANIED BY THE WATER INJECTION EXPERIMENT AT THE NOJIMA FAULT ZONE, JAPAN

Keiichi TADOKORO, Masataka Ando, and Kin'ya Nishigami (Disaster PreventionResearch Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, email: tad@rcep.dpri.kyoto-u.ac.jp; ando@rcep.dpri.kyoto-u.ac.jp; nishigam@drs.dpri.kyoto-u.ac.jp)

After the 1995 Hyogo-ken Nanbu (Kobe) earthquake of M7.2 occurred on January 17, a scientific drilling program called the "Nojima Fault-zone Prove" was carried out at the Nojima fault ruptured during the mainshock. A water injection experiment was executed by the program during the two periods, February 9-13 and March 16-25, 1997. Pressured water (~4 MPa) injected out from one of the three boreholes drilled by the program at depths between 1480 and 1670 m. The total amount of injected water was 258 cubic meters. A seismic observation network was deployed and increase in earthquake was observed 4-5 days after the beginning of each water injection. Because the seismicity increased in the region not far from the injection holes, around 3 or 4 km from the injection point, these earthquakes were likely to be induced by the water injections. Most of the earthquakes were located between 2 and 4 km in depth and had magnitudes ranging from -2 to +1. The values of intrinsic permeability of 10^-2-10^-3 darcy were obtained from the induced seismicity change. The coefficient of friction in an area where the induced earthquakes occurred was estimated to be less than 0.3. The hypocenters of induced earthquakes migrated with speeds of ~5-40 m/h. The speed decreased with time, suggesting diffusion of water. Twenty earthquake clusters were found in terms of waveform similarity. Migration speed of the earthquakes within each cluster also estimated by cross-spectrum method. Moreover, source parameters were computed. The seismic moment ranged from 10^9 to 10^11 N-m. Small values of stress drop, 10^3-10^5 Pa, were obtained.

SEISMIC MIGRATION IN A MINING INDUCED ENVIRONMENT: A CASE OF SPACE-TIME FRACTALITY

David MARSAN, Chris Bean (both at Geology Dept., University College Dublin, Belfield, Dublin 4, Ireland); Sandy Steacy, John McCloskey (both at the School of Environmental Studies, Univ. of Ulster, Coleraine, N. Ireland).

It is observed that the seismicity recorded in Creighton Mine, Canada, in a 6 month period, exhibits scaling both in time (from 1 mn to about 2 weeks) and in space (from the observational resolution of 10 m up to the size of the mine, about 500 m). Temporal migration of earthquakes away from any given earthquake is also statistically observed. We show that both observations are equivalent in terms of dynamical behaviour of the mining system, and argue that space-time fractality is the pertinent framework to explain and model such behaviour.
This model is exploited in order to provide an original method for predicting seismicity level in the mine, based uniquely on scaling.

ACOUSTIC EMISSION AT MATSUSHIRO. ASSOCIATION WITH NEARBY EARTHQUAKES

Andrei V. GORBATIKOV (Institute of Physics of the Earth,B.Gruzinskaya 10, Moscow, Russia, email: avgor70@hotmail.com); Oleg Molchanov (Earth Observation Research Center, NASDA, Tokyo,Japan, email: oleg@eiorc.nasda.go.jp); Masashi Hayakawa (University of Electro-Communications, Chofu,Tokyo, Japan, email: hayakawa@whistler.ee.uec.ac.jp); Seiya Ueda, Katsumi Hattori, Toshiyasu Nagao and Paul Maltsev (all RIKEN, Earthquake International Frontier Project, Shimizu, Japan,(email: hattori@iord.u-tokai.ac.jp)

Acoustic Emission (AE) intensity was recorded at Matsushiro station (Nagano Prefecture, Japan) in the special tunnel inside rocky mountain at depth about 100 meters. Sensitive 3-component AE receiver with frequency response proportional to cube of frequency and four narrow-band filters: 30, 160, 500, 1000 Hz was used. We analyzed the envelopes of the filters averaged in 30-minute samples for 7 months period from February to August 1998. 11 nearby (20km<D<70km)quite strong (3.8<Ms<5.2) and shallow (H<35km) earthquakes happened during this period and we tried to find an association of AE intensity with them. We found definitely AE response on the earthquakes, appearing as increasing of AE intensity. The amplitude of AE increases about 12 hours before earthquakes and decreases afterwards in a similar manner. We conclude, some process of earthquake preparation and some process of post-earthquake relaxation invoke that. This AE response depends on frequency (signal to noise ratio decreases with increase of frequency). The observational results are in agreement with simple theoretical model of propagation the seismic perturbations from the epicenter area. For noise conditions present at Matsushiro, characteristic radius of sensitivity for AE response on earthquake was estimated. It is ~100 km for an earthquake Ms=5(direct observations), and it is expected to be ~250 km for earthquakes Ms=6. But multi- station observations are needed for more reliable evaluations. The evident ULF magnetic emission accompanying AE was found for July 1,98 event.

CRUST DEFORMATION PROCESSES IN STRONG EARTHQUAKES FOCAL ZONES OF TIEN-SHAN (ON SEISMOLOGICAL DATA)

Nailya BAGMANOVA (Institute of seismology, National Academy of Science, Asanbai 52\1, Bishkek 720060, Kyrgyz Republic, email: kis@imfiko.bishkek.su)

We study the crust deformation style observed in focal zones of 9 strong earthquakes (M>5) which have struck Tien-Shan for the period 1978-1992. Initial data were focal mechanisms data for 2500 earthquakes with 1.7<M<5. Six components of strain tensor, intensity of shear strains, orientations of principal strain axes have been calculated. Were revealed the specific features in crust deformation style during a number of years prior to strong event occurrence. Deformation style as result of strong earthquakes seems to be different of that in source zones during earthquakes preparation period. North Tien-Shan and South Tien Shan seismogenic zones serve as examples of difference in styles of crust deformation.

ON A RESONANT PHENOMENA IN THE FLUID-SATURATED GEOPHYSICAL MEDIUM

Dr. Alexey L. SOBISEVICH and Prof. Leonid E. Sobisevich (Institute of Physics of the Earth, Russian Academy of Sciences B.Gruzinskaya 10, Moscow 123810, Russia email: alex@uipe-ras.scgis.ru)

The new approach to understanding the conditions of interaction and transformation of geoacoustic fields is proposed.It is shown that resonance interactions can play the main role in fluid-saturated medium. The reaction of porous fluid-saturated medium to weak seismic force, when the solid phase shifting can be neglected, was studied. The analysis shows the existence of slow waves of porous pressure in fluid-saturated medium. The speed of propagation of such waves can be up to 10 m/sec and depends on the structure of porous medium and some parameters of the fluid. The theoretical model of slow waves of porous pressure is developed. This model may be used for prediction of seismic events.

GENERALIZED RYDELEK-SACKS TEST FOR DISTIGUISHING BETWEEN PERIODIC AND RANDOM PATTERNS IN SEISMICITY

ZHONGLIANG WU(Institute of Geophysics, China Seismological Bureau, 100081 Beijing, China, email: wuzl@cdsndmc.css.gov)

In the study of geodynamics and earthquake prediction, one of the tricky things is to distiguish between periodic and random patterns in the activity of strong earthquakes using undersampled data, namely a few tens of events. For distinguishing the periodicity of strong earthquakes on the time scale of decades, we generalized the Rydelek-Sacks test (Rydelek and Sacks, 1989) to explore whether or not a time series is modulated by a periodic process. The test is conducted by comparing the phasor walkout of seismicity with theoretical results, given a certain statistical significance. The phase angle is defined by the origin time of earthquakes relative to a reference time scale. Using this method we tested two hypotheses in geodynamics and earthquake prediction study. One is the hypothesis of Romanowicz (1993) proposing that great earthquakes alternate in a predictable fashion between strike-slip and thrusting mechanisms on a 10 to 30 year cycle. The other is the observation that strong earthquakes in and around China have a period of ten years. The test obtains a negative concluion for the former hypothesis and a positive conclusion for the latter, with 95% statistical significance. The result is of help in the modeling of geodynamics and the estimation of seismic hazard.

NONLINEAR ANALYSIS OF CAUCASIAN EARTHQUAKES' TEMPORAL AND SIZE DISTRIBUTION

Teimuraz MATCHARASHVILI, Tamaz Chelidze , Zurab Javakhishvili (Institute of Geophysics, Georgian Ac. Sci. 1, Alexidze str. 380093 Tbilisi , Georgia. e-mail:tnmat@hotmail.com)

It is well known that earthquakes' size, time, space and space-time distributions obey power law. At the same time precise details of underlying dynamics is not quite clear. We apply tools of nonlinear dynamics theory, such as correlation dimension, "surrogate" data analysis etc., as well as positive Lyapunov exponent calculation for investigation of dynamical characteristics of earthquakes' temporal distribution in Caucasian region. In this study we have considered interearthquake time intervals sequences for different areas and magnitude windows. We have found significant evidence for low dimensional nonlinear structure of earthquakes' time distribution, obtained by consideration of time interval sequences between all events, encountered in the original catalogue above threshold magnitude. At the same time, based on phase randomised and Gaussian scaled surrogate tests, existence of nonlinear structure in selected sequences of time intervals between independent events as well as between aftershocks (events were picked out from the original catalogue) were rejected. It seems that such kind of filtration of the original catalogue destroys the existing temporal structure. Unlike selected interaftershock time interval sequences, time interval sequences between Racha earthquake original aftershocks reveal clear evidence of nonlinear structure. Caucasian earthquakes size distribution also was investigated. It has been shown that distribution of earthquakes' magnitudes for all considered sequences of magnitudes and magnitude windows reveal high dimensional nonlinearity. These results show that well known scaling laws of earthquakes time and size distribution have different underlying dynamics and from the point of view of prediction of hazardous events must be considered separately.

PAIRS OF LARGE EARTHQUAKES AND GEODYNAMICAL PROCESSES IN CENTRAL AND SOUTH ASIA

Yuri Kopnichev and Inna SOKOLOVA (Complex Seismological Expedition, Joint Institute of Physics of the Earth, Kamo str. 8a, Talgar, Almaty region, 483310 Kazakhstan, email: adm@cse.academ.alma-ata.su)

Pairs of large earthquakes (M~7.0) were observed in Central and South Asia: a deep-focus Hindu Kush earthquake followed by a shallow event during an interval varying from a few weeks to 4.5 months. Distances between epicenters of these events were within a range of 300-1450 km. Strong shallow earthquakes after deep-focus Hindu Kush events have occured in the regions of the Kopet Dag, Iran, Turanian plate, Hindu Kush, the South Tien Shan, and the Himalaya. The probability of occasional occurence of 9 pairs of such earthquakes since the beginning of this century is insignificant. We have established, that these events occur only during episodes of long-term (a few years) increase of the Earth's rotation speed. To interpret this effect, we have considered temporal variations of shear wave attenuation field structure in the earth's crust and upper mantle, which are connected with active fluid migration within large deep fault zones. For this purpose seismograms of local explosions at a small quarry in the region of the North Tien Shan (1965-1995) have been analyzed. Using coda analysis, we have shown, that during periods of increasing the Earth's rotation speed, and especially after the strongest Hindu Kush earthquakes, the fluid field comes to "exited" condition in the earth's crust and upper mantle. This stipulates a sharp acceleration of formation processes of large shallow earthquakes sources in most prepared areas. The data obtained may testify that the information on preparing deep-focus Hindu Kush earthquakes is passed through active deep fault zones due to relatively effective system of hydrodynamical ties.

RELATIONSHIP BETWEEN THE DEEP CRUSTAL FEATURES IN VELOCITY AND THE PREPARATION OF STRONG EARTHQUAKES IN XINGTAI AREA

Jing-yuan YIN and Shi-rong Mei (Both at Center for Analysis and Prediction, CSB, 63 Fuxing Avenue, 10036 Beijing, China, email: yjy55@hotmail.com)

The explosion sounding and seismic tomography analysis implied that most of the strong earthquakes taken place in the North China would be found in the transition zones between the regions with high velocity and the ones with lowvelocity. The source for strong earthquakes would locate in generally in segment between the lower wall of the shallow shovel-like normal fault and the upper part of a steeply inclined fault deeply buried in the crust. Furthermore, upward movement of upper mantle with the irruption of some material frommantle to crust would be found in the Mohodiscontinuity near the epicentral area of strong earthquakes.
By comparing the distribution of main shock and after shock with the detailed tomography data for Xingtai epicentral regions, a new idea on the preparation of strong earthquakes was suggested and a model based upon this idea was presented. The effect of the inhomogeneity of the crust structure on the crustal stress field was calculated by using 3-D finite element method in a model with certain boundary constraints and conscientious selection of mechanic parameters of inhomogeneous media on the basis of the exploration data associated with the deep structures about the meizoseismal regions. The simulation is examined by Xingtai earthquake sequence and the results coincide quite well with its spacial distribution.

NEW NATURE OF AFTERSHOCK SPATIAL DISTRIBUTION, EARTHQUAKE FAULT LENGTHS AND SECONDARY DISASTER PREVENTION

Kazuyoshi NANJO and Hiroyuki Nagahama (both at Institute of Geology and Paleontology, Graduate School of Science, Tohoku University, Sendai 980-8578, JAPAN, email: nanjo@dges.tohoku.ac.jp)

We present new nature of aftershock spatial distribution on the upper limits of aftershock magnitude. This nature gives an useful information about the prevention of secondary disaster by aftershocks.
Consideration of recent earthquake sequences suggests that aftershocks can be even more damaging than main shock in some sense. In order to prevent the secondary disaster by aftershocks, we need to know the spatial distribution of potential of how large aftershocks a main shock can trigger. The potential can be evaluated by the upper limit of aftershock magnitude. Here we examined the upper limits of aftershock magnitude as a function of hypocenter distance from main shock. To examine them, we used aftershock sequences following six main shocks (magnitude of 5.2 to 6.8) occurring in Japan inland from 1983 to 1987. The upper limits of the magnitude do not monotonically decay with increasing distance from main shock hypocenter, but show systematically two peaks at characteristic distances equivalent to earthquake fault length in Japan inland and to maximum earthquake fault length of world earthquakes. The distances of the two peaks from main shock hypocenter can be regarded as especially 'dangerous distances' from the view point of secondary disaster prevention. Moreover, the magnitudes of the two aftershocks giving the peaks correlate positively with those of the main shocks. These magnitude correlations are similar to Bath's law. Thus, our results indicate that the 'dangerous distances' and the aftershock magnitudes at the 'dangerous distances' can be predicted from a main shock.
We derive that Japan inland earthquakes occur under a local tectonic condition from the earthquake fault lengths in Japan inland. Furthermore, according to the energy efficiency of fracturing, earthquake fault lengths necessarily can not be larger than the maximum earthquake fault lengths.

MAJOR EARTHQUAKES IN SOME AREAS OF CHINA AND LUNISOLAR TIDAL GENERATION FORCE

HAN YAN-BEN (Beijing Astronomical Observatory, Chinese Academy of Sciences, Beijing 100012, P.R. China, email hyb@class1.bao.ac.cn) Li Zhi-an (Department of Astronomy, Beijing Normal University, Beijing 100875, P.R. China)

Although the force which leads to occurrence of earthquake is mainly from the interior of the Earth, some forces from other sources will probably trigger the earthquake when the stress has been accumulated to critical state at the focus fault. The relationship between major earthquakes occurred in some seismic areas in China has been analyzed. The result shows that dates of the earthquakes closely related to the variation of a certain component of the force. Probably the result will be significant for providing information on prediction of shorter dangerous period, about one week in each month, when the earthquake prediction lasting several months was made by other methods.

CHANGES IN MATERIAL PROPERTIES BEFORE MAJOR EARTHQUAKES

Tetsuo TAKANAMI (Institute of Seismology and Volcanology, Graduate School of Science (B Hokkaido University, Sapporo, 060-0810, Japan, email ttaka@eos.hokudai.ac.jp) I. Selwyn Sacks (DTM, Carnegie Institution of Washington, 5241, Broad Branch Rd., NW, Washington, DC 20015, USA, email sacks@dtm.ciw.edu)

Observations of changes in seismicity before great earthquakes have long examined for precursory behavior. We report on five examples where the change in seismicity suggest change in fault zone properties. Taylor et al. 1991, Takanami et al. 1991 and Takanami et al. 1996 reported that the region surrounding the eventual earthquakes, became quiescent for earthquakes larger than m=3, even though smaller events seemed unaffected. While the aftershock zone shows no significant change in seismicity for the decade prior to the earthquake, the region surrounding this zone has significantly decreased seismicity for events larger than m=3 for one to three years before the earthquake. In these cases, the seismicity of the surrounding region returned to normal background after the large quake. Assuming that the driving forces are essentially uniform, either the surrounding zone has to weaken, or somehow else allow aseismic slip or the eventual fault zone has to stiffen. If the fault zone becomes stiffer than the surrounding areas, more of the forces due to plate motion will be supported or resisted by the stiffer zone, thus somewhat destressing the adjacent regions. The edge of the stiffened zone would have a stress concentration which could give rise to "Mogi donut" type seismicity.

THE RELATION BETWEEN THE ENERGETIC PARAMETERS OF ALBANIA EARTHQUAKES

Sulstarova Eduard and PECI Veronika; Institute of Seismology, Tirana, Albania,
e-mail: vera@sizmo.tirana.al

In the framework of Project "Seismic Zonation of the Albania Republic in scale 1:200 000" it is under the process of re-evaluation all the earthquake focal parameters of Albania and its surroundings. Among these re-evaluation we are also reconsidering the energetic focal parameters - magnitudes (MS, Mb, ML), seismic intensity in epicenter (Io), seismic moment (Mo), the length and width of fault (L, W), the area of the fault (S) as well as the stress drop. For the re-evaluation of energetic focal parameters of earthquakes besides the source data used in our previous works, we are also using many others sources of information coming from Seismological Bulletins and from other different authors. The region being studied is taken from the parallels 39-43degree North and meridians 18.5-22.0 degree East. We have been investigated the data for the seismic moment (Mo) for strong earthquakes with magnitude MS > 5.0. From the above mentioned data we have found the relations between them (Io - MS, Io-Mb, Io -ML; MS - Mb, MS - ML; ML - Mb; MS - Mo; etc.). It also been studied the influence of focal mechanism in the length and width of the fault. The relations between energetic focal parameters of the earthquakes are of great importance for the homogenous of all the seismological material for the compilation of the New Catalogue of Albanian Earthquakes and the Assessment of the Seismic Hazard.

ANOMALOUS LAND UPLIFTS AND SEISMICITY IN THE EASTERN PART OF THE ALPINE BELT

Vladimir KAFTAN and Juriy Kuznetsov (both at Central Research Inst. of Geodesy, Air Survey and Cartography, Onezhskaya, 26, 125413 Moscow, Russia, email V.Kaftan@relcom.ru)

Regional characteristics of Caucasus land movements are determined thrice. Maps of recent vertical crustal movements of Eastern Europe published in 1971 and 1986 and Map of velocities of recent crustal movements in the Caspian region (preliminary and final variants of 1994 and 1995) demonstrate large zones of anomalous uplifts with the rates of 10-15 mm/year near Greater and Lesser Caucasus ridges. So large rates can not explained by precision levelling errors of both, random and systematic, characters. The accuracy of velocity determination varies from 0.2 to 2.5 mm/year and reliability of the results is undoubted. Mean dates of the first and second epochs of levelling were 1924-1947, 1941- 1970 and 1960-70 - 1980-90 for each map respectively. The latest Map of the resent crustal movements of the Carpatho-Balcan Region showed great uplifts too.
This uplift were preceded to the great earthquakes in the Vrancha region. This behaviour is closed to the Caucasus anomalous vertical crustal movements. Spatial and temporal analysis of vertical land movements comparing with the seismicity behavior shows that large uplifts precede the largest Caucasus and Carpathian earthquakes occurring near such anomalous zones. The interesting fact is that there are many events of the anomalous uplifts occures all over the world. This phenomenons have been occured in the regions of Japan, South California and China. Decades of publications describe this events and their relation with the seismicity.

Revealing and study of empirical dependencies of natural processes allowed to conclude that there is a wide class of self-developing natural processes, the dynamics of which is described by the non- linear differential equation of the second order. At present the methods, allowing confidently to revealing the regularities of the development of natural processes, have been developed. On example of the foreshock-aftershock sequences of destructive earthquakes in southern Kuril arc area it was established, that the development of both of foreshock, and aftershock sequences corresponds to the equation of the dynamics of self-developing natural processes. The following parameters of Nseismic process were investigated: cumulative sum of the number of shocks, the similar sum for energy of earthquakes and square root from the energy. We have analyzed the total seismic events flux within the region for the magnitude M>=4.0 since 1962. We have determined a range of the most probable parameters of this equation and we hope that the future researches will allow reducing this range. The logarithmic dependencies of the development of foreshock-aftershock sequences upon time are being met most frequently. However the foreshock sequences are more poorly expressed. Probably, some updating of seismic observations is required for getting more stably results for foreshock sequences. It is caused by the necessity of study of weak seismicity anticipating destructive earthquakes. Nevertheless the obtained results allow to assume, that the
methods are perspective for the forecast of disastrous earthquakes.

CASCADE EARTHQUAKES IN ALBANIA

Betim MUCO (Seismological Institute, Tirana, Albania, e-mail: betim@sizmo.tirana.al)

A complex web of active faults is distributed throughout all the territory of Albania. The intersection of northwest-trending Adriatic and Ionian longitudinal fault system and northeast-trending shear fault systems, dominates Albanian tectonics and gives rise to recent seismicity backed mostly by the confrontation between Adria microplate and Albanian orogen. Sometimes, activation of some active faults produces the earthquake activity in a neighbor one and this process could continue as a cascade through other faults. This may cause the migration of seismic activity from one system of faults to another and sometimes could lead to wrong deduction about the proper fault responsible for an earthquake.
Based on the available data from the records of Albanian Seismological Network, since 1976, some cases of the so-called cascade earthquakes for Albania are evidenced in this approach trying to explain also their mechanism.

THE PROPERTIES OF THE LOW-FREQUENCY SEISMIC SIGNALS FOREGOING A MAIN SHOCK

Boris W. Levin (*Shirshov Oceanology Institute of RAS and Russian Foundation for Basic Research, 32a Leninsky prosp., Moscow, 117334 Russia; levin@rfbr.ru) Elena V. SASSOROVA (State Oceanographic Institute, 6 Kropotkinsky per., Moscow, 119838 Russia; sasor@geoph.ioras.msk.ru)

The low-frequency seismical signals foregoing a main shock may be considered as a local sign of the earthquake preparation. More than 30 events with low frequency forecasting signals were detected by a special developed software package (above 200 event records were data processing). These signals have a period from 3 to 200 s and forecast time before P-wave arrival in area from 20s to 1.5 hours. The foregoing low-frequency signals were detected only for the events with epicentral distance no more than 1000 km. The classification of the forecasting signals was proposed. The properties of low frequency signals vary over a wide range. The signal properties from the same region vary but sligthly. Thus the connection between the signal type and the event localization was noted. Analysis the signals and records of the acoustic waves from laboratory experiments provided confirmation that a period of radiated signal and an oscillator size are connected by empirical relation. The seismic foregoing signal parameters are depended on the regional characteristics (the oscillator size, features of the environment, structure of the earth crust). Thus the global problem of the prediction search may be replaced by the set of the local problems for each seismoactive region.

SEISMICITY AND CORELATION COEFFICIENT OF MOHO-DISCONTINUITYRELATIVE TO SOME GEOPHYSICAL PARAMETERS FOR THEREPUBLIC OF MACEDONIA

Todor DELIPETROV, Krsto Blazev Delipetrov (Faculty of Mining and Geology, Uni "Kiril and Metodij" Skopje, Stip,MK, Email: todor@rgf.ukim.edu.mk);

Defining the seismicity of a given area is similar to that of earthquakes. In order to do it successfully it is necessary to know seismicity demonstrated so far. Available knowledge indicates that earlier active areas should be expected to be as such in the future. With regard to the geophysical approach in modelling the seismicity of a certain area it is necessary to know the geological structure, tectonic processes, geophysical fields in the region under consideration and further afield. Analysis of the model of earlier earthquakes registered indicates that the hypocentres of the territory of the Republic of Macedonia are situated in the Moho-discontinuity. The dependences of the depth of Moho-discontinuity on the height of the relief and Bouguer's anomaly or their correlation coeffcients are analsed from thaat aspect . It is the opinion of the present authors that defining the moho-discontinuity and its correlation relationshipp with Bouguer's anmaly and the height of the relief can be used in the assessment for possible seismic energy in the earth's crust above moho-discontinuity.

ON SOME ANOMALY PHENOMENA APPEARANCE DUE TO ACTIVE INFLUENCE ON A REAL GEOPHYSICAL MEDIUM

Dr. Alexey L. SOBISEVICH and Prof. Leonid E. Sobisevich Institute of Physics of the Earth, Russian Academy of Sciences B.Gruzinskaya 10, Moscow 123810, Russia email: alex@uipe-ras.scgis.ru

Modern technology of usage of powerful seismic vibrators allows to simulate earthquake conditions. Using this technique were studied earthquake precursors such as: change of water-level in a bore-hole, resonant response of the medium upon powerful vibration, generation of seismic noise by the zone of dilatancy. The explanations to a number of anomaly phenomena caused by resonant interactions in the layered geophysical medium are considered. At the same time the results of experimental observations over some geophysical phenomena discovered are considered.The conditions of interaction between the source of seismic oscillations and the geophysical medium in case of existence of the resonant structures are studied. The case of the source positioned onto a boundary of a half-space and the resonant structure located underneath in the near-field of the source is considered. Given theoretical study allows to perform immediate numerical estimations. The possible relation between the theoretical study and experimental facts is a subject for discussion.

VARIATION OF AUTOCORRELATION FUNCTION'S FIRST ZERO CROSSINGS IN SEISMOLOGICAL TIME SERIES

Teimuraz MATCHARASHVILI, Tamaz Chelidze , Zurab Javakhishvili (Institute of Geophysics, Georgian Ac. Sci. 1, Alexidze str. 380093 Tbilisi , Georgia. e-mail:tnmat@hotmail.com)

It is widely accepted that lithospheric processes underlying earthquake generation are complex and highly nonlinear. Complete evaluation of such processes by tools of nonlinear time series analysis is too difficult task, due to complicated inherent dynamics and shortness and noise problems in time series analysis. Therefore, approaches based on linear properties of generally nonlinear data bases remain important. Autocorrelation function, characterising the resemblance of signal with itself, is one of such tools. Nonlinear time series analysts often use autocorrelation function's first zero crossing as an average measure of linear independence of the observations. In general linear independence between data, like any other linear or nonlinear property of time series can change depending on their length. So in the present study we have analysed the variation of autocorrelation function's first zero crossing as a measure of evolution of linear independence of time series data, by addition in tens of subsequent events, beginning from the first 100 data of the observations. Namely, there were considered variability of Caucasian earthquakes' magnitude and interevent time intervals sequences linear independence measure by addition successive 10 events from earthquake catalogue. It was found that linear independence of interevent time intervals strictly increases after large earthquakes; that can be related to the temporal clustering of earthquakes' aftershocks. On the other hand variation of linear independence of magnitude sequences before large events, and in most cases also after the events, does not change practically. These results confirm differences in dynamical properties in earthquakes' temporal and size distribution, found by nonlinear approach.

SPACE AND TIME PATTERNS OF THE SEISMICITY OF THE VRANCEA REGION, ROMANIA

Luminita ARDELEANU (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: ardel@infp.ifa.ro)

The seismic region of Vrancea is located in a tectonically complicated area, at the contact between the Eastern European plate, Moesian, Black Sea and Intra-Alpine subplates; this complex junction is considered as a continental-type collision, with a paleosubduction from NE to SW.
The seismicity studies show distinctive characteristics of the seismogenic zone of crustal earthquakes (hypocentral depths between 0 and 60 km) relative to the seismogenic zone of intermediate-depth earthquakes (hypocenters in the depth range from 60 to 200 km): the seismic activity in the crust is moderate (maximum MS magnitude less than 5.5) and it is mainly located within the foredeep region, in front of the bend of the Eastern Carpathian Arc; the subcrustal seismicity is almost vertically distributed in the deeper seismogenic segment, in a volume with a well confined epicentral area which includes the major Vrancea earthquakes (1 - 6 events with magnitude MW greater than 7 each century).
To study the space and time seismicity patterns, a parameterization derived from the Weibull distribution is used. The space-time distribution of the shallow earthquakes (local magnitudes greater than 2.0) show a strong clustering tendency, while the subcrustal mainshock sequences (local magnitudes greater than 2.5) are modelled by a completely random pattern. The time occurrence of moderate and strong intermediate depth earthquakes (local magnitudes greater than 5.5) shows also a completely random pattern.

NONLINEAR STRUCTURE OF EARTHQUAKES' SIZE AND TIME DISTRIBUTION BEFORE AND AFTER LARGE CAUCASIAN EVENTS

Teimuraz MATCHARASHVILI, Tamaz Chelidze , Zurab Javakhishvili (Institute of Geophysics, Georgian Ac. Sci. 1, Alexidze str. 380093 Tbilisi , Georgia. e-mail:tnmat@hotmail.com)

It is known that seismological data bases both from qualitative and quantitative point of view are as a rule not sufficient for proper investigation of lithospheric dynamics even for lowdimensional processes. Therefore, similar to other fields, evaluation of nonlinear structure of geophysical data seems to be a more appropriate approach. In this study we have continued qualitative and quantitative investigation of dynamical properties of Caucasian region earthquakes' temporal and size distributions in order to evaluate the contribution of lithospheric processes taking place before and after strongest regional events in observed lowdimensional structure of general seismic dynamics. Dynamical characteristics of seismic processes before and after Daghestan, Paravani and Racha strongest events were investigated by means of nonlinear time series analysis tools, such as correlation dimension algorithm and surrogate data analysis test, using magnitude and interevent time intervals sequences as "time series". It was found that, similar to integral dynamics of regional seismicity, magnitude sequences before and after strongest events remain high dimensional in contrary to revealed low dimensional nonlinear structure of intevent time intervals distribution, although in the last case there is no evidence for deterministic chaos. It means that qualitatively dynamics of earthquake generating lithospheric processes did not change after large events. At the same time, for both earthquakes' size and temporal distributions, nonlinear structure of lithospheric processes before and after large events quantitatively are significantly different.

AN APPRAISAL OF OBSERVED TRANSIENT 'ELECTRICAL EARTHQUAKE PRECURSORS': PHYSICAL PROPETRIES AND IDENTIFICATION

A. TZANIS (Dept. of Geophysics & Geothermy, Univ. of Athens, 157 84 Zografou, Greece, E- mail:atzanis@atlas.cc.uoa.gr) and F. Vallianatos (Technological Educational Inst. of Crete, Chania Branch, Crete, Greece, E-mail:fvallian@teihan.gr).

The quest for observation and study of transient Electrical Earthquake Precursors (EEP) has been vigorous in the past and has produced a prolific variety of signal shapes and durations. To date however there exists no universal theory to describe the mode of appearance and expected waveforms, nor proven techniques to identify and discriminate precursors from noise. Earlier attempts to appraise a signal based on electric field observations only, could only determine whether it was produced from known local sources. Identification was not possible, save for the abstract assumption that a non-local signal ought to have been generated by some distant earthquake source. Statistics were used to establish the association of signals with earthquakes but given the insufficient understanding of their nature, this has led to vigorous controversy and debate. Herein we attempt to appraise a different classes of transient signals observed in Greece and abroad, especially those used in publicised short-term prediction. We base our investigations on their physical characteristics (e.g. shape, duration, properties of their magnetic companion) and attempt to assess whether their sources can be consistent with what is expected from known physics of theearthquake focus and associated electrification processes within the fundamental concept of self- organised criticality. We conclude that only a limited class of the observed signals can be consistent such properties : they can be theoretically modelled and have characteristic transient bay-like shapes, featuring a corner frequency and inverse power energy distribution law. Other types of signals such as single or multiple pulses with shapes like spikes, delta functions or boxcars cannot be produced by such a system. A number of examples is presented and discussed.

FREQUENCY ANALYSIS OF SEISMIC SOURCES AT GOL-E-GOHAR IRON ORE MINE, S.E. IRAN

FARHAD JAVADI and Abdolrahim Javaherian (both at Institute of Geophysics, Tehran University, P. O. Box 14155-6466, Tehran, I. R. Iran, email: javaheri@chamran.ut.ac.ir)

The effect of seismic waves on the stability of structures and buildings is very important. In open pit mines, it is interesting to study the effect of vibrations produced by blasting and mine utilities on the surface structures. The study of microtremors is also helpful in determinig the natural frequency and noise level of the site. Fundamentally, assessment of seismic waves and their effect on structures requires to determine their frequency content.
In this research, the frequency content of main seismic sources at Gol-e-Gohar iron ore mine (blasting, mine utilities and microtremors) is studied. To do this, we recorded seismic signals for three days, using several digital recording systems. Due to short duration of blasting, we extracted part of the seismogram containing the event to determine it's amplitude spectrum. In this way, the frequency range of two normal mine explosions was detected. In contrast to blasting, vibrations of utilities and microtremors are almost permanent. So it's necessary to study variations of their frequency content against time to specify dominant frequecy ranges. In this case, we divided each seismogram to several windows, with 20 second length and calculated amplitude spectrum of each window, separately. Then using three dimensional graphs, showing variations of amplitude against frequency and time (window), dominant frequecy ranges were determined. We also performed a qualitative interpretation on the effect of distance from the source, on the frequency range of seismic waves for explosions and mine utilities.

WHY DOES COEFFICIENT C IN THE MODIFIED OMORI LOW STRONGLY DEPEND ON THE MAGNITUDE CUT-OFF OF THE AFTERSHOCKS?

Peter SHEBALIN (International Institute of earthquake prediction theory and mathematical geophysics, Varshavskoye shosse, 79/2, Moscow 113556, Russia, e-mail: shebalin@mitp.ru); Nikolay Tsybine (Federal Research Institute for Aviation Systems, Ministry of Economics of Russian Federation, 7 Victorenko st., 125319 Moscow, Russia)

For large aftershock sequences after strong earthquakes we observe that in most cases parameter c in the modified Omori low (N(t) ~ 1/(t+c)p) depends exponentially on the magnitude cut-off of the aftershocks. The larger magnitude aftershocks are taken in estimation, the larger value of c is obtained. In some cases the estimated value of c can reach many hours.
The evident reason of this is the lack of events in the catalogue right after strong events.

Smaller aftershocks are easier to be "lost". Some aftershocks can not be identified because they are "shaded" by stronger events on the seismograms. In some cases large number of aftershocks can also "overload" data processing, and as the result the catalogue is not complete. But those factors can not explain very large values of the parameter c. We suggest the explanation by presenting aftershock sequence as self-exciting process. In this case even weak "shading" of small events by stronger ones can be enough to obtain large estimated values of c. We simulated aftershock sequences using epidemic-type model (as proposed by Ogata for the seismicity of a region) and adding the "shading" time intervals after events depending on their magnitude. We succeeded to obtain for real and simulated catalogues of aftershocks of Landers, Northrige and other earthquakes good coincidence of all Omori law parameters, including c, at a large spectrum of the magnitude cut-off. In addition, the estimations of correlation dimension of temporal distribution of aftershocks also well coincide for real and artificial data.

TEMPORAL FEATURES OF SEISMICITY IN THE AREAS OF TWO STRONG EARTHQUAKES OCCURENCE IN THE REGION OF KAMCHATKA AND KURILE ISLANDS

Alexander LUTIKOV, Joint Institute of Physics of the Earth, RAS , Moscow, (B.Gruzinskaya, 10, Moscow, Russia, Email: ail@uipe-ras.scgis.ru)

The areas of occurence of three strong earthquakes in Kamchatka, Kuril Islands and Taiwan have taken place in the last decade (South Kurile s 1994 (Ms=8.1); Kronotskoye (east cost of Kamchatka) 1997 (Ms=7.9) earthquakes) are identified from a statistical analysis of numerous seismic moment tensors time series in terms of its two invariants (the ordering index K (0\<K\<1), which is determinated as ratio of the average seismic moment per year matrix norm to the seismic moment average matrix norm per year, and cumulative scalar seismic moment - Mo(t) per year). The last parameter was used only for Kronotskoye earthquake. For this purpose the CMT-catalog (research group from Harvard University) and regional catalog of Kamchatka have been used. The basic conclusions of this work amount to the following: 1.Time series of order ing index K shows the statistically significant changes before earthquakes: the phase of increasing the value of K (duration - 3-5 years) replaces the short phase of its falling down (1-1.5 years before earthquake). This demonstrates the complicated process of seismicity order and chaoticity in strong earthquake areas of preparation. 2. Statistically significant minima of cumulative seismic moment of about 5 year dura-tion before the Kronotskoye earthquake can be considered seismic qu-iescence. It is interesting that the phase of seismic quiescence for this earthquake coincides with phase of increasing the value of K.

CN MONITORING OF SEISMICITY IN THE ITALIAN AREA

ANTONELLA PERESAN (Department of Earth Sciences, University of Trieste, via Weiss 4, 34127 Trieste, Italy, Email: anto@geosun0.univ.trieste.it) Giuliano F. Panza and Giovanni Costa (both at Department of Earth Sciences, University of Trieste, via Weiss 4, 34127 Trieste, Italy and at The Abdus Salam International Centre for Theoretical Physics, SAND Group, Trieste, Italy) Irina M. Rotwain (Russian Academy of Sciences, International Institute of Earthquake Prediction Theory And Mathematical Geophysics, Warshavskoye, 79/2, 113556 Moscow, Russia and The Abdus Salam International Centre for Theoretical Physics, SAND Group, Trieste, Italy)

A regionalization, strictly based on the seismotectonic zoning and taking into account the main geodynamic features of the Italian area, is used since 1997 for the application of CN algorithm to the Italian territory. The monitoring of seismicity is performed using the Italian catalogue CCI1996 updated with the Preliminary Determinations of Epicentres (PDE) from NEIC. In order to obtain a catalogue as homogeneous as possible, the completeness of PDE data and the relations between different kind of magnitudes reported in the CCI1996 and PDE catalogues have been analysed. A rule for the choice of magnitude priority in PDE, similar to that used for CCI1996, has been formulated. The results obtained in the forward monitoring appear to substantiate the robustness of the algorithm with respect to this change in the catalogue. Results updated at January 1, 1999 show that no alarm is given for the monitored regions, though the reliability of predictions for the Southern region is still insufficient, due to the low completeness level of the catalogue. More updated results will be provided at the meeting, since the monitoring is performed with a time step of two months.
A comparison of the performances of CN algorithm with the different regionalizations proposed up to now for the Italian territory, indicates that the regionalization based on the seismotectonic model should be preferred.

CHARACTERISTICS OF STRONG EARTHQUAKES IN EAST CHINA AND ITS APPLICATION

Chen YUWEI and Huang Xiongang (Seismological Bureau of Anhui Proovince, Hefei, China, Email: anhuigis@puplic.hf.ah.cn)

Earthquake is a complicated phenomenon in nature. Induividual earthquake happens with great uncertainty, studying integrate features of earthquakes and subtracting precursory information from them would be an effective way in earthquake prediction research.
Taking tectonics characters in consideration, authors analyse the temporal-space distribution of earthquakes (M>5.0) and seismicity patterns in East China qualititively. It is shown that the activity of strong earthquake indicates an alternative features between active and periogram analysis of historical earthquake series, it is found that the distribution of earthquakes illustrates the clustering and linear features along longitude and latitude, it is also shown the characteristics of oriented migration with strong earthquakes. Finally , the variation of regional stress field and some precursory information for strong earthquakes are obtained by analysis of evolution of seismicity patterns.

COMPARISON OF THE COSEISMIC RUPTURE WITH THE AFTERSHOCK DISTRIBUTION IN THE HYUGA-NADA EARTHQUAKE OF 1996

Yuji YAGI, Masayuki Kikuchi, Shingo Yoshida, (Both, Earthquake Research Institute, University of Tokyo, Yayoi 1-1-1, Bunkyo-ku, Tokyo 113-0032, Japan; e-mail yuji@eri.u-tokyo.ac.jp) and Takeshi Sagiya (Geographical Survey Institute, Kitagou 1, Tukuba 305-0811, Japan; e-mail sagiya@gsi-mc.go.jp)

On October 19, 1996, a large underthrusting earthquake, the Hyuga-nada, Japan, earthquake occurred along the southern end of Nankai trough. About two months later, a second large earthquake occurred in the adjacent region. We retrieved waveforms recorded at K-NET in Kyushu and GPS data at the network of Geographical Survey Institute. We employed a multiple-time window inversion to determine the temporal and spatial distribution of fault slip. The main source parameters obtained for the first mainshock are: (strike, dip, rake) = (210, 12, 81); the seismic moment Mo = 2.7E19Nm; the rupture area S = 15km x 25 km, and the source duration T = 17 s. For the second main-shock, (strike, dip, rake) = (210, 12, 87); the seismic moment Mo = 1.5E19Nm; the rupture area S = 18km x 18 km, and the source duration T = 15 s. The coseismic rupture areas do not overlap the aftershock areas, while the aftershock areas of the two events mutually overlap. This implies that the common aftershock region takes a role of barriers to dynamic rupture. It is also seenthat the aftershock area expanded during the first one day.

SEISMIC SEQUENCES IN RILA MOUNTAIN

Blagovesta Babachkova, Tatiana TOTEVA, Snezina Rizikova (Department of Seismology, Geophysical Institute, Ak.G.Bonchev Str., Block 3, 1113 Sofia, Bulgaria, toteva@nlcv.net)

This study aims to investigate the sequences in Rila mountain region. The area mentioned above is interesting for some reasons: the lack of strong earthquakes, but this region is closed to active areas especially Kresna seismic zone - the most active region in Bulgaria. (Rila region is included in Knopoff space window for 1904 earthquake, M=7.8). Another reason for investigating the Rila mountain are the observed seismic sequences there. The last seismic swarm occured in 1997. More than 170 events were located in a very narrow area. The wave forms and earthquake recurrence graph were investigated. Great similarity exists in the wave forms for most of the swarm events. Nevertheless, the old sequences in this region were reviewed and an attempt to find a probable relation between them and the strong events was made.

LOCALIZATION OF SEISMICITY BEFORE STRONG KAMCHATKA EARTHQUAKES

ZAVYALOV A.D. and Nikitin Yu.V. (both United Institute of Physics of the Earth, Russian Academy of Sciences, str.B.Guzinskaya, 10, 123810 Moscow, Russia, tel.+7(095)254-2478, fax +7(095)254-2478, email: zavyalov@uipe-ras.scgis.ru

Shrinkage of cracking process to a plane of a future main line rupture and its consequent localization near this plane are qualitatively described by avalancheunstable cracking model (IPE-model). This phenomenon is marked in laboratory on rock samples. In the present work the outcomes of researches on detection of the indicated effect under preparation of strong earthquakes in Kamchatka seismoactive region are shown. As a basic data the catalogue of Kamchatka earthquakes and also information about source mechanisms of the 10 Kamchatka earthquakes with an energy class K>14.0, occurred in central part of Kamchatka seismoactive region were used. In the work the space-time behaviour of distance R from a center of gravity of a hypocenters cloud up to the 1-st source plane of appropriate earthquake, and also distribution of seismogenic ruptures density Ksr were considered. As research area for each strong earthquake the stratum by a breadth 50km, including the 1-st source plane, was selected. It is established that long before strong events in the area of their hypocenters distribution of parameters Ksr and R along source plane have a casual character. Immediately before earthquake in hypocentral area of a main event there are one or two zones, where the parameter R accepts the minimum values (R<5km). It testifies that the seismic events are strapped to one among source planes of the future main earthquake. Its hypocenter places or in one from zones of minimum values of a parameter R, or between them. In turn aftershocks of the first day of a main event envelope square between these zones, mainly placing there, where the parameter Ksr accepts minimum values. However, hypocenters of main events are in zones of minimum values just of a parameter R. It is possible to suppose, that the seismicityis located close to source plane of the future main line rupture, and, apparently, the area of such localization determines a site of future hypocenter of strong earthquake (site of a beginning of destruction process). After a main event in the area of low values of parameter Ksr, close located to hypocenter of a main event, aftershocks are happening and finally finish process of destruction, connected to this earthquake. The work has been executed under financial support of RFBR, projects 94-05-16114 and 96-05-65439.

MONITORING CRUSTAL STRESS VARIATIONS DURING EARTHQUAKE SEQUENCES CULMINATING IN A LARGE, M > 5.0, EARTHQUAKE

BJÖRN LUND, Sverker Olsson, Reynir Bödvarsson and Ragnar Slunga (Dep. of Earth Sciences, Uppsala University, Villav. 16, 752 36 Uppsala, Sweden, email: bl@geofys.uu.se)

Real-time monitoring of the state of stress in the crust would be a very valuable aid in earthquake prediction. We invert microearthquake focal mechanisms to estimate the stress tensor, using a range of acceptable focal mechanisms for each event to account for the errors in the focal mechanism estimates. The stress tensor inversion is rather time consuming so to minimize the number of events included in each new stress estimation we have developed a new event selection method. The selection method rejects new events that have focal mechanisms similar to events already included by correlating the new event's amplitudes with those of the old events. Only if the amplitudes, or polarities, indicate that the event would contribute significant new information to the stress estimation is the event included. Sequential stress tensor estimates are compared at the 10%, 68% and 95% confidence levels in directions of the principal stress axis, the maximum horizontal stress and the relative size of the intermediate principal stress and we have designed criteria to distinguish significant changes in the stress state. The stress tensor inversion with the new event selection criterion was applied to two earthquake sequences in the Hengill region in Iceland. We investigate temporal variations in the crustal state of stress during a three month period before, and one month after, two large, magnitude > 5.0, earthquakes.

AIC ANALYSIS OF CATEGORICAL DATA FOR EARTHQUAKES AND VELOCITY STRUCTURES IN THE NORTH CHINA

SUN Ruomei, SHI Yaolin, LIU Jie, 1) Sun Ruomei in the Institute of Geophysics, Chinese Academy of Sciences, Beijing, 100101, email@sun.ihep.ac.cn, 2) Shi Yaolin in the Graduate School, University of Science and Technology of China, Academia Sinica, Beijing, 100039, email: shiyl@sun.ihep.ac.cn, 3) LIU Jie in the Center for Analysis and Prediction, CSB, Beijing, 100036 email: liujie@ip.cap.ac.cn

The North China plain is an economic flourishing area with high population and large cities, it is also an area of the highest seismic risk in eastern China. Here we quantitatively analyzed the relation between the occurrence of strong earthquakes and the tomographic velocity structure in North China by using the AIC (Akaike Information Criterion) analysis method for categorical data. We will list results of AIC values, single explanation variables first, such as the velocity or velocity gradient in each layer to show their relation with earthquakeoccurrences, then, combinations of two, three, or more explanationvariables. The

corresponding interval division of explanation variables are also given. Finally, all possible variable combinations are listed by AIC order. The results indicate that areas of low P-wave velocity in the lower crust and the top of upper mantle and areas of high S-wave horizontal gradient in the upper and lower crust are correlated with earthquakes of magnitude greater than 5-6. The correlation may be related to the geodynamics of Cenozoic thinning of the lithosphere and upwelling of mantle materials. Zones lateralinhomogeneous in crustal structure and thermal state is prone to occurrence of strong earthquakes.

MULTIFRACTALITY IN AFTERSHOCK SEQUENCES CORRESPONDING TO SHALLOW EVENTS IN THE SOUTH-AMERICAN SUBDUCTION ZONE

Ana M. Osella (Dto. de Física - Fac. de Cs. Exactas y Naturales - Univ. de Buenos Aires - Ciudad Universitaria - Pab. 1 - 1428 - Buenos Aires - Argentina, email:osella@df.uba.ar); Nora C. SABBIONE (Dto. de Sismología - Fac. de Cs. Astr. y Geofísicas - Univ. Nac. de La Plata - Paseo del bosque s/n - 1900 - La Plata - Pcia de Buenos Aires - Argentina, email:nora@fcaglp.unlp.edu.ar); Daniel Cernadas (Dto. de Física - Fac. de Cs. Exactas y Naturales - Univ. de Buenos Aires - Ciudad Universitaria - Pab. 1 - 1428 - Buenos Aires - Argentina, email: cernadas@df.uba.ar)

The spatial distribution of aftershocks following large earthquakes may give information about the behavior of the seismic zones and the physical state of the crust. The low possibilities for modeling the evolution of the fields of stresses and strains make it necessary, al least in a first approach, to face the problem in a statistical way. In the present paper we apply this kind of approach to analyze the aftershock activity corresponding to large and shallow earthquakes occurred in the South-American subduction zone. The degree of clustering of the different events are described through a multifractal analysis and complemented with the pair analysis technique and regional values previously obtained. Monofractality together with low values of D seems to be related to the presence of complex sets of faults responsible of the events, while the multifractal behavior with higher values of D could indicate the presence of a dominant fault around which the aftershocks are clustered. From these results, the behavior of D when applied to aftershock sequences appears to be related to the mechanisms associated to the rupture history and therefore may contribute to propose more realistic models of the seismic sources.

RESEARCH ON DYNAMIC PATTERNS AND PARAMETER CHARACTERS OF CRUSTAL DEFORMATION FIELD BEFORE AND AFTERSTRONG EARTHQUAKE

Shuoyu ZHOU, Yun Wu, Ganjin Deng (All at Institute of Seismology, Chia Seismological Bereau, Wuhan, China)

Based on the dynamic monitoring of crustal deformation, the parameter for the dynamics patern and fractal dimension of crustal deformation field and the integral activity level of many faullts etc. before and after th Tangshan(19760 AND Lijiang(1996) strong earthquakes and others are studied by using the method of pattern dynamics. It is exposed that two time-space characters, the ordered dimension drop for the deformation field and the accelerated motion of multi-fault before an earthquake, are probably caused by the deformation localization and fault softening after the seismogenic process enters the nonlinear stage. They could be an important seismic precursor if they occurred before strong earthquakes.

THE LITHOSPHERE AND ATMOSPHERE INTERACTION ACTIVITY AND ITS POSSIBLE CONNECTION WITH COSEISMIC PROCESS

Viktor A. Volkov (United Institute of Physics of the Earth, Russian Academy of Sciences, Bol'shaya Gruzinskaya str., 10, Moscow, 123810 Russia); Mstislav N. DUBROV and Rostislav F. Matveev (both at Institute of Radioengineering and electronics, Russian Academy of Sciences, ac. Vvedensky sq., 1, Fryazino, Moscow region, 141120 Russia, email: mnd139@ire216.msk.su)

The lithosphere-atmosphere interactive disturbances are investigated. The joint data analysis of synchronous operating and spatial distanced at 140 km laser strainmeter, tiltmeter, and seismogravimeter has been performed. The ultra long period (3 min...6 hours) oscillations of the Earth together with the atmospheric pressure microvariations in the same period range are analysed. Strain-to-pressure ratio at 2-3 m depth varies within (2-4)*10**(-8) /mbar during the year and is one order grater than such ratio at 15 m underground. The dynamic disturbances in atmosphere have the wave microstructure and are accompanied by complicated earth strains, tilts, and gravity variations. These interactive <waves> propagates along the atmosphere-earth boundary with the velocities of 30 - 50 km/h. Being partial coherent they would produce the obstacles into the precise geophysical data exquisition. However the correct knowledge of those ground motions would bring the new technique for earth material testing. We have observed the essential growth of 4-5 hour period disturbances during 2 days before the earthquake March 25, 1998, Mp,s=7.0-7.9. The intensity of atmosphere-lithosphere interaction has to be compared with the Earth's seismic activity . The vertical strains and underground water regime should be investigated.

ST1/E/06-A4 Poster **0930-52**

HYBRID LG + RG AND LG + SN DATA AT REGIONAL DISTANCES: IMPLICATIONS FOR SOURCE SPECTRA AND INFERRED SEISMIC MOMENTS

R.A.W. Haddon (32 Mahuta Road, Five Mile Bay, RD2 Taupo, New Zealand), John ADAMS (Geological Survey of Canada, 7 Observatory Cres., Ottawa K1A 0Y3 Canada. email: adams@seismo.nrcan.gc.ca), and Hilmar Bungum (NORSAR, PO Box 51 N-2007 Kjeller Norway)

While seismic moments are reliably determined from teleseismic P or S waves clearly separated from surface waves, at regional distances the surface waves and the Lg coda overlap, constituting hybrid data. Attempts to infer source spectra and seismic moments using vertical and/or randomly-oriented horizontal component data must take cognisance of the commonly large spectral amplitude contributions from the surface Rayleigh wave Rg for frequencies below about 1 Hz (depending on focal depth). We have computed synthetic wave trains containing Lg + Rg at regional distances for sources at various depths in layered crustal models using a precise f-k method and then computed their amplitude spectra. For Green's function sources we see prominent spectral humps due to Rg with spectral amplitudes as much as about an order of magnitude higher than the associated Lg spectral amplitudes for frequencies between about 0.05 and 1.0 Hz (depending on focal depth). The overall effect of the humps is to elevate spectral levels for low frequencies and to produce spectral "sags". The elevated spectral levels and the "sags" have nothing to do with real source spectra, but are simply artifacts resulting from invalid interpretation of hybrid data and the invalid neglect of excitation, transmission, and surface transfer effects associated with Rg, in particular. For moderate distances (R>250 km, say) and high frequencies (f>6 Hz) the phases Lg and Sn cannot be separated and so Lg + Sn wave trains also constitute hybrid data. Neglect of this fact results in invalid Q models for Lg and significant invalid trade-off effects between inferred attenuation and inferred source spectra. Important consequences of our interpretation are: (1) that seismic moments calculated from the elevated spectral levels (between say 0.05 and 0.2 Hz) without regard to the physics pertaining to Rg overestimate moment magnitude by up to one unit for large (M>6, say) events (depending on focal depth and other factors); (2) high frequency source spectral amplitudes proposed by some authors may be associated with magnitudes up to one unit lower; (3) significant systematic errors in both attenuation and source spectra result from the indiscriminate use of Lg + Sn hybrid data; and (4) claims that the Haddon (BSSA, 1996) source model overpredicts motions at all periods, are unfounded.

ANOMALOUS STRAIN-SENSITIVITY OF ELECTROMAGNETIC PARAMETERS IN A FAULT ZONE

A.A.AVAGIMOV (Institute for High Temperatures - Association, Russian Acad. Sci., 13/19 Izhorskaya Str., Moscow, 127412 Russia, Email: rickman@hedric.msk.su)

The results are presented of temporal dynamics of electrical conductivity, electric and magnetic fields obtained from the combined observation systems in the Central-Copetdagh seismo active region.
Levels are determined of relative strain-sensitivity for anomalous variations of the electrical conductivity as well as quantitative relations between dynamical parameters of the electromagnetic process.
For low-resistive, low-magnetic sedimentary rocks, the anomalies of electrical conductivity, electric and magnetic fields are shown to be spatially localized and connected with the fault zones. The governing role is elicited of a fluid dynamics process for structure forming of temporal variations of the electromagnetic parameters for a fault zone.
On the base of reversed problem solution, parameters are determined of an anomaly constituting body. The determined mechanisms are considered of the anomaly variation generation.

COSMIC PHENOMENA AND THE PROBLEM OF EARTHQUAKES..

Marina Despotashvili, Nodar Khazaradze, Nugzar Nachkebia and Luli SHATASHVILI (Cosmic Ray Department, Institute of Geophysics, Georgian Academy of Sciences, 1 M. Aleksidze st.; Tbilisi 380093; Georgia, email: lkh@cosmr.acnet.ge); David Sikharulidze (Department of Earthquakes, Institute of Geophysics, Georgian Academy of Sciences, 1 M. Aleksidze st.; Tbilisi 380093; Georgia)

It has been shown that a number of revealed anomalous diurnal variations of cosmic rays (CR) corresponds to the periods of the Earth's passage through the neutral sheet of interplanetary magnetic field (IMF). The unusual diurnal CR variations are called the cases when anomalous encreases of b (b is the ratio of CR diurnal variation neutron component amplitude to that of hard component) are observed. It is suggested that in these cases CR diurnal variation hard component amplitude inreases due to the heating of the Earth's upper atmosphere.
The Frequency distribution hystogram of distructive earthquake cases in relation with the moments of Earth's passage through the neutral IMF sheet is presented. The given hystogram with pronounced maximum of the distribution gives the evidence that a lot of cases of the distructive earthquakes coincide with the moment of Earth's passage through the neutral IMF sheet. Analizing complex diagrams of b magnitude decrese cases compared to the moments of Earth's passage through the neutral IMF sheet, to the moments of new Moon and full Moon as well as to the perigee and apogee, it is shown that large distructive earthquakes occur preferentially in the cases, when several (two or three) above-mentioned factors are superimposed.

SEISMIC COUPLING AT SUBDUCTION ZONES - ITS MECHANICAL CAUSE AND FAR-REACHING GEOLOGICAL CONSEQUENCES

Miles OSMASTON (The White Cottage, Sendmarsh, Ripley, Woking, Surrey GU23 6JT, UK. email: miles@osmaston.demon.co.uk)

The phenomenon known as seismic coupling, first recognized by Kanamori more than 20 years ago, has increasingly emerged as a tendency for the subduction interface slip to become locked by some kind of asperity, then sheared off by a major interface slippage, to be followed by a 'normal-fault' event and the re-locking of the interface. Seismic coupling is primarily confined to zones where the subducting plate is <70Ma old. The big question has been 'How do the repeated asperities arise?' The seismicity present to considerable depths within downbending plates led me to outline a step-faulting mode of downbend (IGC92, IASPEI94) in which repeated increments of

step-fault throw generate locking asperities at the interface. The shearing of these asperities would have the effect of transferring hanging-wall material to the downgoing plate and thus of advancing the hanging-wall-controlled position of interface downbend beneath the margin.
This contribution will elaborate upon this model (including the provision of outer rises without elastic support) and illustrate the huge tectonic significance of the resulting basal subduction tectonic erosion (STE) that has emerged from my study of subduction orogens and collision orogens, now ranging in age from the present to the Archaean. STE is to be seen as one of the great tectonic processes of the Earth and, as such, intensive study of its seismological manifestation - seismic coupling - is well warranted, hopefully also leading to improved understanding of seismic hazard. A highly STE-specific form of tectonic melange, generated by it, will also be illustrated.

SIDE EDGE OF KAMCHATKA SLAB: 1998-1999

Jonathan M. LEES, Jeffrey Park, Vadim Levin, Valerie Peyton (all at Department of Geology and Geophysics, Yale University, New Haven, CT, 06511 email: lees@love.geology.yale.edu) Evgenii Gordeev, Alexei Ozerov and Victor Chebrov (all at Russian Academy of Sciences, Petropavlovsk-Kamchatsky, Kamchatka, Russia)

In August of 1998 a joint team of Yale University and Russian Academy of Science investigators installed a broad band array of 15 seismic stations spanning the length of Kamchatka. The purpose of the array is to investigate the possibly torn edge of the Pacific plate as it subducts beneath the Kamchatka Arc at its northern terminus where the Bering fault intersects with the Kamchatka Arc. Connecting the western Aleutian oblique subduction zone to the arc-perpendicular Kamchatka subduction presents certain spatial difficulties in accommodating excess slab material as it bends around the corner. Our model, eliminates this problem by proposing a tear in the slab between Adak Island and Kliuchevskoi Volcano in Kamchatka. Shallowing of seismicity, unusual volcanic products, high heat flow in the Komandorsky basin each contribute to the accumulated data suggesting the torn slab model is correct. One objective of the large scale array is to determine flow in the upper mantle associated with slab roll back as material is ejected from beneath the Kamchatka slab around the edge of the slab beneath the Komandorsky Basin. If our model is correct we expect a consistent pattern of anisotropy as flow curls around the edge of the slab, heating and ablating the cold lithosphere as it plunges into the mantle. On a local scale, seismic investigations of the exploding Karymsky and Kliuchevskoi volcanoes are providing insights into volcano dynamics and the relationship of the subducting plate and surficial eruption products. We will present a first look at the data addressing these issues and present our initial interpretation.

ST2/E/39-A3 0900

THE RELATIONSHIP BETWEEN LARGE SHALLOW INTRAPLATE EARTHQUAKES AND THE INTERPLATE DEEP-FOCUS EARTHQUAKES IN AND NEAR THE KOREAN PENINSULA OF THE FAR EAST

SO GU KIM, Lhasuren Erdenedalai, Seoung Kyu Lee, and Jiseok Song (The Seismological Institute, Hanyang University, Ahnsan, Kyonggi-do, 425-791, South Korea, Tel: +82-345-400-5532, Fax: +82-345-400-5830, email: sogukim@mail.hanyang.ac.kr)

We often have large shallow intraplate-earthquakes in the Far East, NE China, SW Japan and Korea, outside the plate boundary. We investigate the relation between large shallow earthquakes and large deep-focus earthquakes in the East Sea (Japan Sea) in this study.
From shear-wave splittings of SKS and S(ScS) for deep-focus earthquakes, the orientation of the fast shear-wave accords with that of Pacific plate movement, NW in the inner continent of NE China and Korea, while it is NS in the outer continent of the Sakhalin and Japan regions, which may be related to the steep dipping of the pacific plate. Using the 3-D velocity tomography of the crust and upper mantle in and near the Korean Peninsula, the high velocity of the lithosphere slab is found to subduct beneath the Euarasian plate in the NW direction. 660 km ? and 410 km ? discontinuities are also found to be in the inner continent and in the East Sea(Japan Sea), respectively.
Most of large deep-focus earthquakes may induce large shallow earthquakes in the Far East seismic regime because the energy density of deep-focus earthquakes is captured over 1000 km of epicentral distance and accelerate the regional stress of this regime. From principle of energy conservation, the kinetic energy of the earthquake is transformed to the elastic potential energy, which may strongly influence the seismicity in and near the Korean peninsula.

ST2/E/45-A3 0915

DEPTH DISTRIBUTION OF STRESS FIELD IN THE HOKKAIDO WADATI –BENIOFF ZONE AS DEDUCED BY INVERSION OF EARTHQUAKE FOCAL MECHANISMS

Cenka CHRISTOVA (Geophysical Institute of Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria, email: cenka@geophys.acad.bg) Theodoros Tsapanos (Aristotle University of Thessaloniki, Geophysical Laboratory, 54006 Thessaloniki, Macedonia, Greece, email: tsapanos@geo.auth.gr)

This study is based on the detailed geometry of the Hokkaido Wadati-Benioff zone (HWBZ) and the paleosubduction zone (HPSZ) as delineated by Hanus & Vanek. CMT solutions and the inverse technique of Gephart and Forsyth (1984) were incorporated for determining the best fit principle stress directions s1, s2, s3 and the ratio R=s2-s1/s3-s1 for 20 km depth intervals in the HWBZ and for the HPSZ, considered as a whole body. The maximum compressive stresses s1 in all considered depth ranges towards SE trend dip less than 300, indicating the NW-SE convergence between the Pacific and Eurasian lithospheric plates. The depth layer100- 120 km and HPSZ are exclusions, the dip/az of s1 being 42/201 and 30/270, respectively. In all considered depth intervals the minimum compressive stresses s3 are steeper than 45. A tendency of clockwise rotation of s3 from NW (along dip of the subducting plate) to NNE (along strike of the subducting plate) and a decrease of plunge with increasing depth is observed. Exclusions are the 120-220 km layer and HPSZ, where s3 are almost horizontal. The results are discussed in the light of depth distribution of seismogenic properties in the HWBZ.

ST2/E/20-A3 0930

A NEW GRAVITY ANOMALY - IMPLYING STRUCTURES OF SEISMOGENIC LAYERS IN JAPAN

Naomi Gennai and Yoshiteru KONO (both at Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, 920-1192, Japan, email: ngen@hakusan.s.kanazawa-u.ac.jp)

Most earthquakes are occurring within the upper part of the Earth's crust. At the Earth's surface, active faults are indicative of the past seismic activity. On the other hand, gravity anomalies represent the total attraction from shallow as well as deep structure. In particularly, gravity anomalies around the Japanese Islands are strongly influenced by complex geological structures within the upper crust and also by undulations of the Moho and Conrad discontinuities and subducting lithosphere (slab). If we can extract the gravity contribution due only to the upper crust, it may give us information on the geologic structure of seismogenic layers. For this purpose, we apply geophysical gravity reductions to observed gravity anomalies. The reduction procedures begin with the conventional Bouguer anomalies. In contrast to many other geophysical reduction procedures, we start reductions with the gravity contribution of deeper layers. First, we calculated the gravity contribution of subducting slabs beneath the Japanese Islands. Upper surfaces of the slabs are well defined by tracing the upper boundary of hypocentres of deep earthquakes. We evaluated the contribution of the slabs by considering their three-dimensional configuration, thickness and density contrast with the surrounding asthenosphere. Second, reductions due to undulations of the Moho and Conrad discontinuities were performed by employing seismological tomography models. When we subtract gravity contributions due to subducting slabs and undulating Moho and Conrad discontinuities from observed Bouguer anomalies, the resultant gravity anomalies mainly come from upper part of the crust, say shallower than about 14 km. We call the new gravity anomalies thus obtained the "Conrad-Moho-Slab Residual Bouguer Anomaly (CMS-RBA)". The CMS-RBA shows many steep horizontal gradient zones that presumably indicate block boundaries of seismogenic layers. The CMS-RBA was compared with distributions of surface geology, of active faults, of seismicity, and of crustal displacement vectors derived from dense GPS observations. Good correspondence was obtained between the CMS-RBA and those observables, indicating that the CMS-RBA is a useful information for studying active geological structures.

ST2/W/35-A3 0945

CRUSTAL DEFORMATION OF SEISMIC AND ASEISMIC SUBDUCTION ZONES

Takeshi SAGIYA (Geographical Survey Institute, Tsukuba 305-0811, Japan,
e-mail: sagiya@gsi-mc.go.jp)

Recent space-based geodetic measurements revealed seaward motion of aseismic island arcs such as Ryukyu and Mariana. Marine terraces found in some of the islands are evidences of Quaternaryuplifts. These crustal deformations may have a close relationship with geological features like back-arc opening, but physical mechanism is not solved. At aseismic subduction zones, interplate coupling is considered to be very weak. So we calculate crustal deformation due to steady plate subduction along a curved plate boundary in a three-dimensional elastic layer overlying a viscoelastic substratum, based on a dislocation model for plate subduction developed by Sato and Matsu'ura (1988, 1993). The calculated deformation field shows seaward motion and uplift of the island arc and the result may possibly give an explanation for the observed deformation. Curvature of the island arc is an important factor determining the style of deformation. On the other hand, at seismic subduction zones, we need to estimate inhomogeneous distribution of relative displacement and its temporal variation on the plate boundary surface in order to understand the plate subduction process through a whole earthquake cycle. It can be estimated through an inversion analysis of geodetic data taking viscoelastic effects of asthenosphere into account. Four-dimensional (three in space and one in time) inversion technique of geodetic data is now being developed, and it is to be applied for geodetic data during last 100 years along the Nankai trough, southwest Japan.

ST2/E/05-A3 1000

THE INTERACTION BETWEEN PHILIPPINE SEA PLATE AND EARASIA PLATE AND ITS EFFECT ON THE STRESS FIELD IN EASTERN PART OF CHINA

Shaoxian ZANG and Q.Y. Chen (both at Department of Geophysics, Peking University, Beijing 100871, China, email: sxzang@ibmstone.pku.edu.cn)

The Euler parameters of the Philippine Sea plate were studied using the slip vectors of earthquakes obtained from CMT data from 1977 to 1996. Some slip vectors which were used by other authors were also used. According to the deformation within Philippine Sea plate the slip vectors were selected and considered in different way. The Euler parameters were calculated in Nuvel-1A framework firstly, then in 14 plates framework, the Okhotsk sea plate was added. The relative movement between Philippine Sea plate and Eurasia plate were obtained.
The stress field in eastern part of China, Taiwan area, Ryukyu island arc and Okinawa trough was obtained using focal mechanisms of earthquakes, it was found that the stress field in Taiwan and southeastern part of mainland of China is coincident with one another, but different from eastern part of mainland; the stress field in eastern part of the mainland of China, Ryukyu island arc and Okinawa trough are different with one another.
By comparison of the principal compressional axes of the stress field with the direction relative movement of the plates as well as the tectonic structure, such as rifting in Okinawa trough, subduction in Ryukyu arc, collision in Taiwan and strike slip fault in Philippine island. It was found the Philippine Sea plate has less influence on the stress field in eastern part of China except the area near Taiwan.

ST2/E/01-A3 1100

EXTRUSION OF SOUTH CHINA BLOCK AND SLIP RATE OF MAIN ACTIVE FAULTS IN VIETNAM

Trinh PHAN-TRONG, (1), Robin LACASSIN (2), Phillipe Herve LELOUP(2), Paul TAPPONNIER(2), (1) Institute of Geological Science, NCNST, Vien Dia Chat, Nghia Do, Cau Giay, Hanoi. Fax : 84 4 8362886, E-mail: pttrinh@refer.edu.vn (2) Institut de Physique du Globe, 4 Place Jussieu, 75005 Paris.

The continental extrusion that pushed Indochina Southeast wards along the Red River shear zone was a major event in South East Asia. In North Vietnam, various structures associated with strike-slip motion occurred in the first phase of extrusion. More recently (late Cenozoic) the sense of movement on this fault has changed. Paleostress analysis indicate that since the Miocene two main tectonic phases affected. Several active faults associated with the phase 2 are clear in North Vietnam. Amongst these, two main zones seem to be relatively fast movement: the Red River fault zone and Dien Bien Phu fault. In North Vietnam, the Red River fault zone splays into two major active fault branches. The Red River branch that limits to the SW the metamorphic massif of Day Nui Con Voi, follows the Red River valley. The Song Chay river branch, very clear in the geomorphology, is located NE of Day Nui Con Voi. Towards the SE, the Red River itself splays into several faults. The two major one being respectively located NE and SW of the Red River. Right lateral strike-slip offsets of these faults are determined by analyzing tributaries, stream channels, Quaternary alluvial fans, river valley from LANDSAT, SPOT images, detail topographical maps and field observations. Along the SW fault of the Red River, right lateral offsets of stream channels range among 220 and 700 m (mean offsets of 313 m). Drainage offsets (250 - 450 m) are found on the NE branch. Geomorphology and topographical offset suggest that these strike-slip movements are combined with normal slip. Along the Song Chay branch, right lateral offsets of rivers range among 250 and 1000 m (mean value of 566m). Clear evidence of the active strike-slip movement is also found on the conjugate Dien Bien Phu fault, there, measured left-lateral offsets of river rang between 270 and 790 m. Slip rate may be estimate using 2 different approaches. Assuming that major phase of incision visible in this area, close to the Red-river delta is due to the onset of Wurm glaciation and to sea level drop (100 Kyr), slip rate of 3.1 + - 0.9 mm/yr. (SW Red River branch), 3.6 +- 1.1 mm/yr. (NE Red River branch), 5.6 +- 2.3 mm/yr. (Song Chay branch) and 5.3 +- 2.6 mm/yr. are estimate. Using average length of offset channels and a minimum rate of 100mm/yr. for river propagation, slip rates are...

ST2/E/08-A3 1115

CRUSTAL STRUCTURES AND DYNAMICS OF THE 1983 (MS6.6) TUAN GIAO EARTHQUAKE EPICENTRAL REGION, VIETNAM

Cao Dinh Trieu and Nguyen Xuan Binh (Institute of Geophysics, VNCST, P.O. Box 411 Buu Dien Bo Ho, Hanoi, Vietnam, email: trieu@igp.ac.vn) P.O. Box 411 Buu Dien Bo Ho, Hanoi, Vietnam, email: trieu@igp.ac.vn)

In this paper, the authors present a solution of source process of the Tuan Giao earthquake and its tectonic implication. The Crustal structures and Dynamics of the Epicentral Region are also described. Based on obtained analytical results, the following conclusions can be made: 1. Epicentral area of Tuan Giao earthquake located in northwest margin of Ma River zone and coincided with uplifted zone of lower boundary surface of the earth crust, where shifting amplitude into both sides of the Son La fault reached value of 2-3 km. 2. The Son La fault strongly activated during Mesozoic-Cenozoic period and Neotectonic and recent movement. Uplifting movement into northeast part of the fault reached value of about 1-2 mm/year. 3. The largest surface ruptures was characterized by system of 3 parallel fracture which have an azimuth , a width 10-17 cm, and a length of about 200 m, that continuously of distributed at the total length of at least 20 km. The surface ruptures, at smaller level, has maximum length a fracture about 20 m of which direction is NW-SE, concentrated at the northwest part of the epicenter area. The surface break have a type of tension. As to the displacement on surface pure right lateral strike-slip was observed. 4. The fault plane solution from the inversion teleseismic body waves indicates pure right-lateral strike-slip, striking N290E, which is consistent with the fault orientation in this area. The focal mechanism determined from the P-wave fist motion data has the different strike N120E. This fact suggest that the initial rupture occurred at the fault with the different from that of the main rupture.

DISTRIBUTION OF EARTHQUAKE FOCI AND DEEP STRUCTURE OF SUMATRA-JAVA-LOMBOK PLATE MARGIN

Ales SPICAK, Vaclav Hanus and Jiri Vanek (Geophysical Institute, Bocni II, 141 31 Prague 4, Czech Republic, email: als@ig.cas.cz); John Milsom (University of London, Gower Street, London WC1E 6BT, UK)

The detailed study of the geometrical distribution of earthquakes in the Sumatra-Java-Lombok region allowed the authors to distinguish the foci belonging to the recent Wadati-Benioff zone from those occurring in the continental wedge. The morphology of the Wadati-Benioff zone, its geometrical parameters and the variable depth of its penetration into the upper mantle were established. The existence of an intermediate-depth aseismic gap in the Wadati-Benioff zone was observed and its spatial relationship with young calc-alkaline volcanism was confirmed. The subduction processs was correlated with the stratigraphy and geology of the region. The duration of the present cycle of subduction was estimated to be 6-8 Ma. The occurrence of Oligocene volcanism and the location of deep earthquakes point to the existence of a Tertiary subduction zone underlying the present slab. The seismotectonic pattern of the continental wedge was described by well-defined seismically active fracture zones, the orientation and tectonic function of which were checked by fault plane solutions. Considerable shallow and intermediate seismic activity was observed in the vicinity of the Java-Sumatra trench. The distribution of these earthquakes along the trench is not continuous forming seismically active segments separated by aseismic regions or by transverse seismically active fracture zones. All the segments are inclined to the Euro-Asian continent. Fault plane solutions of associated earthquakes indicate normal faulting. The existence of this seismoactive belt can be explained either as a gradual bending of the present subduction zone at the trench or as a manifestation of a new cycle of subduction of the Indo-Australian plate.

ST2/E/60-A3 1145

EVIDENCES FOR CESSATION OF INDIAN PLATE SUBDUCTION IN THE BURMESE ARC REGION

N. Purnachandra Rao and M. Ravi KUMAR (both at National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India, email: postmast@csngri.ren.nic.in

The issue of whether subduction is still active in the India-Burma plate boundary zone continues to be a matter of controversy. In this study, we demonstrate that the subduction in the Burmese arc may no longer be active. A classification of the thrust, strike-slip and normal type of earthquakes in the major subduction zones worldwide, indicates that the number of thrust type earthquakes far exceeds those of the other types, comprising about 75% on an average. In the Burmese arc, however, the strike-slip mechanism is found to be dominant. Also, the P-axis orientations of thrust type earthquakes along all the major subduction zones are in close agreement with the predicted NUVEL1 plate motion vectors. On the contrary, in the Burmese arc region, the P-axes are oriented predominantly in the NNE direction, concurrent with the predicted India-Eurasia plate motion vector, rather than eastward, as would be expected in the case of an active subduction. Further, we find that in an east-west depth section, there is a distinct seggrergation of strike-slip earthquakes in the upper half of the subducted slab (0-90 km) and the thrust type, exclusively in the lower half . This can be explained only in terms of shearing of the Indian plate past the Burmese plate in the zone of contact, and compression of the lower portion of the slab against the asthenosphere, in the NNE direction. Computation of strain rates in the Burmese arc region indicates a ratio of 4:1 for NS-EW convergence, in agreement with the above results. In conclusion, the Burmese arc region is a special situation in where there is a subducted slab, but the direction of plate motion is not down-dip. Instead, the subducted Indian lithospheric slab is sheared past the Burmese plate in the NNE direction.

GEOLOGIC SETTING OF STRONG EARTHQUAKES IN THE EAST-NORTH CHINA

SUN Ruomei and LIU Futian (both in the Institute of Geophysics, Science Academy of China, 100101 Beijing, CHINA, email: sunrm@sun.ihep.ac.cn)

The east-north China is one of high seismicity areas in China. During the past 1000 years more than 200 earthquakes with magnitude M(5.0, 58 with magnitude M(6.0 and 15 with magnitude M(7.0 occurred. The 1976 Tangshan earthquake (M=7.8) is in the area. The catalogues of last 1000 years are compared with tomographic images. The results are:
(1) Hypocenters of most of strong earthquakes distribute near the boundaries between different high velocity blocks or in the transitional zones from high to low velocity on the side of high velocity in the upper crust. Projected locations of strong shocks on the image of the lower crust distribute in transitional zones from low to high velocity at the side of low velocity.
(2) More deep geologic setting of strong earthquakes is as follows. Seismicity distributes in the area, where the lithosphere is thin. The thickness of lithosphere of the east-north China has thinned since early Tertiary basalt eruptions, composed by theoliite and olivine, occurred in several episodes, now about 80km.(3) The 1976 Tangshan earthquake is not located near any known large surface fault, but in sharp velocity gradient zones both in horizontal and vertical cross sections. It might be the result of expansion of covered fault. (4) Seismicity, focal depth and mechanism of the Buohai bay link with upwelling of hot material of mantle and extensional crust there.

NUMERICAL CALCULATIONS ON TECTONIC STRESS FIELD OF CHINESE MAINLAND AND ITS NEIGHBORING REGION AND THEIR APPLICATIONS IN EXPLANATION OF SEISMIC ACTIVITY

MINGRUO JIAO, Guomin Zhang, Shi Che, Jie Liu (Center for Analysis and Prediction, SSB, Beijing 100036, China)

This paper made a numerical simulation to the basic tectonic stress field of Chinese mainland and its neighboring land using the visco-elasticity finite element pattern and the new published displacement rate result. Main contents include the simulation of maximum shear stress and its varying rate, the maximum shear strain and its varying rate, the shear strain energy density and its varying rate. In view of the highly seismic inhomogeneous distribution character in space and time in Chinese mainland and its neighboring area, the normalized background energy value was given by normalized treatment to the earthquake energy release in eastern and western parts of Chinese mainland, obtaining the normalized background energy values. And the comparison of the simulation result with the active seismicity was made. The results show that the simulation values can explain well the earthquake distribution character of Chinese mainland and its neighboring area.
Key words: tectonic stress field, numerical simulation, seismic activity, Chinese mainland

EPISODE OF COMPRESSION IN THE BAIKAL RIFT ZONE IN 1992-1993

Pyotr DJADKOV (Institute of Geophysics, av. Acad. Koptyug, 3, Novosibirsk, 630090, Russia, E-mail: djad@uiggm.nsc.ru), Valentina Melnikova and Vladimir Sankov (both at Institute of the Earth's crust, Lermontova str., 128, Irkutsk, 664033, Russia, E-mail: vimel@crust.irk.ru), Vladimir Timofeev (Institute of Geophysics, av. Acad. Koptyug, 3, Novosibirsk, 630090, Russia,
E-mail: sari@uiggm.nsc.ru)

The Baikal region is the typical continental rift, where the high seismic activity and the explicit predominance of the normal focal mechanisms are observed. The episode of compressive horizontal strain predominance was detected in the Baikal region in 1992-1993 by the geophysical methods of the crustal stress and strain monitoring: the tectonomagnetic observations in the central part of the Baikal rift, the determinations of changes of the focal earthquake mechanisms in time for all Baikal region, the extensometer measurements at station Talaya near the south part of Lake Baikal. During the March 1992 to July 1993 the number of the earthquakes with the thrust component of displacement in the earthquake sources reached 60 - 80 % , while such earthquakes occurred very rare in other periods. After the compressive episode we observed the process of the high-rate extension during 1994-1995, when the normal and strike-slip displacements in the earthquake sources occurred only. The GPS-observations were begun in 1994. These observations showed high rate of the Baikal rift's opening (~ 10-15 mm/y) for period of 1994-1996 [Calais et all, 1997]. The most probable cause of the compressive strain episode in the Baikal rift in 1992-1993 is the irregularity of development of geodynamic process in the West-Pacific subduction zones.

ST2/E/40-A3 1415

SEISMIC DEFORMATION AND THREE DIMENSIONAL VELOCITY STRUCTURE IN THE TIEN SHAN, PAMIR AND WESTERN CHINA

Lira MUNIROVA, (Institute of Seismology, Bishkek 720060, Kyrgyzstan,
email: kis@imfiko.bishkek.su) Tatyana Yanovskaya (St.Petersburg State University, Dept. of the Earth, St.Petersburg, 198904, Russia, email: yanovs@snoopy.phys.spbu.ru)

Focal mechanisms and velocity structure were used for analysis of the rheology in the region and the kinematics of the deformation. All the available data recorded by local seismological networks deployed in Kyrgyzstan (North Tien Shan) were used as the database for body waves velocity structure inversion. This database consisted on about 20000 P and 10000 S arrival time readings from local earthquakes recorded between 1967 and 1998. Also we present a study of the dispersion characteristics of intermediate period (5-60s) Rayleigh and Love waves propagating across the region for tomographic imaging. Broad-band waveform data of the events from distances from 300 to 1500 km from 1992 to 1998 recorded at 10 stations KNET. Group velocities of both Rayleigh and Love waves are used in a tomographic inversion to obtain group velocity maps. The source parameters of moderate- to large-sized earthquakes and the spatial distribution of earthquake hypocenters are used to investigate the active tectonics and three dimensional configuration of the litosphere in the Tien Shan region. Theoretical relationships allow the distributed deformation due to seismic activity to be quantified on the basis of the analysis of moment tensors. This method was applied to a data set consisting of seismic events that have occured in the past 21 yr in the Tien Shan region. As data was used the Centroid Moment Tensor Catalog prepared at Harvard University, covering the last 21 yr. Focal mechanism solutions of events beneath Tien Shan show thrust faulting with approximately E-W oriented P-axes on the North Tien Shan, N-S oriented P-axes on the Sauth Tien Shan. Events beneath Pamir show some strike-slip faulting on the eastern and nothern edge of the Pamir on the border with Western China (Tarim) and Tien Shan. The high velocities of the deformation also are occured on the Pamir, Tien Shan, Tarim boundary. The most of strike-slip events were associated with high gradient and low velocity zone.

ST2/E/57-A3 1430

EVOLUTION CHARACTERISTICS OF CRUSTAL DYNAMICS IN THE NORTH AND EAST MARGIN OF QING-ZANG(TIBET) PLATEAU

Xie Furen, ZHANG Shimin, Shu Saibing, Dou Suqin (Institute of Crustal Dynamics, CSB, Beijing, 100085, China)

The analysis result of tectonic stress field evolution based on faults slip data and crustal deformation charactistics suggest that the north and east margin of Qing-Zang plateau was subjected to an omnibearing compression caused by the collision of India plate with Qing-Zang block approximately from Pliocene to early Pleistocene, when the tectonic stress field was featured by a maximum principal compression stress perpendicular to the boundary of the

plateau and the stress regime was basically of reverse faulting type. Since the end of early Pleistocene, India plate continues to push northward and the compressional deformation of the plateau crust increases continuously and is transmitted through the northern margin of Qing-Zang block to further north. At the same time, the crustal thickening in southeast Qing-Zang decreases rapidly towards east margin indicating that the eastward

ST2/E/19-A3 1445

THE LATEST TECTONIC DEFORMATION AND CRUST MOVEMENT, SOUTHEASTERN MARGIN OF QINGHAI-TIBET PLATEAU

XUHUI SHEN (Center for Analysis and Prediction, Chinese Seismological Bureau, 100036, Beijing, China) Yipeng Wang (Institute of Geology, Chinese Seismological Bureau, 100029, Beijing, China)

The tectonic deformation and crust movement since 30KaBP is the latest period of neotectonism in southwest of China, the southeastern margin of Tibet plateau. According to existing materials, there displays clear stratigraphic unconformity, sedimentary facies change and briefly sedmentation hiatus in this period.In the respect of tectonic geomorphology, it shows tectonic basin altering and river system modifying, such as regional tectonic basins shrivel, partly embryonic basin forming, river courses rejoining-up, river capture, watersheds migrating and some superimposed valleys forming and so on. And in the respect of tectonic deformation,there shows regional stratigraphic unconformity and light fold, and some major fault zones display clear tenso-shear sliding. Tectonic deformation since 30KaBP mainly shows co-existing of escape tendency from Qinghai-Tibet Pleateau and complicated inner deformation of Chuandian Rigion. The escape rate of Chuandian Rhombus-shaped Block is 5.4~7.6mm/a at the northwest part, and 3~3.8mm/a at the center, and only 2.0mm/a at the southeastern corner. The complicated inner deformation shows regional uplifting, block rotation and partly extension and so on. The dynamic mechanicism of present crust movement may sum-up as top layer of crust slide relatively to lower layer, progressive deformation since neotectonism and two-way horizontal compressional field.

ST2/E/35-A3 1500

SEISMOLOGICAL EVIDENCE FOR THE MULTIPLE INCOMPLETE CRUSTAL SUBDUCTIONS IN HIMALAYA AND SOUTHERN TIBET

RONGSHENG ZENG (Institute of Geophysics, China Seismological Bureau, Beijing,100081, People Republic of China, email: zengrs@ public.bta.net.cn)

Geological evidences indicated large -scale shortening by thrust faultings in Himalaya, such as MCT and MBT. The thrust faulting near Yaruzampbo suture was also observed. However, it is still unknown to what depth those thrust faultings have been going down into the crust or mantle. Investigations of the earthquakes show that the thrust faultings underneath MCT, MBT and Yaruzampbo suture are closely related to the multiple crustal subductions in Himalaya and southern Tibet. They provide important constrints for the collision process between India and Eurasia. Seismological evidences also show that the crustal subductions have extended to a depth of 80 to 100 kms, and then stopped. The incomplete subductions in those places suggest that the incoming Indian plate is too light , and prevents it going further down. The multiple crustal subductions are compatible to the multiple episodes of the geological activities in Himalaya and southern Tibet. Firstly, the crustal subduction was produced at Yaruzampbo suture, and stopped at a depth of 80-100 kms. Then it migrated to the south, and another new subduction was started successively at MCT and MBT respectively. They also stopped at a depth of 80-100 kms. Beside the steep north-dipping seismic zones in Himalaya and Yaruzampbo suture, another gentle south-dipping seismic zone, extending from Tangula Shan mountain at the surface to the Moho at Yaruzampbo suture was also observed. It can be interpreted as an obduction at Tangula Shan mountain. The multiple incomplete crustal subductions in Himalaya and Yaruzampbo suture highly suggest that the incoming Indian crust has been splitted apart from its upper mantle, which may be subducted deeper into the Eurasian mantle.

ST2/W/20-A3 1515

ON STRAIN RATE OF SOUTH INDIAN PENINSULA AND SLIP RATE OF GARHWAL HIMALAYAN THRUSTS USING GPS

John Paul, Ananda M B, Dileep Kumar and Vinod Gaur (Centre for Mathematical modelling and computer simulation, Bangalore, India, email: jpaul@cmmacs.ernet.in)

Global positioning system measurements in south Indian peninsula and garhwal himalaya has thrown significant light on the knowledge of deformation mechanisms in south Indian peninsula and Garhwal Himalaya. A network of 12 points south of Bangalore have suggested a shear strain rate 0.002 microstrain/year suggesting regional stability. Baseline repeatabilities were between 3 - 7 mm. Bernese Processing Engine was used to process the data.
Measurements were carried out in Garhwal Himalaya to partition the Indo-Eurasian slip rate. GPS points measured are spread across the main boundary thrust and main central thrust were deformation may be taking place currently. Baseline repeatabilities obtained were between 4 - 9 mm. Results show a 14 mm/yr slip across the main boundary thrust between India and eurasia and 18 mm/yr slip across the main central thrust.

ST2/E/23-A3 1600

SHALLOW EARTHQUAKE SWARMS IN STABLE CONTINENTAL REGIONS

Amy BROWN and Gary Gibson (both at Seismology Research Centre, 2 Park Drive, Bundoora, Victoria 3083, Australia, email: gary@seis.com.au)

A feature of seismicity in some stable continental regions is the occurrence of shallow earthquake swarms. These swarms involve many hundreds of events up to about magnitude ML 3.0 to ML 4.0, usually with several events almost as large as the largest in the sequence. They usually start with a few very small events, then build up in frequency and magnitude over a few weeks, with peak activity lasting a few days. The activity then decays over a period of months or years, perhaps with a reduction in the relative number of small to large events (a decreasing b-value).
These events often occur at very shallow depths, within a kilometre or two of the surface. This means that events smaller than ML 1.0 are often felt within about a kilometre or two from the epicentre. They often occur where granitic rocks outcrop, or are near to the surface. This suggests that shallow swarms may be associated with movement on "joints" within the granite.
Such swarms occur every couple of years in eastern Australia, and there have been recent examples in central and southern India. In these regions, the proportion of felt earthquakes that are members of shallow swarms is much higher than in more active regions. This is possibly because earthquakes are rarely felt in continental regions, so the small events are more likely to be reported. Alternatively, it could be because high horizontal compressive stress within continents allows accumulation of strain energy at very shallow depths.
Modern portable digital seismograph systems have been installed in dense arrays above recent swarms. High sample rates and high precision timing can be used to locate events to a precision of 100 metres or better, in both epicentre and depth. It has then been possible to associate the activity with a regional fault, previously either known or unknown. Examples include swarms at Bradford Hills and Eugowra in eastern Australia.

ST2/E/27-A3 1615

SEISMICITY AND POSSIBLE METAMORPHISM BENEATH MOBILE BELTS

U. RAVAL, National Geophysical Research Institute,Hyderabad-500 007,India.

In this study it is suggested that prograde metamorphism might occur even within the fault-infected crustal column along the continental margins which have undergone severe extension. Because under some situations the necessary (P,T) conditions may be fulfilled at : (i) deeper crustal levels due to large thermal inputs, and (ii) intermediate crustal depths due to additional pressure caused by large compressions across fault-zone provided sufficient amount of hydrous-minerals (e.g. serpentinites) are present particularly in the fillings along the fault and fracture. Such fillings might arise following decompressional melting during the thermal and extensional activities along the continental margins and/or mobile belts. Anomalous gravity and magnetic signatures in the Koyna region support the intrusive activity due to decompression.
Substantial heat and mass transfer, into the crust, is expected since western margin of India where Koyna region lies, has undergone two continental breakups (at ~90 M.a. and 64 Ma.) and has also been affected very largely by outburst and trace of the Reunion mantle plume (between 66 - 60 M.a). This thermal input will elevate the crust-mantle isotherms to much shallower levels so that (P,T) conditions necessary for the prograde metamorphism might get fulfilled, even if transiently, and result in release of fluid. The latter would result in substantial variation of pore-fluid pressure and an interplay before lithostatic pressure and tensile strength. In light of this possibiliy, the metamorphically released deep-seated fluid along the faults of the rifted margins as well as mobile belts need to be evaluated more carefully. Apparently development of the low seismic velocities and high electrical conductivity anomalies/layers in such seismic zones could be the result of such release of fluid.

ST2/E/42-A3 1630

BEHAVIOUR OF HELIUM FLUX IN SEISMIC FAULTS : SOME EXAMPLES FROM STABLE CONTINENTAL REGIONS OF INDIA

R SRINIVASAN, G V Rao, G K Reddy and R U M Rao (National Geophysical Research Institute, PO Bag 724, Uppal Road, Hyderabad 500 007, India, email: postmast@csngri.ren.nic.in)

Helium flux through seismic faults has been measured in the meizo-seismal areas of the 1997 Jabalpur (Mw 5.8), the 1993 Latur (Mw 6.1), the 1900 Coimbatore (Mw 5.7) and the 1967 Koyna (Mw 6.3) earthquakes. The first three were caused by thrusting, along the Narmada south, the Killari and the Bhavani faults respectively and the Koyna by strike slip, along the Donechiwada fault. The Latur and the Koyna are shallow focus (< 10 km) and the Jabalpur and the Coimbatore are deep focus (~30 km) earthquakes. Surface rupturing occurred only in the case of the Latur and the Koyna events. The fault scarp at Killari and an area of 300 x 200 m in its immediate vicinity, recorded up to several tens of ppm helium over and above the regional background level. Outside this zone no excess helium was recorded over secondary fissures. Intermittent monitoring of helium flux over the last five years shows a waning tendency, though higher than background levels still persist. At Koyna, helium anomalies up to 7 ppm have been picked up, even after 27 years, with the peaks aligning over the enechelon fissure representing the surface rupture zone. The Koyna region is an interesting zone with several M > 4 events continuing to occur.
Our observations thus show : 1) shallow earthquakes that produce surface ruptures facilitate excessive helium leakage discerning of which would clearly establish the fault that caused the earthquake; 2) excessive helium leakage may wane with time in some cases indicating annealing of the fault or persist in areas of continued seismicity as at Koyna; 3) faults of deep focus earthquakes, which do not reach the surface, as expected, do not appear to have associated helium anomalies, as is to be expected.

ST2/E/10-A3 1645

THREE DIMENSIONAL P-WAVE VELOCITY STRUCTURE OF CRUST AND UPPER MANTLE BENEATH THE KOYNA SEISMIC ZONE

D.SRINAGESH and K.S.Prakasam (both at National Geophysical Research Institute, Uppal Road, Hyderabad-500 007, India, email: postmast@csngri.ren.nic.in)

P-wave teleseismic tomography of Koyna Seismic Zone has been studied through inversion of teleseismic travel times from a 20 station digital network. Tomographic images reveal presence of lateral velocity variations (5% to 6%) between Koyna Seismic zone and the adjoining region. The high velocity heterogeneity (1%-3%) in the crust straddles the Koyna Seismic zone and further, extends into the mantle upto a depth of 75 km below which the array configuration fails to resolve this heterogeneity. This high velocity anomaly is flanked by lower velocities both in the crust and upper mantle. The high velocity region is also reflected by positive residual Bouguer gravity indicating a deeper source. The high velocity and high density geological feature suggests a tectonic cause for sustained seismicity in Koyna region.

ST2/E/24-A3 1700

SEISMICITY, CRUSTAL RHEOLOGY AND THREE DIMENSIONAL P- AND S-WAVE VELOCITY IMAGES BENEATH KOYNA SEISMIC ZONE (DECCAN VOLCANIC PROVINCE)

S.K. SINGH, D. Srinagesh and S.S. Rai (All at National Geophysical Research Institute, Uppal Road, Hyderabad-500 007, India, email: postmast@csngri.ren.nic.in)

We present results from 20 short period triaxial digital seismic stations operated during April 1996 to December 1997 in Koyna seismic zone covering an area of 60x80 sq.km. Joint hypocentral location of more than 700 local earthquakes confined to an area of 11x25 sq.km. reveals fragmentation in the seismicity pattern - a NE-SW trend approximately dips 45x in NW direction whilst the two NW-SE trends are near vertical. The depth distribution of earthquakes shows more than 90% of the seismicity is confined to the depth range of 3-10 km with the base of seismogenic zone at 11 km. Lack of shallow seismicity up to 3 km indicates a mature fault system with well developed gouge zones which inhibit shallow earthquake nucleation. Reference 1-D velocity model of P and S waves show an increase in velocity indicating absence of LVZ with in the seismogenic crust (up to 10 km). Local earthquake travel time 3-D inversion for P and S waves show about 2% higher velocity seismogenic crust (up to 10 km) beneath the epicentral tract relative to 2 to 3% lower velocity in the adjoining region. Presence of high P and S velocity beneath earthquake epicentrenegates presence of fluid saturated/over pressured zone. The high velocity region is also manifested by a positive residual Bouguer gravity anomaly and a high gradient in magnetic anomaly indicating presence of significant inhomogeneity in the Koyna Seismic Zone. Based on seismicity, crustal rheology and 3-D velocity images we infer segmented and matured seismogenic fault systems in Koyna region where the seismicity is possibly controlled by strain build up due to competent lithology in seismic zone.

ST2/L/01-A3 1715

SOURCE CHARACTERISTICS AND FOCAL MECHANISM SOLUTIONS OF FOUR KOYNA-WARNA (WESTERN INDIA) EARTHQUAKES OF 1997 AND 1998 THROUGH INVERSION OF WHOLE BROADBAND WAVEFORM DATA

S.N.BHATTACHARYA, Seismological Observatory, India Meteorological Dept., New Delhi 110003, India.

The area just south of Koyna dam in Maharashtra state of Western India remains active since the occurrence of 1967 earthquake of magnitude 6.5. Since then the activity has extended 30 km southward to Warna reservoir. Source characteristics and fault plane solutions of a few moderate size earthquakes near Koyna dam have been obtained earlier. It is necessary to evaluate the same for small earthquakes particularly those which are occurring around Warna reservoir. During 1996-97, ten seismological observatories in the Peninsular India have been upgraded with broadband digital seismographs. Since the upgradation 4 small earthquakes of magnitude 3.9 and above have occurred in this area and these were well recorded by the upgraded observatories at Karad and Pune which are at a distance 45 to 154 km from epicentres. The ground displacement waveforms are compared with best fitting synthetic ones to obtain rise time, seismic moment and fault plane solution. The rise time of the earthquakes varies between 0.2 and 0.3 s. The seismic moment obtained has been used to obtain Mw which is only 0.1 to 0.2 higher than the corresponding ML. The earthquake on 1997 April 25, which is close to Warna reservoir, shows normal faulting along a NW striking plane. However, the other 3 earthquakes on 1997 March 20, 1998 February 11 and 14 which occurred close to Warna reservoir, show mainly left lateral strike component along a near vertical fault in NNE direction. Thus earthquakes around Warna reservoir are generally occurring along a near vertical fault in a NNE direction with a left lateral strike slip.

ST2/E/18-A3 1730

SEISMICITY OF THE DECCAN VOLCANIC PROVINCE - AN EVALUATION OF SOME ENDOGENOUS FACTORS

K.V. Subbarao (Department of Earth Sciences, Indian Institute of Technology, Mumbai (Bombay) 400 076, India, e-mail: subbu@geos.iitb.ernet.in) T.M. Mahadevan (Sree Bagh, Ammankoil Road, Cochin - 682 035, India)

The seismotectonics of the western pericontinental belt of active rifts BARS) extending from the Cambay basin in the north, southwards along the country west of the Nasik-Mahabaleshwar line (NML) of volcanic eruption centres seem to have been inherited through the evolutionary stages of the initial thermal doming and uplift at the peak of Deccan volcanism (~ 65 Ma) and subsequent thermal subsidence. The west coast plains (Konkan) and the offshore region subsided more, being predominantly the area of asthenopheric upwelling along and close to the centre of rifting and later due to offshore sediment loading. The western Ghat region forming the eastern collar of the main rift zone maintained higher elevations due both to underplating and the support of the cratonic interior. The Deccan Volcanic Province along with the rest of the shield, has however, passed from the early dilational to a compressive regime due to the impact of the plate boundary and other neotectonic forces. Any uplift, tectonic, isostatic or thermal has to operate in the non compressional set up. The thick basalt and sedimentary cover strengthen basement faults old and new stressed to near failure. Seismicity, therefore results through an interplay of these forces, some of which may compliment and others cancel each other. In areas of thick cover, earthquakes occur when the compressive neotectonics, uplift and importantly the fluid pressure amidst faults compensate the strengthening influence of the overburden cover and destabilize weak faults. There are pointers in the differences in the seismicity of these different lithospheric segments (such as BARS, Son-Narmada-Tapti belt etc.) that the seismogenic forces could operate differently in each of them.

ST2/E/55-A3 1745

CHARACTERISTICS OF THE SURFACE DEFORMATION ASSOCIATED WITH THE 1819 KUTCH (INDIA) EARTHQUAKE AND THEIR BEARING ON THE FAULT BEHAVIOUR

C.P. RAJENDRAN and Kusala Rajendran (Centre for Earth Science studies, Trivandrum, India 695 031, tel +91 471 442451, fax +91 471 442280.) email: geo@giasmd01.vsnl.net.in

The 1819 Kutch, northwest India, earthquake is a significant intraplate event that caused extensive changes in topography, damming of a river and widespread liquefaction. A remarkable feature of the Kutch earthquake is the formation of an elevated tract of land known as the `Allah Bund'. This feature remains an object of scientific interest although no survey has been made since 1846. Our field studies indicate that the maximum throw during the 1819 earthquake may have been ~3m, which varies along the strike and reduces to <0.50 m at the eastern terminus of the fault; lateral extension of the fault is ~100 km and is about 15-20 km wide. Fault geometry based on the field data suggests that 1819 event occurred on a reverse fault. Assuming a northward dip of 40 degree and a focal depth of 15 km, the epicenter would be at a point 18 km north of the maximum throw. Using this geometry, we calculate the moment magnitude of the 1819 event to be MW 7.8. The morphological features at the Runn of Kutch suggest the presence of multiple scarps formed by similar size events. Stratigraphic and trench log data support the occurrence of at least two events prior to the 1819 earthquake. Available radiocarbon age data along with the historical information suggest a recurrence period of ~1000 years for the large earthquakes in the Runn.

SEISMOTECTONICS OF EURASIA

ST2/W/16-A4 0930

SEISMOTECTONICS OF LARGEST EARTHQUAKE SOURCES IN NORTHERN EURASIA AT 1986-1997

Evgeny ROGOZHIN , Sergei Yunga (both at Institute of physics of the Earth, Moscow, 123810, B.Gruzinskaya, 10, Email: evgrog@uipe-ras.scgis.ru; syunga@uipe-ras.scgis.ru)

The largest earthquakes of northern Eurasia in the past two decades (the Kaspii, Spitak, Racha, Zaisan, Susamyr, Shikotan, Kobe, Neftegorsk, and Kronotsk events) are investigated on the base of integrated geological-seismological works in the near-field zone and data from the IRIS global seismographic network. Field investigation in near zone and study of aftershocks process and geological structures at large eartquake sources supply information concerning fault dimensions, type and amplitude of displacements on faults.It is shown that based on geological observations directly calculated characteristics of seismic sources are largely consistent with the source parameters estimated seismologically.
Our study also showed that focal mechanisms of the largest earthquakes are clearly correspond to low-magnitudes populations of fault plane solutions and regularly associated with regional geological structures. Low-magnitude earthquakes are not random events, but are regular manifestations of seismotectonic deformation and contemporary geodynamic.
In each considered case mechanism of large earthquake source is consistent with the deformation pattern of weak and moderate shocks in source region. This feature is suggested to consider as discriminative factor for recognizing characteristic earthquakes and their maximium magnitude. Acknowledgments. This work was partly supported by the Russian Foundation for Basic Research, grants 98-05-65159 and 99-05-64582.

ST2/P/10-A4 0945

THE CASPIAN REGION: INTERACTION BETWEEN THE BRITTLE AND DUCTILE LAYERS AND EARTHQUAKE RISK

Nadezhda Kondorskaya (United Institute of Physics of the Earth, Russian Academy of Science, Moscow, Russia, email: strachov@dir.iephys.msk.su) Leonid LEVIN (Centre GEON Regional Geophysical and Geoenviromental Data, 119034, Chisty per., 4, Moscow, Russia, email: moscow@geon.msk.su.) Leonid Solodilov (Centre GEON - Regional Geophysical and Geoenviromental Data, 119034, Chisty per., 4, Moscow, Russia, email: moscow@geon.msk.su)

Seismicity of the Caspian region is due to an action of a combination of geodynamic processes, namely, a collision of plates, subduction of the above - asthenosphere layer of the mantle, upwelling of the asthenosphere above old and recent zones of subduction, horizontal displacements of blocks along the lineaments; mud volcanism in the South Caspian basin. It has been established, on the base of the <<Caucasus> catalog including the data on earthquakes as of 1998, that 90% of released seismic energy is related to reologically brittle layers which, like in other regions of plate collision, are developed at two levels - the crustal and mantle. Distribution of earthquakes at these levels is controlled by a change in strained state of the ductile layer in time and space. A study of interaction between brittle and ductile layers based on the data of distribution seismic wave's energy and thermal regime of the tectonosphere has revealed a number of indicators for an estimation of earthquake risk.

DOES TURAN BLOCK MOVE TOWARD IRAN?

M. RAEESI (Geophysics Institute, Univ. Of Tehran, Tehran, Iran. email: mraeesi@iman.ut.ac.ir) M. R. Gheitanchi and Z. Zarifi (Raeesi) (Both at the above address, email: mrghchee@chamran. ut.ac.ir and zarifi@iman.ut.ac.ir)

In most researches Turan Block which is part of Eurasian plate is considered fix and geological structures in northeastern Iran are regarded as the result of compression of Iran plate to Eurasia. On Feb. 4, 1997 at 10:37:47.1 GMT a damaging earthquake (Ms 6.7) occurred in northeastern Iran in Bojnourd area. Harvard CMT solution includes two nodal planes; the first 148/80NE and the second 56/83NW. With regard to field observation the first nodal plane is the break surface. As most of earthquakes in NE Iran the quake had a right-lateral strike-slip surface rupture. Institute of Geophysics of Tehran University installed a temporary seismic network for monitoring aftershocks. More than 90% of aftershocks located at northeast of the surface rupture, in other words the northeastern block is hanging-wall and this is contrary to SW to NE compression vector which is considered for the region. Clearly it must be said that this event shows a compression vector from NE to SW. This study focuses on mechanism of moderate to great earthquakes and geological structures with skepticism to previous results and considering new viewpoint.

ST2/P/12-A4 1015

CRUSTAL SEISMIC VELOCITY STRUCTURE WITH LOCAL EARTHQUAKE TOMOGRAPHY IN NW IRAN BY AZARBAIJAN LOCAL ARRAY DATA

HAMID ZANDIFAR (Dept. of Geophysics, Exploration Directorate, NIOC, 1863, Tehran,Iran) Mohammad Reza Gheitanchi (Division of Earthquake Seismology, Institute of Geophysics, Tehran University, P.O.Box 14155-6466,Tehran, iran

Inadequacy of standard crustal models is one of the main sources of errors in locating earhquakes.Relocating will be meaningful if a more acurate crustal model is available.Each earthquake include the data set which required for determing the crustal structure. The principal data gathered in a @croearthquake monitoring network of seismograph stations are first P arrival times form local earhquakes. In order to study the crust in this research we have used the method of two stations which is independent of rnislocation errors. The various types of P phases of given earthquakes from Azarbaijan array have been calculated which the event and stations locations make a straight line on map- Then a primary model was made by a thickness approximation of different layers of crust based on previus studies and also velocity approximation. The events with magnitude between 2 and 4 were selected. Finally main method LET(Local Earthquake Tomography) applied to draw velocity profiles at different depths and directions.These profiles dete@nd the trend of velocity and crustal changes under Azarbaijan array.The damping factor was 10 and the value of RMS changes from 0.001 to 1. 1 17 sec. Compression caused by Arabian plate to southern part of Eurasia in a south-north direction have formed the Azarbaijan miicraton The results of study shows a changes of P-wave velocity near surface from 4.8 to 5 km/s. There is no increase in P-wave velocity at depth of 5 km. In deeper depth, 25 km velocity changes from 5.8 to 6.6 km/s,and velocity variation curve pattern is same as upper layer.The thickness of first layer of model changes from 4.5 to 6.3 kin and the heighest thickness is located in North,North east part. the second layer thickness changes from 18 to 22 km and relative to upper layer is uniform. The heighest thickness at this layer is located in northern part.

ST2/E/15-A4 1100

SEISMOTECTONICS OF THE EASTERN ANATOLIA: SOURCE PARAMETRES OF LARGE EARTHQUAKES OBTAINED FROM INVERSION OF TELESEISMIC BODY-WAVEFORMS

Tuncay TAYMAZ (Department of Geophysics--Seismology Section, Istanbul Technical University (ITU), Maslak-80626-Istanbul, Turkey, e-mail: taymaz@sariyer.cc.itu.edu.tr)

This presentation is concerned with the active tectonics of the eastern Anatolia. The North and East Anatolian Fault Zones accommodates most of the observed motion between the Arabian plate, and the apparently little-deforming interior of central Turkey and Eurasian plate in the eastern Anatolia.
The direction of overall slip across these zones are crucial to the determination of the slip rate on them. I have studied 1966 Varto sequence, 1967 Pulumur, 1976 Caldiran-Muradiye, 1983 Narman-Horasan, and 1992 Erzincan earthquakes in details to improve our understanding of collisional continental tectonics taking place. The waveforms used in this research include the WWSSN, and the digitally recorded seismograms of the DWWSSN, SRO, ASRO, GEOSCOPE, and IRIS networks. I compared the shapes and amplitudes of long period P- and SH-waveforms recorded in the distance range 30—90 degrees, for which signal amplitudes were large enough, with synthetic waveforms. The minimum misfit solutions obtained by the

inversion of teleseismic body waveforms are better constrained than those of the previously published first motion, and Harvard Centroid-Moment Tensor (CMT) solutions. These data allow us to discuss the slip vectors in the earthquakes with much more confidence.

ST2/E/14-A4 1115

SOURCE PARAMETRES OF CAUCASIAN EARTHQUAKES

Onur Tan and TUNCAY TAYMAZ (both at Department of Geophysics--Seismology Section, Istanbul Technical University (ITU), Maslak-80626-Istanbul, Turkey, e-mail: taymaz@sariyer.cc.itu.edu.tr)

This presentation is concerned with the active tectonics of the Caucasus, and consists of studies of two moderate earthquakes. In the Lesser and Greater Caucasus, major structures trend west-northwest, and focal mechanisms indicate primarily thrust faults striking parallel to the mountains, with shallow-dipping planes dipping to the north. Observed convergence along the Eurasian and Arabian plate boundaries is further partioned into almost pure shortening by thrusting in the Greater Caucasus, and pure right-lateral strike-slip motion in eastern Turkey. We used long-period P- and SH-waveforms and first motion polarities of P waves to determine the source parameters of July 16, 1963 (Western Greater Caucasus, to: 18:27:18.4, Ms=6.5) and July 28, 1976 (Eastern Greater Caucasus, to: 20:17:44.0, Ms=6.1) earthquakes. We compared the shapes and amplitudes of long period P- and SH-waveforms recorded by WWSSN stations in the distance range 30--90 degrees, for which signal amplitudes were large enough, with synthetic waveforms. The minimum misfit solutions obtained by the inversion of teleseismic body waveforms are better constrained than those of the previously published first motion, and Harvard Centroid-Moment Tensor (CMT) solutions, and are in good agreement with local geometry of the faults.

ST2/E/09-A4 1130

SEIMIC ACTIVITY OF MOSHA-FASHAM FAULT IN THE VICINITY OF TEHRAN, BY A LOCAL NETWORK

B. Akasheh (Institute of Geophysics, University of Tehran, Iran) M.R. Gheitanchi (Institute of Geophysics, University of Tehran, Iran. email: mrghchee@chamran.ut.ac.ir)

Historical documents of seismic activity in Iran back to more than two thousands years indicated that Tehran region has experienced great earthquakes, frequently. Micro-seismic studies by several researchers, during the past three decades also confirm that Tehran is seismically active region. It is approved that Mosha-Fasham active fault, having a fault length about 175 with a high seismic potential, can be dangerous for the city of Tehran. Therefore, in a research program, by analyzing the records of a local mobile seismic network, detailed information related to the rate and process of the fault activity are obtained.

ST2/P/09-A4 1145

ANALYSIS OF CONTINENTAL DEFORMATION BASED ON SEISMIC AND NON-SEISMIC DATA IN SOUTH-SOUTHWEST OF IRAN

BEHZAD ALAEI (Dept. of Geophsyics, Exploration Directorate, NIOC, 1863 TEHRAN, IRAN) Mohammad Reza Gheitanchi (Division of Earthquake Seismology lnstitute of Geophysics,Tehran University, P.O.Box 14155-6466,Tehran, lran)

The differences of continental deformation with general rules of plate tectonics have been known for many years and several authors have mentioned the diffuse nature of today deformation in continents. So the continental deformation should be studied with continuum mechanics. The mathematical method in order to calculate deformation parameters is mainly based on thin sheet model.The Zagros mountains form the northern border of Arabian plate which thickens due to collision of Arabia and Eurasia.The components of two tensors one M moment rate when all deformation is seismic and the other one the moment rate tensor of whole deformation caused by continent collision have been calculated and also correlated The calculations show that how many percent of deformation which took place in the collision zone is seismic.
Based on the study maximum deformation which can be related to earthquakes is about 15% and rest of deformation is non-seisrnic. Temperature-related deformation in deeper parts of earth such as creep on faults and folding are main controllers of deformation .
Strain rate tensor components, velocity gradient and uplift rate have also been measured. We have used the earthquake data in two ways. Earthquakes after 1977 which their moment data are present and for older earthquakes relationship between Ms and scaler moment can be used. The uncertainties are the short time duration of recorded earthquakes and the other one is the effect of smaller earthquakes In modem earthquakes also there is uncertainty in depth determination. The relationship between deformation and stress in Zagros area shows that the style of deformation is not basement involved and deforming of sedimentary cover is independent of basement and appear in the form of folding which in structural point of view is a good opportunity for hydrocarbon generation and accumulation.

ST2/E/29-A4 1200

SEISMOTECTONICS OF SAHNEH FAULT, MIDDLE SEGMENT OF MAIN RECENT FAULT, ZAGROS MOUNTAINS, IRAN

NOORBAKHSH MIRZAEI (Institute of Geophysics, Tehran University, Tehran 14394, Iran, email: nmirzaii@chamran.ut.ac.ir) Mohammad Reza Gheitanchi (Institute of Geophysics, Tehran University, Tehran 14394, Iran, email: mrghchee@chamran.ut.ac.ir)

A detailed structural analysis and short term micro-earthquake survey in a small region covering Sahneh Fault segment of Main Recent Fault of Zagros mountains, in western Iran, indicate that the Sahneh Fault is an active second order structure of transpression (positive flower structure) type with presently low level of seismic activity.
Meizoseismal regions of historical earthquakes, macro-seismic epicenters of pre-instrumental (1900~1963) earthquakes, as well as location of micro-earthquakes together with structural geology of the region, strongly suggest that the study region should be considered as a localizing structure, so that seismic activity of the region can not reliably be correlated to any known active faults. Present micro-seismic activity is concentrated in the area bounded by southern part of Sahneh Fault and northern elongation of Nahavand Fault, that covers the meizoseismal regions of the Farsinaj earthquake of 13 December 1957 (Ms=6.9).
Focal mechanisms of earthquakes and structural analysis confirm the prominent right-lateral strike-slip deformation along Sahneh Fault that is in consistent with relative motion between Arabian Plate and Central Iran Micro-continent.

ST2/W/19-A4 1215

INVESTIGATION OF THE ACTIVE FAULT SYSTEM DIRECTED ON NE-SW AT THE NORTHERN PART OF NAFZ-ADAPAZARI AND ITS ELONGATION INTO THE BLACK SEA

Naside OZER, Demir Kolcak (both at Department of Geophysical Engineering, Faculty of Engineering, University of Istanbul, Avcilar, 34850, Istanbul, Turkey, Email: naside@istanbul.edu.tr), Recep Cakir, S.Shelton Alexander (both at Department of Geosciences, The Pennsylvania State University, 308 Deike Building, University Park, PA 16802, USA, Email: recep@essc.psu.edu, shel@essc.psu.edu), Erdinc Yigitbas (Department of Geology, Faculty of Mining, Istanbul Technical University, Maslak, Istanbul, Turkey) and Ali Elmas (Department of Geological Engineering, University of Istanbul, Avcilar, 34850, Istanbul, Turkey)

The North Anatolian Fault Zone (NAFZ) is a seismically active right lateral strike slip fault extending E-W direction in Northern Turkey. The NAFZ splits into different branches and the characteristics of tectonic regime changes at Adapazari-Sapanca. Our study takes place at the northern part of this region. The present study aims to clarify the micro seismic activity detected within the area bordered by Kandira, Akcakoca, Black Sea continental shelf and the NAFZ-Izmit Bay, and also its significance in the geological evolution of the region.
The relocation of the earthquakes recorded by the local seismic network of the Turkish-German "Earthquake Research Project" shows NE-SW lineaments at the area which was previously regarded as connection between the Marmara Sea and the Black Sea Basin, prior to the development of Istanbul strait.
In this study, the correspondence between the seismic active zones observed on seismicity map with structural lines lying in the area between Adapazari and Karasu investigated together with their geological relation to the Black Sea and Marmara Sea basins. For this purpose genesis of this lineaments studied incorporating detailed geological and geophysical data and Landsat TM.

ST2/W/27-A4 1230

OBSERVATION OF THE ADANA-CEYHAN EARTHQUAKE JUNE 27, 1998

Naside OZER and Oguz Gundogdu, (both at Department of Geophysical Engineering, Faculty of Engineering, University of Istanbul, Avcilar, 34850, Istanbul, Turkey, Email: naside@istanbul.edu.tr, gundogdu@istanbul.edu.tr)

The Adana-Ceyhan earthquake (June 27,1998) occurred at northeastern land of the Mediterranean Sea and had magnitude Ms=6.2(USGS), M=6.3(KOERI) and Mw=6.3(USGS). 146 people were killed and over a thousand injured by this earthquake. According to the preliminary determination of General Directorate of Disaster Affairs about 9500 buildings were heavy, 2000 moderate and 40000 slight damaged.
Concerning our observations on the field, structures and questionnaires at 72 villages and towns, macroseismic epicentre is near southern part of Abdioglu village (35.56E, 36.89N).
Source of faulting is in Cukurova Basin and faulting could not be traced due to relatively great thickness of alluvial deposits and source depth. The faulting traced place to place about 15kms from southern Abdioglu village to Yeni Kucuk Kapili Ciftligi at South and to Yakapinar at North. Any recent activity and displacement could not be observed on the Misis Fault Zone.
Damage in Ceyhan is over expected as far as alluvial deposit and under ground water level of few meters increased the intensity and caused to the severe damage in this area. Sandblowing and liquefaction observed along the Ceyhan River about 45-50kms and some other place in Cukurova Basin. Unexpected damages in some villages and towns mostly caused by soil conditions. So, soil investigation should be taken into account more seriously as well as geological, geophysical and geotechnical aspects.

SEISMOTECTONICS OF THE MEDITERRANEAN

ST2/W/14-A4 1400

TRANSPRESSIONAL TECTONICS IN SOUTHERN AEGEAN

LOUVARI E., Kiratzi A. and Papazachos B. (All at Geophysical Laboratory, Aristotelian University of Thessaloniki, PO Box 352-1, Thessaloniki 54006, Greece, email: louvari@lemnos.geo.auth.gr, kiratzi@geo.auth.gr)

Southern Aegean has experienced a large number of destructive earthquakes during the last decades mainly due to the interaction between the Aegean and the African plate. To gain quantitative insight into the active tectonics of the area, new fault plane solutions based on body-waveform modeling were computed, including the last two major earthquakes of 13 Oct., 1997 (Mw=6.3) and 18 Nov., 1997 (Mw=6.5), located south of Peloponnese and south-west of Zante, respectively. The source parameters of the 18 Nov. 1997 earthquake revealed a complex pattern. Two sources were determined at the depth of ~31 Km. The time shift between the two sources was ~9 sec and the separation distance ~30 Km. The first source showed a low angle thrust fault while both sources were characterized by a considerable strike-slip component. Distribution of earthquake epicenters, fault plane solutions of small earthquakes, sea bottom topography and GIS analysis were used complementary to the above to define the orientation of the active zones.
All the data show that low angle thrust faults, in many cases having a considerable strike-slip component, coexist with high angle strike-slip faults and normal faults. P-axes mainly trend NE-SW and dip to the SW. Along the Hellenic trench T-axes trend NE-SW to SE-NW, while EW arc-parallel extension dominates along the accretionary prism.

ST2/E/61-A4 1415

THE ACTIVE DEFORMATION FIELD OF THE AEGEAN DETERMINED FROM SEISMICITY AND GPS DATA

Costas PAPAZACHOS (Institute of Engineering Seismology and Earthquake Engineering-ITSAK, PO Box 53, Finikas, GR-55102, Thessaloniki, GREECE, e-mail: costas@itsak.gr)

A model is derived for the deformation velocity and strain rate field in the crust of the broader Aegean area. Using the most reliable seismological (seismicity, fault plane solutions, etc.) and GPS data, the complete main characteristics of the crustal deformation field are retrieved. Comparison between the results obtained from the two data sets, seismological and GPS, shows a very good agreement as far as the deformation pattern is concerned. The largest part of the total deformation (GPS data) is expressed seismically. This "efficiency index" becomes significantly smaller in the southern Aegean-Hellenic Arc area. The final deformation field is more detailed than previous deformation models. According to the results, western Turkey moves towards the W-SW, with respect to stable Europe, with an average velocity of 25mm/yr, which changes in the Aegean where N-S extension dominates and the deformation velocities increase. The deformation reaches an average velocity of 30-35mm/yr in the southern Aegean. This increase further

supports the idea that the Aegean should not be considered as a part of a single Anatolia- Aegean microplate which has been suggested to perform an almost rigid body rotation. The rotational component of the velocity field, which is also retrieved, shows a clockwise rotation in central and SW Aegean and an anticlockwise rotation in the SE Aegean. This rotation is in excellent aggreement with the available palaeomagnetic data while some previous estimates showed a clockwise rotation throughout the whole Aegean area. The proposed model predicts a crustal thinning for the back-arc Aegean region, except along the outer Hellenic Arc where crustal thickening is observed, in excellent agreement with the crustal thickness variations determined for the area.

ST2/W/11-A4 1430

THE FINAL STAGE OF PLATE BREAK-OFF

Friedemann WENZEL, Blanka Sperner, and Frank Lorenz (all at Geophysical Institute, Karlsruhe University, Hertzstr. 16, 76187 Karlsruhe, Germany, email: fwenzel@gpiwap1.physik.uni-karlsruhe.de), Victor Mocanu (Faculty of Geology and Geophysics, Bucharest University, Str. Traian Vuia 6, 70139 Bucharest, Romania, email: mocanu@ter1.sbnet.ro)

When convergence of lithospheric plates ceases and the suction force of the subducting plate becomes negligible, the subducting slab moves into an almost vertical position. Wortel and Spakman pioneered the idea of slab detachment, based on tomographic images of the upper mantle beneath the Mediterranean area: At some point of weakness, the slab starts to detach horizontally. However, to date little attention has been paid to the terminal phase of break-off. What happens at the very last 'moment' before the entire subducted material of a closed ocean is separated from the overlying lithosphere and ready to sink into the mantle? Where is this geodynamic scenario observable? We show evidence that this process is active beneath the Romanian southeastern Carpathians, an area called Vrancea. The main observations that support this hypothesis are: (1) Geological evidence for ocean closure around the Carpathian Arc that progressed along the arc and terminated about 9 m.y. ago at Vrancea. Although crustal deformation has simmered on a small scale ever since, real action has taken place in the mantle, where delamination started through mass, heat, and fluid transport and also by significant strain deforming subducted portions of the lithosphere. The latter process can be quantified by seismological data. (2) Vrancea subcrustal seismicity displays extraordinary characteristics such as localization of earthquakes in an extremely small source volume and massive release of seismic energy (four events with magnitudes in excess of 6.9 within 50 years). Epicenters of Vrancea earthquakes are confined to an area of about 30 x 70 km and occur between 70 and 200 km depth within an almost vertical column. (3) Recent tomographic inversion of regional and teleseismic P-wave arrival times recorded by the Romanian network of seismological stations confirm that the intermediate depth seismogenic volume shows high velocities. As on a global scale, all images of active subduction zones are characterized by high P-wave velocities we interpret this as strong evidence for a remnant piece of a slab of lithosphere beneath Vrancea.

ST2/E/41-A4 1445

NUMERICAL STUDY OF INTERMEDIATE-DEPTH SEISMICITY IN THE VRANCEA REGION

Alik ISMAIL-ZADEH, Vladimir Keilis-Borok and Alexander Soloviev (all at International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Warshavskoye shosse 79, kor. 2, Moscow 113556, Russia, email: aismail@mitp.ru)

The earthquake-prone Vrancea region is modelled as a system of absolutely rigid blocks separated by infinitely thin plane faults. The interaction of the blocks along the fault planes and with the surrounding medium is assumed to be a viscous-elastic. The displacements of the block system are caused by motions of boundary blocks. The velocities of the motions are found from a model of mantle flows induced by a sinking slab beneath the Vrancea region. When a ratio of stress to pressure for some portion of a fault plane exceeds a certain strength level, a stress-drop ('earthquake') occurs. As a result of the numerical simulation a catalog of synthetic earthquakes is produced. Several numerical experiments for various model parameters show that the spatial distribution of synthetic events is significantly sensitive to the directions of the block movements. Small variations in a slab rotation control the pattern of the synthetic seismicity. The results of the analysis show that the catalogs obtained by the simulation of the block structure dynamics have certain features similar to those of the real earthquake catalog of the Vrancea region.

ST2/L/02-A4 1500

DEPTH DISTRIBUTION OF STRESS FIELD IN THE HELLENIC AND TYRRHENIAN WADATI -BENIOFF ZONES

Cenka CHRISTOVA (Geophysical Institute of Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria, email: cenka@geophys.acad.bg)

The study is based on the detailed morphology of the Hellenic (HWBZ) and Thyrrhenian (TWBZ) Wadati-Benioff zones which allows to discriminate earthquakes that belong to the subducting plate from those bound to the overriding one. The inverse technique of Gephart and Forsyth (1984) was used for determining the best fit principle stress directions s1, s2, s3 and the ratio R=s2-s1/s3-s1 for 40 km and 100 km depth intervals in the HWBZ and the TWBZ, respectively. The depth behavior of maximum and minimum compressive stresses in the considered Wadati-Benioff zones is different. In the HWBZ the maximum compressive stresses s1 (all considered depth ranges) are of NE trend (normal to the strike of the western subduction flank and along strike in the eastern flank), indicating the NW-SE convergence between the African and the Eurasian plates; the plunge decreases with increasing depth.
The minimum compressive stresses s3 are along dip; the plunge increases with increasing depth. The 50-100 km layer of TWBZ is characterized by along strike s1 and along dip s3. Within the two deeper layers s1 are along dip and s3 are almost horizontal and normal to the strike of the subducting plate.

ST2/W/34-A4 1515

ACTIVE DEFORMATION IN THE ALPS-DINARIDES JUNCTION (NE ITALY)

Peter SUHADOLC, Abdelkrim Aoudia (both at Department of Earth Sciences, University of Trieste and Abdus Salam International Centre for Theoretical Physics - SAND Group, Trieste - Italy, Email: suhadolc@geosun0.univ.trieste.it) and Alexei Kiryushin (Institute of Earthquake Prediction and Mathematical Geophysics, Moscow, Russia, Email: kiriush@mitp.ru)

The Alps-Dinarides junction, NE Italy, is an active part of the Adria-Eurasia collision zone. It is dominated by a NNW-SSE convergence. The Alpine structures are represented by E-W trending thrusts and folds that link towards the east with NW-SE Dinaric structures. Until recently, identification and understanding of active geological structures in this area were hindered by the lack of reliable and organised seismological data, the complex geological setting and the very dense vegetation cover. This zone has been the site of the 1976 6.5Ms Friuli thrust faulting earthquake and of the 1998 5.7Ms Bovec (NW Slovenia) strike slip faulting earthquake. We use high resolution DEM, field geology, long period surface waves inversion, joint hypocenter determination and a robust statistical method for stress tensor reconstruction to identify active geological structures and understand the present day kinematics in this region. We show: 1)evidence of active folds and flexural-slip anticlines along the E-W striking structures, where the most frontal structure has been reactivated by the 1976 Friuli earthquake; 2) how the drainage and the moraines know about fold growth in this area; 3) evidence of two active parallel strike slip faults on the Dinaric system inferred from a combined study of: the 1998 Bovec earthquake, the local microearthquakes polarity data and the DEM; and 4) that the inherited geological structures are controlling the present day fault geometry and behaviour. Clearly, most of the geological and geomorphological evidences we discuss are in an active piedmont area, at the foot of a major continental mountain range.

ST2/W/06-A4 1600

SEISMOTECTONICS OF THE BETICS AND ALBORAN SEA (WESTERN MEDITERRANEAN)

E. Buforn, A.M. NEGREDO and A. Udías (Department of Geophysics, Faculty of Physics, Universidad Complutense de Madrid, Av. Complutense s/n, 28040 Madrid, Spain, Email: figeo07@sis.ucm.es)

The two principal characteristics of the seismicity of the Betics an Alboran sea are: earthquakes of moderate magnitude (M<5.5) and focus at shallow (h<30 km), intermediate (30<h<150 km) and deep depth (h=650 km). Most of shallow shocks on the Betics have normal faulting mechanism with small component of strike-slip. In the Alboran sea, shallow earthquakes show predominantly strike-slip solutions. Intermediate depth events show vertical tension axes, indicating vertical extension. Focal mechanisms of deep events show the tension axes dipping about 45 degrees to East. The most striking feature of the area is the presence of E-W extension in the internal Betics and Alboran sea, in contrast with the general NW-SE compressive stresses associated with the convergence between Africa and Eurasia. To investigate the possible tectonic mechanisms responsible for the described pattern, we have applied to the study area numerical finite element models using the thin plate approximation. Model predicted principal stress direction and velocity distribution are compared with seismotectonic and geodetic data.

ST2/E/36-A4 1615

SEISMOTECTONICS OF THE HERCYNIAN BELT IN NW SPAIN. A GEOPHYSICAL INTERPRETATION

Julio MEZCUA (Instituto Geografico Nacional, 28003 Madrid, Spain, e-mail: julio@ign.es) Juan Rueda (Instituto Geografico Nacional, 28003 Madrid, Spain, e-mail: juan@ign.es)

The recent increase of moderate seismicity in the Hercynian belt in NW Spain started January 1979 and continuing up to present, having a maximum event on 21 May 1997 of 5.1 magnitude, near the Sarria tertiary basin. In order to characterize the seismicity of the region a comprehensive revision of both historical and instrumental seismicity had been perfomed, including the calculation of 16 new focal mechanisms. The seismotectonic interpretation had been possible incorporating not only the tectonics of the tertiary basin generation but also the crustal models obtained by gravity and aeromagnetic studies. The result points out that under a NNW-SSE stress field, a crustal layer of a few kilometers thick underthrusting in E-W direction is responsible of that activity and may be interpreted as a reactivation of the tertiary basin formation.

ST2/E/47-A4 1630

SEISMICITY, FOCAL MECHANISMS AND SOURCE PARAMETERS IN SOUTH OF PORTUGAL AUGUSTO

J. S. FITAS, M. Bezzeghoud, J. F. Borges, (Dept. de F EDsica, Apt 2E 94, 7002-554, C9vora, Portugal, tel 351 66 744616, email: mourad@uevora.pt). F. Carrilho and L. Senos (Instituto de Metereologia, Rua C do Aeroporto, 1700, Lisboa, Portugal, tel 351 1 848 39 61, email: fernando.carrilho@meteo.pt).

The Algarve province in the southern region of Portugal, where important historical seismic events took place, presents a potentially moderated and high seismic hazard. To reach a better understanding of seismicity in Algarve and its Atlantic adjacent zone, a project was implemented from January 1996 till December 1998. The results already obtained correspond to a period of three years of seismological observations. (1) The recorded spatial distribution of seismicity shows clearly five subregions: Monchique, Portimao, Loule (continental seismicity), South Faro and Golf of Cadiz (Atlantic seismicity). A more recent calculation of the parameters of Gutenberg-Richter distribution for all region is presented (a=3D3.27 and b=3D0.74). (2) The anelastic attenuation, Q facto (Q=3DQof**v), following the analysis of the high frequency of seismic code a (regional values of Qo and v) has been estimated. (3) Source parameters, seismic moment, stress drop and source radius of 12 earthquakes (with M ranging from 2.0-3.5) occurred in this region, have been determined by analysing the P-waves spectra. The computed seismic moment ranges from 8.0 10e+11 to 3 10e+13 Nm, the static stress drop ranges between 1 and 10 bars and show an increasing trend with the earthquake size. (4) Focal mechanisms determined from of 9 events, with magnitudes between 2.0 and 3.5, show that is region is under horizontal pressure about NW-SE direction, resulting in strike-slip motion. This sense of motion is consistent with the general relative motion of Eurasia and Africa.

ST2/P/02-A4 1645

EARTHQUAKE POTENTIAL ALONG THE SEISMOGENIC GEOLOGICAL STRUCTURE OF ORAN (ALGERIA): THE MURDJADJO ANTICLINE IS IT ASSOCIATED TO A BLIND FAULT?

Youcef BOUHADAD & Djamel El-Foul (National Center of Applied Research in Earthquake Engineering (CGS) 1, Rue, Kadour Rahim , H. Dey Algiers- Algeria).

We have studied the Geological structure of Oran which consists of an asymmetric fold-the Murdjadjo anticline. We analysed its relationships with the historical seismicity of the region, particularly the Oran earthquakes of 1790 (I=X) and December 1959, (M=4.5). During the October 9, 1790 about 3000 human lives were claimed following strong earthquake which hit the Town of Oran. New field observations indicates that the Murdjadjo anticline of about 32 km of length and a direction of NO5O is faulted in it's Southestem flanc. The faulted flanc bound to the North the quaternary basin of Mletta which is characterised by a high subsidence (more than 400 in of quaternary deposits).The direction of isoseismal maps of historical earthquakes are elongated in the direction of the anticline.
Quaternary terraces are observed along the Oued El Malah River (alluvial terraces) and along the coast (marine terraces where Neo-Tyrrhenien deposits are observed at altitude of 8 to 10 m above sea level).The Northwestern part is marked by small basins triggered by secondary normal faults (Ain Turck plain). Analysis of drainage network suggest that the fault present also a senestral strike component. The geological structure of Oran present analogies with the oued Fodda fault that produced the El-Asnam earthquake of October lO,1980 of magnitude Ms=7.3. In term of seismic hazard the blind fault could produce in the future strong earthquakes of magnitude greater than 6.5.

STRESS FIELD PATTERN IN EGYPT AND ITS ADJACENT AREAS BASED ON EARTQUAKE FOCAL MECHANISMS

K. ABOU ELENEAN (Nat. Res. Inst. of Astronomy and Geophysics, Seismology Department, Helwan, Egypt) Abou El Ata (Ain Shams University, Faculty of Science, Geophysics Department, Cairo, Egypt) C. Christova (Seismology Department, Geophysical Institute, Bulgaian Academy of Science) E. IBRAHIM (Nat. Res. Inst. of Astronomy and Geophysics, Seismology Department, Helwan, Egypt)

The distribution of earthquake epicenters, geological and structural setting and earthquake focal mechanisms are used for division the area into different seismic zones. The stress tensors are deduced from earthquake focal mechanisms using Gephart and Forth (1984) inversion technique for the different seismic zones. The results indicate a dominant tension stress affecting the NE corner of the African plate, which may be related to the counterclockwise of African plate with the respect to Eurasia or to the suggested radial extension centered on Cameron. The stress field is changing to compression to the north along the subduction zones beneath the Hellenic and Cyprean arcs.

ST2/E/51-A4 1715

FOCAL MECHANISMS OF SMALLER EARTHQUAKES CLOSE TO VBB KOTTAMIA STATION, EGYPT

K. ABOU ELENEAN (National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt) R. Arvidsson (Department of Earth science, Uppsala Univ. Villavagen 16, S-752 36 Uppsala) O. Kulhanek (Department of Earth science, Uppsala Univ. Villavagen 16, S-752 36 Uppsala)

The three components of the VBB Kottamia station are used to determine the focal mechanisms of smaller local events up to a distance of 200 km. The digital data is band pass filtered and the inversion is done to get the double couple solutions at different depths of each event. The root mean square errors between the observed and synthetic at different depths are calculated to find the best fit solution. The synthetic seismogram is derived for the best fit solution at different frequency bands (.01-.1, .01-.2 and .01-.5 Hz). The solution gives a good match between the observed and synthetic is selected for each event. The focal mechanisms for the events located along the Suez gulf show normal faulting mechanism which reflect that the rifting process is still be active along the gulf. These solutions give planes trending parallel to the gulf. The solutions of the events to the west of the gulf indicate normal faulting with slight horizontal movement along planes trending WSW-ENE, NW-SE and NNE-SSW. The mechanisms of the events located along the northern extension of the gulf (west of Bitter Lake) show normal faults mostly directed E-W.

ST2/E/49-A4 1730

PROBABLE ORGIN OF THE ABU DABBAB EARTHQUAKE SWARMS IN THE EASTERN DESERT OF EGYPT

E. M. IBRAHIM (National Research Institute of astronomy and Geophysics, Seismology Department, Helwan, Cairo, Egypt, email: seism01@frcu.eun.eg) I. Yokoyama (Higashi 1-17-7-1304, Kunitachi, Tokyo 186-0002 Japan)

Earthquake swarms accompanied with sound at Abu Dabbab in the Eastern Desert of Egypt have been known since the beginning of the 20th century. One of their characteristics is a periodic clustering for a long period, probably for a century. After 1970, the swarms have been instrumentally observed and discussed by several authors. Some of them proposed that the origin of the swarms was attributable to igneous activity in the Precambrian basements, showing an analogy with the activity at rifted margin of the Red Sea. In the present paper, the authors try to review and supplement the previous studies of the Abu Dabbab swarms and to discuss the circumstantial evidence to investigate their origin. The authors analyze the seismograms registered at the nearest station to the epicentral area by local seismic network for a limited period: the m-values in relation ship between maximum trace amplitude and frequency are discussed for the purpose of studying characteristics of the earthquake swarms. To find similarity, if any, among the Abu Dabbab swarms and others, four swarms are exemplified: the 1907-1915 Vogtland earthquake swarms (Germany), the 1930 Ito earthquake swarms (Japan), the 1965-1970 Matsushiro earthquake swarms (Japan), and the 1992 Al-Udayn earthquake swarms (Yemen). To explain the origin of the Abu Dabbab earthquake swarms, circumstantial evidence is examined from the standpoints of tectonics, geology and volcanology. From the discussion, it is concluded that the origin of the Abu Dabbab earthquake swarms is probably igneous.

ST2/W/09-A4 1745

SOURCE PARAMETERS AND TECTONIC IMPLICATION FOR THE TWO CONGO EARTHQUAKES OF MARCH AND APRIL, 1998

ATALAY AYELE, Geophysical Observatory, Addis Ababa University, Box. 11 76, Addis Ababa, Ethiopia, tel + 251 1 11 72 53, fax +251 1 55 21 12, email: observatory.aau@telecom.net.et

Two earthquakes occurred in Congo, in March and April, 1998. These two events are reported to have comparable size (5.5mb) and nearly same epicentral location, farther west of the western branch of the East African Rift System. The area is not much associated with the major rift trends in East Africa and the occurrence of seismic events is relatively sporadic. P-wave first motion readings from Broadband stations and waveform data at teleseismic distances are employed to study the fault mechanism and other source parameters of these earthquakes.
The preliminary result shows that the two earthquakes have similar rupture process with slight variation. The duration of each event is less than 2 secs. and the scalar seismic moment Mo is in the order of 2~3x1017 Nm. The style of the dominant deformation is thrust type, which is not common in the East African Rift System. A compressive stress environment possibly created by the extensions of the Atlantic ridge and the East African Rift System may influence this type of rupture process.

SEISMOTECTONICS OF NORTH AMERICA/FENNOSCANADIA

ST2/W/12-A5 0830

STRUCTURAL AND TECTONIC SETTING OF THE DYNAMICS OF SEISMICITY

Vladimir KEILIS-BOROK, Irina Rotwain, (both at the International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Warshavskoye shosse 79 kor.2, Moscow 113556, Russia, email: vkborok@mitp.ru) Dmitry Rundkvist (State Geological Museum, Russian Academy of Sciences, Mokhovaya 11 kor. 2, Moscow 103009).

Dynamics of seismicity is to a large extent controlled by the structure of the tectonic blocks&faults system, comprising the seismically active lithosphere. We describe powerful mechanism of such control concentrated to a large extent in the fractured zones (nodes) surrounding the faults intersections. This includes reconstruction of the system, nucleation of the earthquakes, emergence of transient asperities and weak links and, premonitory phenomena, specific to geometry of the system. Model of this mechanism brings together the data on the movements in a broad velocity range - from seismicity, to creep, to GPS, to neotectonics, - and possibly also the data on fluids migration. Pilot applications of similar approach to intraplate regions are discussed, North American platform included.

ST2/W/08-A5 0845

NEW INSIGHTS INTO THE SEISMOTECTONICS OF NORTHEAST PACIFIC OCEAN SPREADING CENTERS, TRANSFORM FAULTS, AND MICROPLATES USING HYDRO-ACOUSTIC MONITORING METHODS

Robert P. DZIAK and Christopher G. Fox (OSU/NOAA, Marine Science Center, Newport, OR 97365 U.S.A., email: dziak@pmel.noaa.gov)

Since August 1991, NOAA/PMEL has been monitoring seismicity from the northeast Pacific Ocean using the U.S. Navy's SOSUS hydrophone array. Oceanic earthquakes are detected on the hydrophone array using the acoustic Tertiary (T-) wave that propagates within the ocean's low-velocity sound channel. Use of T-waves for detecting and locating northeast Pacific ocean earthquakes has lowered the regional detection threshold to mb~1.8. Optimum hydrophone array distribution coupled with precise ocean sound-speed models has resulted in low-error epicentral locations with excellent correspondence to active seafloor faults and volcanic features. During the past 8 yrs, three major seafloor spreading episodes have been detected, two along the Juan de Fuca Ridge in 1993 and 1998, and one along the Gorda Ridge in 1996. Each spreading event was characterized by: 1) Several hundred earthquakes that occurred for 1-3 weeks, 2) low-magnitude (Mw < 3.5) events that went undetected by land-seismic networks, and 3) earthquake epicenters that migrated, during the first few days, distances of 35-65 km along the ridge segments. Earthquake epicenter migration was inferred to be the lateral injection of a magma dike into the shallow ridge crust, which was later supported by extensive field observations. The Blanco Transform Fault (BTF) and Sovanco Fracture Zone (SFZ) are two major right-lateral transforms within the optimum coverage of the SOSUS array. Hydroacoustic monitoring of BTF seismicity has shown evidence of tectonic earthquake sequences limited to individual strike-slipfault segments, and volcanically active pull-apart basins. Moreover, acoustic locations of large BTF events (4<Mw<7) show good correlation of earthquake source parameters to geologic structure. In December 1991, >700 earthquakes were detected along the Heck Seamounts, a chain parallel to and south of the SFZ. The acoustic location of a (Ms=6.0) strike-slip event within the swarm suggests the initiation of a previously unrecognized transform segment. In 1991-1992, a band of acoustically detected microseismicity (Mw<3.5) was located within the outer-rise of the Gorda Plate. The microseismicity ceased following the occurrence of a large thrust earthquake at the adjacent subduction zone.

ST2/W/07-A5 0900

ESTIMATES OF STRESS DIRECTIONS BY INVERSION OF EARTHQUAKE FAULT PLANE SOLUTIONS IN THE CENTRAL WASHINGTON CASCADE MOUNTAINS (USA)

GIAMPICCOLO E., Gresta S., Malone S.D. and Musumeci C., Istituto di Geologia e Geofisica – Universit di Catania, Corso, Italy, 55. email: Eligiamp@mbox.unict.it

The tectonic setting of north-western United States is dominated by the interaction between three plates. The small oceanic Juan de Fuca plate subducts beneath the North American one which, on a larger scale, is moving to the south-east relative to the Pacific plate. While the Cascade Range volcanoes result from the subduction process, crustal tectonics are dominated by N-S compression due to the North American Pacific plates interaction. In this study we used ca. 800 earthquakes recorded between 1980-1998 in the central Washington Cascade Mountains to investigate, on a local scale, how uniform the regionally dominant north-south compressive stress field is and if there are some changes that can be associated with local structures. Earthquake locations from the Pacific Northwest Seismograph Network (PNSN) catalogue were grouped into four different zones. Two of them are referred to the volcano body of Mount St. Helens (last eruption in October 1986) and to the Mt. Rainier one (last eruption more than 200 years ago). The other two seismic zones run NNW-SSE and are located respectively 5 km to the north of Mt. St. Helens (St. Helens Seismic zone or SHZ) and 15 km to the west of Mt Rainier (Western Rainier Seismic Zone or WRSZ). The stress field inferred from the focal mechanisms of different subsets was calculated using the Gephart and Forsyth technique. As in previous similar studies we found that the maximum compressive stress axis (s1) in the Mount Rainier area is nearly horizontal and trending ca. N-S and NNE-SSW, in all but one subset. In fact, events beneath Mount Rainier (0-5 km) show a near vertical s1 suggesting that gravitational forces dominate the maximum compressive stress. For other subsets the minimum compressive stress axis (s3) deviates from vertical to horizontal for events in the depth range of 10-14 km in the WRSZ. We hypothesize that the change in orientation of s3 for the 10-14 km depth range in the WRSZ is probably due to the influence of the nearby Mount Rainier magmatic system as suggested from the deep low-frequency or long-period (LP) earthquakes located in the south-west part of Mount Rainier summit. In the Mt. St. Helens area we found a uniform stress field along the SHZ, with the maximum principal stress s1 oriented horizontally in a NNE-SSW direction and the minimum principal stress s3 oriented ENE-WSW, consistent with the regional tectonics of the Washington part of North America. No evidence is found of stress change as a function of the depth and the subdivision in subsets does not appreciably change the results. Contrarily, earthquakes directly under the volcano body Mount St. Helens (0-10 km) show some variability of the stress field as function of space and time, related to magmatic processes occurring within the conduit.

ST2/E/34-A5 0915

DEEP CRUSTAL STRUCTURE OF THE SAN ANDREAS FAULT SYSTEM IN CENTRAL CALIFORNIA AND ITS RELATION TO THE GENERATING PROCESS OF M6-7 EARTHQUAKES

Kin'ya NISHIGAMI (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, email: nishigam@drs.dpri.kyoto-u.ac.jp)

We estimated 3-D distribution of coda scatterers in the crust in central California by using an inversion analysis of coda envelopes from local earthquakes. 3,801 seismograms of the Northern California Seismic Network were analyzed. The San Andreas fault and other sub-parallel faults seem to be almost vertical from a surface to about 15km depth. The scatterer distribution also shows a sub-horizontal detachment structure connecting the San Andreas fault (SAF) and the Hayward-Calaveras faults (HCF) in the lower crust, and some deeper heterogeneous structure at 30-45km depths below the detachment. This image suggests the

sub-horizontal detachment structure may transfer the shear stress due to a continuous slip across the Pacific-North American plate boundary to the bottom of the SAF and the HCF. Segmentation structure of the SAF is also estimated from south of San Francisco to San Juan Bautista. Partially locked segments with a horizontal length of about 20-30 km are ruptured during respective M6-7 earthquakes and the segment boundaries are estimated to be weak zones characterized by stronger scattering and stationary micro-seismicity. The segment boundaries estimated by the present analysis almost exactly agree with one of those proposals estimated from the slip distribution of the great 1906 San Francisco earthquake as well as the fault geometry, although the segment boundaries along the SAF in and around the San Francisco Bay area are still under discussions and speculative.

ST2/W/10-A5 0930

SEISMOTECTONICS OF SOUTHERN CALIFORNIA: RECENT DEVELOPMENTS

E. HAUKSSON, J. Hardebeck, J. Nazareth Seismological Laboratory, Caltech, Pasadena, CA, 91125 USA; L. Jones U.S. Geological Survey, 525 S. Wilson Av., Pasadena, CA, 91106, USA

Near the US Mexico international border, the Pacific North America plate boundary is characterized by extensional tectonics as it emerges from the Gulf of California, reflected by dextral fault steps in Imperial Valley. To the north of Los Angeles the big bend of the San Andreas causes compressional tectonics to west, within the Pacific plate. A separate zone of right-lateral shear and some extensional tectonics extends into the North America plate, referred to as the eastern California shear zone. We synthesize seismicity, Vp and Vp/Vs velocity structure, and state of stress along these tectonic features. The heterogeneity of the crustal structure as imaged in both the Vp and Vp/Vs models is larger within the Pacific plate than the North America plate reflecting regional asymmetric variations in the crustal composition and past tectonic processes. Similarly, the spatial distribution of the seismicity reflects shallower seismicity within the North America plate and more complex three-dimensional distribution within the Pacific plate. The change in depth of seismicity appears to coincide with the major northwest striking strike-slip faults such as the San Andreas, San Jacinto, and Elsinore faults. The most complex three-dimensional seismicity distributions within the Pacific Plate are in areas of compressional tectonics. We have inverted for the state of stress from focal mechanisms to determine the predominant type of faulting and the orientations of the three principal stresses. The predominant orientation of the maximum principal stress varies from due north to 30deg east of north. The small scale spatial variations in the stress state may be affected by presence of high pressure pore fluids and proximity to the active fault strands of the San Andreas fault.

ST2/E/44-A5 0945

LATERAL VARIATION OF SEAFLOOR ROUGHNESS NEAR THE TRENCH AND LARGE EARTHQUAKE OCCURRENCE ALONG THE MEXICAN SEGMENT OF THE MIDDLE AMERICAN TRENCH

Carlos A. MORTERA-GUTIERREZ (Instituto de Geofísica, Universidad Nacional Autonoma de México, Cd. Universitaria, D.F., C.P. 04510, México, email: carlosm@ollin.igeofcu.unam.mx)

The lateral variation in surface roughness of the subducting plate along the western margin of Mexico is examined in correlation with the mode of large-earthquake occurrence along the northern segment of the Middle American Trench (MAT). From the seafloor topography derived from satellite altimetry and topographic profiles, the occurrence of large earthquakes correlates with regions where the surface roughness of the ocean bottom near the trench is greater. Along the MAT, the seafloor roughness near the trench is greater to the east and west of the Guerrero Seismic Gap (GSG) region. In the Jalisco-Colima-Michioacan segment, west of the GSG, horsts and grabens trending diagonal to the trench dominate the ocean bottom roughness fear the trench. In the Guerrero-Oaxaca segment to the east of GSG, the seafloor roughness contains linear trends of fracture zones striking nearly normal to the trench. The region where the ocean bottom is relatively smooth along the MAT coincides with the region of seismic quiescence along the Guerrero coast. It has been proposed for the Japan Trench where the seafloor roughness is smooth that the subducted seafloor form a homogeneous, strong contact zone in the plate interface and that the seismogenic zone extends to greater depths. Therefore it is expected that large thrust earthquakes should occur in the deeper part of the seismogenic plate interface (e.g. 1968 Tokachi-oki event). However the reverse is observed for the Mexican subduction zone. In the GSG region, it is observed that no large earthquake have occurred along the plate interface zone. Whereas in the regions of rough surface along the Japan Trench, the subducted structures (e.g. horsts and grabens, seamount chains and fracture zones) create zones of sufficient contact with the overriding plate at shallow depths of the plate interface zone, causing large tsunami-earthquakes (e.g. 1896 Sanriku event) and large normal-faulting intraplate events (e.g. 1933 Sanriku event). Both areas of rough-seafloor along the MAT correlate well with regions where: (1) large normal intraplate earthquake have occurred in the subducting plate (e.g.1997 Michioacan event of Mw 7.1), (2) large underthrust earthquakes have occurred in the shallow region of the plate interface zone (e.g. Jalisco 1932 event with a magnitude of 8.1, 1957 San Marcos of Mw 7.8, 1995 Colima-Jalisco event of Mw 8.0), and (3) tsunamis have been seismically generated (e.g. 1978 Oaxaca event of Mw 7.8, 1985 Michioacan event of Mw 8.3, 1995 Colima-Jalisco event of Mw 8.0).

ST2/W/05-A5 1000

THE WESTERN GUERRERO, MEXICO, SEISMOGENIC ZONE FROM THE MICROSEISMICITY ASSOCIATED TO THE 1979 PETATLAN AND 1985 ZIHUATANEJO EARTHQUAKES

D.A. NOVELO-CASANOVA and C. Valdes-Gonzalez (both at Instituto de Geofisica, UNAM, Mexico 04510 D.F., Mexico, email: david@ollin.igeofcu.unam.mx)

The Western Guerrero, Mexico, seismogenic zone was completely ruptured by the 1979 (Ms= 7.6) Petatlan and 1985 (Ms= 7.5) Zihuatanejo earthquakes. Hypocenters of the Petatlan aftershocks define an approximately 10-km-thick Wadati-Benioff zone of high seismic activity and a thinner seaward region that is primarily an extension of the deeper part of the 10-km-thick zone. The aftershocks of the Zihuatanejo earthquakes occurred in the seaward portion of the same epicentral region but the hypocenters were shallower. The spatial distribution of the closely timed microseismicity following the two earthquakes outlines a seismogenic zone which begins at about 40 km from the trench axis of the Western Guerrero subduction region and extends approximately 90 km. These results indicate that the maximum possible size of thrust eartquakes in the Guerrero seismic gap is of Mw ~ 8.4.

ST2/W/18-A5 1015

FOCAL MECHANISM STUDY IN COSTA RICA AND VICINITY, CENTRAL AMERICA

Ronnie QUINTERO and Federico Guendel (OVSICORI, Costa Rica, email: rq@geofys.uu.se)

We have relocated 1698 earthquakes which have occurred in Costa Rica and vicinity. Relocated earthquakes were used to investigate the fault plane solution within the mentioned area. The analysis was made using the polarities of first motions of P waves. The area in study is characterized by the subduction of the Cocos under Caribbean plate. Therefore the dominant fault plane solutions are reverse fault with some anomalies caused by the subduction of sea mounts and a trancurrent plate boundary that traverses central Costa Rica from west to east. These anomalies produces normal and strike slip faulting, especially along the frontal arc in central Costa Rica.

ST2/L/03-A5 1030

SUBDUCTING PLATE MORPHOLOGY AND ITS RELATED SEISMICITY: NEW BATHYMETRIC EVIDENCE FROM THE TONGA AND MIDDLE AMERICA TRENCHES

Nancy KANJORSKI: Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093

The extreme geometry of the Tonga trench creates significant changes in the seismicity of the subduction zone. The northern bend to the west is known to add a strike slip component of motion to the numerous earthquakes in this region. New bathymetric data of this area illustrates the physical manifestation of this seismicity in magnificent faulting along the outer rise over a series of extensional "tear" faults. This influence of plate geometry on the activity of the subduction zone persists over 150 km east of the trench. However, we find that the exceptional Tongan type crook in the axis is perhaps unnecessary to influence the outer rise morphology and subduction seismicity. A comparison between the curvature of the Tonga trench and the muted bend of the Southern Mexico trench off Oaxaca is instructive as both display similar trench morphology and seismicity.
The Mexico trench has always been a region of interest for its patterns of seismicity. Here along the trench a subdued bend of the axis creates some notable outer rise weaknesses evident in unique faulting and anomalous seismic activity. The weakened subducting crust with its rough inherited
volcanic terrain allows for regular moderate stress release along the interplate thrust zone. Around the bend to the east the background seismicity common along much of the Middle America Trench is tranquil. The few larger historical events in this area display components of strike slip activity. Missing here from the outer rise are the perpendicular scarps which enhance the seismicity north of the bend. Dividing these two territories the trace of an extensional tear fault like that of the northern Tonga Trench fractures the outer swell of the subducting plate. This Puerto Angel Fault extension has created deep outer rise sediment ponds which run along the sinuous scarp. It is likely that, as recognized in the Tonga trench, the Mexico trench exhibits seismicity related to the subducting plate weakness and geometry.

ST2/W/28-A5 1115

SEISMOTECTONICS OF THE NORTHEASTERN UNITED STATES

John E. EBEL (Weston Observatory, Department of Geology and Geophysics, Boston College, Weston, MA 02493, USA, email: ebel@bc.edu)

The northeastern United States is an intraplate region with low or moderate seismicity located on a passive margin. Earthquake activity is scattered broadly across the region, from the coastal areas through the Appalachian orogen and into the precambrian craton. The principal stresses associated with the earthquakes are consistent with those from plate driving forces. Regional seismic network monitoring is being carried out to determine which geologic structures are seismically active and how large an earthquake can occur on those structures. Currently, there have been insufficient data collected to determine which specific structures are seismically active. On a regional basis, most of the modern earthquakes are occurring on or near structures that formed or were reactivated during Mesozoic rifting. These structures include faults, dikes and uplifts. Since some of these faults are hundreds of kilometers in length, major earthquakes (M7+) may be possible at a number of localities in the region, although with a relatively low frequency of occurrence.

ST2/E/50-A5 1130

SEISMICITY AND RHEOLOGY OF THE CHARLEVOIX SEISMIC ZONE, QUEBEC, CANADA

G. RANALLI (Department of Earth Sciences, Carleton University, Ottawa, Canada K1S 5B6; email: granalli@ccs.carleton.ca) M. Lamontagne (Geological Survey of Canada, 1 Observatory Crescent, Ottawa, Canada K1A 0Y3; email: maurice@seismo.nrcan.gc.ca)

The Charlevoix Seismic Zone (CSZ) is the most active seismic zone of Eastern Canada, with five historical earthquakes in the 6-7 magnitude range and high background activity (about 1500 shocks with magnitude 0 to 5 from 1977 to 1997). Epicentres define a 30x85 km ellipse along the St. Lawrence River 100-150 km downstream of Quebec City. The hypocentre distribution shows an increase with depth to a peak at 10-12 km, followed by a decrease: 99% of all events are shallower than 25 km. Most events occur in highly fractured volumes that are sometimes bounded by regional faults.
The temperature at a depth of 25 km is estimated to be between 220 and 360 C. Values in the upper range coincide with the brittle/ductile transition if the rheology of the lower crust is quartz-controlled. However, most interpretations of the CSZ require a more basic lower crust. Consequently, neither the peak nor the cutoff of seismicity in the CSZ appear to be related to the transition to bulk ductility.
Focal mechanism solutions show predominantly reverse faulting on steeply dipping planes. The reactivation of these fractures requires high pore fluid pressure and/or low friction coefficient. If earthquakes in the CSZ are a consequence of frictional Coulomb failure, the evidence points to the occurrence of relatively high fluid pressures (~ 60-90 of lithostatic) in the lower crust.

ST2/E/32-A5 1145

NEW SEISMIC ACTIVITY IN THE NORTH ATLANTIC RIDGE

Bela Assinovskaya (Geodynamical Laboratory, CAO RAS, Bolshoi pr.50G, V.O., 199034, Saint-Petersburg,Russia, email: bela@ba2248.spb.edu)

Connection of two global North Atlantic and Arctic ocean rift systems it is known to have distinctive features as rapid change of submeridional rift strike to subparallelal and closeness to the Svalbard High with its continental type of crust.The earthquake data of the 20th century from the Knipovich Ridge and Spitsbergen fracture zone and the seismic process trend of the region are examined. According to seismic, morphological and geophysical information complex combination of some rift and transform fault zones is recognized here. The seismicity of these zones is distinguished by many parameters: 1.earthquake concentration density 2. source depth 3.seismic regime 4. laws of seismotectonic deformation release. For example, transform fault zone spaced more closely to the Svalbard High is characterized by occurring of rare but large earthquakes, focal depth about 20 km and nonlinear mode of seismic energy

release . Reciprocating migration of earthquake sources with Mb>5 along the North Atlantic ridge strike is studied. Two slow channels (V=3-10 km/y) with sources that travel to the south direction and one quick channel (V=40 km/y) with of earthquake sources that travel to the of rift split direction are marked out in the time-space field by numerical method. At the intersection of these channels the largest event of region of 28 March 1998 Mb=5.9 occurred. All together four large (Mb =5.7-5.9) earthquakes occurred within the Knipovish rift zone and Spitsbergen Fracture zone during the last 6 years, all of them had focal mechanisms of the same type – predominance of right-side strike slip along the main faults. In total these sources migrated along half-round way clockwise from the north of the Knipovish Ridge to central part of it and then to the north to the parts of Spitsbergen Fracture zone.The described seimic activity was predicted earlier (B. Assinovskaya "Earthquakes in the Barents Sea").

ST2/E/31-A5 1200

SEISMOTECTONICS OF THE NORWEGIAN CONTINENTAL MARGIN

H. BUNGUM (1,2), C. Lindholm (1), O. Eldholm (2) and E. Hicks (1,2) 1. NORSAR, Kjeller, Norway 2. University of Oslo, Oslo, Norway

The Norwegian continental margin is less seismically active than some other passive margins, but still highly active on a northern European scale, with historical earthquakes up to magnitude 6, and with some 60 earthquakes above magnitude 2.5 every year. Historical data and more recent instrumental studies using dense networks of stations and arrays have shown that the seismic activity is concentrated to the local zones along the margin and to coastal regions, but with seismic activity also in the Viking and Central Grabens and the Oslo Rift zone. The earthquake depths vary from about 30 km (offshore) to shallow microactivity at around 5 km in coastal regions, reflecting not only the varying physical properties of the crust but also a regional differention of deformation processes with depth. The stress field complies in general with the ridge push force, but with significant contributions also from regional and local sources of stress (including lateral density inhomogeneities, deglaciation, sediment loading, and topographic effects), the latter in fact being necessary for explaining the earthquake activity. The relative importance of these local sources of stress is supported by several cases of 90 degree stress reversals relative to the ridge push direction. One of the most significant local sources of stress has been found to be the rapid deposition of late Pliocene-Pleistocene glacial sediments, particularly in parts of the Lofoten and Norway ocean basins and below thick glacial depocenters on the margin, where the excess load has enhanced the local stress field, and consequently the seismic activity. In contrast, crustal underplating may contribute to crustal strengthening and thereby less seismicity, in particular at marginal highs. We suggest that increased stress due to appreciable post-glacial rebound gradients in the coastal region also may be a contributing factor.

ST2/E/11-A5 1215

CONCENTRATED EARTHQUAKE ZONES ON THE NORWEGIAN CONTINENTAL MARGIN

HICKS, E.C. (1,2), C.D. Lindholm (1) & H. Bungum (1,2) 1. NORSAR, Kjeller, Norway; 2. Dept. of Geology, University of Oslo, Norway

The Norwegian continental margin is comprised of a complex system of deep rifted sediment basins and adjacent highs. The southern parts of the margin are dominated by Triassic to early Cretaceous rift basins in the North Sea, while the Mid-Norwegian margin to the north sustained rifting mainly in Late Cretaceous to Paleocene, leading up to the continental breakup and opening of the North Atlantic ocean with associated volcanic activity.
Earthquake swarms in coastal areas of Mid- and Northern Norway are known to occur fairly regularly, the Ms 5.8-6.2 earthquake of 1819 was also located in this area, while the southern parts of the Mid-Norwegian coast have lower levels of activity. Since 1997, a local network in the Rana area (Northern Norway) has located a large number of small, shallow coastal earthquakes (magnitudes up to Ml 2.8). Several new focal mechanism solutions with inverted (90 deg. rotation) horizontal stress directions compared to the regional case have also been determined. The earthquakes show a complicated spatio-temporal activity pattern, with the activity distributed among several distinct groups, all having similar NW-SE elongated trends. There does not appear to be any connection between the observed earthquakes in this area and the nearby Baasmoen fault, a major fault thought to have been postglacially active. The northern parts of the North Sea have the highest levels of seismic activity in Fennoscandia. Recently, a new local network (in the Bremanger area) has provided new insight into this activity through improved location and detection capabilities. Although detailed correlation of earthquakes and faults is always difficult due to hypocenter location uncertainties and problems in tracing the fault plane with depth, new detailed fault mapping in this area combined with improved earthquake data may be able to provide more insight into the interaction of existing faults and seismic activity.

HIGH SEISMO-TECTONIC ACTIVITY IN SWEDEN AT THE TIME OF DEGLACIATION AS RECORDED BY MULTIPLE PALEOSEISMIC EVIDENCE

Nils-Axel MOERNER Paleogeophysics & Geodynamics, S-10691 Stockholm, Sweden, email: morner@pog.su.se

Today, Fennoscandian is characterized be a low to moderatly low sesmic activity. At the time of deglaciation, the situation was quite different, however: the whole region was characterized by both large and frequent earthquakes. The rate of isostatic uplift then amounted to some 10 cm per year (i.e. about 10 times as high as the present sea floor spreading rates). In Sweden, we have the possibility of utilizing the varve chronology for the dating of paleosesmic events. This means that we can achieve an annual resolution despite ages in the order of 10,000 years. This technique has successfully been applied to some regions in Sweden. In the Stockholm region, we have been able to date an extremely large paleo-seismic event to the autumn of varve year 10,430 BP. This event caused liquefactions and varve disturbancies over an area of about 60 x 320 km, which exceeds the liquefaction distribution of the famous Alaska 1964 event. We have also been able to identify multiple events re-occurring about every 20 varve (~10,490, 10,469, 10,447, 10,430, ~10,410 BP) indicating an unusually high frequency of the event, too. A Holocene event occurred along the same fault zone at about 3500 BP. At Iggesund, we have recorded heavy bedrock deformations in association with strong sediment deformations from both ground shaking and tsunami waves, and turbidites over an area of 60 x 210 km at varve 9663 BP. Other high-amplitude events are the Äspö event at ~12,200 BP, the Kinnarumma event at ~11,700 BP, the Billingen event at ~10,400 BP, the Gillberga event at ~10,000 BP, the Lansjärv event at ~9,150 BP and the Pärve event at -9,000 BP (Ref.: Quaternary Science Reviews 15: 939-947, 1996). They occur all over Sweden. Our paleoseismic records give a totally new situation for issues of a long-term deposition of high-level nuclear waste in the bedrock.

LONG-PERIOD AFTERSHOCKS OF A MODERATE-SIZE EARTHQUAKE NEAR THE IWATE VOLCANO, NORTHERN JAPAN, OBSERVED BY A BROADBAND SEISMIC ARRAY

Masahiro KOSUGA, Kazutoshi Watanabe, Yoshimichi Senda, and Hisayuki Sakoi (all at Faculty of Science and Technology, Hirosaki University, Hirosaki 036-8561, Japan,
email: mkos@cc.hirosaki- u.ac.jp)

We have examined the origin of long-period (LP) aftershocks associated with a moderate-size (M=6.1) earthquake that occurred on September 3, 1998, to the south of Iwate volcano in northern Japan. The broadband array was deployed to observe volcanic tremors and low-frequency earthquakes near the volcano whose activity has increased from the beginning of 1998. We could obtain array recordings of many aftershocks with epicentral range from 15 to 30 km.
The noticeable feature of aftershocks is the existence of LP events aligned along the eastern margin of the aftershock zone. LP phase that appears about 10 s after the P-wave is characterized by a predominant period of 2 s, larger amplitude than that of S-wave, and long (> 20 s) duration. From the semblance analysis we found that the LP phase comes from the direction of epicenter. The facts of large slowness and retrograde particle motion suggest the wave type of Rayleigh wave. The basin structure extended to the east from the aftershock zone probably play a key role to enhance the surface wave, however, UP Diliman campus, Diliman, Quezon City 1100, Philippines) we used hypocentral (1619 to 1997) …and focal mechanism (1963 to 1997) data in order to characterize the tectonic configuration of northern Luzon and refine a model for describing the geometry of the subducted slab of the Eurasian plate beneath the northern segment of the Manila Trench. We considered the bend in the trench line of the Manila Trench at 20°N lat, the collision and subduction of an extinct mid-oceanic-ridge at 16-17°N lat and the intraplate deformation pattern in the North Luzon Ridge region in depicting a new model that will be consistent with most of the observed features and phenomena in the study area. The model suggests the collision and subsequent partial subduction of a buoyant plateau at around 20°N lat to explain the sharp bend in the trench line, the complicated deformation pattern on the overriding plate fronting the bend and the shallow dip of the subducted slab beneath this zone. The shoaling of the dip of the slab may be due to the buoyancy effect of the subducted part of the buoyant plateau. The change in...

AN ALTERNATIVE MODEL FOR THE GEOMETRY OF SUBDUCTING SLABS IN NORTHERN LUZON, PHILIPPINES

BARTOLOME C. BAUTISTA (1,2,) Ma. Leonila P. Bautista1, (2) and Kazuo Oike (1) (1), Dept of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, Sakyoku, Kyoto, Japan, 606-8502; (2), Philippine Institute of Volcanology and Seismology, C. P. Garcia Avenue, UP Diliman campus, Diliman, Quezon City 1100, Philippines)

We used hypocentral (1619 to 1997) and focal mechanism (1963 to 1997) data in order to characterize the tectonic configuration of northern Luzon and refine a model for describing the geometry of the subducted slab of the Eurasian plate beneath the northern segment of the Manila Trench. We considered the bend in the trench line of the Manila Trench at 20°N lat, the collision and subduction of an extinct mid-oceanic-ridge at 16-17°N lat and the intraplate deformation pattern in the North Luzon Ridge region in depicting a new model that will be consistent with most of the observed features and phenomena in the study area. The model suggests the collision and subsequent partial subduction of a buoyant plateau at around 20°N lat to explain the sharp bend in the trench line, the complicated deformation pattern on the overriding plate fronting the bend and the shallow dip of the subducted slab beneath this zone. The shoaling of the dip of the slab may be due to the buoyancy effect of the subducted part of the buoyant plateau. The change in dip shifted the position of the magma generation level towards the east and may have led to the subsequent extinction of the western chain of volcanic centers and the eastward shift of active volcanism in the region. A tear in the slab is also inferred to be present as evidenced by the observed gap in strain energy release and the abrupt change in dip from shallow to steep south of 18oN lat. The gap in seismicity and strain energy release (65-300 km depth) at around 17oN lat may be used to infer the trajectory and location of the subducted extinct mid-oceanic-ridge. The subducted ridge is still probably hot and is deforming plastically causing the aseismic behavior. The subducted part of the mid-oceanic ridge may serve as the weakest zone where this tear could be localized. The tear may also explain the cause of the abrupt termination of the eastern chain of volcanoes south of 18oN lat. The above model, which is a refinement of the model introduced by Yang et al (1996) is consistent with the observed seismicity and deformation pattern, bathymetric features, spatial distribution and geochemical character of volcanism in northern Luzon.

ST2/W/04-A5 Poster 1400-03

DECAY OF MICRO-EARTHQUAKE SEISMICITY ACTIVATED BY STATIC STRESS CHANGE

Mamoru NAKAMURA (Department of Physics and Earth Sciences, University of the Ryukyus, Senbaru, Nishihara-cho, Okinawa, 9030213, Japan, email: mnaka@sci.u-ryukyu.ac.jp)

Background seismicity of micro-earthquakes activates occasionally in the surrounding of the mainshock area after the large earthquake. The activated background seismicity decays with time. We investigated the index of decay of activated background seismicity (p value) using 1995 Hyogo-ken Nanbu (Kobe) earthquake, Japan and 1989 Loma-Prieta earthquake, California. The micro-earthquake seismicity changed in the surrounding of the aftershock area of the Kobe earthquake. The background seismicity in this area activated five times higher than that before the mainshock. We obtain the estimate of p value in Ohmori formula for the activated background seismicity. Hypocenter data we used are catalogued by DPRI, Kyoto University. The p values scatter from 0.5 to 0.9. These values are much lower than that obtained from aftershock decay (usually p = 0.9-1.5). We compare them with change of the CFF using dislocation model by Hashimoto et al. (1996), which is estimated using geodetic data. High p value (p=0.9) is obtained in a region where the increase in CFF is large (100 kPa), and low p (p=0.5) is obtained in a region where that is small (50 kPa). Next we compare the activation of seismicity with CFF change for 1989 Loma-Prieta earthquake. We pick up the seismically active area along the San-Andreas fault from southern part of the aftershock area. We divide this into three segments with the length of 10 km. We calculate change of the CFF using dislocation model by Lisowski et al. (1990), which is estimated using geodetic data. Finally, we compare the change of CFF with p-value at each segment. We use the seismicity data cataloged by NCEDC. High p value (p = 0.7) is obtained in a region where the increase in CFF is large (130 kPa), and low p (p = 0.4) is obtained in a region where that is small (70 kPa). These suggest that the low decay of activated seismicity would usually occur when seismicity has changed by small CFF change and degree of the decay is inversely proportional to the increase in CFF.

CONIGURATION OF THE PHILIPPIN SEA PLATE UNDER THE TOKAI REGION, SOUTHERN COASTAL AREA OF CENTRAL JAPAN, AND THE SEISMICITY IN THE SLAB

Satoshi HARADA (Seismology and Volcanology Research Department, Meteorological. Research Institute, Ibaraki, Tsukuba, Nagamine, 1-1, 305-0052 Japan, email: sharada@mri-jma.go.jp) Akio Yoshida (Seismological and Volcanological Department, Japan Meteorological Agency, Tokyo, Chiyoda, Ote-machi, 1-1-1, 100-8122 Japan, email: akio.yoshida-a@met.kishou.go.jp)

Relation between configuration of the oceanic plate and the seismicity in it is investigated for the Philippine Sea slab subducted under the Tokai region, southern coastal area of central Japan. The upper surface of the slab is delineated by tracing an envelope of the hypocentral distribution of earthquakes in the cross section for each parallel narrow region taken east-west and north-south direction, respectively. A noticeable feature of the configuration is that the slab warps downward in the middle of this region. That is, the slab deepens toward west in the eastern part and inclines northward in the western part. The deepest portion of the Tokai slab exists in the northwest. We consider that the above-described configuration of the slab and the result obtained by an analysis of the GPS data which the direction of the relative motion between the subducting Philippine Sea slab and the overriding continental plate changes clockwise are related each other. According to the back-slip analysis of the interplate coupling the slab moves westward in the eastern Suruga Bay region, while it subsides more northerly in the western part (Sagiya, 1998). On the other hand, the seismicity in the slab is high in a relatively narrow zone of NNW-SSE direction in the western part of the Tokai region. When the seismicity in the slab is compared with the above-described configuration of the slab, we find a noticeable feature that the seismicity is high around the area where the slab changes its gradient steeply. This correspondence between the shape of the slab and the distribution of seismicity indicates that seismogenetic stress field in the slab is mainly originated by the bending of the slab at each local site in the course of the subduction process. The fact that the earthquake mechanisms in the high seismicity zone are mostly normal fault type (Noguchi ,1996) also supports the idea

SEISMIC ACTIVITY ALONG ATOTSUGAWA FAULT, CENTRAL JAPAN, AND ITS RELATION TO CREEP MOVEMENT AND TECTONICS

Kiyoshi ITO (Disaster Prevention Research Institute, Kyoto University, Uji Kyoto, Japan, 6110-0011, email: ito@rcep.dpri.kyoto-u.ac.jp) Hiroo WADA (Kamitakara observatory, Disaster Prevention Research Institute, Kyoto University, Kamitakara. 506-1317 Gifu Pref., Japan, email: hiroo@ktj.rcep.dpri.kyoto-u.ac.jp)

Activity of microearthquakes along the Atotsugawa fault, a prominent active fault in northwest Honshu, is relatively high and well concentrated at the surface fault compared to other active faults in Japan. Although a large inland earthquake of M7.0 occurred in 1858 .at the fault, aftershock activity must be low because of long time after the main shock. Besides, a creep movement was found at a northwestern portion of the fault from the surveys with electro-optical distance-meters. Some new seismic stations were set to make clear the seismicity, in particular focal depth distribution of microearthquakes along the fault. Focal depth distributions, obtained from new data show, are deeper by about 2-3km than those determined without temporary stations. Moreover, few events have been located in the upper crust down to 8-9km deep beneath the creep portion of the fault. This detailed hypocenter distribution suggests heterogeneous stress state or barriers along the fault. Cutoff depth of seismicity also changes along the fault, and it is deepest in the creep portion as about 18km. The heat flow value near the area is about 75mW/m2, which is rather high and corresponding cutoff depth is usually 10-15km. The focal depths are deeper than the usual value in this area. On the contrary, seismicity is also high but the cutoff depth is less than 10km at both ends of the fault, where there are active volcanoes. The displacement pattern derived from GPS surveys is changed at the fault. Thus, the fault seems to play an important role in the deformation of the area.

UPPER AND LOWER CUTOFF DEPTHS OF SEISMICITY AND ITS RELATION TO TECTONICS OF JAPAN

Kiyoshi ITO (Disaster Prevention Research Institute, Kyoto University, Uji Kyoto, Japan, 611-0011, email: ito@rcep.dpri.kyoto-u.ac.jp) Shuichi NAKAMURA (Mitsubishi Research Institute Inc. , 2-3-5 Ohte-machi, Chiyoda-ku, Tokyo, Japan, 100-8141, email: shuichi@mri.co.jp)

Upper and lower cutoff depths of seismicity have been determined from many microearthquake hypocenters in the inland area of Japanese Island. More then 150,000 well-determined hypocenters were used for the determination of depths, D10%, D50% and D90%, i.e. the depths above which 10, 50 and 90% events occur in the grid of 0.25x0.25 degree latitude and longitude. D10, D90 and D50% roughly correspond to the upper, the lower and the mean depths of seismogenic layer, respectively. Regional variations in the D90%, as well as D10% and 50%, are well correlated with topography, and also with the thermal structure of the crust. Active faults and large inland earthquakes occurred in the area of steep changes in the seismogenic layer. This shows the deformation of the island arc is closely related to the thickness of the seismogenic layer, or brittle regime in the crust. Strain pattern derived from repeated GPS survey shows the changes relating to D90%. Moreover, the upper cutoff depth (D10%) is well correlated with D90% and D50% and the average thickness between D10% and D90% is about 10km. This suggests that not only the lower cutoff depth but also the upper cutoff are related to the thermal structure of the crust.

SEISMOTECTONICS OF CONVERGENT PLATE MARGINS AND CHRONOLOGICAL EVOLUTION OF SUBDUCTION

Ales SPICAK, Vaclav Hanus and Jiri Vanek (Geophysical Institute, Bocni II, 141 31 Prague 4, Czech Republic, email: als@ig.cas.cz)

The study of geometry of distribution of earthquake foci in convergent plate margins, if based on a large body of high-quality seismilogical data, enables us to investigate the morphology and the basic parameters of the Wadati-Benioff zone, to elucidate the character of seismicity in the continental wedge above the Wadati-Benioff zone, to correlate the position of present and ancient volcanic events with the morphology of the Wadati-Benioff zone and with the seismicity of the continetal wedge, and to contribute to the knowledge of deep structure of different regions of convergent plate margins and of chronological evolution of subduction. From the distribution of earthquake foci inside the Wadati-Benioff zone an intermediate-depth aseismic gap can be observed, the position of which correlates with the position of active volcanism on the surface. On the basis of the distribution of earthquakes in the continental wedge above the subduction zone, seismotectonics of the continental lithosphere can be derived. Groups of deep earthquakes clearly divided by a vast region without earthquakes and shifted in the relation to the active subduction zone in several convergent plate margins, interpreted as remnants of paleosubduction zones buried in the upper mantle, give a possibility to speculations on the chronological evolution of subduction zones and on the geodynamic development of respective regions. The applicability of the above method is exemplified in the areas of Andean South America and in the Indonesian island arc.

GPS DERIVED SLIP RATE ALONG THE KARKORAM FAULT IN THE INDO-EURASIAN CONTINENTAL COLLISON ZONE

Sridevi jade (C-MMACS, NAL Belur Campus, Bangalore-560037,India) Bhat, B.C (Indian Institute of Astrophysics,Bangalore,India) Anand,M.B.(C-MMACS, NAL Belur Campus, Bangalore-560037,India) Gaur,V.K.(C-MMACS, NAL Belur Campus, Bangalore-560037,India)

The long Karakoram fault stretching for over 1000km from Pamir to Manasarovar in Tibet is a right lateral strike slip fault and a major feature of continental deformation north of the Himalaya. Current Estimates of annual slip along the fault, regarded as facililating the eastward extrusion of Tibet in response to the continued Indo-Eurasian convergence, based on geological investigations, however, vary from 3 to 30mm/yr. This paper presents slip rates along the Karakoram fault based on GPS monitoring of sites in Ladakh since 1997.

ON SEISMODYNAMIC OF CENTRAL ASIA

A.R.YARMUKHAMEDOV (Institute of Seismology, Khurshid str.3, 700128 Tashkent, Uzbekistan, email: root@seismo.tashkent.su)

In contrast to the traditonal statistical study of the seismic regime for the seismogeodynamic approach development we consider seismic phenomena of different scale as an indivisible dynamic system taking into accont peculiarities of the hypogene structure, crustal dynamics, stress state, processes of deformation and geophysical fields caused by the processes. The regional determinate seismogeodynamic model characterizing nature and spatial distribution of the seisodangerous zones (junctions) in Central Asia is developed and maps of junctions and recent geodynamic activity was constructed proceeding from the above-stated preconditions. The Central Asia recent crustal geodynamic activty is estimated for the first time through the integral index of the geologo-geophysical parameters and the territory under investigation is zoned on the basis of the index. It is noted that seismisity as a process is connected with the areas of high geodynamic activity and orders of blocks of different activities. Sources of destructive and disastrous earthquakes in Central Asia and Uzbekistan in particular spatially and genetically are connected with junctions. Data about the Gazli (1976 and 1984, M=7.1-7.3), Tashkent (1966, M=5.6), Nazarbek (1980, M=5.3), Tavaksai (1977, M=5), Chimion (1982, M=6.2), Pap (1984, M=5.2), Kairakum (1985, M=6.0), Khumsan (1987, M=5.0), Shamaldysai (1988, M=5.0), Izbastkend (1992, M=6.8) earthquakes can be the confirmation of the fact. Energetics of the seismotectonic process depends not only on internal structure of the lineaments and proesses in them but also on the geoblock dynamics, their displacement and interaction. Character of seismicity within the young Turan platform and in ogenesis of the Tien-Shan and Pamirs depends on their geodynamic and structural-tectonic conditions.

NEOTECTONIC STRUCTURE AND SEISMICITY OF THE INTERIOR TIEN SHAN

Alexander MIKOLAICHUK and Oksana Lesik (both from the International Research Center - Geodynamic Proving Ground in Bishkek, 720049, Bishkek-49, Kyrghyzstan, email: mav@laurel.gdirc.ru)

The Tien Shan orogenic belt is bounded by major fault zones along the north and south margins as well as by the Talas-Ferghana dextral strike-slip fault, which separates the Western and Central segments of this orogen. These fault zones are delineated by seismically active zones. All historically documented destructive earthquakes are localized within these zones. The remaining portions of the Tien Shan were traditionally considered to be less active sites of neotectonic deformation and seismicity. The Suusamyr earthquake (1992, M=7.3) in the interior of the Tien Shan demonstrated that this traditional seismotectonic concept was flawed, highlighting the need to identify the active geological structures which are responsible for the high seismisity of this region. Two east-west trending strike-slip faults and linked northwest striking reverse faults and overthrusts were mapped in the areas bordering the Suusamyr earthquake zone. The mapped tectonic structure of this region resembles a series of rhomboidal uplifted (push-up) blocks separated by asymmetric depressions filled by Neogene and lower Pleistocene sediments. Results of detailed seismic observations conducted from 1967 to 1997 for the territory are considered. These push-up blocks are clearly shown on epicentrum field as seismic or aseismic areas. One of these blocks provides a strong match with the focal zone of the Suusamyr earthquake. It was completely aseismic before 1992. These data suggest that other presently aseismic push-up blocks could produce strong earthquakes in the future. Paleoseismic dislocations features are often found within such tectonic units.

CONTEMPORARY DEFORMATIONS AND SEISMICITY AT THE TIEN-SHAN

Nelly Bagmanova, Zoya Kalmetieva and ELENA MUSIENKO (all at THE INSTITUTE OF SEISMOLOGY, NAS KYRGYZ REPUBLIC, ASANBAI 52/1,720060 BISHKEK,KYRGYZSTAN, email: kis@imfiko.bishkek.su; itmc@imfiko.bishkek.su);

Components of strain tensors determined from fault plane solutions (more than 5000 events since 1938) show general east-west extension as well south- north shortering accross Tien-Shan resulted India-Eurasia plates convergence. However there are separate areas where total sub-horizontal extension or compression or south-north extension take place during the last 60 years. At the same time geodetic and GPS measurings reproduce annual modifications of velocity vectors on horizontal and vertical components against a background of present uplift of the range. Inversion of vertical tectonic motions on surface produced corresponding alternation of fault plane solutions types for small events (3.0<M<6.0) into the crust. Faulting associated with major earthquakes M>6.0 revealed predominant component of thrust on planes trending east-northeast-west-southwest. However strike-slip component on plane trending east-west prevails at the area of the Tien-Shan and Pamir convergence. Space distribution of the Tien-Shan major earthqukes M>6.0 points out that most events occure within large faults zones demarcated areas wich have been undergoing contrast vertical tectonic motions since late Oligocene or rather between faults segments that differ by styles of tectonic deformation for the last 60 years . In distinction from strong earthquakes M>6.0 small events demonstrate various patterns of fault plane solutions and happen everywhere at the region.

THE PECULIARITIES OF THE DENSITY SECTIONS OF THE STRONG EARTHQUAKES FOCUS ZONES IN THE NORTH TIEN-SHAN

Oksana M. LESIK (Experimental-Methodical Expedition of Joint Institute of High Temperatures RAS, 720049, Bishkek-49, Kyrgyzstan, e-mail: olesik@gdirc.ru) Kanatbek E. Abdrakhmatov (Institute of Seismology, NAS, Asanbai 52/1, 720060, Bishkek, Kyrgyzstan, e-mail: kis@imfiko.bishkek.su) Apas B. Bakirov (Institute of Geology, NAS, av. Erkindik, 30, 720481 Bishkek, Kyrgyzstan, e-mail: bakirov@geol.freenet.bishkek.su)

Recently to study the distribution of density the results from a seismic tomography study on P-wave as well as S-wave velocities were used. Using empirical formula on the relationship between velocity and density their distribution has been calculated. Zoning of different density types of crust (Lesik, 1998), the density characteristics of the "crust-mantle" transition (Sabitova, Lesik, 1997) was carried out for the Tien-Shan. In this study, we are considering the peculiarities of the density sections of the seismic focus zones of the strong earthquakes (M > 6) which had happened in the North Tien-Shan. It is an actual problem to reveal the inverse low density layers which promote both the realization of the subhorizontal displacements and the relative autonomous movement of the layers during deformation events. Joint analysis of obtained results with the neotectonics data (dynamic characteristics of the newest structures, active faults and blocks, their relationship etc) allowed to conclude about the geodynamic conditions in the focus zones of the strong earthquakes in the North Tien-Shan.

RATES OF CRUSTAL DEFORMATION IN EASTERN ANATOLIA

Günruh BA_CI (General Directorate of Disaster Affairs, Earthquake Research Department , Ankara , TURKEY. e-mail: seis@sismo.deprem.gov.tr) The purpose of this study is to investigate the seismicity of Eastern Anatolia.

Earthquakes located in the region between 35 N - 44 N latitude and 34 E - 46 E longitudes are investigated for this purpose . Eastern Anatolia is located between the Eurasian , African plates. It is " squeezed " and driven by the stresses exerted on it through the northward movements of the Arabian and African plates. The Earthquake epicenters covering the period 1900-1998, delineate the major fault zones and show the great activity and seismicity in Eastern Anatolia. Seismic moment values and fault plane solutions for large earthquakes which occurred in Eastern Anatolia are used to calculate the average rate of deformation in the area. The seismic moment tensor Mij is the most direct measure of deformation associated with earthquakes. The moment tensor Mij can be described when the strike, deep and rake of the fault are known in addition to the scalar value Mo. Eastern part of North Anatolian Fault Zone (NAFZ) , Northeast Anatolian Fault Zone(NEAFZ) , East Anatolian Fault Zone (EAFZ) and Çald_ran Fault Zone(CFZ) are selected as seismotectonic zones with high seismic activity. The results show that the deformation in the eastern part of NAFZ is taken up by extension on EW direction 28mm/yr and as compression an NS direction at a rate of 18 mm/yr. The average right-lateral displacement rate is about 33mm/yr. In the EAFZ, the EW extension at a rate of about 7.5mm/yr. The average left-lateral motion has a rate of about 3.5 mm/yr. The deformation rate in NEAFZ is 20 mm/yr with compression in the NS direction and left-lateral displacement rate is 2.5 mm/yr justifying the left-lateral strike-slip fault mechanism. NS compression rate in CFZ is 40 mm/yr. Right-lateral deformation rate in CFZ having right-lateral strike-slip fault mechanism is calculated as 15 mm/yr. As a result of NS compression in all zones, thickening rates are found as 0.16 mm/yr in eastern part of NAFZ , 0.12 mm/yr in NEAFZ ,0.40 mm/yr in EAFZ and 1.15 mm/yr in CFZ , respectively. P.S. POSTER presentation

SEISMOTECTONICS OF THE TEHRAN REGION

Mohammad Ashtari JAFARI (Institute of Geophysics, University of Tehran, P.O.Box 16765-533, Tehran 16, Iran, email: mjafaree@chamran.ut.ac.ir)

The city of Tehran(13 million of inhabitants) is located at the southern foothils of the central Alborz mountains over Quaternary alluvial sediments. This is an area of active deformation as attested by the nearby active faults and historical seismicity. A permanent seismological network has been installed since 1996 in order to monitor the regional seismic activity and several hundreds of earthquakes are located every new year. We present preliminary results regarding the local velocity structure, and discuss the seismicity and focal mechanisms in relation with tectonic information

COMPOUND POISSON PROCESS APPLIED TO AFTERSHOCK SEQUENCE MODELS

DRAGOMIR GOSPODINOV, Geoph.Inst.Bulgarian Ac.Sci., Akad.G.Bonchev str. bl.3, Sofia, Bulgaria

Some applications of marked Poisson process are presented to analyze catalog data for aftershock sequences. In most cases when studying aftershock occurrences as a stochastic process, only their behaviour in time is considered. It has always been of interest to try to enrich time models of aftershocks with information about other parameters i.e. to develop space-time models or the ones relating the occurrence times with a quantity, representing the size of an event (magnitude, intensity or energy). A compound Poisson process has been used to model cumulative energy release of events in several aftershock sequences, following the assumption of their independence. Results reveal, that there are some discrepancies between the model and the real processes, pointing that not always the assumption of independence is true. On the whole results reveal, that marking of the process is a helpful instrument, enabling us to catch some features of the seismotectonic process underlying the data.

SEISMOTECTONIC RE-INTERPRETATION OF THE ZONE ALONG THE STRUMA LINEAMENT

Savka Dineva and Dimitar Mihaylov (both at Geophysical Institute, BAS, Ac.G. Bonchev street bl.3, 1113 Sofia, Bulgaria. E-mail: dgm-sid@geophys.bas.bg), TORILD VAN ECK (Seismological Division, Royal Netherlands Meteorological Institute, PO Box 201, 3730 AE De Bilt, The Netherlands. E-mail: vaneck@knmi.nl)

The Serbo Macedonian Massif and the Rhodope Massif are separated by the NNW-SSE oriented Struma lineament. The neotectonics along this old fault zone is complicated. Presently, seismic activity suggests mainly activity on more recent SW-NE oriented faults instead of on the known N-S oriented older faults. Also the strong April 1904 earthquakes near Kresna most probably occurred along a SW-NE oriented fault zone. We reanalysed arrival time data and focal mechanisms from the region. A combined relocation and velocity inversion of more than 20.000 phase observations have resulted in a new crustal velocity model estimate and relocation of about 1000 small events in the region. Stress tensor inversion using 180 focal mechanism solutions provide an estimate of the present day stresses within the crust in this region. Finally an effort has been made to relate known surface faulting with the relocated seismic activity and stress tensors. Our results may have significant impact on the seismic hazard estimates in the region.

SEISMIC ACTIVITY IN THE WESTERN BOHEMIA

Vladimir NEHYBKA, Zuzana Skacelova, Jan Svancara (Institute of Physics of the Earth, Masaryk University, Tvrdeho 12, 602 00 Brno, Czech Republic, Email: nehybka@ipe.muni.cz, zuzka@ipe.muni.cz, svancara@ipe.muni.cz)

Institute of Physics of the Earth has been acquiring data in Western Bohemia since April 1991. The monitoring network consists of five stations. The registration is continuous with the digital recording of selected parts of the seismic signal. The purpose of the measurement is to map the active tectonic lines from their seismic manifestations. Western Bohemia is known by the swarm type seismic activity from the former times; the last strong swarm was in years 1985-86, the last swarm with the big number of the weaker earthquakes was in January 1997.
We have registered thousands of earthquakes in the time period 1991-1998 and we have observed seven areas with the occurrence of the seismic activity. The main activity is in the Novy Kostel vicinity. The epicenters in this area seem to map some tectonic lines. We constructed maps of the epicentres on the locality of Western Bohemia.The data obtained from the comparison of surface manifestations and seismological results indicated connection with the Marianske Lazne deep fault. The syntetic map shows the comparison of the seismic data with the gravimetric measurement.

MASCARA EARTHQUAKE OF AUGUST 18TH 1994, MW= 5.8 (MS=6.0), IN THE CONTEXT OF THE QUIETNESS OF THE ORANIE REGION, ALGERIA

Abdelhakim Ayadi (Dept. E.S.S./C.R.A.A.G., BP 63 Bouzaréah, 16340, Algiers, Algeria, e-mail: ess1@ist.cerist.dz) Seid Bourouis (Deptartement de Geophysique, C.R.A.A.G., BP 63 Bouzaréah 16340, Algiers, Algeria) Farida OUSADOU (Dept. E.S.S./C.R.A.A.G., BP 63 Bouzaréah, 16340, Algiers, Algeria, e-mail: ess3@ist.cerist.dz)

A seismic event of magnitude M=5.6 (C.R.A.A.G., Algiers) struck Mascara province (western part of Algeria) on August 18th 1994. This event is the strongest one censused in the Oranie region since that of May 21st 1889. The earthquake was located by C.R.A.A.G., using data of the ASTN network stations, at 00.30°w and 35.40°N with a depth of 10 km. From August 18th to August 23rd we have recorded many aftershocks among them we have 16 events with magnitude ranging between 3.9 and 5.1.
The maximum observed intensities map 5MOI) made for Algeria (Bezzeghoud et al., 1996) shows that the MAscara region is located in a X intensity's zone, which explain partially the damages caused by the 18/08/1994, M=5.6 event. The gravity and the seismotectonic maps and also the focal solution have been used to better understand the source origin of that event.

SURFACE FAULTING AND ACTIVE TECTONICS IN THE UPPER ATERNO VALLEY (CENTRAL ITALY)

BLUMETTI, A.M. (DSTN - Servizio Sismico Nazionale, Via Curtatone, 3, 00185, Roma)

Surface faulting effects are still not widespread documented in Italy. By now they where recognise in the Fucino basin (Michetti et al., 1995), in Irpinia (Pantosti & Valenzise, 1990) and in other very few areas. On the other hand many geomorphological features of the Apennine and particularly along fault generated range fronts, emphasize a very recent tectonic activity presumably connected with repeated surface faulting events. The long Italian historical record reports many seismic events of intensity >IX MCS; this gives the possibility of comparing the geological effects described in such reports with the mentioned features of the relief. The area investigated in this study is the Upper Aterno Valley, a tectonic depression bounded to the NE by two NW-SE trending normal faults which generate the Mt.Marine and M. Pettino fault escarpments, belonging to the Gran Sasso structure. These range fronts and the relative piedmont belt show many evidences of Upper Pleistocene-Holocene tectonic activity. In this area the seismic catalogue recorded some events of very high intensity: (1349 e 1461, I = X MCS; 1703 e 1762, I = IX MCS). In particular, during the January -February 1703 seismic sequence spectacular geological effects occurred (Blumetti, 1995). In this study, geological and morphological evidence of active tectonic processes will be shown, and slip rates, size, and recurrence intervals of major earthquakes discussed.

FAULT DEDECTION BY MIGRATION OF EARTHQUAKE EPICENTERS: CASE STUDIES FROM ALBANIA

Betim MUCO (Seismological Institute, Tirana, Albania, e-mail: betim@sizmo.tirana.al)

It is well known that not all the active faults display theirself on the earth surface. Many of them are the so-called blind or fhidden faults. In this case the accurate determination of earthquake parameters and focal mechanism solutions are the most important means to give insights on these faults where the earthquakes are buildup and release their energy. Analysing the migration of epicenters for the earthquakes, which belong to the same active tectonic fault, one can get information on the geometry and kinematic characteristics of the hidden faults. The method of fault dedection by lineaments of consecutive epicenters of micro-earthquakes it is of importance because it can give the information on active faults for relatively short period of data and time, without waiting the occurrence of high magnitude earthqakes. Using the above method, some segments of active faults are revealed for Albania. A verification of these lineaments with long-term observation of the seismological data and tectonic consideration it is also provided here.

SEISMOTECTONIC PECULIARITIES INFLUENCE OF THE STRONG VRANCEA EARTHQUAKES ON MACROSEISMIC EFFECT ON MOLDAVIAN TERRITORY

Anatol DRUMEA and Nila Stepanenko (both at Institute of Geophysics and Geology Moldavian Academy of Sciences), Academy str. 3, Kishinev, MD-2028, Moldova; email: drumea@geo.moldova.su

On the basis of the detailed study of four strong Vrancea earthquakes, observed in XX century, were made the conclusions about the peculiarities of source zone's tension conditions. The

study results indicated that in case of 4.03.1977 earthquake the rupture was multishock and has been spread from north-eastern border of focal zone from the depth of about 90 km to south-west direction and the depth reached 120 km. The first shock of 1990 seismic double, observed 30.05, was located nearly in the same place, but its rupture has been spread on the opposite direction, i.e. north-east. The second shock, taking place on 31.05, spread towards south-west (as 4.03.1977 earthquake). The 30.08.1986 earthquake occurred in the south-western limit of Vrancea active zone and its depth was about 140 km. The rupture spread toward north-east. As a result the intensive macroseismic action and significant Doppler's effect created by 30.08.1986 shock, the damage was twice stronger in Moldova, then in 1977 one, in spite of smaller magnitude. The hypocenter of 10.11.1940 earthquake took place in the south-west border of focal zone and rupture spread toward north-east (by analogy with 1986 earthquake). Two weeks before the main shocks of 1940 and 986 events there were observed forshocks. The additional analysis of the strong earthquakes of XIX century and detailed investigation of the manifestations of such events in XX century revealed the effect of mutual repelling preceding and following events and alternate focal depth. It was determined, that the most dangerous for the territory of Moldova are the seismic sources having the strike slip in azimutal range 30-60 of degrees.

RELOCALIZATION OF SEISMIC EVENTS IN SOUTH PORTUGAL

Fernando BORGES, and M R Duque, (Departamento, de Fisica,Universidade de Evora, Rua Ramalho59, 7000, Evora, Portugal, tel 351 66 744616, email: jborges@uevora.pt). Fernando Carrilho, (Instituto Nacional de Metereologia e Geofisica, rua C do Aeroporto, 1700, Lisboa, Portugal, tel 351 1 848 39 61, email: fernando.carrilho@meteo.pt).

The Southern of Portugal is a region of significant seismic activity, and it can divided in two areas: Atlantic underwater adjacent zone and continental zone. The first one is characterized by a more intense instrumental and historical seismicity, which is strongly correlated to the border zone between Euroasian and African plates. The second zone is characterized by a seismicity of low or moderated magnitudes (often less than 5) and with epicenters concentrated in tree areas: The Algarvian coast, the Evora region and, the Low Valley Tagus zone. Most of this events, mainly those that possess low magnitude or poor azimuthal coverage, present high localization errors. The present study is an attempt to use the data collected by the National seismic network in order to improve the epicenter and hypocenter localization. So we used different models of the crust based in refraction profiles, and we are also employed a technique of simultaneous inversion for hypocenters and velocity models.

SOURCE OF THE ML 5.2 EARTHQUAKE OF 1994 SEPTEMBER 1 IN THE BITOLA REGION, REPUBLIC OF MACEDONIA

Vera CEJKOVSKA (Seismological Observatory, P.O.Box 422, Faculty of Natural Sciences and Mathematics, Sts Cyril and Methodius University, 91000, Skopje, Republic of Macedonia, email: vcejkovska@seismobsko.pmf.ukim.edu.mk) Lazo Pekevski and Dragana Cernih (both at Seismological Observatory, Faculty of Natural Sciences and Mathematics, Sts Cyril and Methodius University, Skopje, Republic of Macedonia)

A P-nodal solution has been obtained for the earthquake occurred in the Bitola region (Republic of Macedonia) on 1 September 1994, at 16h 12min 40.40s UTC, with magnitude ML = 5.2 and without any evidence of surface rupturing. The solution has been discussed in the view of the neotectonic conditions in the Bitola region and compared with the observed macroseismic effects and aftershocks distribution. Assuming the P-nodal planes as two possible fault planes, synthetic far-field seismograms of the main shock and aftershocks have been generated and compared with the empirical far-field seismograms. In result, a choice for a fault plane has been made, suggesting a normal left-lateral fault, striking toward WNW, as a source of the main shock. That seismic source has been recognized in the neotectonic Pelister fault. The contribution of the Pelister fault to the historical and recent seismic activity in the Bitola region has been discussed.

REGIONAL CENTROID MOMENT TENSORS OF THE MEDITERRANEAN AREA AND THEIR TECTONIC IMPLICATIONS

PONDRELLI S. (Istituto Nazionale di Geofisica, Rome, Italy; e-mail: pondrix@ing750.ingrm.it) Boschi E. (Istituto Nazionale di Geofisica, Rome, Italy) Dziewonski A., Ekstr"om G. (both at Department of Earth and Planetary Sciences, Harvard University, Cambridge, Massachusetts) Mazza S., Morelli A. and Piromallo C. (all at Istituto Nazionale di Geofisica, Rome, Italy)

The complex active tectonics associated with the convergence of the Africa and Eurasia plates, and the relative motion of a few microplates, characterise the Mediterranean region and produce its high level of seismicity, mostly of moderate energy. Earthquake focal mechanisms contribute to the determination of the current mode of crustal and lithospheric deformation. Together with geodetic data they allow the study of regional tectonic strains and strain rates. Teleseismic observations are routinely used to determine focal mechanisms of events with Mw>5.5 worldwide, but for smaller events, regional and local records are needed. We routinely calculate Regional Centroid Moment Tensors (RCMT) for seismic events of the Mediterranean area with moderate magnitudes (4.5-5.5), using intermediate period surface waves recorded by MEDNET and other observatories located at regional distance. Seismograms are collected automatically in nearly real time. Moment tensor results from more than one year of near real time RCMT computations, in addition to additional results for selected moderate earthquakes of last few years, have considerably increased the available catalog of earthquake focal mechanisms for the Mediterranean area.

THE ALGIERS EARTHQUAKE OF 4 SEPTEMBER 1996: SEISMOTECTONIC ASPECT

Said MAOUCHE, Djillali Benouar, Assia Harbi and Hadj Benhallou

On the 4th September 1996, a moderate earthquake struck the sahel of Algiers. Taking into account the type of damaged buildings, maximum intensity has been estimated at Io = VII (MSK) at Ain Benian in the Wilaya of Algiers. The main shock was felt with same intensity in most of the localities around Algiers. Accordin to the Center of Research in Astronomiy, Astrophysic and geophysics (CRAAG, Algeria), the local magnitude was calculated at Ml=5.7 and Mb=5.5 (IPG at Strasbourg, France). It seems that the main shock was not preceded by any kind of premonitory sign; but it was followed by a long sequence of aftershocks continuig until late November, 1996. The aftershocks distribution of this earthquake occupieses a large area at west of Algiers and off-shore zone of about 20 Km long, the focal mechanism of this event exibits an reverse fault. The earthquake was associated with landslides and rockfalls along the coast as well at about 6 Km west of Ain Benian; but no sign of liquifaction was revealed. From seismotectonic point of view, the Mitidja basin constitutes a part of the folds and thrust geological structures that belong to the Tellien Atlas montains. This region is characterised by a fold and thrust geological domain which displaydomain which displays active reverse or thrust faulting related to the folding trending NE-SW. This active structures have "en echelon" distribution in the intermontain basins where young quaternary deposits are deformed by the compressional tectonic processus.

RELOCATION OF THE BOVEC 1998 EARTHQUAKE SEQUENCE: IMPLICATION FOR ACTIVE TECTONICS IN NW SLOVENIA

Jure Bajc (1,2), Abdelkrim Aoudia (1,3), Peter SUHADOLC (1), Mladen Zivcic (2) ADDRESSES: (1) Department of Earth Sciences, University of Trieste, Via E. Weiss 1, 34127 Trieste, Italy, (2) Geophysical Survey of Slovenia, Pot na Golovec 25, 1000 Ljubljana, Slovenia, (3) The Abdus Salam International Center for Theoretical Physics, Miramar, P.O.Box 586, 34100 Trieste, Italy

On April 12th, 1998, an M=5.7 strike-slip faulting earthquake has occurred in NW Slovenia. The main shock has been followed by a series of aftershocks, the strongest one exceeding M=4. Three local networks (Slovenian national seismic network, Osservatorio Geofisico Sperimentale seismometric network, and Dipartimento di Scienze della Terra, Universita' di Trieste accelerometric network) provide a set of high-quality recordings of these events on a local scale (epicentral distances < 150 km). The main shock and related aftershocks have been relocated with a modified joined hypocentral determination method that is based on numerically calculated travel times, using a 1D velocity model, while the lateral velocity variations are accounted for by usual station-phase corrections. Improved locations are combined with digital elevation model analysis and field investigations to get a better insight into active tectonics of the area and its implications on earthquake hazard. In particular, the significance of the Idrija fault is reconsidered and its seismogenic potential is discussed.

SEISMOTECTONIC MODEL OF THE FAULTING DURING THE 1986 STRAJITZA EARTHQUAKE SEQUENCES (BULGARIA)

Stefan SHANOV (Geological Institute of Bulgarian Academy of Sciences, Acad.G.Bonchev Str., bl.24, 1113 Sofia, Bulgaria, email: shanov@geology.bas.bg)

According to the seismotectonic prognosis for Gorna Oriahovitza seismic zone (Northern Central Bulgaria), based on the evaluation of the seismotectonic potential and the fault setting, earthquakes of M=5.6-6.0 may be expected in the fault knot near the town of Strajitza. This prognosis was confirmed by the 1986 earthquakes. A comparison of the tectonic setting with all seismological data and the fault-plane solutions of nine consecutive earthquakes of magnitudes Ms more than 3.0 permits to create a model of the progressing of the process of faulting in the time and the space. The process was initiated in the fault knot and advanced to NE. The fault-plane solutions confirmed the earthquake capability of the lineaments, detected by analyzing the geological, geophysical and remote-sensing data. The principal axes P and T of the solution for the strongest earthquake with magnitude 5.6 coincide with the reconstructed regional trend of maximum and minimum tectonic stress axes. The process fades south-southwestwards and this indicates the screening role of some lineaments for the stress redistribution. The model is in a good agreement with the idea for the hierarchical system of the Earth's crust blocks. The smallest blocks are volumes of low energy accumulation and the appropriated earthquake mechanisms follow the local stress field peculiarities. The strongest earthquake mechanism reflects the regional tectonic stress field.

TECTONIC SETTING OF WEST QARUN AREA, WESTERN DESERT, BASED ON AEROMAGNETIC AND SEISMIC STUDIES

Nasser M. HASSAN (Geophysics Dept., Fac. of Sc., Ain Shams Univ., Egypt.
Email: aboashor@asunet.shams.eun.eg); Mohamed F. Mohamed,, Hussein Hammouda (Expl. Dept., GUPCO, Egypt.)

The study area is located in the North Western Desert of Egypt between Latitudes 29°24` N and 29°47` N and longitudes 29°00` E and 29°24` E. Comprehensive interpretation of aeromagnetic and seismic surveys were attempted to delineate the main tectonic trends that affected the area and its structural frame work.
A basement tectonic map was established; the Basement depth ranges between 4 and 4.6 Km. Sixty four migrated seismic lines were interpreted using the available well velocity surveys and synthetic seismograms to identify seven selected horizons from the Cretaceous to the Basement. Two way time maps, interval velocity maps, two dimensional depth conversion and seismic depth maps for all the interpreted horizons were constructed. In addition, three geoseismic cross sections were generated and the magnetic basement tectonic map was interpreted for better understanding of the structural setting of the study area.
The study revealed that the study area is characterized by complex step faults, horsts, grabens and flower structures of different trends; Syrian arc, Suez and Aqaba trends

SOURCE PARAMETRES OF SEPTEMBER 3, 1968 BARTIN (SW BLACK SEA) AND OCTOBER 5, 1977 KURSUNLU (NAF) EARTHQUAKES FROM INVERSION OF TELESEISMIC BODY-WAVEFORMS

TUNCAY TAYMAZ and Onur Tan (both at Department of Geophysics--Seismology Section, Istanbul Technical University (ITU), Maslak-80626-Istanbul, Turkey, e-mail: taymaz@sariyer.cc.itu.edu.tr)

This presentation is concerned with the active tectonics of the SW margin of Black Sea, and consists of studies of two moderate earthquakes. Seismic activity occurs at shallow depths along the Turkish margin of the Black Sea, and the relation of this activity to the North Anatolian Fault is not clear. The source mechanisms of these earthquakes are therefore crucial for understanding the present tectonics and recent evolution of the Black Sea. We used long-period P- and SH-waveforms and first motion polarities of P waves to determine the source parameters of September 3, 1968 (Bartin-NW Turkey, Ms=6.6) and October 5, 1977 Kursunlu (NAF, Ms=5.8) earthquakes. Bartin earthquake is the largest instrumentally recorded earthquake to occur, and provides first evidence for active thrust faulting along the SW-Black Sea margin. We compared the shapes and amplitudes of long period P- and SH-waveforms recorded by WWSSN stations in the distance range 30—90 degrees, for which signal amplitudes were large enough, with synthetic waveforms. The minimum misfit solutions obtained by the inversion of teleseismic body waveforms are better constrained than those based solely on first motion polarity readings and other reported solutions. The Black Sea appear to be closing under north-south compression.

ST2/W/24-A5 Poster **1400-30**

RELATIVE FAULT STRENGTH IN THE TJÖRNES FRACTURE ZONE, NORTH ICELAND, AS INFERRED FROM STRESS TENSOR INVERSION OF MICROEARTHQUAKE FOCAL MECHANISMS

Björn LUND and Ragnar Slunga (Dep. of Earth Sciences, Uppsala University, Villav. 16, 752 36 Uppsala, Sweden, email: bl@geofys.uu.se)

Using micro-earthquake focal mechanisms we are studying the relative strength of faults in two major fault zones in the Tjörnes Fracture Zone (TFZ) of Northern Iceland. The TFZ is a transform zone that connects the Kolbinsey Ridge with the Icelandic Northern Rift Zone. Most of the transform motion is accommodated by the well developed, 7-9 Ma old, right-lateral, Husavik-Flatey Fault (HFF). We inverted focal mechanisms from the HFF for the local stress tensor using two different criteria to select the fault plane from the two nodal planes. First a stability constraint was used that selects the nodal plane with the highest instability; I = _ - __n, in the tested stress field as the plane most likely to fail. For the second inversion we used information from high accuracy relative location of the events, fitting groups of events to common faults, to pick the correct nodal plane. Although the stress states resulting from the two inversions are similar, we infer a strike-slip state of stress with the maximum principal stress being approximately horizontal and in the direction N 165 - 175 E, the instability criterion frequently selects the wrong nodal plane. The correct fault planes, which are parallel to the strike of the HFF, are thus not the most likely to fail in the estimated stress field but since they do fail we infer that the HFF is a relatively weak fault. The weakness can be explained either as a zone of low coefficient of friction in the vicinity of the fault or as an increase in pore pressure in the fault zone. We estimate the necessary decrease/increase of these parameters. Preliminary results from a similar study on the Grimsey lineament, also in the TFZ approximately 40 km to the north of HFF but considered a feature with very recent tectonic activity, show that the fault planes there are at high angles to the overall trend of the lineament. Stress tensor inversion show that these planes also are the most unstable in the stress field, i.e. there are no indications of weak faults. Combining the methods of high accuracy relative locations with stress tensor inversion using the instability criterion might thus prove a feasible way of detecting mature fault systems or oppositely areas of recent or diffuse seismicity.

NEOTECTONICS IN NORWAY: NEONOR

H. BUNGUM, E. Hicks, C. Lindholm, (NORSAR, Kjeller, Norway; HB and EH also at University of Oslo, Norway) O. Olesen, J. Dehls, L. Olsen (Norwegian Geological Survey, Trondheim, Norway) L. Bockman (Norwegian Mapping Authority, Hxnefoss, Norway) F. Riis (Norwegian Petroleum Directorate, Stavanger,Norway)

The NEONOR project is a multidisciplinary research project conducted in cooperation between a number of research institutes in Norway and funded by both public institutions and private industry. The project is aimed in general at delineating and understanding recent crustal deformations, with more specific aims on driving processes, migration of crustal fluids (including hydrocarbons), and geohazard implications. A comprehensive review and analysis of earlier claims for neotectonic phenomema in Norway has been conducted, resulting in positive evidence for neotectonic faults in Masi and Kefjord and for recent crustal deformation also in Rana, Steigen and Melfjord. Other claims have been classified either as gravitationally induced faults, erosion along older zones of weakness, overburden draping of underlying bedrock features, and stress release features. The project also includes other geological and geophysical investigations, including detailed seismological studies (new arrays in northern and western Norway), geodetic measurements at several locations (GPS, triangulation, relevelling) and mapping of recent offshore faulting. The 3-year (1997-99) project will publish a new 1:3,000,000 scale neotectonic map of Norway.
The detailed studies have shown that there exist two systems of postglacial faults. The Stuoragurra (Masi) Fault consists of large scale (up to10 metre) NE-SW trending reverse faults while the Nordmannvikdalen (Kefjord) Fault in Troms is one or two minor (1-2 metres offset and 2-3 km length) NW-SE trending normal faults. The faults are interpreted to represent a conjugate set, with normal faults perpendicular to the extensive system of NE-SW trending reverse faults in northern Fennoscandia. Trenching of the Stouragurra Fault indicates formation during one seismic event during or immediately after deglaciation (9.300 years BP). Dating of several large rock avalanches in the vicinity of the Nordmannvikdalen indicate a similar age for this faulting.

EARTHQUAKE FOCAL MECHANISMS AND STRESS IN NORWAY

HICKS, E.C.(1,2), H. Bungum (1,2) & C.D. Lindholm (1) 1. NORSAR, Kjeller, Norway 2. Dept. of Geology, University of Oslo, Norway

A total of just under 100 earthquake focal mechanism solutions from onshore and offshore parts of Norway have been analyzed with regard to crustal stress orientation. The study area was divided into six areas assumed to have a relatively homogeneous stress field, each containing between five and 25 focal mechanism solutions. Inversion of the focal mechanism data within each group for stress was performed, yielding a stress tensor representative for each of the six areas.
Overall, it appears that the regional stress field in Norway has a NW-SE to WNW-ESE orientation of the maximum horizontal stress direction, which can most likely be attributed to the gravitational effect of the mid-Atlantic ridge, the "ridge-push" effect. However, certain areas show a 90 degree rotation (or inversion) of the horizontal stress directions. This is particlarly evident for parts of the Northern North Sea and coastal areas in Northern Norway, and is to some extent observable in the Oslo Rift area. This indicates significant influences from regional and/or local stress sources. These same areas also have elevated levels of seismic activity compared to the regional activity.

ON THE METHOD OF SEISMIC REGIONALIZATION OF THE FENNOSCANDIAN SHIELD

BELA ASSINOVSKAYA (Geodynamical Laboratory, CAO RAS, Bolshoi pr.50G, V.O., 199034, Saint-Petersburg, Russia, email: bela@ba2248.spb.edu)

The seismic regionalization methods are probably the least developed and formalized among the all seismic hazard assessment stages. Due to this fact certain regions especially with weak seismic activity areas such as the Fennoscandian Shield seem groundlessly large and generalized. Whereas the maximum earthquake magnitude(Mmax) is low as for the Fennoscandian Shield the simple cell square for assessment of Mmax should not exceed the area 10x10 km. Development of Mmax determination method described by us earlier is suggested. The method is based on the geological information and the most possible full data on the rock mechanical properties of the crust simple cell. This work uses relationships between accumulated energy and calculated strike slip rock strength at the depth of earthquake sources taking into an account pressure and temperature. In the Fennoscandian Shield conditions Early Proterozoic granite batholite intrusions formed in compression environment have the most seismotectonic potential that becomes less as geometry intrusion changing. Gneissic rocks with the same quartz contents as in granite, have lesser strike slip strength. The method was used to estimate Mmax in the region of seismic profile Kostamuksha -Pechenga on the north-east of the Fennoscandian Shield.

THE MARCH 25, 1998 BALLENY ISLAND EARTHQUAKE: GREAT EARTHQUAKE CAUSED BY POSTGLACIAL REBOUND

Seiji TSUBOI(Department of Geoscience, National Defense Academy, Yokosuka 239-8686 Japan, e-mail: tsuboi@cc.nda.ac.jp) Masayuki Kikuchi and Yoshiko Yamanaka(both at Earthquake Research Institute, University of Tokyo, Tokyo 113 Japan, e-mail: kikuchi@eri.u-tokyo.ac.jp) Masaki Kana (National Institute of Polar Research, Tokyo Japan, e-mail: kanao@nipr.ac.jp)

A large Mw=8.1 earthquake occurred off southeast coast of Antarctica near the Balleny Island region on March 25, 1998. We inverted teleseismic body-wave records to determine the rupture pattern using an iterative deconvolution method. The source parameters obtained are: the centroid depth=31km; (strike, dip, rake)=(288, 87, -2); the seismic moment M0=2.1x10^21 Nm (Mw=8.1); the length L and the width W of the fault: L=140km and W=40km; the average slip D=5.4m. This earthquake occurred in the mid-plate but there has been no reports of such large earthquakes in this region ever before. Furthermore, the source mechanism cannot be related to the plate motion inferred from the nearby transform faults. Therefore this earthquake should not be considered as a usual tectonic event. Here we show that the compressional axis of our source mechanism coincides with the horizontal crustal motion predicted by the Earth's response to present-day and past ice mass changes in Antarctica. Our result suggests that the 1998 Antarctica earthquake is caused by the postglacial rebound in the Antarctica.

SEISMOTECTONICS OF THE SOUTH SANDWICH ISLAND ARC

ANYA M. READING, University of Edinburgh, Dept. of Geology and Geophysics, Grant Institute, West Mains Road, Edinburgh, EH9 3JW, UK

The South Sandwich Plate lies in the South Atlantic bounded to the west by a spreading ridge and the Scotia Plate. To the east, the South American Plate is subducted, forming the South Sandwich Arc; a simple but relatively unstudied area of active intra-oceanic tectonics.
As well as data from the global seismic network, this work uses local earthquake records from broad-band stations on three of the South Sandwich Islands and records from ocean-bottom seismometers deployed across the arc. These were recorded as part on a multi-disciplinary geological and geophysical campaign undertaken by British Antarctic Survey in early 1997.
Seismicity results are obtained from OBS instruments below the threshold of the global network and together with structural information from travel-times and dispersion modelling are interpreted in terms of spreading ridge and slab roll-back dynamics and likely mantle flow beneath the arc.

VELOCITIES OF SEISMIC WAVES IN ANDESITE ROCKS OF NORTH-WEST IRAN

Minoo KOSARIAN, Saeed Amiri, and Majid Nabi-Bidhendi (all at the Institute of Geophysics, Tehran University, P.O. Box 14155-6466, Tehran, Iran, email: minoo@iman.ut.ac.ir)

In this paper based on the results obtained from laboratory measurements of compressional and shear-wave velocities on 15 different andesite rock samples in both dry and saturated states a few relationships have been found between physical properties of the rocks. A pair of piezoelectric transducers with the central frequency of 63 kHz is employed to measure P-wave velocities. Similar transducers but with the central frequency of 33 kHz have been used for S-wave velocity measurements. The cubic samples are prepared in various sizes between 45 mm and 55 mm. Dry samples are made by placing them in a 70 C oven for 24 hours. The velocity measurements are made in both dry and saturated states under low axial stress. Our data show excellent linear relationships between P and S-wave velocity for both dry and saturated states as follows:
Vp = 1.45 Vs + 0.65 (dry) R = 0.93
Vp = 1.61 Vs + 0.38 (sat.) R = 0.97
Where velocities are in km/s and R is the correlation coefficient. Also the data demonstrate excellent linear relationships between bulk modulus normaliesd by density and Vp as follows:
K/p = 2.56 Vp + 3.90 (dry) R = 0.87
K/p = 2.53 Vp + 3.85 (sat.) R = 0.90
Where density, p, is in g/cm3 and bulk modulus, K, is in kbar and Vp is in km/s.

COMPOSITE LOGS INTERPRETATION OF SOME BOREHOLES IN CENTRAL IRAN AND RADIOACTIVE MINERAL EXPLORATION

F.YEGANI (Atomic Energy Organisation of Iran, P 0 Box 14155-1339, Tehran, Iran) B.A. Feizabadi and M. Nabi-Bidhendi (both at Institute of Geophysics, Tehran University, P0 Box 14155-6466, Tehran, Iran, email: mnbhendi@chamran.ut.ac.ir)

At the end of ground survey for testing acquired data, it is customary to drill some boreholes in estimated targets. Due to economical condition, it is obvious to get the most information from the drilled boreholes in order to have a clear and meaningful profile of intersected layers. It could then be possible to locate the cordinations of the next boreholes precisely.
In this article the composite logs of six boreholes are interpretated. The composite logs consist of electric, IP, SP, density, porosity, natural gamma-ray, spectral gamma-ray, magnetic susceptibility, deviation, caliper and temperature logs. The main aim of this survey is uranium and radioactive Minerals exploration. In addition to geological column which is obtained

directly from the cored samples, the geophysical column is drawn by correlating the different logs. It is observed that the latter method exhibits more accurate and detailed information. Based on geophysical column the radioactive zones and uranium mineralization layers are identified and then by borehole to borehole correlation the uranium orebody is outlined. Although an excellent coincidence of these two columns is observed, the fine discrimination of the layers by geophysical column is more significant.

SPATIAL-TEMPORAL FEATURES OF CHANGES IN THE CONDITION OF THE ROCK MASSIF IN THE CONTOUR ZONE

V.N. TATARINOV (Geophysical Center, Russian Academy of Sciences, Molodezhnaya, 3, Moscow, 117296, Russia), T.A. Gupalo, N.I. Seleznev (VNIPIpromtechnology, Ministry of Nuclear Power, Kashirskoe shosse, 36, Moscow, Russia)

The processes resulting in restructuring of local stress fields and structural discontinuity of rocks around mine openings and producing force effect on rock massif composed of structural blocks of different hierarchy have been studied. Result are presented of the study of the effect of explosion mining of ores on rock distribution in dynamic representation. Force effects of explosion mining as well as natural tectonic processes are manifested as stepped in spatial and cyclic in time dislocation of zones of relative packing and failing towards the worked out room. The developed methods of geophysical observation of the effect of space-time changes on stress fields in the contour zone of a blocks rocks during explosion mining of ores can by applied for solution of a wide range of practical problems in the mining industry.
The established time regularities in geophysical fields and in the deformation of rock massif, parameters like the velocity of dislocation of failure zones, effective radius of their development in the massif, the distance to the packing zone shield, especially when predicting rock bump strength, and geometrical parameters of sites where the changes of geophysical fields characterizing the condition of separate structural blocks of the massif occur can serve as prognostic criteria for dynamic destruction of rocks. New data have been obtained on the deformation in the contour zone of large-diameter chambers in which hazardous techniques are used under prolonged effects of high temperature and rock pressure.

STRESSES IN A SUBDUCTING SLAB IN THE PRESENCE OF A METASTABLE OLIVINE

WEDGE J.P. DEVAUX, L. FLEITOUT (Laboratoire de Geologie, 24 Rue Lhomond, 75005 Paris, email: devaux@jadeite.ens.fr), G. Schubert (ESS, UCLA, Los Angeles CA 90095-1567), C. Anderson (LANL, Los Alamos NM 87545)

The transformation of olivine to spinel in a subducting slab gives rise to thermal strain, transformation strain and buoyancy stress inside this slab. We use a finite element method to solve the mechanical equation and we follow the evolution of the stresses inside the slab during its descent. We use a viscoelastic rheology with a viscosity that depends on pressure, temperature and grain size. The stresses due to buoyancy are found to be negligible compared to the internal stresses due to the phase transformation. A zone of very high diffential stress coincides with the olivine spinel phase boundary. This zone is associated with large down-dip compressive stresses inside the metastable olivine wedge, and large down dip tensile stresses in the spinel region, along the wedge. If we assume that the failure criterion can be related to the differential stress, our model is in agreement with the patterns of deep seismicity. However, patterns of deep seismicity cannot reflect buoyancy stress, which are negligible compared to the internal stresses.

FRACTAL MICROSTRUCTURE OF ROCKS OF KAINUU SCHISTS BELT (FINLAND). RESULTS FROM INTERPRETATION OF SVEKA AND EL DEEP SEISMIC SOUNDING PROFILES

Elena KOZLOVSKAYA (Department of Geophysics, University of Oulu, POB 3000, FIN-90401 Oulu, Finland, e-mail: elena@babel.oulu.fi), Jukka Yliniemi (Sodankylä Geophysical Observatory, Oulu Unit, POB 3000, FIN-90401 Oulu, Finland, e-mail: jyl@babel.oulu.fi)

The wide range of velocities associated with Earth materials makes it difficult to relate seismic data to specific lithologies. A review of geological parameters show that depth, lithology and age are not as specifically related to velocities as are the physical parameters of density, elastic constants, and porosity. The former, in turn, are strongly influenced by the rock microstructure (pore shapes, pore size distribution, grain-to-grain contacts etc.). Recent theoretical investigations of rock physical properties have shown that the real rocks can be adequately described by structural fractal models. The assumption of a fractal geometry is in accordance with the experimental data about real rock structure. The fractal conception gives possibility to connect rock microstructure with rock elastic properties and with macroproperties like seismic P-and S-wave velocities and seismic anisotropy.In our investigation we make an effort to use the fractal model for elastic properties of porous rock and to estimate the microstructure of rocks of Kainuu Schists belt from experimental seismic data of SVEKA and EL deep seismic sounding profiles in Finland.The results of modeling are proposed for discussion.

TITANATE PEROVSKITES AT HIGH TEMPERATURE: THERMOELASTICITY, SHEAR MODULUS DISPERSION, ATTENUATION AND MICRO-CREEP

Sharon Webb, IAN JACKSON and John Fitz Gerald (Research School of Earth Sciences, Australian National University, Canberra ACT, Australia)

Ultrasonic measurements of the bulk and shear moduli for polycrystalline specimens of Ca- and Sr-titanate perovskites to ~500°C provide additional insight into the high-temperature thermoelastic behaviour of oxide (and by analogy silicate) perovskites. Torsional micro-creep and seismic frequency forced oscillation tests demonstrate strong viscoelastic relaxation at high temperature in each of these fine-grained materials, resulting in large reductions in shear modulus G (by >70%) and enhancement of its temperature sensitivity as much as 10-fold relative to ultrasonic values. The temperature of onset of this frequency dependent behaviour is grain-size dependent. The frequency-dependent and time-dependent data have been described in terms of the elastic, anelastic and viscous components of deformation using the Andrade model. The relatively smooth variation with temperature of G and 1/Q for Ca-titanate suggests that its high temperature phase transitions have little effect on the viscoelastic behaviour.
In the absence of melt films, twinning and dislocations, the long-timescale viscoelastic deformation of Sr-titanate is attributed to grain- boundary sliding accommodated by lattice or grain- boundary diffusion, controlled by the slowest diffusing species, which is expected to be either Sr or Ti. The low viscosities determined for the Ca-titanate samples, together with the low values (with respect to the extrapolated ultrasonic data) of shear modulus associated with Andrade model fits to the data suggest that its long-timescale viscoelastic deformation may reflect relatively faster grain-boundary diffusion of the slowest moving species through the thin (<2 nm) melt films and larger impurity segregations present in these samples. Implications for the seismic properties of the lower mantle will be discussed.

PROCEDURE AND APPARATUS TO MEASURE ELASTIC, DEFORMATIONAL AND TEXTURAL-STRUCTURAL CHARACTERISTICS OF ROCKS AND MINERALS UNDER HIGH THERMODYNAMIC CONDITIONS IN THE NEUTRON BEAM

Efimova G.A., Kireenkova S.M., and SOBOLEV, G.A. (United Institute of Physics of the Earth, Russian Academy of Sciences, Moscow, 123810, B.Gruzinskaya 10, email: sobolev@uipe-ras.scgis.ru) Ivankina T.I., Nikitin A.N. (Joint Institute of Nuclear Research, Dubna, Moscow Region, 141980)

Unique procedure and apparatus are described that are applied to measure a set of physical parameters of rocks and minerals under high temperatures in the neutron beam. The freshness of this procedure is that it allows us with the same material to conduct research on physical properties of rocks and minerals under high thermodynamic parameters in combination with the studies of rocks and minerals texture and structure by neutron diffraction. As distinct from traditional methods this procedure enables continuous recording of all investigated parameters. The cylindrical samples from natural marble consisting only of calcite were chosen for first experiments. The samples were 20 mm long with diameter 16mm. A experimental run comprised loading up to 20 MPa, step by step temperature increase, recordings of strain, ultrasonic wave velocities and diffraction patterns. Comparison of preliminary measured diffraction spectra of chamber without sample and sample showed that diffraction peaks of material used for chamber did not overlap the main peaks of calcite. The changes of diffraction pole figures were obtained as result of loading and heating of the samples.

SHOCK INDUCED MELTING OF MGSIO3 PEROVSKITE AT 100 GPA AND ~5000 K: A NEW CONSTRAINT ON LOWER MANTLE TEMPERATURE

J. A. Akins, T.J. Ahrens (both at Lindhurst Laboratory of Experimental Geophysics, Seismo Lab, Caltech, Pasadena, CA 91125, USA, Email: jakins@gps.caltech.edu),G. Jyoti (present address: High Pressure Physics Division, Bhaba Atomic Research Centre, Trombay, Mumbai 400085, INDIA)

New equation of state (EOS) and shock temperature data have been obtained, using a 25mm light gas gun, for MgSiO3 (glass) shocked into the shock pressure range > 80 GPa where densities and current knowledge of the MgSiO3 phase diagram indicate that the perovskite structure is stable. Initial experiments have sampled the region in which the shock temperature decreases from 5650 +/- 553K at 97GPa to 5050 +/- 465K at 107 GPa. This observation is qualitatively similar to experiments on alkalai halides, SiO2 shocked into the stishovite range, and our recent experiments on Mg2SiO4 shocked into the MgSiO3 (perovskite) + MgO (periclase) range. This phenomenon results from superheating of the solid, over a pressure range of 5 - 15 GPa, followed by melting. The comparison of V(partialP/partialE), at constant V, between the glass data and previous ceramic data indicates a Gruneisen parameter (gamma) of 1.18 +/- 0.30 at a density of 4.67 g/cm^3, corresponding to approximately 45GPa and 1100km depth in the Earth, based on PREM. We expect these data, along with future data, to better constrain the adiabatic temperature profile of the lower mantle as well as provide a long sought independent determination of the melting curve of MgSiO3. Previous static melting data differ by approximately 2000K when extrapolated to the CMB. As present data suggest melting of MgSiO3 perovskite occurs at ~5000 K at 100 GPa it appears highly unlikely that the ULVZ, at the base of the mantle, is due to MgSiO3 perovskite melt. The slope of our preliminary melting curve is similar to (Brown and Shankland, 1981) mantle adiabat with a homologous temperature, T/Tm, of ~ 0.46.

IS HYDROUS PHASE MORE COMPRESSIBLE?

Lin-gun LIU (Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, R.O.C. 11529, email: lliu@earth.sinica.edu.tw)

Raman study of both anhydrous and hydrous alpha, beta and gamma phases of Mg2SiO4 provides us with the unique opportunity to compare the compressional behavior between anhydrous and hydrous phases. It is generally believed that hydrous phases are more compressible than anhydrous phases. The data combining both compression and elasticity studies of the above mentioned materials showed that the hydrous phases are more compressible than the anhydrous phases. On the other hand, the data of pressure dependence of Raman frequency of these materials do not substantiate the convention that hydrous phase should be more compressible. Instead, the latter data seem to suggest that hydrous phases are slightly less compressible than anhydrous phases, if the pressure variation of vibrational frequencies depends solely on volume.

THE INFLUENCE OF METAMORPHISM PROCESSES ON ROCKS PHYSICAL PROPERTIES ON EXAMPLE OF COLA SUPER DEEP BOREHOLE

G.A.Efimova (United Institute of physics of the Earth, Russian Adademy of Sciences,123810 Moscow, B.Gruzinskaya,10, e-mail:slavina@uipe-ras.scgis.ru)

The practical works with the samples from super deep boreholes have shown that the elastic waves velocities of rocks determine by "mineral skeleton" of rocks. The measuring of the longitudinal waves velocities were conducted by ultrasonic method in the high-pressure cell known as cylinder-piston up to 1,5 GPa. It was established that elastic waves velocities of rocks of Cola super deep borehole from different facieses of metamorphism depende from second processes taking place in rocks under action of metamorphism. The rocks having the same compositions have the same meanings of physical characteristics.

THE MICROSCOPIC ORIGIN OF THERMAL CRACKING IN ROCKS STUDIED BY TIME-OF-FLIGHT NEUTRON DIFFRACTION

P.G. MEREDITH (1), K.S. Knight (2), S.A. Boon (1) and I.G. Wood (1), (1) Department of Geological Sciences, University College London, London WC1E 6BT, UK, (2) ISIS Facility, Rutherford Appleton Laboratory, Didcot, Oxfordshire, UK. (E-mail: p.meredith@ucl.ac.uk)

Recent research focused on mid-ocean-ridge processes and geothermal energy extraction

has highlighted the importance of thermal cracking as a rock deformation mechanism in regions of high geothermal gradient and heat flow. In particular, thermal cracking can lead to significant reductions in bulk strength, and to dramatic increases in fluid transport properties. We report results from an experimental programme that made use of time-of-flight neutron diffraction to study the microscopic origin of thermal cracking in a pure quartzite. The High Resolution Powder Diffractometer (HRPD) at the Rutherford Appleton Laboratory was used to measure the thermal strain in (i) quartzite cores, and (ii) finely ground quartzite powder, as a function of temperature over the interval 293K to 573K. It was observed that the powder expanded more than the cores over the same temperature interval. The difference in thermal strain between rock powder and solid rock is due to the internal self-constraint experienced by the solid rock, and generates a differential thermal stress in the rock cores. The onset of thermal cracking was monitored by continuous recording of acoustic emission (microseismic) output, and was seen to commence at some critical value of this differential thermal stress. Calculation of the critical stress for the onset of thermal cracking showed that it corresponded closely to the bulk tensile strength of the quartzite.

PHYSICAL PROPERTIES AND COMPOSITION OF CARBONATE ROCKS: CASE STUDY FROM ESTONIAN LOWER PALAEOZOIC SEDIMENTARY BASIN

Alla SHOGENOVA (Institute of Geology at Tallinn Technical University, 7 Estonia Avenue, EE10143, Tallin, Estonia, Email: alla@gi.ee.

Petrophysical properties and chemical composition of some 600 samples of Ordovician and Silurian rocks of different genesis were studied and compared using regression and factor analysis. Lower, Middle, Upper Ordovician and Silurian data sets were analyzed and compared. The most important factors influenced the physical properties of carbonate rocks were revealed. These are clay content, dolomitization and porosity. Increase in the clay content causes the increase in primary porosity decrease in density, P-wave velocity, apparent resistivity and increase in magnetic susceptibility in most of Ordovician and Silurian limestones. Dolomitization of rocks causes increase in secondary porosity, grain density and magnetic susceptibility of Lower and Middle Ordovician rocks. The influence of widespread dolomitization and that associated with fracture zone were studied and compared for different groups of properties. The properties of different age limestones are controlled most of all by clay content. The properties of different age and genesis dolomites vary more and depend on the composition of dolomitization fluids and on the secondary porosity caused by leaching of the rocks during dolomitization. The differences between properties of limestones and dolomites are the most contrast in the Middle and Lower Ordovician rocks and they are the least contrast in the Upper Ordovician and Silurian sequences. But there were found the most porous dolomites. Their porosity is close to that in the Lower and Middle Ordovician fracture zones. The most contrast chemical parameters in the different rock groups were found to be iron and manganese. They increase in the most studied dolomite types. The physical properties of different genesis limestones and dolomites may be used to distinguish different rock types and their genesis.

THE ELASTIC AND DEFORMATIONAL CHARACTERISTICS OF SALTS AND THEIRS CHANGES DURING PROCESS OF PHASE TRANSITIONS AT HIGH PRESSURES.

S.M. KIREENKOVA (Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya 10, 123810 Moscow, Russia, Email: kireenk@ipmnet.ru)

The experimental study of processes of earthquake preparation of geophysical methods has allowed to establish that the properties of geomaterials within area of a future source undergo significant changes. From this point of view the processes of solid phase transition occurring at high pressures and temperatures and accompanied by anomalous changes of the physical properties of rocks and minerals are of prime interest. The behavior of salts have been demonstrated with ammonium iodide that is the rocks analog, of a NaCl structure. The elastic waves velocities and density of the pressing ammonium iodide were determined by the impulse ultrasonic method in the process of pressing inside a device of the cylinder-piston type at pressures up to 700 MPa. The jump changes of the elastic waves velocities were observed during phase transition under pressure. The change of values of longitudinal waves velocities during transition amounted 0.25 km/s and in shear waves velocities to 0.16 km/s and the change in the decrement volume amounted, on the average, to 30%. The deformational characteristics samples were determined at different values of constant hydrostatic pressure and additional axial compression with a constant rate 0.0000018 mm/s. A decrease of strength characteristics of ammonium iodide in the process of phase transition takes place during its deformation at the constant hydrostatic pressure of 12.5 MPa. Variations of the physical parameters of geomaterials, in the main of deformational characteristics during phase transitions at high pressure, serves as a criterion of quantitative estimation of the conditions for the preparation of an earthquake.

THERMAL CONDUCTIVITY OF ROCKS IN THE AREA OF THE KOLA SUPERDEEP WELL (SG-3)

Yuri POPOV and Raissa Romushkevich (Moscow State Geological Prospecting Academy, Miklukho-Maklai str., 39-1-191, Moscow 117485, Russia, email: Yupopov@mgga-sec.msk.ru) Christoph Clauser (Joint Geoscientific Research Institute (GGA), Stilleweg 2, D-30655 Hannover, Germany;
email: c.clauser@gga- hannover.de)

22 boreholes with a depth of 250-2000 m surrounding the Kola superdeep borehole (SG-3) were chosen to study geothermal parameters of this strata. Rocks intersected by these boreholes include diabases, tuffs, sandstones, phyllites, gabbro, serpentinites, chlorite-talk and chlorite-amphybolite shists, gneisses, amphybolites. Thermal conductivity was measured with the optical scanning device on 1375 cores. The principal components of the tensor of thermal conductivity was found to be in a range of 1.05-7.11 W/(m*K). Anisotropy is often significant and reaches factor of two. In most cases thermal conductivity varies within a range of 2-5 W/(m*K) along the boreholes. Local variations and trends along the boreholes are significant but not straightforward to interprete for most of the boreholes. For gneisses and amphybolites of the Archean complex we found the thermal conductivity of our samples to be larger by about 20 % compared to previous measurements on samples from the SG-3 borehole below 6800 m. This may be due to the decompression and mechanical wear the cores from the SG-3 borehole experienced. We gratefully acknowledge financial support for this project by the European INTAS organization (project INTAS-93-273-ext) and by the German Science Foundation (DFG) under grant CL 121/4-1,2.

COMPOSITIONS IN YOUNG OROGENIC CONTINENTAL CRUST BENEATH TAIWAN

DER-RU SONG and Kuo-Fong Ma (both at Institute of Geophysics, National Central University Chung-Li, Taiwan, ROC, e-mail: fong@sal.gep.ncu.edu.tw) Lin-Gun Liu (Institute of Earth Sciences, Academia Sinica, Taiwan, ROC)

Recently, three dimensional seismic velocity structure beneath Taiwan had been fully investigated. The results show obvious velocity contrast between the foreland and the hinterland of the Taiwan Orogenic belt at various depths. On the basis of the geophysical observation and comparison, we obtained the bulk crustal compositions under the young orogenic belt of Taiwan by comparing the tomographic inverted P-wave velocities with the measured P-wave velocities of relevant metamorphic rocks at the pressure and temperature conditions corresponding to the crust. The crustal composition derived in the present study is correlated to general lithologic categories rather than a specific rock type. The results were also further constrained by geological and geophysical data available in the area and the Poisson's ratio derived from reliable S-wave. It is concluded that, generally, the foreland of Taiwan is composed of a mafic bulk crust. The distribution of the crustal SiO2 is comparable with that of global observation for Mesozoic-Cenozoic Contractions and rift margins. The crust having a sialic bulk composition in hinterland is the main character in responds to the lower crustal velocity.

TEMPERATURE DEPENDENCY OF STRENGTH OF GRANITE AT HIGH CONFINING PRESSURE AND MICROMECHANICS

Mitsuhiko SHIMADA (Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University, Uji, Kyoto 611-0011, Japan, email: shimada@rcep.dpri.kyoto-u.ac.jp) Junlai Liu (Department of Earth Sciences, Changchun University of Science and Technology, Changchun 130026, P. R. China, email: jliu@public.cc.jl.cn)

Triaxial testing on a dry granite (Man-nari granite) was conducted at a confining pressure of 1500 MPa and temperatures to 600_Bo_(B with an averaged st rain rate of approximately 2 x 10-6 s-1. All the experiments fall in the high-pressure type fracture regime, which occurs when the compressive strength equals the frictional strength. The experiments were conducted with small temperature intervals at a fixed confining pressure to ascertain an unusual behavior of strength in our previous experiments temperature with a trend. The trend is similar to that for Westerly granite obtained previously. The strength values between 200_$Bo__(Band 280_$Bo$_(B, however, deviate fro m the trend and very low with a minimum at around 250_Bo_(B. The rock exhibited macroscopically brittle fracture behavior accompanied by occurrence of AE events and stress drop up to 530_Bo_(B. However, it deformed microscopically wit h several factors for crystal plasticity with increasing temperature. Micromechanical studies suggest that the unusual behavior of strength is caused by switching the dominating factors from the activation of crack groups to the inhibition of them and the dominance of crystal plasticity. If we estimate the lithospheric strength using these results and our previous assumption that the high-pressure type fracture occurs in the crust considering the size effect of rock strength, a low-strength zone between 8 and 12 km depth is suggested. This suggestion could provide an alternative explanation for the brittle-ductile hypothesis for seismogenic zones in the crust: earthquakes could occur or nucleate more easily where the strength is low. that the strength of the granite at 250_Bo_(B appears to decrease with increasing confini ng pressure or to have a minimum value in the high-pressure type regime whereas those at 100_$Bo__(Band 300_$Bo$_(B increase with increasing confining pressure. The strength of the granite decreases with increasing

MONITORING OF GEOMATERIAL STRESS STATE TIME DEPENDENCIES ON A BASIS OF THE SURFACE INFRA-RED EMISSION MEASUREMENTS

Vladimir I. SHEININ, Edward A. Motovilov and Alexander A. Morozov A.A. (Gersevanov Research Institute of Basements and Underground Structures, 2-nd Institutskaya str.,6, 109428, Moscow, Russia, E-mail: geo-mech@rinet.ru

A new technique has been elaborated to detect changes of the stress state in geomaterials and to describe the stress variations quantitatively by the processing of surface infra-red (IR) flux power records. The method is based on the known thermodynamical effects. Changes of the stress tensor first invariant at a point of an elastic medium being deformed "adiabatically" produce temperature variations proportional to the invariant variations with the factor depending on physical properties of the medium. These variations generate the IR-flux power changes which are practically proportional to the stress variations as well. The method efficiency is demonstrated in laboratory geomechanical experiments for samples of rock under temporally changing uniaxial compression. It has been shown that one can treat conditions as "quasiadiabatic" if the stress state changes quickly enough. The features of IR-signal components (i.e. carrying signal, noise and summand defined by heat change) have been considering. Original devices and facilities allow to read and then to process the radiation flux changes with amplification factor up to ten million. The multichannel analogue- to-digital converter was used so that one can get synchronous radiometric and "key" tensiometric data records. The experimental series with the impulse and oscillation loading of samples shows a satisfactory coincidence of the IR-radiometric and tensiometric descriptions of the stress state "time histories". Possible schemes, involving IR-radiometer, are considered for monitoring variations of instrumentation. The work is supported by the Russian Foundation for Basic Researches.

SIMULTANEOUS ULTRASONIC MEASUREMENTS OF X-RAY DIFFRACTION AT HIGH PRESSURE AND HIGH TEMPERATURE FOR MAJORITE GARNET

Gabriel GWANMESIA, (Department of Physics & Pre-Engineering, Delaware State University, Dover, DE 19901, email: ggwanmesia@dsc.edu), Baosheng, Li and Ganglin Chen (both at CHiPR and Mineral Physics Institute, SUNY at Stony Brook, Stony Brook, NY 11794-2100), Jun Liu and Robert C. Liebermann (both at ChiPR and Department of Geosciences, SUNY at Stony Brook, Stony Brook, NY 11794-2100)

Precise determination of the elastic properties of the mantle minerals at pressure and temperature conditions of the Earth's interior is very important for understanding the composition of the mantle. In our laboratory, we have developed techniques to measure elasticity of mantle minerals up to 8 GPa and 1500K using simultaneous ultrasonic velocity measurements and X-ray diffraction studies in a DIA-type, cubic anvil high pressure apparatus (SAM85) installed at beamline X17B at NSLS in Brookhaven National Laboratory. Ultrasonic measurement is implemented by mounting an acoustic transducer at the back of the WC anvil and including a buffer rod inside the cubic boron epoxy pressure medium. X-ray diffraction spectra from both the sample and NaCl were recorded at elevated pressures and temperatures from which the unit cell volumes of the sample and cell pressures were retrieved.

Using this technique, compressional (Vp) and shear (Vs) wave velocities measurements and equation of state (P-V-T) study for MgSiO3-majorite garnet have been conducted on a polycrystalline specimen previously hot-pressed at 18 GPa and 2100 K; the bulk density is 99.7% of the single crystal X-ray value. Compressional and shear wave velocities at ambient P and T agree with single crystal data within 1%. Complete P-V-T and Vp and Vs data have been collected up to 8 GPa and 1000 K along several decompression/heating/cooling cycles. Analyses from present P-V-T and acoustic measurements provide independent determination of elastic moduli and their pressure and temperature derivatives for this phase which is believed to be a major component of the transition of the Earth's mantle.

SOME NEGLECTED THERMOPHYSICAL PROPERTIES OF PLATE MATERIALS AND THEIR WIDER SIGNIFICANCE

Miles OSMASTON

Phase changes. Geophysical treatments of thermal subsidence, doming or uplift usually refer solely to the thermal expansivity of silicate rock. If it is found that not enough heat can have been conducted in, it is common to invoke advective introduction of the heat (e.g. delamination, plumes). Similarly, in the case of ocean floor subsidence, measured heat flow out to 50-60Ma is less than half what the observed subsidence would require with pure thermal contraction, so hydrothermal extraction of heat has been invoked. Solid-state phase changes, e.g. spinel-to-garnet peridotite, are, however, an inescapable consequence of cooling or heating the mantle and are enormously (>10x) more efficient at converting joules to volume change. Low velocity zone (LVZ). It now seems that up to ~3% interstitial melt can be held without migration, so volcanism should not be regarded as a foregone conclusion. Water partitions strongly into the interstitial melt so the water-weakening of the mineral fabric is removed, possibly making the LVZ more resistant to creep than if no melt were present (Karato 1986). This contradicts the perception that the LVZ is, by definition, a mobile zone. The thermal conductivity of silicate melt is at least 10x less than that of upper mantle minerals, lowering LVZ thermal conductivity by up to 30%, so thermal gradient in an immobile LVZ will be markedly superadiabatic, affecting temperatures throughout the mantle. Here I will suggest in outline how to accommodate the impact of these matters upon the interpret- ation of Earth behaviour, and aim to do so in more specific detail in other symposia at this meeting.

Tuesday 20 July PM

DYNAMICS OF MANTLE PLUME: FIELD EVIDENCE AND EXPERIMENTAL CONSTRAINTS

Eiichi TAKAHASHI (Earth & Planetary Sci., Tokyo Inst. of Tech., 2-12-1 Ookay ama, Meguroku, Tokyo 152-8551, Japan, Email: etakahas@geo.titech.ac.jp)

Recently, the role of recycled oceanic crust in the magma source region of L IP (large igneous provinces) have been reemphasized (i.e., Hauri, 1996; Takahashi et al, 1998). In order to constrain the chemistry and temperature of the hot rising material (mantle plume), detailed field works have been carri ed out in Koolau and some other Hawaiian shield volcanoes. Based on the petrology of the Koolau lava and high-pressure melting experiments on them, we propose a model that the Hawaiian plume had a potential mantle temperature (PMT) of only 1350C in the Koolau stage (ca 2.5 Ma) and the primitive Koolau magma was formed by extensive melting of recycled old oceanic crust but not ambient peridotite. This PMT is much lower than the estimate for the modern Hawaiian plume by Watson & McKenzie (1991, PMT=1558C) assuming homogeneous peridotite source. Our experiments (melting of basalt/peridotite hybrid source at 3 GPa) show that only slight temperature increase (50deg) will shift the Koolau type primary melts (SiO2=53, MgO=7 wt.%) to the parental Mauna Loa and Kilauea type melts (SiO2=49, MgO=14) when solidus origin of the mantle plume and the mechanism of its upwelling transport. Presence or absence of the old oceanic crust in the plume heads will explain chemical diversi ty and the contrasting melt productivity between hot spots (e.g., Iceland vs . Azores). Mantle upwelling flows are expected to obtain extra buoyancy at a round 650-700km because of the phase transition from the perovskite dominant to majorite dominant facies. Subducted old oceanic crust residing at the base of the upper mantle due to the neutral buoyancy may be easily entrainedin this upwelling flow.

MELT STRUCTURE IN FE-FES BINARY SYSTEM AT HIGH PRESSURE

Satoru URAKAWA (Department of Earth Sciences, Okayama University, Okayama 700-8530, Japan, email: afeg0320@cc.okayama-u.ac.jp) Kenichi Funakoshi (Japan Synchrotron Radiation Research Institute, Mihara 679-5198, Japan, email: funakosi@sp8sun.spring8.or.jp) Keiji Kusaba (Institute for Material Research, Tohoku University, Sendai 980-8577, Japan,
email: kusaba@jpnimrtu.imr.tohoku.ac.jp) Hideo Ohno and Osamu Shimomura (SPring-8 Japan Atomic Energy Research Institute, Mihara 679-5198, Japan, email: simomura@sp8sun.spring8.or.jp)

The physical properties of molten iron alloy, such as density and viscosity, are important to elucidate the formation and the dynamics of the earth's core. Thus, it is expected to reveal these properties at high pressures. Structural study is essential to understand the physical properties of melt. In order to clarify the relations between physical properties and structure, we have conducted some experimental studies on molten iron alloy at high pressures. Here we report the results of structural study using synchrotron radiation.
X-ray diffraction experiment of melt in the Fe-FeS system was carried out up to 5 GPa by the energy dispersive method. Total radial distribution function was derived from X-ray diffraction profiles. We found the change of melt structure with sulfur content between Fe and FeS. Structure of molten iron alloy is very simple, which corresponds to low viscosity for Fe-FeS eutectic melt measured by Dobson et al. (1998).

ST6/W/10-A2 **1440**

DYNAMICS OF HCP TRANSITION METALS AT ULTRAHIGH PRESSURES

Andrew JEPHCOAT (Department of Earth Sciences, University of Oxford, Oxford OX1 3PR, UK, email: andrew@earth.ox.ac.uk) Helmut Olijnyk (Department of Earth Sciences, University of Oxford, Oxford OX1 3PR, UK, email: helmuto@earth.ox.ac.uk)

Despite recent experimental progress towards measuring the physical properties of iron at core conditions, the crystalline structure of solid core phases remains unknown, making it difficult to interpret seismological evidence for the elastic anisotropy of the inner core. Recent elastic constant measurements for hcp iron (assumed to first order to dominate inner-core properties) have highlighted significant differences with parallel theoretical predictions of the elastic moduli suggesting a need for improvements in the theoretical treatment and/or a re-examination of models for the origin of the seismic velocity anisotropy of the inner core. Experimental measurements related directly to lattice-dynamical properties have not been available up to the present time at high compressions, but recent work has shown that the transverse-optical, doubly-degenerate (E2g) phonon mode in hcp transition metals is Raman-active and can be measured at high pressure in the diamond-anvil cell (DAC) with sensitive CCD detectors. If theoretical techniques reproduce the observed room-temperature pressure dependence of these modes in various metals, confidence in the elasic-constant calculations at core conditions would be substantially increased.
We report on studies of several hcp transition metals by Raman scattering techniques in the DAC up to 100 GPa under hydrostatic and nonhydrostatic pressure conditions. The pressure response of the E2g phonon mode in metals includes normal behaviour (positive pressure shift) as well as anomalies involving splitting and negative pressure shifts. For Fe and Re, well studied by x-ray diffraction and observed to remain hcp to 200-300 GPa, there is no information on their high-pressure dynamics. Measurement of the hcp phonon in Fe should be possible above 12 GPa at room temperature, where the fcc-hcp transition occurs; the Re phonon mode shows normal hard-mode behaviour with pressure. Calculations of selected phonon frequencies and their pressure dependence have recently been performed for Re, Fe and Zn and are compared with the new experimental data.

IN SITU X-RAY DIFFRACTION STUDY OF THE POST SPINEL TRANSFORMATION KINETICS IN MG2SIO4

Kubo Tomoaki, EIJI OHTANI, Akio Suzuki, Kiyoshi Fujino(1), Takumi Kato(2), Satoru Urakawa+ Institute of Mineralogy, Petrology, and Economic Geology, Tohoku University, Sendai 980-8578, Japan; (1) Department of Earth and Planetary Sciences, Hokkaido University, Sapporo 060-0810, Japan; (2) Institute of Geoscience, University of Tsukuba, Tsukuba 305-0006, Japan; Department of Geosciences, Okayama University, Okayama 700-0082, Japan

The postspinel transformation is believed to be the cause of the 660 km seismic discontinuity. In order to evaluate the effects of the postspinel transformation on the dynamics of the slab descending into the lower mantle, we studied the kinetics of the phase transformation of Mg2SiO4 on the basis of the high pressure and temperature in situ X-ray diffraction experiments. The experiments were conducted using "SPEED1500" and "MAX90" multianvil high pressure apparatus installed in the synchrotron radiation beam line BL04B1 at SPRing-8 and BL14C at the Photon Factory, respectively. We observed that spinel Mg2SiO4 dissociates metastably into MgSiO3 ilmenite and periclase, and stishovite and periclase in the stability field of perovskite and periclase. These metastable assemblages nucleate at the grain boundary between spinel grains and grow with the lamellar texture. The spacing of the lamellae composed of the post-spinel phases decreases with the overpressure, and it reduces to less than 0.5 micrometers at the overpressure of 1 GPa. Existence of this very fine grained lamellae of the post spinel phase strongly suggests that there is a transformation superplasticity around 660 km discontinuity due to significant grain size reduction by the transformation. We measured the growth rate of the post spinel phase transformation and analyzed by the diffusion-controlled model. The activation energy of the growth is estimated to be 350(+-240)KJ/mol. The present results give basic data to constrain the post-spinel phase transformation kinetics in the descending slabs.

APPLICATIONS OF IMPULSIVE STIMULTED SCATTERING AT ELEVATED PRESSURE AND TEMPERATURE

J. Michael Brown (Geophysics Program, University of Washington, Seattle, WA 98195 USA
Email: brown@geophys.washington.edu)

Dynamic processes within Earth, including heat removal through large-scale convection within the mantle and magnetic field production in the core via the geodynamo, are intrinsically regulated by the physical properties of constituent materials. Such properties are dependent on intermolecular interactions at short distances. To a large extent, the physics that has been successful in rationalizing condensed matter behavior near ambient conditions has been simplistically extrapolated to deep Earth conditions of reduced intermolecular distances. New experimental confrontation with theory is now possible using a family of time-domain optical techniques. These methods, "holographic grating spectroscopy", "thermally stimulated Brillouin scattering", "laser-induced phonon spectroscopy," and "impulsive stimulated scattering," are exploited in determination of a set of equilibrium and dynamic properties of solids and fluids at elevated pressure and temperature. The experiments and selected results are discussed in the context of a renewed need to improve theory essential in understanding Earth processes.

HYDROLYTIC WEAKENING IN FORSTERITE

John BRODHOLT (Dept. of Geological Sciences, UCL, Gower Street, London WC1E 6BT, UK) and Keith Refson (Department of Earth Sciences, University of Oxford, Oxford OX1 3PR, UK)

Even small amounts of water can profoundly effect the physical properties of minerals. In olivine less than 1 H in every 1000 unit cells acts to increase creep rates of dunite by about two orders of magnitude. Although the mechanism for this is not known, it is not unreasonable to suggest that it is in some way related to an increase in vacancy population. In order to understand this better we have performed ab initio pseudopotential calculations within the generalised gradient approximation on protonic defects in Mg2SiO4 forsterite. Three mechanisms for incorporating protons are considered: a) interstitial, b) binding at cation vacancies, and c) binding at silicon vacancies. Assuming the existence of both Si and Mg vacancies, on energetic considerations, protons will initially populate Si vacancies until there are three protons in the vacancy. At this point the addition of one more proton (to make a hydrogarnet substitution) is energetically unfavourable in comparison to populating the Mg vacancy, and the next two protons will enter the Mg site. Interstitial protons will be very rare.Since it is greater than 3 eV more favourable to put the first proton into the Si vacancy than the magnesium site, the presence of water will certainly act to increase the the population of silicon vacancies. In fact in the presence of water, the energy required to form a Si vacancy is about the same as to form an Mg vacancy. This is in stark contrast to dry olivine where Si vacancies are many eV less favourable. If creep is rate limited by the diffusion of the slowest species, silicon in olivine, then increasing the Si vacancy concentration could provide a mechanism for hydrolytic weakening.

SHEAR ATTENUATION IN UNIFORM, FINE-GRAINED FERROMAGNESIAN OLIVINE AND OLIVINE-MELT AGGREGATES: GRAIN BOUNDARY RELAXATION AND THE PHYSICAL SIGNIFICANCE OF THE ANDRADE MODEL OF VISCOELASTICITY

Reid F. COOPER and Tye T. Gribb (both at Department of Materials Science & Engineering, University of Wisconsin, Madison, WI 53706, USA, e-mail: cooper@engr.wisc.edu)

High-temperature (1100–1300°C), driven (10–3–100 Hz) torsional attenuation and creep

experiments have been performed on uniform, fine-grained (d~3mm) olivine aggregates and texturally equilibrated olivine-basanite partial melts. Both materials demonstrate mechanical linearity: for these conditions, inelastic deformation is accomplished via ionic diffusion. The materials display relatively high QG–1 values (–2<log10QG–1<0.5) that are but moderately dependent upon frequency, with QG–1~f–0.35. The partial-melt material displays but a modest increase in shear attenuation (~0.35 log units in QG–1), with no change in the form of the attenuation "band." Predictions of the QG–1 behavior based on the Laplace transform of the best-fit Andrade function replicate exactly the directly measured QG–1. Although the anelastic portion of the Andrade function (i.e., gxy,a = btn) is numerically equivalent to an infinite distribution of compliances, our controlled-microstructure material and fully linear rheology indicate that the observed attenuation and creep behaviors cannot be attributed to spatial variations, e.g., in grain size or in density of lattice dislocations. The Andrade function here attests, rather, to an intrinsic aspect of diffusional creep: the redistribution of grain boundary traction via chemical diffusion. The effect on QG–1 of the melt phase is related solely to its modest impact on the aggregate viscosity; there is no unique shear-attenuation signature of equilibrated, grain-scale melting. Comparison of our results to other experimental studies, and their extrapolation to geological conditions, raises the suggestion that subgrain boundary dynamics may play a significant role in seismic-frequency absorption in the upper mantle.

ST6/C/JSS02/W/15-A2 Invited 1640

HIGH-TEMPERATURE VISCO-ELASTIC RELAXATION IN SYNTHETIC OLIVINE AGGREGATES: INFLUENCE OF GRAINSIZE AND BASALTIC MELT FRACTION

B.H. Tan, I. JACKSON, J.D. Fitz Gerald, U. Faul, H. Kokkonen and G.R. Horwood (all at Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia, E-mail: ian.jackson@anu.edu.au Telephone No: +02 624 92498 Fax No: +02 627 98253)

Progress made since our preliminary report (Tan et al., GRL, 24, 1055-1058, 1997) of forced oscillation tests on a dense hot-pressed aggregate of San Carlos olivine of composition Fo90 and grainsize 0.05 mm will be described. Additional specimens have been synthesised from San Carlos- derived material, in both Fe and Ni/Fe containers, with and without added basaltic melt. The use of synthetic sol-gel precursors is also being investigated. Microstructural studies have continued in parallel with further torsional forced oscillation and microcreep measurements and developments in data processing in an attempt to identify the mechanism(s) contributing to the observed viscoelasticity.
All specimens so far examined have been shown to be of low dislocation density. It therefore appears unlikely that dislocations are responsible for the high-temperature relaxation in these relatively fine-grained materials, and grain boundaries have therefore become important targets for closer examination. The levels of impurity in the nominally melt-free synthetic Fo90 specimens are generally low with small pockets of quenched melt glass located mainly in the grain-edge triple junctions at an overall concentration of ~0.01 %. Significant grain-boundary enrichment in Al and Ca point to impurity segregations, and the probable existence everywhere of reasonably continuous but very thin (< 2 nm) grain boundary films. The unrelaxed shear modulus and viscosity associated with both the Andrade and generalised Burgers fits to the torsional microcreep data are lower than those inferred from short-period (ultrasonic) and large-strain creep tests, respectively. Both 'discrepancies' can be explained by invoking the presence of thin grain-boundary films of relatively low viscosity. The strength of the 'high-temperature background' relaxation varies inversely with grainsize and is increased by the addition of basaltic melt.

ST6/E/01-A2 1700

ELASTIC NONLINEARITY AND SLOW DYNAMICS IN ROCKS

James A. TenCate, Eric Smith, Loren W. Byers, Thomas J. SHANKLAND, and Paul A. Johnson (all at Earth and Environmental Sciences Division, MS D443, Los Alamos National Laboratory, Los Alamos, NM, 87545 USA, Email: shankland@lanl.gov).

As revealed by longitudinal bar resonance experiments, materials such as sandstone and concrete show a rich diversity of nonlinear elastic behavior. As a function of increasing drive level, resonance frequencies shift downward by as much as several percent, the resonant lineshape changes, and harmonics and slow dynamics appear. Slow dynamics [Geophys.Res. Lett., 23, 3019-3022, 1996] refers to the following sequence: a large strain applied to a rock ("conditioning") reduces its modulus (i.e., it behaves like a softer spring); if the strain is applied for several minutes, the rock remains "soft" even after the strain is removed; the rock eventually recovers to its initial stiffness. In order to explore the mechanisms of nonlinear response including slow dynamics, we performed experiments to study conditioning and recovery, rocesses that appear to be asymmetric. Conditioning takes place quickly, but recovery of the elastic modulus as measured by drift of the resonance peak takes place in two stages. After the conditioning strain is removed, the modulus first quickly recovers most of its initial stiffness. However, the next stage of recovery to the original modulus takes minutes to hours, depending on the length of time the conditioning strain was applied. In this stage, resonant frequency goes as log(time). Logarithmic time-dependence is a phenomenon associated with static friction and restoration of surface contacts, which in rocks probably take place at contacts across crack surfaces. Not only do these effects help reveal the causes of nonlinearity, they can be of use in evaluating damage to materials.

ST6/C/JSS02/W/08-A2 Invited 1720

SOUND VELOCITIES AND ELASTICITY OF MANTLE MINERALS AT HIGH PRESSURES AND TEMPERATURES, AND IMPLICATIONS FOR MANTLE COMPOSITION

J D BASS and S V Sinogeikin (both at: Department of Geology, University of Illinois, 1301 W. Green St., Urbana, IL 61801 USA; E-mail: bass@hercules.geology.uiuc.edu)

The most direct and detailed observations on Earths interior consist of seismologically determined velocities as a function of depth, including velocity anisotropy and heterogeneity. Experimental advances within the mineral physics community have progressed to the point that direct measurements of elastic wave velocities on mantle minerals are now being performed at high pressures and temperatures. This technological progress permits a more direct comparison between laboratory velocity measurements on minerals and the seismic properties of the Earth than was possible even just a few years ago, and suggests that inferences about mantle mineralogy can be made with a higher degree of certainty. In our laboratory we have been performing high pressure and high temperature measurements of sound velocities on single-crystal samples by Brillouin scattering, utilizing a diamond anvil pressure cell and resistance heating. Experimental studies have been completed on ringwoodite (the high-pressure spinel-structured polymorph of olivine), pyrope garnet, and MgO, all of which are thought to be important components of the mantle. Experiments on other high-pressure silicates of importance to the mantle, such as majorite, are in progress and will be presented. The results presently available allow us to investigate the possibility of chemical stratification in the mantle. In particular, the increases in velocity across the 410 and 660 km discontinuities, and the high gradients of velocity with depth in the transition zone are diagnostic of the mineralogy of this region. Measured pressure derivatives of velocity for the high-pressure polymorphs of olivine and for garnet do not match velocity gradients in the transition zone. The general conclusion to be drawn from the high-pressure velocity measurements is that it is difficult to reconcile the velocity structure of the transition zone with a uniform pyrolite composition for the mantle.

ST6/C/JSS02/W/19-A2 1740

CORRELATION OF MAGNITUDE AND T-DEPENDENCE OF HIGH PRESSURE VISCOSITY OF FE LIQUIDS WITH SULFUR CONTENT

SECCO, Richard (Bayerisches Geoninstitut, Universitdt Beyreuth, Beyreuth D-95440 GERMANY. E-mail: Richard.Secco@Uni-Bayreuth.DE Telephone No: 49-(0)921-553729 Fax No: 49-(0)921-553769)

The viscosity of liquids in the Fe-S system at high pressures are being experimentally determined using the electro-detection method. The method was developed for in-situ sphere speedometry measurement and is based on the detection of time resolved sphere position from an electrical resistance anomaly produced by an insulating sphere passing through a pair of Fe electrodes located in the conducting liquid sample. The experiments are carried out in 1000 ton multi-anvil and cubic-anvil presses with heating rates as high as 2500C/min using LaCrO3 or Nb furnaces and W/Re or Pt/Pt-Rh thermocouples. Spheres of ruby or sapphire, 0.5-0.7 mm diameter, are used in BN contained samples of 2.5 mm diameter and 2.5-3.5 mm height. There is no evidence of reaction between the sphere and melts on the time scale and at the P,T conditions of the experiments. Comparison of Fe-S melt compositions with 20.7wt%S and 27wt%S in the ranges 5-8 GPa and 1050-1300C show that the higher S content melt has a higher viscosity by 2-3 ln units. The T-dependence of viscosity also appears to correlate positively with S content and this relationship is preserved on comparison with 1 atm viscosity data on pure liquid Fe. This is consistent with the large viscous activation energy values obtained for 27wt%S in an earlier study and the interpretation of S content control on the viscosity through the size of viscous flow units.

INTERNATIONAL TRAINING COURSES ON SEISMOLOGY AND SEISMIC HAZARD ASSESSMENT

PETER BORMANN (GeoForschungsZentrum Potsdam, Division on Solid Earth Physics and Disaster Research, Telegrafenberg E428, D-14473 Potsdam, Federal Republic of Germany,
email: course@gfz-potsdam.de)

The post-graduate International Training Courses on Seismology and Seismic Hazard Assessment are run annually for participants from developing countries in the framework of the UNESCO educational and know-how transfer programme, the IDNDR and the IASPEI Sub-Committee on Training. Since 1992 they are carried out alternatingly every second year in Germany as world-wide open courses and in developing countries, respectively, as regional courses, e.g. 1993 in India, 1995 in Nicaragua, 1997 in Kenya and 1999 in China. Sometimes, these regular 5-weeks courses are, on special request, complemented by thematically focussed regional 2-weeks courses (e.g.in 1993 in Iran and in 1998 in India). In total, 440 participants from 77 countries attended these courses since 1980. But none the less, the number of applications still exceeds every year by far the number of fellowships (20-25) available.
The courses are strictly praxis-oriented. The approach is learning-by-doing. Accordingly, about 40 per cent each of the time is allocated for introductory lectures, which provide the theoretical basis and interdisciplinary problem understanding, and for practical exercises, respectively, on all fundamental tasks of seismological observatory practice and seismic hazard assessment. This is complemented by extended workshop discussions and by field excursions to relevant institutions, seismological stations and data analysis centers as well as to famous seismotectonic features and sites of earthquakes or volcanic eruptions. The paper outlines the course philosophy, programme and approach, evaluates their effectiveness and demonstrates the course web-page.

ST7/E/04-A2 0950

THE NEW IASPEI MANUAL OF SEISMOLOGICAL OBSERVATORY PRACTICE

PETER BORMANN (GeoForschungsZentrum Potsdam, Division on Solid Earth hysics and Disaster Research, Telegrafenberg E428, D-14473 Potsdam, Federal Republic of Germany,
email: course@gfz-potsdam.de)

The last edition of a Manual of Seismological Observatory Practice dates back to 1979. It covered analog techniques only and is out of stock. Since that time, computer and communication technologies as well as the availability of modern boadband sensors have revolutionized seismological observatory practice. Related know-how is chiefly available in industrial countries only. Besides this, classical university curricula do not provide suitable education and training of observatoy personnel. Therefore, the IASPEI Commission on Practice has launched an initiative to produce within the next few years a New Manual of Seismological Observatory Practice (NMSOP). It will be developed step by step as an electronic database and is freely accessible, together with the old manual, via Internet.The systematic tutorial body of the manual, complemented by index search, annexed job-related worksheets and data bases, extensive references and contact addresses of authors, institutions, firms etc. will make it in future easy to assist station operators and analysts in their daily work and to retrieve relevant pieces of information or teaching/training modules tailored to specific needs. A later publication of a condensed NMSOP version as a text book is envisaged.
The paper outlines the philosophy, structure and list of contents of the NMSOP and demonstrates its use by way example. A more comprehensive web-side demonstration and user/contributor guidance will be given in a complementary presentation by E. Bergman.

ST7/E/08-A2 1010

TRAINING FOR HAZARD MITIGATION IN CENTRAL AMERICA

Jens HAVSKOV (Institute of Solid Earth Physics, Allegaten 41, 5007 Bergen, Norway, email: jens@ifij.ubi.no Conrad Lindholm (NORSAR, Box 51. 2007 Kjeller, Norway, email: conrad@norsar.no

Earthquake hazards is common in the developing countries which are often the countries which least can afford the mitigation of natural hazards. The University of Bergen and NORSAR has for the last 8 years been involved in a project of earthquake disaster prevention in Central America. The project involves the aspects of improving instrumentation, determination of earthquake parameters, calculating seismic hazard, doing microzonation for city planning and proving formal education on the MSc and PhD level. Our main experience is that, for educational programs in hazard mitigating, to have any effect at all, they must include all elements starting with basic training on a technical level to formal training on a PhD level and the effort must be long term and include human network building. There must also be a minimum level of infrastructure so that the level of training matches the possibility of using that training. In our opinion, far too much money is wasted in international high quality training and educational programs because the training received does not match possibilities in real life. Obviously this kind program cost more than just a training course, but if we want to be serious about hazard mitigation, our experience is that all the above mentioned elements must be included.

ST7/L/01/C/U1-A2 1050

WINDOWS TO THE UNIVERSE - A GLOBAL RESOURCES FOR EARTH AND SPACE SCIENCE EDUCATION FOR THE GENERAL PUBLIC AND THE PRECOLLEGE ENVIRONMENT

Dr. Roberta Johnson, Dr. Janet Kozyra, Ms. Jennifer Leonard, Mr. Ryan Deardorff, Mr. Mike Burek, Dr. Terry Weymouth (all at The University of Michigan, 2455 Hayward, Ann Arbor, MI 48109, email: rmjohnsn@umich.edu), Dr. Claudia Alexander (Jet Propulsion Laboratory, Pasadena, CA), Dr. Jon Linker (SAIC Corporation, San Diego, CA), Mr. David Mastie (Ann Arbor Public Schools, Ann Arbor, MI)

Windows to the Universe is a NASA-supported award-winning Internet-based learning system on the Earth and space sciences for students, teachers, and the general public. The web site (http:// www.windows.umich.edu) is used extensively in the home environment, classrooms, hands-on science museums, and libraries worldwide, by users with ages ranging from 5 to 85. The web site, composed of ~4500 html files, ~4700 image files, currently serves about 190,000 visitors per month. The web site is truly interdisciplinary, integrating science content with content on the humanities, and provides interactive activities designed to draw users into further learning and exploration of the Earth and space sciences. Content on the site is presented at three levels of sophistication approximating the upper elementary, middle, and high school levels. In addition, a supplementary CD is available that allows most images on the site to be accessed from the users local CD drive rather than potentially time-consuming internet transfer. Resources for educators are also provided, including easy to use classroom activities, extensive science standards-based search capabilities, and an area for sharing information with other teachers.

ST7/W/06-A2 1110

A STUDY OF AWARENESS ABOUT NATURAL DISASTERS

Noriko SUGI (Kyoritsu Women's University, Moto-hachioji, Hachioji, Tokyo 193-8501, JAPAN, Email: sugi@s1.kyoritsu-wu.ac.jp)

To study how ordinary public is aware of natural disasters, we have made questionnaires repeatedly to students at Kyoritsu Women's University since the occurrence of the 1995 Hyogo-ken Nanbu Earthquake, which caused a huge damage to the central area of southwest Japan. The students did not experience the earthquake nor had seen a big damage by any natural disaster. By summing up their answers, we examined what are important to inform to and to educate the broader public in the 21st Century. One of the questions in the questionnaires was "Which disasters in the world made the strongest impressions on you?" Many of the students cited the 1995 Hyogo-ken Nanbu Earthquake, the 1993 Hokkaido Nansei-oki Earthquake accompanied by a large tsunami, and the 1991 Eruption of Unzen Volcano accompanied by pyroclastic flows. The factors that impressed people about disasters, such as time or place they occurred, number of people who suffered damage and kinds of damage, were investigated. Another question was "What do you think are the significant remaining problems related to the Hyogo-ken Nanbu Earthquake?" After one year, the most common answers were those related to reconstruction of the victims' normal daily lives. As time goes by, those answers changed to concern for disaster prevention.

ST7/E/06-A2 1130

QUALITATIVE AND SEMI-QUANTITATIVE SEISMOLOGY

ZHONGLIANG WU (Institute of Geophysics, China Seismological Bureau, 100081 Beijing, China, email: wuzl@cdsndmc.css.gov)

The qualitative and semi-quantitative aspects of physics and seismology plays an important role in the education of modern seismology which is characterized by quantitative and computational modeling. Besides the usually cited qualitative skills in physics, such as dimensional analysis, estimation of the order of magnitudes, qualitative analysis of differential equations, and using of simple system, and so on, qualitative and semi-quantitative knowledge in seismology also includes the empirical approaches in seismological observation and practice, visualization of seismological phenomena, and the universalities in the extreme simple dynamic models (toy models) of earthquakes. It is specially important that seismology is facing to some outstanding problems, e.g., the prediction of earthquakes, in which the qualitative and empirical understandings are of help in the identification, formulation, and solution of seismological problems. In this presentation we try to figure out some of the important topics in qualitative and semi-quantitative seismology. Also, it is worth pointing out that with the development of high-technology, qualitative and semi-quantitative knowledge becomes of more use not only in education but also in research.

ST7/W/01-A2 1145

THE NEED FOR EARTHQUAKE EDUCATION IN ITALY

Laura Alfonsi (Istituto Nazionale di Geofisica, Roma, Via di Vigna Murata 605, 00143 Roma, email: alfonsi@ing750.ingrm.it)

In a densely populated country such as Italy, where culture and social structures are strongly connected, any natural event is potentially adisaster. The impact on the community of the 1997-98 Umbria seismic sequence will be briefly outlined enhancing how the lack of earthquake culture and education in the media, politicians and population can somehow increase the earthquake impact.

ST7/E/05-A2 1200

SCIENTIFIC CORRESPONDENCE IN SEISMOLOGY: ITS SCIENTIFIC AND HISTORICAL VALUE

Graziano FERRARI (S.G.A. Storia Geofisica Ambiente, Bologna, Italy, email: ferrari@sga-storiageo.it)

Among the historical documentary materials produced by earth scientists the epistolary correspondence is of importance both for the outline of their biographies and for the reconstruction of the theoretical and experimental paths of the disciplinary history of seismology. This correspondence between seismologists is an important source of instrumental and descriptive data on the earthquakes of the past. Often, it contains references to seismic effects, to descriptions of instrumentsor of their adaptations, and to interpretations. In Italy, for the period from 1850 to 1940 alone, have been identified about 30,000 letters, of which only a part has been catalogued and used. Unfortunately, this particular kind of documentation is too often at the high risk of being lost or destroyed as it is being unrightfully considered of little interest by the more recent generations of seismologists. Recent experiences within specific projects of study and recover carried out in Italy and in the rest of the world have allowed the possibility to re-establish the just value of this documentation. There will be presented some results of an original method to catalogue the historical-scientific processing applied to files of correspondences between Italian and foreign seismologists.

ST7/E/07-A2 1215

THE NEW IASPEI SUB - COMMITTEE "HISTORICAL INSTRUMENTS AND DOCUMENTS IN SEISMOLOGY": AIMS, OBJECTIVES AND FIRST RESULTS

Graziano FERRARI (S.G.A. Storia Geofisica Ambiente, Bologna, Italy, email: ferrari@sga-storiageo.it)

At the end of 1998 a Sub-Committee IASPEI was created within the Committee Education, aimed at promoting: (1) research, inventory, and restoration of historical instruments, recordings, station bulletins, papers, and scientific correspondence, (2) preservation and reproduction of seismograms and historical documents, especially scanning/digitizing into computer files, (3) experimentation of techniques for the scientific investigations of all historical seismic data. The Sub-Committee draws the inspiration for its own aims and objectives from the recent experiences carried out in Italy within the TROMOS project realised by SGA for the Istituto Nazionale di Geofisica (National Institute for Geophysics) and in Europe within the WG ESC "History of Seismometry". Some of the objectives are: (a) to create a database of seismic observatories, including their histories, installed instruments and activity period, access to the recordings and related documents, (b) to produce biographies of the deceased scientists who contributed significantly to seismology and earthquake engineering, including their life, work, and publications, (c) to collaborate with local historians of science and of scientific instruments, (d) to compile and edit materials for inclusion in the "International Handbook of Earthquake and Engineering Seismology", a Centennial Volume of IASPEI to be published in 2001. The first results of the activity of the S-C will be presented and discussed.

AN INVENTORY OF SPANISH OLD SEISMOGRAPHS

Josep BATLLO (Escola Universitaria de Ciencies Empresarials Dr. Manya, E-43500 Tortosa, Spain, Email: jbo@tinet.fut.es)

A new, exhaustive, catalogue of old seismographs operated at Spanish sites is presented. It has been intended to be useful not just for historians, but mainly for researchers dealing with old data and seismograms recorded by such instruments. As a result, the beginning of instrumental seismology in Spain shows now a much more lively and complex process than expected. The catalogue summarises more than one hundred instruments and includes recording sites up to now forgotten. A cataloguing card has been elaborated for every seismograph. It contains the main physical characteristics, recording characteristics and periods, ground motion response, bibliography, hand written documents, actual condition and other data of interest for the instrument. Also, photographies of such described instruments, if available, have been included and referenced. Instruments have been classified according to its design: warning devices, seismoscopes, vertical pendulums, conic pendulums, inverted pendulums, electromagnetic, etc. Main features of the elaborated catalogue and results, concerning to the historical seismometry in Spain as well to the possibilities of its use on further studies are presented.

VESUVIUS 2000: A VOLCANIC RISK MITIGATION INITIATIVE FOR A MEGACITY OF THREE MILLION PEOPLE

Flavio DOBRAN

Millions of people surround very dangerous volcanoes where effective risk mitigation strategies cannot be based on unreliable predictions of eruptions, poor evacuation infrastructures, and inadequate volcanic risk education of the population. Over three million people surround Vesuvius and Phlegrean Fields in the Bay of Naples, and an even greater number surround many other volcanoes in Mexico, the Philippines and elsewhere. Computer simulations and past eruption history of Vesuvius strongly suggest that a large explosive eruption will occur in the next 100 years and that it is necessary to prepare the territory through information campaigns and provision of economic incentives.
The ultimate objective of VESUVIUS 2000 is to produce an accurate probabilistic risk assessment, or expected human, material, socio-economic, environmental, and cultural losses due to future eruptions, for the purpose of reorganizing the Vesuvius area and creating a security culture. Solicitations of Italian and European Union institutions for collaboration has only produced frustration and demonstrated that its leaders prefer to hide behind an unreliable evacuation plan that only provides an illusion of safety. This plan, promoted by the volcanologists within the Italian government, is a shameful consequence of a special interest group that is protecting the politicians from taking a direct responsibility for the Vesuvius area. Further details are available on the Internet (http://idt.net/~dobran).

WEB-BASED EDUCATIONAL TOOLS IN AND ITS POTENTIAL USE IN PUBLIC AWARENESS PROGRAMS

VALIYA M. HAMZA, Observatório Nacional - CNPq, Rio de Janeiro, Brazil

At present most of the web-based courses are academic oriented while facilities for interactive learning by the public is limited. Such difficulties are being overcome with recent advances in the use of server-side CGI (common gateway interface) scripts that allow inquiry-based interactive learning more effective than is possible in conventional systems. Thus various aspects of natural phenomena and their environmental impacts can be illustrated on the web, in the form of simulations in response to user inputs. Examples of virtual geothermal measurements (VGM) are presented which demonstrate how interactive techniques can be used to examine environmental consequences of human activities that lead to long term changes in vegetation cover and accumulation of greenhouse gases. Trial experiments with VGM also reveal that facilities for stimulating creative thinking can be setup more easily in web-based systems than in those which emphasize traditional teaching techniques. The fact that web-based information packages can be developed at relatively low cost has important implications for setting up cost-effective programs aimed at improving education and public awareness of the environment and of natural hazards. For example, maintaining infrastructures for education, information and training for such tasks as disaster preparedness, early warning and mitigation are turning out to be relatively expensive operations for institutions in developing countries. On the other hand, developing web-based informative and educational packages require no significant additional investments in infrastructure or personnel and can be carried out promptly by many of the scientific and educational institutions. A major advantage of web-based programs is the efficiency and ease with which background information can be made available to the general public, properly blended with links to more detailed educational material. This approach minimizes the need for qualified personnel necessary to develop detailed informative material at the initial stages. In addition, availability of properly designed introductory material, should allow inexperienced users in gaining familiarity in using web-tools and to acquire confidence in facing more elaborate learning tasks based on context-sensitive queries and answers.

CONTRIBUTIONS TO A HISTORY OF EARTHQUAKE PREDICTION RESEARCHES

Giovanni MARTINELLI, (Regione Emilia-Romagna, Serv.Cartogr. e Geol., Bologna, Italy,
email: email: g.martinelli@mo.nettuno.it)

Data coming from observations lasted 25 centuries have been systematized in the last 120 years and have become the object of applied research in the last 30 years in coincidence with a better understanding of physical and chemical phenomena which accompany earthquake occurrence.
The main procedures of diffusion of knowledges on earthquake prediction researches in space and time have been reconstructed. Scientific and economic constraint factors that caused difficulties or accelerations in seismic precursors researches have been investigated and commented. Future research tendencies are also described and commented.

ST7/L/03-A2 1430

TROMOMETRIC MEASUREMENTS AS A TOOL FOR CRUSTAL DEFORMATION INTERPRETATION

Graziano Ferrari (S.G.A. Storia Geofisica Ambiente, Bologna, Italy, email: ferrari@sga-storiageo.it); Dario ALBARELLO, (Dip. Scienze della Terra, Universit=E0 di Siena, Italy,
email: Dario@ibogfs.df.unibo.it) Giovanni Martinelli, (Regione Emilia-Romagna, Serv.Cartogr. e Geol., Bologna, Italy, email: g.martinelli@mo.nettuno.it)

In the past and still today crustal deformation has been considered as a powerful tool in the understanding of seismogenetic processes. In 1870, Timoteo Bertelli, inspired by the observation of small and natural movements of pendulums recorded by scientific and historical witnessess, began in Florence his first elementary observations by using a vertical pendulum and a magnifying lens. Thanks to his collaboration with Michele Stefano de Rossi which started in 1873, Bertelli came to the definition of the standard tromometer: a pendulum of 150 cm. in length and 100 gr. of mass whose horizontal shifts were observed through a microscope tube and a prism. The great simplicity and economy of the construction made this instrument easily widespread in many private, ecclesiastic and public observatories. Perhaps for the first time an actual network was established for the instrumental observation of earthquakes. In 1880 31 standard tromometers were being used in various Italian observatories. Between 1873 and 1930 more than 100,000 observations were performed. Previous researches have demonstrated that these data are highly useful for the identification of preseismic or coseismic phenomena. The results of a statistical analysis of a set of data collected in Florence, Bologna and other localities from 1878 until 1887 are presented and compared with the local seismic activity.

CREATION OF 'GEOLOGICAL MENTALITY' DURING EDUCATIONAL PROCESS AT THE HUMANITARIAN FACULTIES IN RUSSIAN UNIVERSITIES.

Nickolai V.Koronovsky (Faculty of Geology,Moscow State Lomonosov University, Moscow 119899, Russia, E-mail: koronovsky@dynamo.geol.msu.ru

The matter of this thesis - teaching experience of different geological curses to humanitarian students of such specialties as historishians, biologists,lawyers,economists, linguists and others.The main purpose of the curses of various duration (from 12 to 48 hours) for students and graduates is to give them knowleges about basic elements of geology such as Earth origin, structure and composition, evolution; to get them know different geological processes that are most affectable on human life: earthquakes, land-slides, floods and other natural hazards. We pay particular attention to modern methods of effective predictions and prevention of geological hazards.

PUBLIC EDUCATION AND AWARENESS OF EARTH AND ENVIRONMENT: THE INDIAN CONTEXT

K.S. Murty, (E-3 Vishnukamal Apts.,, 160 Shivajinagar, Nagpur 440 010, India)

There is a traditional way of predicting natural disasters in India. Ancient classical works like the 'Brihat Samhita' of Varahamihira(5th century A.D.) have chapters devoted to cloud formation, rainfall, groundwater studies and earthquakes. The almanacs in regional languages do predict these phenomena fairly accurately, though not perhaps the exact date and time. Indeed, agricultural operations in India are still guided by these fore casts. However, modern education in related sciences has created greater public awareness among the general public, apart from the fact that topics of geological background have been included in the slilabii at school, college and post-graduate levels. Almost a decade ago, a debate was launched on the Integrated Economic and Environment Accounting Framework for India. The public consciousness has also grown to such an extent that mass resistance to projects that could cause great environmental consequences the Chipko movement and the Narmada Protest being the direct results of degradation of the Himalayas, location of Tehri and Narmada dams in seismically active areas. TV, Radio and other mass media are used to warn people of impending floods and cyclones so that they could be evacuated to safer places. Remote sensing techniques have helped in studying soil erosion, forest cover loss and related phenomena and informing the general public. Environmental education with reference to conservation, ecology and health has been introduced at formal and informal levels.

ST7/P/02-A2 1515

PROPOSAL ON EARTHQUAKE EDUCATIONAL PROGRAMMES FOR INDIA AND NEIGHBOURING COUNTRIES

H.N. SRIVASTAVA (India Meteorological Department New Delhi- 110003, India,
e-mail: snb@imd.ernet.in)

Damaging earthquakes in India and neighbouring countries occur not only near the Indian Eurasian Plate boundary but also within the Indian Plate. Larger destruction due to the earthquakes in these countries occur in villages, urban slum and hilly areas which is attributed to lack of education, financial constraints and lack of availability of cheaper designs of dwelling units to suit the local environment. Even in cities, awareness about earthquake resistant designs is lacking.
The programme to face disaster mitigation needs to introduce earthquake safety rules right from primary and secondary schools and adult education centres. Since radio and television are now very common in India, frequent educational programmes through these media is essential. Also since more and more people are now joining computer-oriented management courses, a package needs to be designed for specialised programmes in such institutions. Refresher courses in Government and autonomous institutions may also be introduced so that very large trained manpower is available for disaster mitigation efforts.

ST7/E/11-A2 1530

EDUCATION ON SEISMIC AND NATURAL HAZARD MITIGATION IN SOUTH EAST ASIA

PHAN-TRONG Trinh, Institute of Geological Science, NCNST , Nghia do, Cau Giay, Hanoi, E-mail: pttrinh@refer.edu.vn, Fax: 84 4 8362886

South east Asia region with population of 530 Million is one of highest risk of natural hazard in the world. Many countries are threatened every time by storms, floods, earthquakes, volcanic eruptions, landslides and coastal zone erosions. The Asian Disaster Preparedness Center (AIT) have effected the Asian Urban Disaster Mitigation Program strike the education to reduce the vulnerability of urban areas and commitment to earthquake mitigation. We suggest here to extent the education system on seismic and other natural hazard for secondary school and publics by media and telecommunication. The education for public will focus on how self protection with Hazard and management plan of emergency works after destructive hazard to reduce hazard losses. This education will present in text book for secondary school and in the scientific education program of Television and radio. We suggest also the cooperation between scientific institutions in ASEAN countries for training post-graduate and high level education in seismic hazard assessment with the support from IASPEI training committee and experts form other institutions in Asia such as IIEE, CSB, ERI, INCEDE... in parallel with training course organising every years, internet will be a powerful tool for education. In near future this communication technique is a cheapest way for education for large region although it is rather expensive currently for certain countries in ASEAN such as Vietnam. It will be used not only for transferring lectures but also sofwares, examples, data and examinations. We could think of the system " request - answer" at the first stage by E-mail. One regional center for hazard education is responsibility to answer the questions of students in collaborating with experts. For seismic and natural hazard, the lectures will cover not only on seismic data but also geological data. We expect 4 main points will be paid more attention in seismic and natural hazard education: 1. The linking between paleoseismicity, seismotectonics, active tectonics, seismicity, geochemistry (Radon, Hydrogen) and some other advance techniques such as GPS, GIS, RADA interpherometry, remote sensing. 2. the combination between probabilistic and deterministic approach in estimation of seismic and natural hazard. 3. estimation of the losses (property and lives) is the complex result of seismic and natural hazard, population, housing structures, facilities, experiences... 4. As other developing countries, we need the know - how transfer from IASPEI and institutions of developed countries. The transfer of sources of some basic sofwares such as EQRISK will speed up the rapid progress of seismic and natural hazard mitigation in the region.

SCHOOL SEISMIC NETWORK IN EUROPE BY SCHOOLS FOR SCHOOLS

Jean-Luc BERENGUER (Centre International de Valbonne, France) Anne Deschamps, Antony Lomax, Jean Virieux (Geosciences Azur, Universite de Nice-Sophia Antipolis, France) Antonella Bobbio, Andre Herrero, Aldo Zollo (Dipartimento di Scienze Fisiche, Universita di Napoli "Federico II") Anne-Marie Bruyas, Angela Palma (European Services, Fondazione IDIS-Citta della Scienza, Italy) Marc Daignieres, Erik Doerflinger (Geophysique, Tectonique et Sedimentologie, Universite de Montpellier II, France) Jean-Francois Karczewski (DT-INSU/CNRS, France) Bernard Dost(Orfeus Data Center, The Netherlands)

A dedicated seismic station has been designed for schools and has been presented at the last IASPEI meeting. The features of this station are high dynamic recording (24 bits with 5 bits of electronic noise), broadband sensor (from 10 Hz to 300 sec), gps time reference, continuous time serie in a cyclic buffer, post triggering through telephon maintenance with possible on-line extraction of data signals.
This station has been installed in different schools both in France and in Italy. These stations through a seismic network have recorded different local, regional and teleseismic events. The extraction of these events has been organized in an automatic way through seismic catalogs. Different illustrations of school applications as velociy wave estimation, comparison of seismic waveforms between stations, localization of events will be presented.

EDUCATIONAL NETWORK OF THE GEOLOGICAL FACULTY OF THE MOSCOW STATE UNIVERSITY

Pavel Pletchov, Dmitry Koshchug (both from Geological department, Moscow State University, Moscow, Russia E-mail: lym@ccas.ru)

The Educational Network (EduNet), which includes some multimedia lecture courses, was created on the basis of Geological Department local area network. All lecture courses are represented via Internet as an HTML files and has a multimedia support (sound, video etc.). Hypertext connections of summaries of different courses allow creating more than simple archive of the courses. By the hypertext links, we have an opportunity to create union educational network (WWW-system) with common navigation, across and thematic searches, common database of definitions etc. Besides, a manual management (insert, update and support) of Educational Network too hard. We need to use the automatic system with next properties: Each part of EduNet is a valuable information resource, which interconnected to other resources via common and thematic searches and hyperlinks EduNet supports a free and convenient access for lecturer to edit and update his lecture courses and supplementary materials. The new course of lectures would be conformably inserted to EduNet. All interconnection to other information resources would be created automatically EduNet has a common navigation scheme for quick search of needed information resource. All navigation pages would be dynamic and would have both thematic and across search systems. Some aspects of multimedia courses creation, lecture-to-lecture interconnections, common navigation scheme would be discussed in this presentation.

NATURAL HAZARDS EDUCATION ON THE WEB

Paula K. Dunbar, and ALLEN M. HITTELMAN (both at NOAA's National Geophysical Data Center, 325 Broadway, Boulder, CO 80303, USA, email: ahittelman@ngdc.noaa.gov)

Each year natural disasters take a huge toll in deaths and injuries, property damage, and economic loss. Much of this devastation can be reduced through existing mitigation techniques and greater public awareness of them. The National Geophysical Data Center (NGDC) is using state-of-the-art World Wide Web tools for natural hazards education and public outreach.
NGDC acquires, processes, and analyzes technical data that are useful in natural hazards risk assessment. These include earthquake, tsunami, and volcano data. Interactive search and retrieval capabilities via the Web are now available for these datasets. A three-CD collection of hazards slides is also available online. Photographs of damage caused by natural hazards represent a unique form of data that capture the transient consequences of Earth's periodic upheavals. They not only remind us that such events can and probably will recur, but that we should be prepared to handle their consequences in the future.
NGDC recently created an online "Natural Hazards Quiz" to test the user's "Natural Hazards IQ." The quiz presents multiple-choice questions on all types of natural hazards. The questions range in difficulty and include historic, mitigation, and scientific information.
The Natural Hazards Data Resources Directory is also available online. The Directory includes information on more than 230 organizations that provide natural hazards data and information.

DISTURBED GEOPHYSICAL FIELDS AND FUNCTIONING OF NEURORECEPTORS

NONNA S. VASILYEVA-VASHAKMADZE (Tbilisi State University,1, Chavchavadze Ave., Tbilisi 380028, Georgia, email: vazha@excite.com) Anzor Gvelesiani (Institute of Geophysics, Georgian Academy of Sciences,1, M. Alexidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com)

In view of importance of helio-geophysical disturbed field influence on men and animals problem investigation - electro-magnetic, acoustic waves emission accompanying earthquakes, thunderstorms, magnetic storms, etc. – it is carried out the theoretical, by quantum electrodynamics and quasi-classical mechanics methods, study of the neuroreceptors functioning dynamics in chemical synapsis. As experiments and observations show external disturbed fields can penetrate into the central nervous system (CNS) across the isolating layer of glia. In those cases when the glia is not enough developed or it is exhausted or at anomalous external fields, resonance frequences, when their intensity exceeds the protective barrier then direct influence on the CNS takes place, clearing up as encephalogramm change. According to the suggested model theoretical values of synaptic receptors parameters (at a state of rest), in particular, of acetylcholin neuroreceptor for human CNS are calculated. It is shown that the frequences of electro-magnetic and acoustic and infraacoustic radiation was respectively of order about 9 and less and 3-2 and less are active and can initiate the generation and spreading of nerve impulses in the same parts of the cerebral brain and disturb the CNS normal functioning.

A MACROSEISMIC NETWORK OF SCHOOLS FOR THE COLLECTION OF EARTHQUAKES EFFECTS IN A LARGE CITY

Andrea TERTULLIANI (Istituto Nazionale di Geofisica, Via di Vigna Murata, 605, 00143 Roma, Italy, email: tertul@ing750.ingrm.it) Francesca Funiciello, Stefano Donati and Francesca Cifelli (all at Dept. of Geology, University of Roma Tre, Largo S. L. Murialdo, 00146 Roma, Italy, email: sdonati@uniroma3.it)

In order to obtain a realistic picture of the distribution of earthquake effects in large urban areas it is necessary to apply a suitable kind of macroseismic survey taking into the right account the distinctive features of modern megacities. To outreach such an objective a cooperation among Istituto Nazionale di Geofisica, University of Roma Tre and many roman high schools has been created, compounding scientific results and didactical development in earthquake preparedness. By using limited man-power and money we involved in the macroseismic survey the students of a sample of high schools (14-19 years). The schools were previously selected to obtain the best geographical distribution and to achieve us the creation of a macroseismic network in the urban area. Schools headmasters and teachers were previously contacted by our staff, providing them information about the aim of the study and the method. Two high density macroseismic surveys were for the first time performed to evaluate the intensity of shaking in the city of Rome (Italy) during the September 1997-March 1998 Umbria-Marche (Italy) sequence. At last the involved students resulted over 2000, with a final density of observation points never reached before in the city of Rome for earthquake surveys. From the scientific point of view the results are in the high definition of the intensity points distribution, basic for site response analysis especially in large urban areas; besides valuable results arise in the educational and didactical field, with a development of the attention to preparedness topics, mainly due to the direct and practical involvement of young people into the reasearch. We feel that this effort will be fruitful in the future as it would be an important corner-stone in the growing awareness about information, training and mitigation of geo-hazards, combining educational and scientific goals.

A NEW METHOD FOR IMPROVEMENT OF EDUCATION, INFORMATION AND TRAINING IN THE FIELD OF EARTH AND ENVIRONMENTAL SCIENCES

Tarzadin ULAANBAATAR (Department of Earth Sciences, National University of Mongolia, email: numelect@magicnet.mn)

A best way to improve education, information and training in all levels of persons and to better serve society in the new century is to show mathematically the nature of Earth, geophysical systems, climate system and environmental sciences. The conditions of their wide use are to be of very elementary mathematics and described by uppermost simple parameters for facility to understand, be interested everybody from ordinary public, through schools and apprenticeship, to more research-oriented university studies or to application-oriented post-graduate training.
In this paper geometry in daylight, thermal regimes, climate conditions on and near the Earth's surface, and some methods of their applications in society described brand-newly by time of calculation, date, geographical latitude, terrain height and albedo. Furthermore, results are shown in comparison with observed data and calculations and model results of other researchers.
All of these are summarized in a monograph, some chapters of which seem to be selected for ordinary public, elementary schools and apprenticeship, some for research-oreinted university studies and others for application-oriented post-graduate training.

EDUCATION AND OUTREACH IN THE 21ST CENTURY: TOWARDS HIGH-LEVEL RESEARCH ORIENTED EDUCATION IN DEVELOPING COUNTRIES

Author: Isaiah Tumwikirize, Uganda National Seismological Network, Geological Survey and Mines Department, Ministry of Energy and Mineral Development, P. Box 9 Entebbe (Office) or Box 404 Entebbe (Private) Uganda.

Education is crucial for an society. It is through education that human capital of the society is developed. The quality of labour, productivity in all sectors of the economy, social services, welfare, all depend on the education and its policy of a country. Investment in education promotes innovativeness due to the desire for economic improvement hence accelerated growth and development.In this paper, an effort is made to analyse the level of research oriented education activities in the developing countries; and at the same time the portion of the Gross National Product (GNP) invested in such activities as compared to the developed countries. The paper also looks into the extent of internal and external inabilities that challenge the Research Oriented Education (ROE) today and perhaps will remain bottlenecks in Education Outreach in the 21st Century. The author also summarises the lessons learnt from international efforts towards the high-level research education activities in developing countries. In the conclusion, developing countries therefore must create an atmosphere that encourages to work in partnership with the owners of technologies so as to promote international technology transfer that will enable in building up ROD infrastructure. This certainly will require the developing countries develop a S&T culture through national policies, but remains a question of political will and innovativeness.

VESUVIUS 2000 EDUCATIONAL ACTIVITIES FOR SECURITY CULTURE

Flavio Dobran (Gianfranco Gambardella, Anna Ibello, Ida Mascolo, Global Volcanic and Environmental Systems Simulation, P.zza Matteotti, CP418, 80133 Napoli, Italy,
Email: dobran@idt.net)

Vesuvius is a volcano in the Bay of Naples that is surrounded by about three million people. Computer simulations and past eruption history strongly suggest that a large explosive eruption will occur in the next 100 years. In the past such eruptions devastated the territory, but today they would also produce a human catastrophe because of the widespread abusive urbanization of the area and lack of security culture among its people. The central objective of the VESUVIUS 2000 initiative is to produce risk mitigation guidelines for the Vesuvius area aimed at informing the population about the potential risk of future eruptions and how this risk can be reduced through the reorganization of the territory and establishment of security culture. The basic premise of the initiative is that a secure cohabitation of people with volcano is possible and that this cohabitation can produce socio-economic, scientific, and cultural benefits without creating adverse effects to the environment. For this purpose, a Global Volcanic Simulator which physically models the entire volcano is being developed and computer simulations of possible eruptions used to study their effects on the territory and how it can be reorganized and the people protected. The development of a proper educational methodology for the Vesuvius area is fundamental for establishing new habits of mind conducive for the creation of security culture. For this purpose we have been conducting public seminars in town halls, churches, private clubs, military establishments, schools, private residences, and producing written and visual material. On the anniversaries of large eruptions of Vesuvius (August 24, 79, and December 16, 1631) we have been issuing international appeals and involving Vesuvius area schools in sharing their cultural works associated with their environment. We have also produced educational material directed at better acquainting school teachers on the interdisciplinary issues of their environment. Much of this information has been available on the Internet (http://idt.net/~dobran) since 1995 and has been often visited by children and adults from around the world.

CIRCULATION FEATURES IN THE ARCTIC OCEAN REVEALED BY THE NUCLEAR FUEL REPROCESSING TRACERS, 129I AND 137CS

John N. SMITH - Marine Environmental Sciences Division, Bedford Institute of Oceanography, Dartmouth, N. S., Canada B2Y 4A2

The development during the past 10 years of analytical techniques to measure 129I by accelerator mass spectrometry has led to recent advances in its use as an oceanographic tracer, particularly in the Arctic Ocean. This stems from the fact that large quantities of 129I (t1/2 = 16 x 106 y) have been discharged from the Sellafield (UK) and La Hague (France) nuclear fuel reprocessing plants into the Irish Sea and English Channel, respectively since the 1960s. Together with 137Cs (t1/2 = 30 y), derived mainly from Sellafield, the 129I reprocessing signal is transported into the North Sea and Norwegian Coastal Current and then enters the Arctic Ocean through Fram Strait and the Barents Sea where both tracers reflect the circulation of Atlantic-origin halocline and intermediate water. Measurements of 129I and 137Cs, combined with a knowledge of the historical record of reprocessing plant discharges, can be used to identify a given year of transport through the Norwegian Coastal Current (NCC), thereby permiting the determination of a transit time from the NCC to a given sampling location, similar to a ventilation age determined using atmospherically-derived tracers such as tritium and chlorofluorocarbon compounds (CFC's). One difference is that the release rate of 129I from La Hague and the dynamic range of the tracer pair for transit time measurements is rapidly increasing while the input functions for many ventilation tracers are leveling off or decreasing owing to global constraints placed on their production and usage.
Measurements of 129I and 137Cs conducted on seawater samples collected during icebreaker and US Navy nuclear submarine cruises (SCICEX program) to the Central Arctic Ocean since 1993 provide a basis for evaluating the utility of these tracers. 129I results in halocline waters clearly delineate the front between Atlantic-origin water having an elevated 129I reprocessing signal (> 100 x 107 at/l) and Pacific-origin water labeled mainly by fallout (< 5 x 107 at/l), that is aligned with the Mendeleyev Ridge. Low 129I levels (< 2 x 107 at/l) measured in Atlantic and intermediate water in the Northern Canada Basin and over the Alpha Ridge indicate that ventilation rates are extremely low …

USING CHEMICAL TRACERS TO ASSESS OCEAN MODELS

Matthew H. ENGLAND Centre for Environmental Modelling and Prediction (CEMAP), School of Mathematics The University of New South Wales, NSW 2052 Australia and Ernst Maier-Reimer Max Planck Institut fur Meteorolgie, Hamburg, Germany

Geochemical tracers can be used to assess the simulated circulation in ocean models. Tracers that have been used in this context include tritium, chlorofluorocarbons, natural and bomb-produced radiocarbon; and, to a lesser extent, oxygen, silicate, phosphate, isotopes of organic and inorganic carbon compounds and certain noble gases (e.g., helium and argon). This paper reviews the use of chemical tracers in assessing the circulation and flow patterns in global and regional ocean models. It will be shown that crucial information can be derived from chemical tracers that cannot be obtained from temperature-salinity (T-S) alone. In fact, it turns out that a model with a good representation of T-S can have significant errors in simulated circulation, so checking a model's ability to capture chemical tracer patterns is vital. Natural chemical tracers such as isotopes of carbon, argon, and oxygen are useful for examining the model representation of old water-masses, such as North Pacific and Circumpolar Deep Water. Anthropogenic or transient tracers, such as tritium, chlorofluorocarbons, and bomb-produced 14C are best suited for analysing model circulation over decadal time-scales, such as thermocline ventilation, the renewal of Antarctic Intermediate Water, and the ventilation pathways of North Atlantic Deep Water and Antarctic Bottom Water. Tracer model studies have helped to reveal inadequacies in the model representation of certain water-mass formation processes; for ex- ample, convection, downslope flows, and deep ocean currents. They show how coarse models can chronically exaggerate the spatial scales of open ocean convection and deep currents, while underestimating deep flow rates and diffusing downslope flows with excessive lateral mixing. Higher resolution models typically only resolve thermocline ventilation because of shorter integration times, and most resort to high-latitude T-S restoring to simulate reasonable interior water-mass characteristics. This can be seen to result in spuriously weak chemical tracer uptake at high latitudes due to suppressed convective overturn and vertical motion. Overall, the simulation of …

WATER MASS FORMATION AND CIRCULATION IN THE SOUTHERN AND SOUTHERN INDIAN OCEANS: RESULTS FROM STABLE OXYGEN ISOTOPES

M.P.MEREDITH, K.J.Heywood, R.D.Frew and P.F.Dennis

Measurements of the stable isotopes of oxygen made from samples collected on the Antarctic Deep Outflow Experiment (ADOX) cruises in the Southern Ocean and southern Indian Ocean, February to March 1993 and 1994, are discussed. The data are used in conjunction with hydrographic data to infer characteristics of the formation and mixing of water masses found in the region. The isotopically heaviest waters of the survey were found at the surface of the Madagascar Basin, a consequence of evaporation-induced enrichment of the heavier molecule. The isotopically lightest waters were found on the continental shelf of Antarctica, adjacent to the Princess Elizabeth Trough (PET); these waters are made isotopically light by the injection of around 1% of glacial ice melt, and are probably advected to the region from further east by the current associated with the Antarctic Slope Front. They appear to be locally disassociated from the Antarctic Surface Water and Winter Water (WW) further north in the PET. The WW of the Enderby Basin is isotopically lighter than the PET WW, and also fresher, indicating the presence of an additional component of glacial ice melt or high-latitude precipitation. North of the Antarctic Circumpolar Current (ACC), the delta 18-O of the surface waters show a strong correlation with salinity, but extrapolate to an apparent freshwater endmember which is too isotopically light to be reasonable; advection and mixing of the water masses dominate over the local water balance at this location. The Subantarctic Mode Water of the southern Indian Ocean lies on the line of the surface waters in salinity-delta 18-O space, a consequence of its formation at the surface of the region by deep convection. The Antarctic Intermediate Water also lies on the same line, but this is somewhat coincidental since it does not originate in the region. Consequently, the observation does not, in fact, imply formation by local deep convection. There is no evidence in the data from the two repeated surveys of the Crozet-Kerguelen Gap to suggest interannual variability in the amount of glacial ice melt contributing to Antarctic Bottom Water (AABW) formation in the Weddell Sea. A previous hypothesis based on a subset of the data used here…

TRACER STUDIES OF ARCTIC SEA-ICE GROWTH AND ABLATION

H. EICKEN (Geophysical Institute, University of Alaska, Fairbanks, AK 99775-7320, USA, Email: hajo.eicken@gi.alaska.edu), S. Pfirman (Barnard College, Columbia University, New York, NY 10027-6598, USA), H. R. Krouse (University of Calgary, Calgary, T2N 1N4, Canada), C. Haas, J. Freitag, A. Mackensen (Alfred Wegener Institute, D-27515 Bremerhaven, Germany)

In conjunction with ice sampling, stable-isotope and fluorescent tracer studies can yield substantial insight into the processes controlling growth and ablation of the Arctic sea-ice cover. Similar to drifting buoy measurements, the isotopic record of sea-ice cores extracted from the pack ice may provide time series of parameters relevant in the context of ocean-ice-atmosphere interaction. Drawing on field studies the following research will be discussed.
(1) Stable-isotope measurements (delta-18O and delta-D) allow discrimination between the contribution of meteoric (precipitation, snow meltwater, river water) and marine waters to the total ice volume. In the Eurasian Arctic, with its substantial inflow of river water onto the shelves, this helps in identification and tracking of coastal ice into the deep basins. Based on a linear-mixing/fractionation model, the stable-isotopic composition of sea ice has furthermore been utilized to reconstruct the formation and growth of sediment-laden ice in the Laptev Sea.
(2) For a given parent water-mass composition, the growth-rate dependent fractionation of stable isotopes during ice accretion allows a reconstruction of the growth history and - through integration of surface-energy balance data - the oceanic heat flux at the base of the ice cover. In the Transpolar Drift, where isotopic gradients in the surface water are associated with the entrainment of Atlantic water into the Arctic halocline, the isotopic ice-core record may provide insight into the spatial and temporal variability of entrainment processes.
(3) The pronounced isotopic contrast between snow and ice meltwater and the strong seasonality of the melt signal can furthermore be utilized in studies of meltwater dispersal in the ice cover and the underlying water layers. Recent work at the SHEBA field site has demonstrated the great potential of fluorescent tracers in determining lateral and vertical advection of meltwater and associated heat transport through the ice cover on time scales ranging from hours to several weeks. It was shown that hydraulic properties and processes may play an important role in controlling the evolution of summer ice albedo.

THE APPLICATION OF RADOTRACEDRS TO A STUDY OF BLACK SEA CIRCULATION: VALIDATION OF NUMERICAL SIMULATIONS AGAINST OBSERVED WEAPON TESTING AND CHERNOBYL 137CS DATA

J. V. STANEVA, E. V. Stanev (both at the University of Sofia, 5 J. Bourchier Street, Sofia 1126, Bulgaria, Fax: +359-2-9625276; e-mail: joana@phys.uni-sofia.bg); Ken. O. Buesseler (Department of Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Clark-447, Woods Hole, MA 02543 USA); Hugh D. Livingston (IAEA Marine Environment Laboratory, Monaco)

In this paper, we use the distribution of the artificial radionuclide, 137Cs, to investigate mixing and ventilation in the Black Sea. Time-series data of vertical radionuclide distributions are combined with model simulations in order to follow the magnitude and depth of penetration of surface oxic water into intermediate depths, below the oxic/anoxic interface. Simulated data are produced by a three-dimensional circulation model that includes a new parameterization of the Bosphorus inflow/plume to simulate the effects of Mediterranean water on internal mixing. A radioactive tracer model for pre-Chernobyl 137Cs (weapon testing 137Cs) and Chernobyl 137Cs is coupled to the circulation model. The model results are compared to field data collected between 1986 and 1992. The main output from the simulations is the identification of the contribution of entrainment in the mixing of surface waters into subsurface layers. The trend of tracer penetration into the deeper layers following isopycnal surfaces is well demonstrated in the model and is consistent with the known circulation and physics of the Black Sea. The correlation between the activities of radionuclides and salinity, found in the field data, is supported by the simulations. These model results illustrate that the time-space abundance of the existing field data is sufficient for reconstructing the distribution of tracers in space and time, provided reliable estimates of Black Sea circulation exist.

P07/L/02-A3 1125

REGIONAL AND INTERANNUAL DATA ARCHIVED BY DRIFTING ARCTIC SEA ICE

S. PFIRMAN (Barnard College, Columbia University, New York, NY 10027-6598, USA, Email: spfirman@barnard.columbia.edu); H. Eicken (Geophysical Institute, University of Alaska, Fairbanks, AK 99775-7320, USA); R. Colony (International ACSYS Office, Postboks 5072 Majorstua, N-0301 Oslo, Norway); P. Schlosser (Lamont-Doherty Earth Observatory of Columbia University, Palisades, New York, 10964); I. Rigor (University of Washington, Polar Science Center, 1013 NE 40th Street, Seattle, WA, 98105); R. Mortlock (Lamont-Doherty Earth Observatory of Columbia University, Palisades, New York, 10964); D. Bauch (GEOMAR, Kiel, Germany)

Arctic sea ice drift trajectories coupled with measurements of d18O values in cores from multiyear ice floes can provide information on regional and interannual variations in sea surface d18O values. The isotopic composition of newly formed sea ice is influenced by the parent water d18O composition and fractionation during ice formation. Under floe ice accretion can be estimated by an ice growth model. Drifting sea ice trajectories are reconstructed from the International Arctic Buoy Programme database. Stepping back along the trajectory, sea surface d18O values are derived from either the measured profiles or a gridded compilation of measured sea surface d18O values. Comparison of the two approaches yields information on regional and interannual variations in sea surface d18O along the drift trajectories as well as ice accumulation and hence heat flux along the drift track. Errors include:1) errors in ice floe trajectories, 2) volume averaging in core samples, and 3) misrepresentation of energy balance terms at the upper or lower surface.

P07/W/15-A3 1145

ADDITION OF GLACIAL MELTWATER TO ANTARCTIC SHELF WATERS DERIVED FROM HELIUM ISOTOPES

Peter SCHLOSSER (email: peters@ldeo.columbia.edu; Department of Earth and Environmental Sciences, Columbia University, NY; Lamont-Doherty Earth Observatory of Columbia University), Roland Hohmann, Andrea Ludin, and Ralf Weppernig (all at Lamont Doherty Earth Observatory, POB 1000, Palisades, NY, 10964)

The ice shelves surrounding Antarctica contain about 10 percent of atmospheric air. During melting of the glacial ice a significant fraction of this air is dissolved in the sea water. Helium has the lowest solubility among the gases contained in air. Therefore, the melt water is highly supersaturated in helium. The helium signal imprinted by addition of glacial meltwater can be detected in large portions of the shelf region of the Southern Ocean.
Here we present He-4 data from all sectors of the Southern Ocean and interpret them in terms of addition of glacial meltwater to the shelf waters, as well as the deep and bottom waters. An attempt is made to quantify the flux of glacial meltwater into the individual water masses around Antarctica. Where available, the helium data are compared to stable isotope ratios of water.

P07/E/04-A3 1205

ANALYZING ANTARCTIC BOTTOM WATER FORMATION IN A GLOBAL ICE-OCEAN MODEL USING PASSIVE TRACERS

Jean-Michel CAMPIN and Hugues Goosse (Institut d'Astronomie et de Geophysique G. Lemaitre, Universite Catholique de Louvain, 2 ch. du cyclotron, 1348 Louvain-la-Neuve, Belgium, email: campin@astr.ucl.ac.be and hgs@astr.ucl.ac.be)

Antarctic Bottom Water (AABW) is formed near Antarctica. In those regions, the brine released on the continental shelf during ice formation is responsible for an increase of the water salinity. After mixing with ambient water (mainly Circumpolar Deep Water) at the shelf break this salty and dense water sinks along the shelf slope and invades the deepest part of the global ocean. Ocean General Circulation Models generally fail to represent this mechanism correctly. Two potential causes of this problem are a too simple parameterization of the sea-ice influence and the difficulty to simulate the downward movement of the dense water along the slope in large-scale models. In the present study, AABW formation is analyzed in a global coupled ice-ocean model which takes into account these two processes: the sea-ice component has a representation of both thermodynamic and dynamic processes and the ocean component includes an explicit parameterization of downsloping flows. The investigation of the T-S properties of the water masses in the Southern Ocean shows that the model is able to reproduce the main characteristics of AABW although regional differences are not well represented. In addition, the CFC concentrations computed by the model compare favorably with observations. They depict the pathway of the newly formed bottom water and offer a quantitative estimate of the recent ventilation of the Southern Ocean. The simulated natural C14 distribution extends this estimation to longer time scales and provides supplementary information concerning the water masses involved in AABW formation.

P07/W/11-A3 1225

AN OXYGEN ISOTOPE DATA SET FOR MARINE WATERS: DEEP CONVECTION IN THE NE PACIFIC?

Grant R. BIGG (School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, U.K., email: g.bigg@uea.ac.uk); Eelco J. Rohling (School of Ocean and Earth Sciences, University of Southampton, Southampton Oceanography Centre, Southampton SO14 3ZH, U.K., e-mail: ejr@soc.soton.ac.uk)

The proportion of 18O in a sample of seawater is an excellent tracer of its past history as, away from the surface, it is conservative and also non-dynamical. The range of values in source waters is also large, and the accuracy achievable in modern measurement high. Here we bring together for the first time a global dataset of over 6000 individual measurements from the past 40 years. The properties of this dataset are described. Noteworthy features include the hitherto unnoticed, but distinctive, contribution of Pacific intermediate water to the 18O:salinity relationship, and different origins of the deeper waters of the Atlantic and Pacific Oceans. As an illustration of the contribution that this dataset could make to oceanography we examine evidence in the 18O distribution for at least occasional deep convection in the Gulf of Alaska of the North-east Pacific.

ENVIRONMENTAL CONTROL ON MEDITERRANEAN SALINITY AND DELTA18O

Eelco J. ROHLING (School of Ocean and Earth Science, Southampton University, Southampton Oceanography Centre, Southampton SO14 3ZH, United Kingdom, email: E.Rohling@soc.soton.ac.uk)

A simple box-model presenting the long-term average Mediterranean is developed that resolves, within one system, for change in both salinity (S) and delta18O. In spite of its basic configuration and schematic input, the model successfully approximates: (1) present-day Atlantic-Mediterranean salinity and delta18O contrasts (using relative air humidity of 70%); (2) milennium-scale variability in Mediterranean inflow volume as also inferred from micropaleontological records; and (3) general changes in basin-average planktonic foraminiferal carbonate delta18O since the last glacial maximum. This justifies the use of the model to explore the nature and principal causes of temporal changes in Mediterranean S and sea-water delta18O (SM and dM, respectively). The model indicates that dM shows temporal variability of much greater amplitude than SM. Relative to the present, reversed Atlantic-Mediterranean delta18O gradients may have occurred, while present-day type salinity gradients were maintained, albeit somewhat weakened. A strong temporal variability is observed of the non-proportionality between dM and SM responses to forcing by an internally consistent set of environmental changes. Consequently, the results suggest that oxygen isotope results cannot be used to reliably approximate paleosalinity change in the Mediterranean. However, oxygen isotope residuals still hold vital information on interactions between the freshwater cycle and advective processes, and so remain an important element in studies of the (paleo-)circulation state of the basin. From foraminiferal carbonate delta18O records, it has been inferred that distinct dM depletions occurred during sapropel deposition. The model results immediately imply that such depletions are possible only if run-off at those times was isotopically more depleted than today. The model results also allow speculation on the nature of particularly strong depletions such as observed in sapropel S5 from the penultimate interglacial maximum. These can no longer be interpreted as immediate evidence of major freshening of Mediterranean surface waters, but might equally likely have resulted from slight (of order 5%) increases in relative air humidity over the basin, relative to the present.

P07/E/03-A3 1430

HOLOCENE MONSOONAL AND UPWELLING RECORDS DERIVED FROM THE MARGIN SEDIMENTS OF THE EASTERN ARABIAN SEA

B.L.K. SOMAYAJULU, A. Sarkar, R. Agnihotri, R. Ramesh, K. Dutta, R. Bhushan. Oceanography & Climate Studies Area, Physical Research Laboratory, Ahmedabad 380 009, India, e-mail: soma@prl.ernet.in) A.J.T. Jull, G.S. Burr (NSF Arizona AMS Facility, The University of Arizona, Tuscon, AZ 85721, USA, e-mail: AMS@physics.arizona.edu)

Eastern continental margins of the Arabian Sea viz. West Coast of India experience widely varying annual rainfall, ~30 cm at 22˚N to ~250 cm at ~9˚N peaking to ~400 cm at ~13˚N. Between ~200 m and ~1000 m, the waters are perennially anoxic and upwelling induced biological productivity results in high concentrations Corg (~2% - ~6%) in the underlying sediments. Five of the ten gravity cores dated by AMS 14C on planktonic foraminiferal separates yielded fairly uniform sedimentation rates (4-100 cm/k yr) three of which have so far been studied for paleomonsoonal and productivity and/or upwelling trends using d18O, d13C, Corg, Sr/Al, Ba/Al as proxies.
We infer that the Evaporation-Precipitation (E-P), decreased steadily during the last 10 Ka, indicated by d18O of G. sacculifer, after correcting for SST variations, which are minor. Such a trend is also shown on Corg (%) and Sr/Al, indicators of productivity. Significant periodicities of 700 and ~1450 years seen in d18O record indicating possible teleconnection with the North Atlantic Oscillation.

P07/W/09-A3 1450

TESTING ASSUMPTIONS FOR STABLE ISOTOPE PROXY DATA: WHAT CAN MODELS TELL US?

Gavin SCHMIDT (NASA Goddard Institute for Space Studies and Center for Climate Systems Research, Columbia University, 2880 Broadway, New York, NY 10025, USA, Email: gschmidt@giss.nasa.gov)

The ratio of oxygen isotopes (O-18 to O-16) in foraminiferal carbonate deposits in ocean sediments and corals is a record of both the ambient ratio of the oxygen isotopes in the surrounding seawater and the temperature-dependent fractionation that occurs as the carbonate precipitates from the seawater. In addition, the record contains influences of thermocline or seasonality changes on planktonic foraminifera ecology. All these factors are functions of climate.
We attempt to untangle these competing effects using results from the GISS global ocean model with water isotope tracers, in conjunction with simple ecological models that forward model the isotopic signals recorded in the carbonate. Models of planktonic foraminiferal abundance estimate the distribution in the vertical over time as a function of monthly column temperature, season, light intensity and density stratification. Carbonate is assumed to precipitate in isotopic equilibrium contemporaneously with abundance. Comparisons with core-top data show reasonable matches when conditions typical for N. pachyderma (l), G. bulliodes and G. ruber (white) are used.
Time series of these virtual proxy data as the model climate changes are then examined to investigate the accuracy of derived climatic variables (SST, SSS) and the sensitivity of the results to changes in the assumptions concerning foraminiferal growth and seawater isotopic variation. Error estimates for paleo-temperatures and paleosalinity records are given for different regions. Errors due to measurements are generally negligible, however, errors due to the "goodness of fit" of various regressions used in calculations can be significant. In regions such as the North Atlantic, co-variance of d18Ow and temperature are the biggest source of error in paleo-temperature reconstructions. For paleo-salinity calculations, the largest errors occur because of the differences between temporal and spatial d18O: salinity relationships and through the use of non-concurrent temperature measurements.

P07/W/10-A3 1510

HIGH-RESOLUTION CORAL D14C RECORDS FROM THE TROPICAL AND SUB-TROPICAL PACIFIC: RECONSTRUCTING OCEAN DYNAMICS.

T.P. GUILDERSON (Center for AMS, LLNL, Livermore CA), D.P. Schrag (Harvard Univ., Cambridge MA), M. Kashgarian, and J. Southon both at (Center for AMS, LLNL, Livermore CA).

We have generated several new near-monthly resolution, coral-based, post-bomb radiocarbon (D14C) time series from the subtropical and tropical Pacific. In general, the subtropics (Hawaii, Rarotonga) have higher D14C reflecting the stability of the gyres and high air-sea exchange. D14C in the eastern equatorial Pacific (Galapagos) are lower and reflect the subsurface pathway of the Equatorial Undercurrent and entrainment of deeper thermocline waters which feed the upwelling in this region. Radiocarbon values in the "warm pool" region (Nauru) are intermediate between the higher subtropics and those in the east. The long-term trend reflects the invasion of bomb- 14C into the surface ocean. The post-bomb maxima in the subtropics is reached in the early 1970s whereas at Nauru and Galapagos it is delayed by 10 years. The delay is a consequence of the subsurface history of waters upwelling in the east and the subsequent advection and mixing of these water in the west. Superimposed upon the long term trend is seasonal to interannual variability. The patterns of radiocarbon variations in the Galapagos timeseries can be explained in terms of variability in the intensity of upwelling and changes in source water feeding the upwelling. During ENSO warm events, the depth of the thermocline increases in the east so that Ekman pumping no longer brings water from the undercurrent to the surface. This creates high D14C anomalies in the coral timeseries which are most pronounced from July through September. Large interannual variability is observed in the Nauru record and also follows ENSO. During ENSO warm phases D14C is higher reflecting the reduction of low-14C water upwelling in the east and the invasion of subtropical water into the western equatorial tropical Pacific. Warm events tend to be sharply terminated with sharp overshoots. These series of coral records demonstrates the potential for using radiocarbon time series for documenting variability in Pacific shallow circulation over interannual and decadal timescales. Timeseries such of these hold great promise to augment onetime surveys such as GEOSECS and WOCE.

P07/W/19-A3 1550

RIVER, SEA-ICE, AND PACIFIC WATER MASS COMPONENT SEPARATION FROM ATLANTIC WATER IN THE ARCTIC OCEAN USING DELTA O-18 AND PO4*

Brenda EKWURZEL (email: ekwurzel1@llnl.gov), Peter Schlosser
(email: peters@ldeo.columbia.edu), Rick G. Fairbanks (email: fairbank@ldeo.columbia.edu), and Rick Mortlock (email: mortlock@ldeo.columbia.edu), (all at Lamont-Doherty Earth Observatory, POB 1000, Palisades, NY, 10964, present address for Ekwurzel: Lawrence Livermore National Laboratory, POB 808, Livermore, CA 94551)

Immense river discharge combined with the small ocean basin volume gives the Arctic Ocean the distinction of having the highest percentage of river runoff of all the world ocean basins. The resulting surface mixed layer and highly stratified halocline form a low salinity layer of

water with temperatures close to the freezing point that overlie the more saline and warmer layer of Atlantic origin. Three freshwater sources maintain the halocline: river runoff, sea ice meltwater, and the low salinity Pacific Water entering through the Bering Strait.
Identifying the freshwater components in the halocline provides a clue to possible causes for the diminished halocline observed over the past few years. We use delta O-18, PO4* (= PO43- + O2/175 - 1.95 micro mol/kg), and salinity to quantify the spatial and temporal distribution of freshwater sources in the halocline. Fractionation between the heavier and lighter oxygen isotopes due to temperature and distance from the source area results in significant depletion of O-18 in Arctic River runoff relative to Standard Mean Ocean Water. The phase transition during sea ice formation fractionates the oxygen isotopes and can be used to separate the sea ice component. The large range between the nutrient-rich Pacific Water PO4* (~ 2.4 micro mol/kg) and the three other components (range: 0.1-0.7 micro mol/kg) make it a good tracer for the Pacific Water component.
River runoff circulation in the Kara Sea in 1993 exhibited a cyclonic circulation from the Ob and Yenisey rivers, plus a net eastward flow toward the Laptev Sea. River runoff exhibited a net eastward surface circulation in the Laptev and East Siberian Sea, with a northeastward component flowing toward the Lomonosov Ridge and Mendeleyev Ridge region in 1994…

CONSTRAINING OCEAN GENERAL CIRCULATION MODELS USING CFC OBSERVATIONS

Suzanne GRAY (Department of Meteorology, University of Reading, Earley Gate, Reading RG6 6BB, UK, Email: S.L.Gray@rdg.ac.uk) Thomas Haine (Atmospheric, Oceanic and Planetary Physics, Department of Physics, University of Oxford, UK).

We have developed and tested an inverse method, based on Green's functions, for using transient tracer observations to constrain Ocean General Circulation Models. The method has been tested using a North Atlantic configuration of MICOM (the Miami Isopycnic Coordinate Ocean Model) with 4/3 degree resolution. A substantial quantity of North Atlantic CFC-11 and CFC-12 data has been collated.The fluxes of these tracers into the ocean and the errors in the fluxes and in the tracer data have also been estimated.
Systematic differences can be seen between the observed CFC concentrations and an optimal prediction of these concentrations by the model. The errors in these predictions (due to errors in the assumed tracer flux into the ocean) and in the observations are incorporated into the inverse calculation to yield a quantitative measure of the degree of fit between the predictions and the observations. A poor fit is a consequence of deficiencies in the model circulation and may be due to processes which are not well parameterized in the model. We find that the model circulation is inconsistent with the CFC dataset, the estimated tracer fluxes, and the estimated errors on scales of order a few 100 km.

P07/W/03-A3 1640

STABLE ISOTOPES OF OXYGEN IN SEAWATER IN THE NORDIC SEAS AND NORTHEAST ATLANTIC

Karen J. HEYWOOD, Michael P.Meredith, Timothy A. Winters, Paul F.Dennis (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, email: k.heywood@uea.ac.uk)

We present analysis of the stable isotopes of oxygen (O18 and O16) in seawater samples collected in 1991, 1996, 1997 and 1998 in the Nordic Seas and Northeast Atlantic. Most of the work has been undertaken through the EU MAST programme VEINS (Variability of Exchanges in Northern Seas).
In Fram Strait, preliminary calculations of the flux of meteoric water and sea ice melt out of the Arctic show a strong meteoric outflow, and negative sea ice meltwater. Negative values imply sea ice formation, equivalent to 4 m of ice. Just southwest of Svalbard, observations in the Storfjord plume of bottom water indicate that while the surface water is predominantly fresh due to sea ice melt, the bottom water is fresh due to mainly meteoric imput (probably glacial melt from Svalbard).
Results from Denmark Strait show that between August 1972 (GEOSECS data) and August 1991, the core of Labrador Sea Water (LSW) had both freshened and ecreased in O18, due to changes in the formation properties of LSW. Because there is a change in O18, the freshening of LSW must be due to the inclusion of meteoric water precipitation or runoff from land/ice) and not due to changes in sea ice melt quantities or locations. In the deep water overflows, the O18 data indicate that the water has undergone sea ice freezing processes during its formation, showing that sea ice formation is an important component of the deep convection process.
In contrast, deep waters in the Faeroe-Shetland Channel are diluted with fresh water or meteoric origin (probably Arctic precipitation) and no influence of sea ice freezing processes is required. Isotope ratios in the European Shelf Edge Current, observed in the Faeroe-Shetland Channel and the Rockall Trough, imply influence of water from the Mediterranean.

P07/W/05-A3 1700

AN ESTIMATE OF THE ANTHROPOGENIC OFFSET OF OCEANIC DELTA C-13 (DIC) BASED ON THE VENTILATION OF THE CALIFORNIA CURRENT AT 42°N

J.D. ORTIZ 1, A.C. Mix2, P. Wheeler2, and R.M. Key3, 1Lamont-Doherty Earth Observatory of Columbia University, 2College of Oceanic and Atmospheric Sciences, Oregon State University, 3Department of Geosciences, Princeton University

Nutrient and delta C-13 (DIC) measurements from depth profiles down to 2,500 m at four stations across the California Current (42˚N) constrain the magnitude of the oceanic anthropogenic delta C-13 9DIC) shift (denoted Delta delta C-13a-p). At these stations, nitrate, rather than phosphate, provides the strongest correlation to delta C-13 (DIC). Values of Delta delta C-13a-p vary systematically as a function of water mass, similar to the pattern of Delta C-14 and Tritium penetration for these waters. Near surface waters of potential density (sq) < 25.1 and within the Shallow Salinity Minimum (sq 25.1 to 26.5) have a mean Delta delta C-13a-p offset of -0.6 +/- 0.24. This estimate is within the range of surface water values cited by Beveridge and Shackleton [1994] and suggests that near-surface waters obtain their anthropogenic signature by direct contact with the atmosphere, while waters of the Shallow Salinity Minimum (SSM) obtain their anthropogenic signature through winter ventilation of outcropping isopycnal surfaces. Below the SSM, a simple scaling argument suggests that the anthropogenic signature is transmitted diffusively across the North Pacific Intermediate water (NPIW). Our results suggest the magnitude of Delta delta C-13a-p in well ventilated waters is essentially constant, and decreases diffusively into less well ventilated waters.

P07/W/18-A3 1720

HELIUM-3 BALANCE OF THE UPPER WATERS OF THE WEDDELL SEA: IMPLICATIONS FOR OCEANIC HEAT FLUXES

Roland HOHMANN and Peter Schlosser (Lamont-Doherty Earth Observatory of Columbia University, Route 9W, Palisades, NY 10964-8000, USA, email: hohmann@ldeo.columbia.edu)

To a large extent the hydrographic structure of the upper waters of the Weddell Sea is the result of atmosphere/ice/ocean interaction. During winter, a seasonal ice cover develops over the marginally stable ocean surface layer. Brine release during sea ice formation induces convection in the Winter Mixed Layer (WML) which leads to the erosion of the pycnocline that separates the WML from the underlying Weddell Deep Water (WDW) and to subsequent entrainment of relatively warm, salty, low-oxygen and 3He-rich WDW into the WML. In summer, after the melting of the sea ice cover, warm and fresh Antarctic Surface Water (AASW) is formed by addition of sea- ice meltwater to the WML water and by solar heating. The remnant water of the WML is preserved as Winter Water (WW) and centers around 80 to 100 m depth. It is not possible to determine the rate of WDW entrainment into the WML directly from temperature and salinity, because the heat transferred into the WML by WDW entrainment is lost to the atmosphere by heat flux through the sea ice cover and leads, and the mixed layer salinity is altered by sea ice formation and melting. An alternative method is provided by the evaluation of gas balances (e.g. 3He) of the upper layers in the ice-covered regions. If we assume that the elevated 3He concentrations of the WML are chiefly the result of entrainment of 3He-rich WDW into the WML and that gas exchange is to a large extent suppressed by the sea-ice cover, we can convert the observed 3He excess into the apparent fraction of WDW contained in the WML and calculate entrainment rates and heat fluxes. Data obtained from samples collected during the Winter Weddell Sea Project (ANT V/2, 1986), the drift of Ice Station Weddell (ISW, 1992), and the Antarctic Zone Flux Experiment (ANZFLUX, 1994) provide a consistent picture of the entrainment of WDW into the WML and the oceanic heat fluxes in the central Weddell Sea during winter. The fraction of WDW in the WML derived from the 3He excess in the surface layer increases with latitude and reaches 20–30% at 68˚S…

WATER MASS ANALYSIS IN THE WESTERN EQUATORIAL PACIFIC USING ANTHOPOGENIC TRACERS

Olaf KLATT, Birgit Klein (both at Institute of Environmental Physics, Department of Tracer Oceanography, P.O. Box 330440, 28334 Bremen, Germany, Email oklatt@physik.uni-bremen.de)

During R/V Sonne cruise 113 in late 1996, in the Western Equatorial Pacific, hydrographic properties were measured as well as (anthropogenic) tracers (Chloroflourocarbons (including CCl4), Tritium, Helium). The goal of the tracer analysis is to further our knowledge about intermediate and deep waters in this area of investigation. The anthropogenic origin of CFCs and tritium makes them useful tools to investigate water mass formation and spreading. Making use of the different input-function of the above mentioned tracer one can distinguish temporal and spatial differences in the spreading of water masses. Whereas CFCs allow a temporal differentiation, tritium measurements allow a spatial distinction of the formation areas. Helium marked the water masses at the bottom of the ocean due to the geothermal activity of the East Pacific Rise, hence it is qualified for the deduction of spreading of deep water. We found elevated CCl4 concentrations at the bottom north of the Caroline Seamounts. The presence of higher CCl4 concentrations at the bottom is interpreted as a signature of the spreading of Lower Circumpolar Deep Water (LCDW) in a western boundary current. It has been postulated that a deep boundary current should exist north of the Caroline Seamounts in which a faster advection of LCDW could be expected. The tracer measurements indicate the boundary current must include a component of LCDW which is younger than 80 years.The different behaviour of CFC and tritium leads to a large dynamical range with respect to the ratio of CFC-11 and tritium. By means of this ratio we are able to separate intermediate water masses of North Pacific origin from those of South Pacific origin.

210PB BALANCE IN THE SEDIMENT AND WATER COLUMNS OF THE EAST SEA

Deok-Soo Moon (Chungnam National University, Dept. of Oceanography, Taejon, Korea, 305-764; E-mail: s_dsm@hanbat.chungnam.ac.kr) and Kee-Hyun Kim (Chungnam National University, Dept. of Oceanography, Taejon, Korea, 305-764; E-mail: khkim@hanbat.chungnam.ac.kr)

The balance of radioactive lead in the East Sea was constructed by comparing the deficiency of 210Pb in given water column (its supply from the atmosphere and in situ decay of 226Ra) with inventories of excess 210Pb in underlying sediments. The scavenging effectiveness defined as the ratio of 210Pb deficiency in water column to total supply into sediment column, was estimated to be 82-98 % in regions as the shelf of Korea Strait and upper slope of Ulleung Basin, and less than 82 % in the central Ulleung Basin. These high scavenging effectiveness in coastal regions indicates that 210Pb adsorbed onto sinking particles is actively removed from water column by scavenging. A estimation of the relative importance of vertical and lateral processes in 210Pb scavenging is derived from the ratio of sediment 210Pbex inventories to the deficiency of 210Pb in the overlying water column. The 210Pbex fluxes in coastal sediment were deposited in the range of 116-170 %, compared to the values estimated from 210Pb deficiency relative to 226Ra profiles with the atmospheric flux. This is interpreted as evidence that the sea floor of these regions are supplied much fine sediment in the past 100 years compared to other regions. The increased 210Pb deliveries to these areas located in outflow of the Nakdong river is a consequence of sediment focusing in the last century, rather than surface productivity. In contrast, sediments in the central Ulleung Basin were accounted for only 35 - 70 % of the 210Pb scavenged from the overlying water column, and the remainer were transported to sinks outside the area. The data coverage is insufficient to permit a quantitative mass balance to be constructed, but cores taken in areas of frequent bottom disturbances and underlying the relatively high productivity waters have surpluses of 210Pbex.

FRESHWATER BALANCE OF THE LABRADOR SEA

Samar P. Khatiwala, Peter Schlosser, Richard G. Fairbanks, and Richard Mortlock
Lamont-Doherty Earth Observatory of Columbia University, Palisades NY 10964, USA

Oxygen isotope (H2O18/H2O16)/salinity data are used to identify freshwater sources to the Labrador Sea. The dominant freshwater source for the low-salinity Labrador and West Greenland Currents is runoff into the Arctic Ocean. It is estimated that 2-3.5 m of freshwater is extracted from the water column on the Labrador Shelf to form sea ice, a process which significantly modifies the isotope-salinity characteristics of waters on the Labrador Shelf, as well as further downstream on the Scotian Shelf, Gulf of Maine, and Middle Atlantic Bight. In

the interior Labrador Sea, low-salinity water originating in the Arctic is diffusively mixed in from the boundaries and is of primary importance in freshening the upper 200m. Sea ice meltwater is added to the surface ocean by local melting of sea ice, and its influence is restricted to the upper 10-15m. We also examine the impact of interannual variations in sea ice formation on (a) the strength and T/S properties of the Labrador Current, and (b) exchange rates between the Shelf and open ocean. These results have important implications for convection in the Labrador Sea.

TRANSPORT OF ICELAND SCOTLAND OVERFLOW WATER FROM THE ICELAND BASIN TO THE WESTEUROPEAN BASIN

Uli FLEISCHMANN, Reinhold Bayer, Alfred Putzka

Increased values of freon (CFC-11) and tritium at the western flank of the Mid Atlantic Ridge at 48˚ N (WHP A2 section) hint to newly ventilated Iceland Scotland Overflow Water (ISOW). This water has passed the Gibbs Fracture Zone (52° N) and flows topographically leaded towards the south along the Mid Atlantic Ridge. By comparison of the tracer concentrations in the eastern and western part of the eastern basin a surplus of tracers is determined. This surplus is used to calculate a CFC-11/tritium ratio age for the ISOW, which is compared with the CFC-11/tritium ratio age of the ISOW on the section WHP A1 (58° N) distance of the two sections, the area covered by the measurements with a tracer surplus on the WHP A2 section and the fraction of ISOW resulting from the ratio dating on A2 result in a lower limit for the transport of newly ventilated ISOW past the Gibbs Fracture Zone of (1.08±0.20) Sv.

ASSIMILATING A GLOBAL OCEAN OXYGEN-18 ISOTOPE DATA SET INT0 AN OCEAN GENERAL CIRCULATION MODEL

Martin WADLEY and Grant Bigg (both at School of Environmental Sciences, University of East Anglia, Norwich, UK, email: m.wadley@uea.ac.uk) Eelco Rohling (Southampton Oceanography Centre, Southampton, UK)

A global ocean oxygen-18 isotope data set (Bigg and Rohling, 1999) has provided a new method of validating ocean general circulation models (OGCMs). An OGCM is forced at the surface to the observed oxygen-18 isotope distribution, and the resulting modelled sub-surface distribution compared with observations. In regions of agreement between the modelled and observed values the OGCM provides a valuable tool for interpolating between sparse observations. However, in regions of disagreement between the modelled and observed oxygen-18 distributions, the use of this extra passive oceanic tracer provides a useful tool for understanding the weaknesses of the OGCM, and evaluating improvements.

A RESISTANCE METHOD OF TRACER DATA ANALYSIS.

Mikhail Vladimirovich ANISIMOV, P.P Shirshov Institute of Oceanology, Nakhimovskiy pr.,36, Moscow 117851, Russia

A one-dimension task of radioactive tracer transfer is considered. The purpose is to find a space distribution of transfer coefficient, when discrete observatons of concentration are available. The base is using of a "resistance" value, which is bound with transfer coefficient like an electrical resistance with conductivity. The method seems to be simple and flexible and applied to RN-222 data in the ocean.

STRUCTURE AND VARIABILITY OF THE THERMOHALINE FIELDS AND THE CHARACTERISTICS OF THE CURRENTS IN THE ARGENTINE ISLANDS (THE WESTERN SHELF OF THE ANTARCTIC PENINSULA) IN MARCH 1998

Juriy ARTAMONOV, Pavel Lomakin, Irina Orlova, Juriy Popov, Vladimir Ukrainsky (all at Marine Hydrophysical Inst.,2 Kapitanskay str., Sevastopol, 335000, Crimea, Ukraine;
email:ocean@mhi2. sebastopol.ua. Tel: 380 (0692)522236, Fax: 380 (0692) 444253).

The thermohaline structure and the characteristics of the currents in the region of the Argentine Island shelf on the base of CTD- and current observations during the Second Ukraine Antarctic Expedition (March 1998) are analyzed. It is shown that the vertical thermohaline structure had 2-layer stratification, which is typical for the Antarctic shelf water in the autumn season. Tidal activity is the essential factor induced variability in the thermohaline fields. Part connected with this phenomenon in the summary dispersion of the temperature and salinity on the synoptic temporal scale is estimated as 50 – 70%. Tidal currents are produced by the semi-diurnal and the diurnal tidal waves. Semi-tidal waves spread from NNW to SSE, diurnal waves – from WNW to ESE. Tidal and remainder currents were very week. Theirs speeds were not more then 2-4 sm/s. Reverse and elliptic tidal currents were fixed.

FLOW THROUGH BATHYMETRIC CHANNELS AT THE MOUTHS OF ESTUARIES

R. P. Mied, R. A. Handler, and T. Evans, Naval Research Laboratory Remote Sensing Division Washington, D.C.20375

In-situ observation and remote sensing imagery indicate the presence of velocity convergences located over bathymetric channels in the mouths of tidal estuaries. In the Chesapeake Bay for example, there are three such features which extend partially or completely through the mouth of the Bay. As such, they are riven by strong tidal forcing, and convergent features are formed over them. In this talk, we present numerical simulations performed to investigate these velocity structures in an estuary with a channel in an otherwise flat bottom.
The equations of motion are solved using a fully spectral code in the vertical plane (x-z) on a rotating earth. No along-channel flow variations (in the y direction) are permitted The bottom bathymetry is generated by using a unique virtual surface approach (Goldstein et al., J. Comp. Phys.,105, 1993) in which the no-slip bottom is generated using feedback forcing. A Gaussian-shaped channel is employed to simulate typical bathymetry observed in estuarine regions. In the along-channel direction, a constant pressure gradient is imposed and the flow is integrated until a steady state results.
The simulations are performed at high Rossby number (of order unity) based on the width of the groove and a typical surface velocity. Simulations show the development of a localized surface jet co-located with a bottom feature. This bottom feature takes the form of a recirculation cell, and results from the coupling of the along-channel flow with the motion in the vertical plane. The associated across-channel surface flow in the vicinity of the jet exhibits convergent and divergent regions, which correlate reasonably well with features observed in radar imagery. Their position and strength are seen to vary with the along-channel Reynolds number, Ekman layer thickness, and aspect ratio of the channel.

THE TRANSFER OF 99TC FROM SELLAFIELD TO THE ARCTIC

Peter Kershaw (a), Lars Foyn (b), Gordon Christensen (c), Kins Leonard (a), Hilde Elise Heldal (b), Per Varskog (c).; Centre for Enviromental, Fisheries and Aquaculture Science (CEFAS), Pakefield Road, Lowestoft, Suffolk, NR33 0HT, UK, (b) The Institute of Marine Research, Nordnengaten 50, P.O. Box 1870, N-5024 Bergen, Norway, (c) Institute for Energy Technology, P.O. Box 25, Kjeller, Norway

Substantial increases in the discharge of 99Tc occurred in the mid-1990's, from the Sellafield nuclear fuel reprocessing plant in the UK, against the overall trend of most other radionuclides. 99Tc is long-lived radionuclide which normally is considered to behave conservatively in seawater and is readily taken up by by the brown seaweed Fucus sp. The "pulsed" release of 99Tc in 1994-96 has provided a new opportunity to study transport pathways and transit times from the Irish Sea to other parts of the NE Atlantic and Arctic Oceans. The distribution of 99Tc has been mapped from a series of RV cruises, extending from the Irish Sea to Fram Strait and the Barents Sea. A comparison is made between the response of seawater concentrations and those in Fucus vesiculosus (used as a bio-accumulator) to variations in the release rates. Transit times within UK waters and the North Sea from the 99Tc data were significantly shorter than rates reported previously using other radiotracers. The possible reasons for this are discussed, together with the scope for continuing to follow this tracer as it enters the Eurasian Basin.

ROLES OF BIOGEOCHEMICAL PRODUCTIVITY IN THE CARBON CYCLE USING A SIMPLE GLOBAL OCEAN MODEL

Masahiko FUJII, Motoyoshi Ikeda and Yasuhiro Yamanaka (Graduate School of Enrironmental Earth Science, Hokkaido University, Sapporo 060-0810, Japan, email: fujii@ees.hokudai.ac.jp, mikeda@ees.hokudai.ac.jp and galapen@ees.hokudai.ac.jp)

A simple physical and biogeochemical ocean model is constructed. Horizontally, the global ocean is divided into four regions; i.e., the Pacific/Indian Ocean (PI), the Atlantic Ocean (AT), the Southern Ocean (SO) and the Greenland/Iceland/Norwegian Sea (GIN). The PI and AT are vertically continuous, while the SO and GIN are divided into two, the surface layers (50m thick) and the lower layers. This model is used to estimate the oceanic carbon cycle contributed by physical and biogeochemical processes. The physical parameters are chosen to represent the air-sea CO2 flux, the thermohaline circulation, and vertical and horizontal diffusions. The biological productivity is controlled only by phosphate in the surface layers. The geochemical process is parametrized by a calcite productivity in the surface layers. The products are remineralized in the lower layers. The observed distributions of radiocarbon, phosphate and alkalinity are used as tracers to optimize the parameters. The total carbonate concentration is then calculated, and the vertical carbon flux is quantitatively estimated. A major feature is a clear contrast between the PI and AT; i.e., the total carbonate is richer in the PI than the AT, along with the other biogeochemical components. As the anthropogenic sources increase the CO2 concentration in the atmosphere, the effects appear significantly in the AT, while a signal is extremely weak in the PI.

BIOGEOCHEMICAL VARIABILITY AND THE NORTH ATLANTIC OSCILLATION

Michael J. FOLLOWS, Stephanie Dutkiewicz, John C. Marshall (Program in Oceans, Atmospheres and Climate, Massachusetts Institute of Technology, Cambridge, MA 02139, USA); Watson W. Gregg (NASA/Goddard Space Flight Center, Maryland, USA)

Through better understanding of interannual and decadal climatic and biogeochemical variability in the observed record we seek to identify patterns and mechanisms which may be important in global climate change. Time-series observations of biogeochemical indicators in the North Atlantic ocean exhibit significant interannual and decadal variability which, in some cases, correlate with indices of regional climate such as the North Atlantic Oscillation (NAO) index. Remote observations of ocean colour indicate that interannual changes are manifested with coherent patterns on the gyre and basin scale.
We examine the hypothesis that biogeochemical variability in the surface ocean may, in part, be a response to variability in ocean circulation and mixing and thus reflect the large-scale patterns associated with the dominant atmosphere-ocean climate regimes of the region. We use a North Atlantic biogeochemical model driven by twelve-hourly, observed, surface wind-stress and heat fluxes, examining the variability of export and primary production and surface gas exchanges on interannual timescales. We find basin wide patterns in the biogeochemical variations of the model. These patterns resemble those in the physical forcing associated with the North Atlantic Oscillation.
In a model with highly idealised biological cycle, variability in surface heat fluxes and associated convective mixing result in significant variability of nutrient supply and export production on year to year time-scales even in the subtropical gyre where the longer term balances are dominated by advective processes. Introducing an explicit ecosystem model in order to address remote ocean colour observations, biophysical interactions result in a more complex relationship between chlorophyll, primary production and physical forcing.

NUTRIENT SUPPLY TO THE UPPER NORTH ATLANTIC OCEAN: A MODEL STUDY

A. OSCHLIES, W. Koeve (Institut fuer Meereskunde,D-24105 Kiel,
email: aoschlies@ifm.uni-kiel.de)V. Garcon (UMR5566/LEGOS, F-31401 Toulouse,
email: garcon@pontos.cst.cnes.fr)

A high-resolution coupled biological-physical model of the North Atlantic is used to investigate regional patterns of nitrogen supply and primary production. For the subtropical gyre, episodic nutrient pulses by eddy-induced upwelling have been suggested to explain why geochemical estimates of nitrate supply to the euphotic zone are an order of magnitude higher than biological and physical ones. This is investigated by varying the level of activity in the model by assimilating altimeter data and by changing the parametrization of horizontal friction. It is found that eddies contribute about one third of the nutrient input into the subtropical Atlantic. The associated mechanisms of the eddy-induced supply are discussed in relation to that of mean advection and different representations of subgrid-scale diapycnal mixing. At higher latitudes, the main pathway of nutrient supply is via deep winter mixing which, after rapid shallowing of the mixed layer, leads to a spring bloom. When forced with daily atmospheric fluxes from the ECMWF reanalysis, the model shows both typical spring blooms characterized by a rapid development of a shallow phytoplankton bloom which is terminated by depletion of nutrients, as well as transient blooms characterized by intermittent chlorophyll maxima separated by phases of a deepening mixed layer. Both simulated scenarios agree well with observations taken at the JGOFS NABE (47N, 20W) site in 1989 and 1992, respectively. The interannual differences in spring bloom development, corresponding nitrate supply, and primary and export production are shown to be closely related to surface heat flux patterns.

P08/E/07-A2 1050

THE VARIABILITY OF EXPORT PRODUCTION OVER THE NORTH ATLANTIC

ALISON J. McLAREN, Richard G. Williams (Oceanography Labs., University of Liverpool, Liverpool. L69 3BX. U.K.); Michael J. Follows (Program in Oceans, Atmospheres and Climate, MIT, Cambridge, MA 02139, USA.)

The dominant physical processes that supply nutrients to the pelagic ecosystems are advection by the circulation and convective mixing. The variability of these physical processes is predicted to cause changes in export production. Follows and Marshall (1999) show that changes in convection linked to the North Atlantic Oscillation (NAO) affect the interannual variability of export production. However, it is unclear which physical process will cause the longer term variability in export production.
An idealised ocean basin model is used to investigate the variability of export production during a five year period with the same NAO phase. The model results suggest that the initial change in the export production in a subtropical gyre is controlled by the anomalous convective supply of nutrients. However, after several years, the anomalous export production is caused by the advective supply of nutrients. During NAO conditions, the changes in advection and convection reinforce each other to enhance or reduce export production over the subpolar gyre. In contrast, the advective and convective changes oppose each other in the subtropical gyre. A method is developed to quantify the variability of the horizontal Ekman advection of nutrients using available data for the North Atlantic; this Ekman supply is particularly important along the flanks of the subtropical gyre (Williams and Follows, 1998). The Ekman nitrate supply into the subtropical gyre is found to follow the NAO cycle and vary annually by up to 40% from the annual mean during 1945-93. This variable Ekman supply is expected to cause changes in the export production when the NAO remains in the same phase for several years.

P08/W/09-A2 1110

REDFIELD RATIOS IN THE DEEP EASTERN NORTH ATLANTICZ

Uli FLEISCHMANN, Alfred Putzka and Alexander Sy

The Redfield ratios for the deep eastern North Atlantic are a difficult subject because of the complex mixture of water masses. This mixture is analysed with a quantitative water mass analysis for a collection of hydrographic data from the deep eastern North Atlantic between 10° N and 60° N. A multiparameter approach was used for this based on the parameters potential temperature, salinity, oxygen and nitrate. A consumption quantity which accounts for oxygen consumption (deltaO) and nitrate (deltaN) remineralisation is included in the analysis. The ratio of deltaO:deltaN in the consumption quantity is varied in the range from 8:14. A deltaO:deltaN ratio of 9 is found to be the best estimate from considerations of the phosphate values, their remineralisation and the quality of the representation of the mixture. The resulting range of the Redfield ratios for the deep eastern North Atlantic is 1:(14.9-15.8):(132-150) for deltaP:deltaN:deltaO with an optimum at 1:15.3:137.

P08/W/02-A2 1130

AN EVALUATION OF GAS-EXCHANGE PARAMETERIZATIONS USING A GLOBAL MODEL OF THE OCEANIC N2O FLUX AND DISTRIBUTION

P. SUNTHARALINGAM (Department of Earth and Planetary Sciences, Harvard University, Cambridge, MA 02138, USA, email: pns@europa.harvard.edu); J. L. Sarmiento (Atmospheric and Oceanic Sciences Program, Princeton University, Princeton, NJ 08544, USA,
email: jls@splash.princeton.edu)

A significant source of uncertainty in deriving large-scale oceanic flux estimates directly from surface partial pressure anomalies arises from the parameterization of the gas-exchange coefficient relating the two quantities. In this study, global ocean general circulation model simulations of the marine nitrous-oxide distribution and sea-air flux are used in conjunction with observations of surface N2O partial pressures to evaluate the performance of two commonly used wind-speed dependent parameterizations, namely, Wanninkhof (1992), and Liss and Merlivat (1986).
The net global marine N2O flux of the ocean model is determined by an embedded biological source function and constrained independently by observations of excess N2O and Apparent Oxygen Utilization (AOU) at depth. The model transfer of this predetermined N2O source across the sea-air interface under different gas-exchange parameterizations gives rise to different surface distributions of the air-sea partial pressure anomaly. These are then compared to observational values to evaluate the success of each gas-exchange formulation. Results indicate that the larger averaged transfer coefficients provided by the Wanninkhof (1992) parameterization produce modeled N2O partial pressure anomalies closer to the observed levels. The sensitivity of our conclusions to the assumptions of the underlying biological and circulation models will also be discussed.

P08/W/03-A2 1150

AIR-SEA EXCHANGE COEFFICIENTS OF GASES

David WOOLF (School of Ocean and Earth Science, University of Southampton, Southampton Oceanography Centre, European Way, Southampton SO14 3ZH, UK,
email: dkw@mail.soc.soton.ac.uk)

Some recent laboratory experiments give new insights into the kinetics of air-sea gas exchange. Processes and rates of gas exchange are investigated in two sets of experiments. In the first set, gas transfer is measured at moderate wind stress, with and without artificial bubble plumes. The gas supply to the bubbles is manipulated, allowing the contribution of sub-surface bubbles (bubble-mediated transfer) and surface exchange (including that resulting from surfacing bubble plumes) to be separated. In the other experiments, gas transfer is measured at high wind stresses, but low rates of bubble entrainment (relative to the ocean).

P08/W/07-A2 1400

COUPLED PHYSICAL/BIOLOGICAL MODELLING IN THE ANTARCTIC POLAR FRONT

CH. DIETERICH; I. Hense; R. Redler (Alfred Wegener Institute, 27568 Bremerhaven, Germany); C. Böning (Institute für Meereskunde, 24105 Kiel, Germany)

During JGOFS cruises in the Atlantic sector of the Southern Ocean relatively high chlorophyll concentrations were observed along the Antarctic Polar Front. It has been hypothesized that small-scale variability plays a major role in setting up the prerequisites for phytoplankton growth. Enhanced vertical transports of nutrients and trace elements along the front, mesoscale upwelling and shallow mixed layers promote phytoplankton blooms.
To investigate the influence of mesoscale dynamics on the regional ecosystem we use a coupled physical/biological model. The physical model is a primitive equation model encompassing the South Atlantic Frontal System from about 60S to 40S, run in both eddy-resolving and non eddy-resolving resolution. It has been developed in the framework of FLAME (Family of Linked Atlantic Model Experiments). The physical model is coupled with an ecosystem model, with special emphasis on the regional phytoplankton community. In sensitivity studies with the physical model we examine the impact of mesoscale variability on phytoplankton dynamics.

P08/W/08-A2 1420

A COUPLED PHYSICAL-CHEMICAL-BIOLOGICAL MODEL OF THE INDIAN OCEAN

P.S.SWATHI and M.K.Sharada (CSIR Centre for Mathematical Modelling and Computer Simulation NAL Belur Campus, Bangalore 560 037, India, e-mail: swathi@cmmacs.ernet.in, sharada@cmmacs.ernet.in); K.S.Yajnik (Regal Manor, 2/1 Bride St., Langford Town, Bangalore 560 025, India, e-mail: ksy@letterbox.com)

A coupled physical-biological-chemical model for studying the time-variation of primary productivity and air-sea carbon-di-oxide exchange in the Indian Ocean is being developed at C-MMACS. The physical model is based on the Modular Ocean Model, Version 2 (MOM 2) and the biological model describes the non-linear dynamics of a 7-component system. The chemical model includes dynamical equation for the evolution of dissolved inorganic carbon (DIC) and total alkalinity. The interaction between the biological and chemical model is through the Redfield ratio. The CO2 content of the surface layer is obtained from the chemical equilibrium equations of Peng et. al, 1987. Transfer coefficients for air-sea exchange of CO2 are computed dynamically based on the wind speeds. The coupled model reproduces the strong upwelling blooms seen during the SW Monsoon and the weak blooms in the Northerna Arabian Sea in winter caused by convective overturning. The Bay of Bengal is strongly affected due to the low salinity in the area leading to a much smaller pCO2 concentration that the Arabian Sea. On an annual scale the entire Indian Ocean is an out-gassing region for air-sea CO2 transfer.

P08/W/01-A2 1440

TESTING THE IRON HYPOTHESIS IN SITU IN THE PACIFIC AND ANTARCTIC OCEANS

Cliff LAW and Phil Nightingale (CCMS, Plymouth Marine Laboratory, Prospect Place, West Hoe, Plymouth, Devon PL1 3DH, UK, Email: csl@ccms.ac.uk., pdn@ccms.ac.uk. A. Watson (School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, UK, Email: a.watson@uea.ac.uk. P. Boyd (Centre of Excellence for Chemical and Physical Oceanography, University of Otago, Dunedin, NZ, Email: P.Boyd@alkali.otago.ac.nz).

Iron (Fe) limitation of phytoplankton productivity in the High-Nutrient Low-Chlorophyll regions of the oceans has long been suspected. However, it is only with the in situ releases into the surface waters of the equatorial Pacific within IronEx1 and IronEx2 that this has been proved conclusively. The strong response of the phytoplankton to iron addition, with chlorophyll increasing 30-fold and a decrease in surface fCO2 of 70 atm during IronEx2, supports previous observations that iron flux may influence atmospheric CO2. However increased iron fertilisation of the Equatorial Pacific may be relatively insignificant in terms of the global ocean sink. Instead consideration of ocean circulation suggests that it is the Southern Ocean where Fe-induced increases in productivity may impact the ocean carbon sink. The first in situ release of iron into the surface waters of the Antarctic took place during the SOIREE cruise to the south of the Polar Front at 61-62S in February 1999. The response of the biota and the biogeochemistry will be reviewed, with re-assessment of the role of Fe in limiting productivity and the ocean carbon sink.

P08/E/04-A2 1500

SPATIO-TEMPORAL VARIABILITY OF PCO2 IN THE MEDITERRANEAN SEA

Miléna BEGOVIC and Claire Copin-Montégut (Laboratoire de Physique et Chimie Marines, Université Pierre et Marie Curie, Observatoire Océanologique de Villefranche-sur-Mer, 06238 Villefranche-sur-Mer Cedex, France, email: milena@obs-vlfr.fr)

Time series observations provide valuable insights into the natural seasonal variability of the oceanic carbon cycle. Monthly measurements of hydrography and biogeochemical properties have been made in the central part of the northwestern Mediterranean Sea (Ligurian Sea), in the course of the DYFAMED (France-JGOFS) operation. The annual cycle of the Ligurian Sea is defined from well-mixed conditions in winter to a progressive stratification in spring and early summer and a strong thermohaline stratification in summer and fall. So hydrological and trophic conditions encountered along the year are representative of conditions existing in large areas of the world ocean (from mesotrophy to oligotrophy). Continuous underway measurements of the partial pressure of CO2 in surface water have been made monthly since February 1998, from the Riviera coast to the DYFAMED site (56 km off Nice, 43°25' N, 7°52' E) and twice a year

to Calvi (Corsica, 42°34' N, 8°45' E).
Characteristic seasonal patterns were observed along these transects. The changes in pCO2 ranged in 1998 from ~315 µatm in winter, to ~450 µatm in summer. Winter mixing induced high variations of pCO2 in surface waters. In February and March, the coldest waters were supersaturated with respect to the atmosphere. These cold waters result from the mixing of surface water with deep water up-welled at sea surface. On the other hand, waters of any tenth degrees warmer were largely under-saturated with CO2. This under-saturation results from the biological production, which has been emphasised by up-welling of nutrient-rich waters. Surface sea waters were under-saturated until the end of May, and become supersaturated as a consequence of the summer warming. But if pCO2 values calculated at the same temperature are compared, a general trend toward a decrease in pCO2 with temperature since winter months is observed. This decrease can be explained by the biological production in surface water, which should stop when surface water becomes depleted in nutrients. When surface waters are super-satured, gas exchange of CO2 with the atmosphere is not sufficient to explain this decrease. So in fact, the biological uptake of CO2 should continue in absence of nutrients, which has been also observed during previous studies in the same region.

MODELLING THE VERTICAL BIOCHEMICAL STRUCTURE OF THE BLACK SEA: DYNAMICAL COUPLING OF THE OXIC, SUBOXIC AND ANOXIC LAYERS

Temel OGUZ (Middle East Technical University, Institute of Marine Sciences, Erdemli, Icel, Turkey, e-mail: oguz@ims.metu.edu.tr); Hugh W. Ducklow (Virginia Institute of Marine Sciences, The College of William and Mary, Gloucester Point, VA, USA, e-mail: duck@vims.edu); Paola Malanotte-Rizzoli (Massachusettes Institute of Technology, Department of Earth, Atmospheric and Planetary Sciences, Cambridge, MA, USA, e-mail: rizzoli@mit.edu); James W. Murray (University of Washington, School of Oceanography, 104 Ocean Teaching Building, Seattle, WA 98195-7940, USA, e-mail: jmurray@ocean.washington.edu)

The upper layer biogeochemical structure of the Black Sea is simulated using a one dimensional vertically-resolved coupled physical-biochemical model. The physical model involves the mixed layer dynamics endowed with Mellor-Yamada turbulence parameterization, and is coupled with the biochemical model by the specification of water column eddy diffusivity and temperature structures. Its biological component considers two phytoplankton species groups (flagellates and diatoms), three zooplankton size groups (micro-, meso- and macrozooplankton), bacterioplankton, particulate and dissolved organic materials. They are complemented by the equations for the ammonium, nitrite, nitrate as well as for the dissolved oxygen, hydrogen sulphide and additional ones for major redox reactions taking place across the suboxic-anoxic interface. The model is thus able to represent different biochemical processes interacting with each other in different parts of the water column, and allows a dynamical coupling between the euphotic zone, the oxycline/upper nitracline layer, the suboxic and the anoxic layers.

P08/E/01-A2 1600

THE POSSIBLE RELATIONSHIP BETWEEN EUTROPHICATION AND SUB-OXIC ZONE OF THE BLACK SEA

Sergey K. KONOVALOV (Marine Hydrophysical Institute, Kapitanskaya 2a, Sevastopol 335000, Crimea, Ukraine, email: sergey@alpha.mhi.iuf.net); James W. Murray (School of Oceanography, University of Washington, Box 357940, Seattle, WA 98195-7040, USA,
email: jmurray@ocean.washington.edu)

Sub-oxic zone of the Black Sea appears to be related to the nature of oxygen/sulfide interactions rather than eutrophication of this marine basin. The existing hypotheses on the nature of the sub-oxic zone cannot solve the main question about the redox imbalance of this zone. It is known that the downward diffusive flux of oxygen at the upper boundary of sub-oxic layer is 10-times larger than the upward diffusive flux of sulfide at the lower boundary. To solve the redox balance we have proposed the presence of other sinks of oxygen, beside oxidation of sulfide. We have analyzed existing data on the distributions of oxygen, sulfide, nutrients, temperature and salinity in the Black Sea from 1960 to 1995. We highlight a number of observations regarding temporal variations in the structure of sub-oxic zone and adjacent layers of water: different dynamics of the upper and lower boundary of sub-oxic zone, a correlation between the intensity of eutrophication and distribution of oxygen in the layer of the oxycline, significant correlation between apparent oxygen utilization and nitrate concentration in the middle oxycline, and a highly significant correlation between changes in distribution of nutrients. These observations suggest that about 90% of that oxygen should be consumed during oxidation of sinking particulate organic matter rather than oxidation of the upward flux of sulfide from the anoxic zone. This hypothesis highlights new links in the oxic/anoxic ecosystem of the Black Sea. It demonstrates that the entire biogeochemical structure of the Black Sea depends on the intensity of eutrophication.

COMPARATIVE RELIABILITY ASSESSMENT OF VARIOUS METHODS OF PRIMARY PRODUCTION MEASUREMENTS

GORIOUNOVA V.B, Sapozhnikov V.V, (All Russian Federal Research Institute of Fisheries and Oceanography, V.Krasnoselskaya 17, Moscow, 107140, Russia, e-mail: vera@pisarev.msk.ru)

The comparative measurements of primary production (PP) with different methods: oxygen, radionucleic and with the help of sounding device PrimProd, were made during ecosystem cruise in the Norway Sea. Preliminary analysis of data showed, that the absolute values, received with the help of oxygen methods exceed those of PrimProd by 3-4 times. However, the sounding device PrimProd was calibrated using radionucleic method, and even more significant difference was obtained while comparing the results of oxygen and radionucleic methods. Radionucleic estimation of PP value was made in small volume bottles (100 ml), that provided hypertrophied growth of microheterotrophic organisms onto the walls of the bottles and so the results become lower. The sounding device PrimProd have certain advantages: it gives the opportunity of PP measuring "in situ" not only at the day time, but at night as well; it also allows more correct computation of integral PP value in photic layer.
Received results were compared with the distribution of nutrients, dissolved oxygen and main hydrophysical parameters. Hydrophysical parameters' influence on the formation of mesoscale ecosystems with different values of PP is shown.

P08/W/05-A2 1640

EARLY DIAGENETIC CHANGES IN THE SHELF SEDIMENTS OF THE NORTH JAPAN SEA

K. ABDULLA BAVA and Ken Ikehara (Marine Geology Department, Geological Survey of Japan, 1-1-3 Higashi, Tsukuba, 305-8567 JAPAN. Phone: +81-298-543627 Fax: +81-298-543589 Email: bava@gsj.go.jp)

The exchange of dissolved substances across the sediment-water interface is an important process affecting the chemical composition of water bodies. This is particularly important for coastal marine environments, where nutrient regeneration in benthic sediments can supply a significant fraction of the nutrient requirements of primary producers in overlying water. In this investigation, sediment cores and its associated pore waters were collected from shelf region of North Japan Sea to understand the characteristics in the vertical profile of this highly productive marginal sea. Seven cores were collected using Multiple Corers and sectioned with an interval of 0.5 cm up to 10 cm and with 1 cm afterwards. Physico-chemical parameters such as Eh, pH, total C and N in the sediments and Fe, Mn, Ca, Mg, Si, Sr, Zn, NO2, NO3, PO4, and NH4 in the pore waters were measured.
A general downward decrease of Eh, NO2, NO3 and increase of pH, NH4, PO4 in their vertical pore water profile, and C and N depletion downward in the sediment column, indicate the microbial degradation of the organic matter and remineralization. In our results, significant enrichment of NO3 in interstitial waters is recorded in a thin layer of 0 to 2 and 0 to 7. 5 cm in the shallower sediments and a layer of 0 to 13 cm layer in the case of deeper sediments. The sharp decline of of NO3 values and the uniformly very low NH4 profiles at surficial levels are also noted. The consistent NH4 minimum in the upper sedimentary layer is mainly caused by the chemical removal of NH4 by oxidation to NO2 and NO3. The increase in PO4 concentration in interstitial waters with depth can be explained due to the release of PO4 during mineralization of organic matter and dissolution of phosphorus bearing solid phases in the existing reducing condition. Fe and Mn distribution in the pore waters are controlled by the redox condition of the sediment. The distribution of the other elements are influenced by mobility of the Fe and Mn and their relation to other parameters are also discussed in the paper.

THE STUDY OF RED TIDE FORECAST MODEL IN THE YANGTZE ESTUARY

Wang Zhengfang (Second Institute Oceanography, SAO 310012 Hangzhou PRC) I v haiYan Zhang qing lu yong (Second Institute Oceanography, SAO 310012 Hangzhou P.R.CHINA)

The study about red tide short time forecast model was carried on the Yangtze river estuary on May to August 1995 to May to September 1997. In the seasons of easy discoverable red tide, some of chemical and physical times, such as: water depth, water temperature, transparent degree, water colour, specific gravity, dissolved oxygen, chemical oxygen consumption, nutrients (N,P) were determined in the studied sea area.
The result was indicated that suit to short time forecast about red tide in the Yangtze river estuary. The model is Z = SAL-3. 96DO-26. 97pH-5.42PO4-P.

OBSERVATION-BASED VERTICAL TURBULENT FLUXES OF MOMENTUM AND MASS IN A PARTIALLY MIXED ESTUARY

Hartmut PETERS (Rosenstiel School of Marine and Atmospheric Science, University of Miami, USA. email: hpeters@rsmas.miami.edu); Helmut Baumert (Hydromod Scientific Consultants, Wedel, Germany. email: baumert@hydromod.de)

Profiling microstructure measurements were made during 5 cruises in the Hudson River Estuary off Manhattan in 1994/95. Some 6000 drops taken in a relatively straight and uniform section of the estuary with typically 15 m depth cover fortnightly and tidal cycles in stratified and sheared flow of 1-2 m/s. Observed mixing characteristics show pronounced tidal and fortnightly variability, mixing across the estuarine halocline being strongest during ebbs on spring tide. The vertical (diapycnal) fluxes of momentum and mass can be estimated from the measured viscous dissipation rate, shear and stratification using a simple model for the flux Richardson number as function of the gradient Richardson number. The estimated turbulent momentum flux, or stress, and mass flux as well as the dissipation rate are related to the estuarine momentum, mass and energy balances.

P09/W/03-A1 0930

CIRCULATION AND MIXING IN A HYPERSALINE LAGOON

C. D. Winant, Scripps Institute of Oceanography, Centre for Coastal Studies-0209, 9500 Gilman Drive, La Jolla, CA 92093-0209. USA. E-mail: cdw@coast.ucsd.edu

Laguna San Ignacio is a coastal lagoon located along the Pacific coast of the Baja California peninsula in Mexico. Evaporation exceeds precipitation all year, and the total evaporation exceeds 2 m a year. T he concentration of salt in the lagoon has been found to remain steady, therefore a net flux of salt into the lagoon must be returned to the open ocean through circulation and mixing processes. Observations made over a year-long period reveal three mechanisms responsible for this return of salt. Near the ocean, tidal pumping dominates the mixing processes. Midway between the ocean and the closed end of the lagoon, a buoyancy-driven two-layer flow carries relatively fresh ocean water into the lagoon at the surface, while salty, denser water returns to the ocean near the bottom. Near the closed end of the lagoon, where depths are shallow and wind forcing is large, a horizontally variable circulation develops which carries relatively fresh water towards the closed end over the deeper channels near the central axis, and saltier water towards the ocean over the shallower areas near the sides of the lagoon.

P09/W/07-A1 0950

TIDAL CIRCULATION AT THE QUEQUEN GRANDE ESTUARY (ARGENTINA) MOUTH

Diana G. CUADRADO and Gerardo M.E. Perillo (both at Instituto Argentino de Oceanografía, CC 107, 8000 Bahía Blanca,Argentina, and Departamento de Geología, Universidad Nacional del Sur, San Juan 670, 8000 Bahía Blanca, Argentina, e-mail: cuadrado@criba.edu.ar, perillo@criba.edu.ar)

The Quequén Grande Estuary is located at SW of the Buenos Aires Province, Argentina. The Quequén Harbour, one of the most important harbours in Argentina, is placed at the mouth of the estuary. To accommodate the large cargo vessels that operate there, the estuary has been dredged to 12-m depth from the mouth to a distance of 2-km headward. Natural depths in the river upstream of this limit are 2-4 m. Therefore, a major step separates both reaches. We hypothesise that this abrupt change in depth introduce major disturbances in the tidal circulation within the harbour. Profiles of current velocity and direction as well as salinity and temperature were made for over a tidal cycle at three stations. One current station was placed over the step (riverside) another was placed immediately after the step (harbour side), whereas the third one was located at the harbour mouth. From the analysis of the data, we found a three layer circulation system marked by a strong stratification of the water column. T here is an upper layer (1-1.5 m thick) with almost freshwater during all the tidal cycle and with water flowing seaward. A second layer is 2-3 m thick and has salinities that vary with tidal stage and with reversing current. Whereas, on the two stations located within the harbour, there is a lower layer 6-8 m thick in which the salinity is quite homogeneous on the order of 35 and practically no currents. A situation that it is not observed in the river station. A possible explanation for the phenomena is the influence of the in the tidal wave propagation within the estuary that may induce a standing wave by reflection against the step. .

FLOW THROUGH BATHYMETRIC CHANNELS AT THE MOUTHS OF ESTUARIES

R. P. MIED, R. A. Handler, and T. Evans, Naval Research Laboratory Remote Sensing Division Washington, D.C.20375

In-situ observation and remote sensing imagery indicate the presence of velocity convergences located over bathymetric channels in the mouths of tidal estuaries. In the Chesapeake Bay for example, there are three such features, which extend partially or completely through the mouth of the Bay. As such, strong tidal forcing drives them, and convergent features are formed over them. In this talk, we present numerical simulations performed to investigate these velocity structures in an estuary with a channel in an otherwise flat bottom.
The equations of motion are solved using a fully spectral code in the vertical plane (x-z) on a rotating earth. No along-channel flow variations (in the y direction) are permitted. Using a unique virtual surface approach (Goldstein et al., J. Comp Phys., 105, 1993 generates the bottom bathymetry.) in which the no-slip bottom is generated using feedback forcing. A Gaussian-shaped channel is employed to simulate typical bathymetry observed in estuarine regions. In the along-channel direction, a constant pressure gradient is imposed and the flow is integrated until steady state results.
The simulations are performed at high Rossby number (of order unity) based on the width of the groove and a typical surface velocity. Simulations show the development of a localised surface jet co-located with a bottom feature. This bottom feature takes the form of a recirculation cell, and results from the coupling of the along-channel flow with the motion in the vertical plane. The associated across-channel surface flow in the vicinity of the jet exhibits convergent and divergent regions, which correlate reasonably well with features observed in radar imagery. Their position and strength are seen to vary with the along-channel Reynolds number, Ekman layer thickness, and aspect ratio of the channel.

P09/E/04-A1 1050

STUDIES ON ESTUARINE MIXING ZONES AND CIRCULATION ON CONDUCT OF DESILTING ACTIVITIES

K.RASHEED and A.N. Balchand (Department of Physical Oceanography, Cochin University of Science and Technology, Fine Arts Avenue, Cochin 682 016,INDIA, email: oceans@md3.vsnl.net.in)

In tropical regions, large volume of freshwater and heavy loads of suspended sediments ultimately reach the coastal seas through narrow tidal inlets backed by extensive water bodies where complex estuarine processes occur. Sedimentation is one of the conundrums facing most of such locations and in cases of harbours added significant is attributed. In order to counteract sedimentation, planners and policy makers usually adopt dredging measures of varied degree and applications. Dredging operations in the mixing zone have proven effects to alter the circulation pattern, tidal flushing action, influence the bed load movement and distribution of suspended solids. As a case study, the features at Cochin estuary, the second largest port along the southwest coast of India is reviewed. This study brings out the various processes in the context of desilting at this estuarine harbour and attempts to explain particularly the changes in circulation pattern, salinity and suspended solids in the mixing zone under changing hydraulic conditions. The positive and negative aspect of dredging as well as the impact assessment for the region is comprehensively presented.

P09/E/06-A1 1110

RESIDUAL CIRCULATION IN AN ELONGATED INVERSE ESTUARINE SYSTEM: THE GULF OF SUEZ, EGYPT

MOHAMMED EL-SABH (email: mohammed_el-sabh@uqar.uquebec.ca), M.A. Rady (both Département d'océanographie, Université du Québec à Rimouski, Rimouski, Québec, G5L 3A1, Canada, T.S. Murty (Baird & Associates, 1145 Hunt Club Road, Suite 1, Ottawa, Ontario, K1V 0Y3, Canada, and J.O. Backhaus (Institut für Meereskunde der Universität Hamburg, Hamburg 13, Germany

A three-dimensional non-linear hydrodynamical numerical model has been used to study the water movement in the shallow Gulf of Suez at the northern end of the Red Sea. The computational grid used to schematize the Gulf has a horizontal resolution of 3x3 km and levels at 5, 15, 30 and 60m in the vertical. The simulations were carried out separately for tidal forcing and wind forcing. Further, in each case, stratified conditions were considered to represent the state of the Gulf during late summer periods. In the case of wind-induced circulations, a uniform wind speed of 5 m/s was applied over the Gulf, blowing from NW, N and NE directions. The results suggest that the dynamics of the Gulf of Suez are governed by the interaction of wind and density forcing. Only occasionally, for instance in the vicinity of headlands and islands, tidal residuals are of similar importance. For the overall residual currents, it was found that the typical (quasi) baroclinic two-layered inverse estuarine circulation observed in the Gulf of Suez can be produced under the combined action of M2-tide and winds blowing steadily from the north-eastern direction. Northwestern and northern winds produced the reverse patter.

PHYSICAL PROCESSES IN INVERSE ESTUARINE SYSTEMS

MOHAMMED EL-SABH (Département d'océanographie, Université du Québec à Rimouski, Québec, G5L 3A1, Canada, email: mohammed_el-sabh@uqar.uquebec.ca), Than H. Aung (National Tidal Facility, The Flinders University of Australia, Adelaide, S.A.-500, Australia, T.S. Murty (W. Baird & Associates Coastal Engineers Ltd, 1145 Hunt Club Road, Suite 1, Ottawa, Ontario, K1V 0Y3, Canada

An inverse or negative estuary is a semi-enclosed sea or embayment within which loss of fresh water is more than the gain by runoff and precipitation combined. The tide-averaged internal circulation comprises as outflow of saline water near the bottom and an inflow of less saline water near the surface. Inverse estuaries are not common features of the worl's coastal environment and one can distinguish two subsets according to geographical location. The first subset includes those estuaries in which fresh water removal is the result of an excess of evaporation over precipitation. These mostly occur in low latitudes of both hemispheres and are associated with arid conditions (e.g. the Red Sea, the Mediterranean, the Arabian Gulf, the Adriatic and the South Australia gulfs). The second subset covers those estuarine systems in which fresh water removal is achieved by freezing and the production of sea ice, which involves rejection of salt from the ice crystal lattice and hence increases the salinity of the underlying fluid. This type is therefore confined to high latitudes and pricipally the polar regions (e.g. the Weddell Sea, the Ross Sea and the Beaufort Sea). Although there have been many observational and numerical studies of the dynamics of classical positive estuaries since Pritchard's pioneering work in the early 1950's, inverse estuaries have received relatively little attention. This paper reviews available literature relating to physical processes in several inverse estuarine systems and provides a framework for better understanding their characteristics and dynamics, hence providing another perspective on estuarine processes in general.

P09/P/02-A1 1150

ESTUARINE PROCESSES AND GEOMORPHOLOGY, KARNATAKA COAST, INDIA

K S JAYAPPA (Marine Geology Faculty, Mangalore University, Mangalagangotri-574199, Karnataka, India, email: jayappa@mnglr.ernet.in).

Estuarine siltation especially during SW monsoon is a common processes of southern Karnataka coast. The two main sources of sediment input are river discharge and littoral drift. Because of continuous accumulation of sediment, the draft required for navigation is reduced and capsizing of fishing boats and loss of lives has become a frequent phenomenon. To achieve minimum depth for navigation, the channels need to be dredged regularly. To avoid littoral drift entering the estuaries, construction of breakwaters is necessitated.
Erosion of beaches close to river mouths is more complex than that of open beaches. It is more complex due to the presence of forces like tidal and fluvial currents in addition to storm waves, longshore currents and influence of man–made structures. Most of the marshy and swampy zones bordering the estuaries are getting silted. Mangroves covering tidal creeks and estuarine borders act as land builders, natural buffers and give protection to the coastline against stormy winds and floods.
Migration of estuaries and confluence of two or three of them before debauching into the sea and occurrence of various types of spits are the peculiarities of this coast. Spits indicate secreting tendency of beaches. Migrations of estuaries are mainly due to longshore drift while evolution of spits are due to longshore and river drifts. The net drift has been inferred to be southerly on the basis of accretion on updrift and erosion on downdrift directions of barriers, shifting of estuarine mouths, heavy mineral distribution, length of drift sectors and longshore sediment transport studies.

CURRENT OBSERVATIONS OFFSHORE BAHIA BLANCA ESTUARY, ARGENTINA

M. Cintia Piccolo and Gerardo M. E. Perillo (both at Instituto Argentino de Oceanografía, CC 107, 8000 Bahía Blanca, Argentina and Universidad Nacional del Sur, email: pIccolo@criba.edu.ar)

Continuous current measurements at two stations offshore Bahía Blanca Estuary (Argentina) in late spring, 1993 were employed to analyse the magnitude and relative importance of tidal and wind driven motion in the area. Hourly wind and tides were obtained from an oceanographic tower located at the mouth of the estuary and from three coastal navigation lights that cover all the coast of the study region.
Subtracting the tidal components from the original records revealed non-tidal flow. Instantaneous motion is characterised by semidiurnal tidal currents of 5-56 cm s-1amplitudes. Mean velocities at both stations (located at both sides of the estuarine mouth) were 22.6 and 22.1 cm s-1, respectively. Winds were strong practically during all the measurement period being always higher than 18-m s-1 from the SE. Tidal and higher frequencies motions were smaller than the instantaneous and well correlated with the prevailing winds.

P09/W/04-A1 1440

EFFECT OF THE EARTH FS ROTATION ON THE CIRCULATION IN ROFIS

AKIHIDE KASAI (Graduate School of Agriculture, Kyoto University, 606-8502, Japan, email: kasai@kais.kyoto-u.ac.jp) Edward Hill (School of Ocean Sciences, University of Wales, Bangor, LL59 5EY, U.K.) Tateki Fujiwara (Graduate School of Agriculture, Kyoto University, 606-8502, Japan) John Simpson (School of Ocean Sciences, University of Wales, Bangor, LL59 5EY, U.K.)

Recent surveys in various channel-type ROFIs (regions of freshwater influence) have shown considerably different flow patterns in each. A simple model including viscous effects and the Earth fs rotation is proposed to explain these differences and to examine the along-channel flow pattern. Model results show that the flow pattern is strongly dependent on the Ekman number. With a large Ekman number, the system is governed by gravitational circulation and thus the along-channel density gradient is important. However, the contribution by the baroclinic component becomes large when the Ekman number is small. Density structure and residual currents were observed on the two sections in the Kii Channel, Japan. Since the Ekman number is O(10^-2) in the channel and the current is highly dependent on the across-channel density structure, the flow pattern was different from those observed in many classical drowned river valley estuaries. The along channel flow in the Kii Channel was successfully reproduced by the model based on the observed density field. The model can be applied to the other ROFIs and satisfactorily explained their flow patterns. In Delaware Bay or Chesapeake Bay, contrary to the Kii Channel, shallow depth makes large Ekman numbers (~1) and the barotropic flow penetrates in the whole water.

P09/W/10-A1 1500

OBSERVATIONS OF FRONTOGENESIS IN DIFFERENT ESTUARINE SYSTEMS

Arnold Valle-Levinson, Center for Coastal Physical Oceanography, old Dominion University, Crittenton Hall, 768 52nd Street, Norfolk, Virginia 23529 USA, email: arnoldo@ccpo.odu.edu

Underway current velocity profiles obtained in two different estuaries (the James River and the lower Chesapeake Bay) and one coastal lagoon (Yavaros Bay in Mexico) are used to depict the appearance of surface lateral flow convergences during both flood and ebb stages of the tidal cycle. Lateral surface flow convergences appear over the edges of the channels and are produced by the phase lag of the flow in the channel relative to the shoals. In the three systems studied, flood convergences consistently develop on the right edge of the channel (looking into the estuary) in the late tidal stages. Ebb convergences appear over the left edge of the channel soon after maximum currents. Most of these convergences cause fronts in the density field and flotsam lines that also appear over the edges of the channel and that last less than two hours. In the lower Chesapeake Bay, the position of the fronts is compared to concentrations of measured near-surface chlorophyll and optical backscatter (a proxy for zooplankton). This work shows that the strength of lateral convergences along the estuary is proportional to the tidal amplitude and the channel steepness. It also suggests that the convergences are produced mainly by the tidal flow interacting with the channel-shoal bathymetry, i.e., that they do not require the presence of density gradients.

P09/W/14-A1 1520

UPWELLING IN A SEMI-ENCLOSED COASTAL SEA INDUCED BY INTERMITTENT INTRUSION OF OCEANIC WATER

SHIGEHO KAKEHI (Graduate School of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan, email: kakehi@kais.kyoto-u.ac.jp) Tateki Fujiwara (Graduate School of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan, email: fujiwara@kais.kyoto-u.ac.jp) Satoshi Sato (Hydrographic Department Maritime Safety Agency, Japan, Minato-ku, Nagoya, 455-8528, Japan, email: stssato@cue.jhd.go.jp) Sugiyama Youichi (Electric Technology Research Department, Chubu Electric Power Co., Inc., Midri-ku, Nagoya, 459-8522 Japan, email: Sugiyama.Youichi@chuden.co.jp)

Estuaries are affected by not only river but also ocean. Estuarine circulation, one of the dominant flows in estuaries, is the mechanism which steadily transports and lifts nutrient-rich deep water to the euphotic zone. In contrast, oceanic water may intrude intermittently into estuaries and induce sporadic upwelling. Because of the difficulty of observing the intermittent intrusion of oceanic water, its magnitude and its effect on estuarine ecosystems remain unknown.
CTD and ADCP surveys were conducted in Ise Bay, Japan, on 29 and 30 October 1994. The data observed by mooring system in center of the bay showed that oceanic water flowed into the bay on 29 October. The water, influenced by earth's rotation, flowed in along the bottom along the eastern edge of the bay. The upwelling velocity at each 1m is estimated from volume flux by residual current at 5.7m/d on 29 October, the day on which large scale intrusion occurred. This value exceeds 10 times the upwelling velocity estimated from salt budget under the steady state assumption. This suggests that upwelling induced by intermittent intrusion is lager in magnitude than that driven by the mean estuarine circulation. It is considered that large amounts of nutrients are supplied to the upper layer by this upwelling. This indicates that the intermittent intrusion plays an important role on the primary production in estuaries.

P09/W/08-A1 1600

INTERNAL SEICHES IN THE QUEQUEN RIVER ESTUARY, ARGENTINA

Gerardo M. E. PERILLO and M. Cintia Piccolo (both at Instituto Argentino de Oceanografía, CC 107, 8000 Bahía Blanca, Argentina and Universidad Nacional del Sur, email: perillo@criba.edu.ar)

Quequén River Estuary is one of the largest of the Buenos Aires Province (Argentina) containing one of the most important grain and fisheries harbour of the country. The last 2000 m of the estuary have been dredged to 12 m to accommodate the large cargo vessels. The average river headward of the dredging border is almost 4 m, which resulted in a 8 m step between them.
Historical tidal records from the gage located at mid distance from the mouth and the step present short period (3-25 min) fluctuations superimposed over the regular tide. These fluctuations are almost permanent with and amplitude of 4-10 cm. However, there are examples of large fluctuations up to 1.5 m that have produced serious consequences to loaded vessels.
Two tide gages sampling at 1-min interval were located at the mouth and at the step (on the harbour side) for a period of 1 month. Although no major fluctuations occurred both gages have registered the same fluctuations but displaced 3-6 min being earlier at the step. CTD data gathered at 1.5 m depth for one tidal cycle presented a similar fluctuation that occurs at a strong halocline that is present almost all the time at that depth.

P09/E/07-A1 1620

LOW FREQUANCY RESPONSE OF BAIE DES CHALEURS, CANADA, TO WIND FORCING

MOHAMMED EL-SABH (Département d'océanographie, Université du Québec à Rimouski, Rimouski, Québec, G5L 3A1, Canada, email: mohammed_el-sabh@uqar.uquebec.ca) Diane Lavoie (Institut Maurice-Lamontagne, B.P. 1000, Mont-Joli, Québec, G5H 3Z4, Canada

The response of the Baie des Chaleurs (BdC), a large-scale stratified estuarine system in eastern Canada, to the passage of three storms in 1990 is discussed. Current meter, sea-level data and time-series temperature observations are analyzed and compared with output from a 3-layer numerical model. The model incorporates realistic coastal geometry and is driven by wind stress calculated from observed winds. The results show that the kintetic energy is dominated by a low frequency periods of 5-12 d, with the strongest signal at 10-12 d. This corresponds to similar variability in the synoptic wind forcing due to the rapid propagation of extratropical cyclones and the passage of pressure systems over the Gulf of St. Lawrence, including the BdC. The spectra for temperature show similar features, with the strongest signal near the density interface. The 5-12 d peak may also be related to fluctuations in the Gaspe Current, near the entrance of BdC, which are likewise correlated with wind stress at the NW of the Gulf of St. Lawrence. Further data analysis show a relationship between upwelling coastal wave propagation and alongshore wind stress in the north shore of the bay. The corresponding wave, with phase speed of 0.50 m/s, can be interpreted as a coastally trapped wave with the characteristics of a baroclinic Kelvin wave. Results from the numerical model show good agreement with observed currents in the bay during the height of the storms.

P09/W/05-A1 1640

OBSERVATIONS AND MODEL STUDY OF THE DNIEPER-BOOG ESTUARY

V. Serenko and V. Kovba (both at Main Ecological Inspection, Kiev, Ukraine) J. Greenfield (EPA, Athens, GA, USA) and J. Marlar (EPA, Athens, GA, USA, retired) R. Demchenko, V. Maderich, N. Margvelashvily, M. ZHELEZNYAK (all at Institute of Problems of Mathematical Machines and Systems, Glushkov pr., 42, Kiev, 252187, Ukraine; E-mail: mark@immsp.kiev.ua)

The Dnieper-Boog Estuary (DBE) located on the north-west coast of the Black Sea, is the sea's largest estuary. It is plagued with problems caused by the man-made alterations. The most important factor, which changed state of whole ecosystem, was construction of the Kakhovka Reservoir dam at approximately 60 km from the mouth of the Dnieper. Industrial and agricultural development are also significant factors. The results of observations and simulations of water quality using 1985-1998 data are presented. The, two- and three-dimensional real time models, consisting of linked hydrodynamic and water quality models were applied to the DBE. The submodel of water quality simulates the transport and transformation reactions of four interacting systems: phytoplankton kinetics, the phosphorus cycle, the nitrogen cycle, and the dissolved oxygen balance. The models were calibrated using historical data from 1985 and 1987. New field data collected in 1998 by the joint USA-Ukraine project were used for verification of the models. The models reproduced the behavior of the main nutrients as well as the summer hypoxia. A set of numerical experiments was carried out to predict and assess the impact of the Kakhovka Reservoir operational mode on the environmental situation in the downstream river/estuary system. The preliminary results of this study demonstrate that decisions involving complex environmental problems can be addressed with the coupled hydrodynamic and water quality models.

HYPOXIA IN THE GULF OF MEXICO: POLITICAL MANIFESTATIONS OF SCIENTIFIC AMBIGUITY

TODD M. KENNEDY and Timothy W. Lyons (Department of Geological Sciences, University of Missouri, Columbia, MO 65211, USA, Email: c694575@showme.missouri.edu)

Seasonal occurrence of hypoxia has been observed in the Gulf of Mexico since 1985. The hypoxic zone extends for up to 18,000 sq. km and encompasses up to 80% of the total water column. Hypoxia has already caused massive fish kills, significantly impacting the economy of the Gulf region and disturbing the trophically linked aquatic community. While the magnitude of hypoxia and its effects are well documented and undisputed within the scientific community, and although fertilizer usage has been identified as a contributor, there is significant scientific uncertainty in the causal relationship between upstream nutrient sources and downstream eutrophication.
Separation between cause and effect and uncertainty in the linkages between complex coupled systems is manifested in the current approaches to remediation: (1) treatment of symptoms rather than causes, (2) allocation of limited resources to address hypoxia in the context of related coastal issues [e.g., harmful algal blooms] that are politically more visible but may ultimately represent red herrings, and (3) failure to co-ordinate currently isolated efforts to address what is likely a diverse nonpoint-source pollution issue. Most intriguing about the latter is that lack of co-ordination may exacerbate hypoxia. Insular upstream efforts to reduce the flux of a specific nutrient may shift biological production downstream, facilitating accelerated oxygen consumption in the Gulf. The dilemma lies with co-ordinating the regulatory response within the time frame of the problem in an atmosphere of scientific uncertainty and disparate political and societal agendas.

INTRUSION OF OCEANIC WATER INTO ISE BAY AND ITS INFLUENCE ON HYPOXIA

TETSUYA TAKAHASHI (Graduate School of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan, email: tetsuya@kais.kyoto-u.ac.jp) Tateki Fujiwara (Graduate School of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan, email: fujiwara@kais.kyoto-u.ac.jp)

Ise Bay is a semi-enclosed sea connected with the Pacific Ocean through Irako Strait and has an area of 1700 square km and mean depth of 30 m. A large amount of fresh water(annual mean: 600 cubic m/s) flows into the head of the bay and water in the bay is strongly stratified. In contrast the water column is well mixed at the bay mouth (Irako Strait) because of strong tidal stirring. This heterogeneity of stratification leads to a horizontal density gradient and strong estuarine gravitational circulation.
Below the pycnocline in the bay, severe hypoxia occurs during the summertime every year. This hypoxic water mass is cold and isolated from the surrounding waters. The supply of oxygen to the hypoxic water mass is restricted to the intrusion of the well mixed water in Irako Strait. The mixed water intrudes into the bay along isopycnals. We define the intrusion depth as the depth where the water density equals that of the intruding mixed water. The temporal variation of the intrusion depth explains the temporal and spatial variation of hypoxia. When the mixed water intrudes into the middle layer in the bay, the hypoxia progresses below the intrusion depth, and when it intrudes into the bottom layer, the hypoxia disappears. The age of the intruded water, which is defined as elapsed time after the intrusion, is estimated from the water temperature. The age explains 80% of variance in the concentration of oxygen in the bay. This indicates that physical processes can explain the major part of the behaviour of hypoxia and that the seasonal variation indensity difference between the bay and shelf waters plays an important role in the development of hypoxia in Ise Bay.

P09/W/13-A2 0930

INFLUX OF NITROGEN AND PHOSPHORUS FROM THE OUTER OCEAN INTO EUTROPHIC ESTUARIES DRIVEN BY ESTUARINE CIRCULATION

Tateki FUJIWARA, Tetsuya Takahashi and Natsuko Uno (all at Graduate School of Agriculture, Kyoto University, Sakyo, Kyoto 606-8502, Japan, email: fujiwara@kais.kyoto-u.ac.jp, tetsuya@kais.kyoto-u.ac.jp, uno@kais.kyoto-u.ac.jp)

Nitrogen and phosphorus from human activity make estuaries eutrophic. In highly populated bay areas, such as Tokyo Bay, Ise Bay and Osaka Bay in Japan, red tide may occur throughout the year near the bay head, where large amounts of terrestrial N and P collect. Until recently it has been widely believed that the greater part of this inflow of N and P is transported to the open ocean by water exchange between the bay water and oceanic water. However, the research necessary to verify this hypothesis has not been carried out because of the difficulty of observation.
We developed a method to directly measure the flux of N and P, and applied it to surveys at various cross-sections in Osaka Bay-Kii Channel System, and obtained results contrary to the previous hypothesis. We found that N and P flow into the System from the outer ocean, and their

fluxes exceed the terrestrial N and P loads.
The inflow of these oceanic nutrients is caused by the coexistence of two factors: the estuarine circulation (inflow in the lower layer and outflow in the upper layer) and nutrient depletion in the upper layer by the photosynthesis. Both phenomena are common in many stratified estuaries. We can therefore estimate that the inflow of the oceanic nutrients is not a unique but rather common phenomena.

A MULTI AND INTERDISCIPLINARY APPROACH IN STUDY OF ESTUARINE PROCESSES IN A TROPICAL WATERBODY

A. N. BALCHAND, K. J. Ajith, K. Rasheed, M. G. Sreedevi, M.S. Madhusoodanan, J. K. Jossia, T.K. Anujee, P.R.Saritha and T.T.M. Asharaf (Department of Physical Oceanography, Cochin University of Science and Technology, Fine Arts Avenue, Cochin 682 016, India, email: oceans@md3.vsnl.net.in)

Tropical waterbodies exemplify complex biogeochemical processes coupled with extensive geomorphological variability capable of signaturing sensitive land sea boundary changes and (hydrological) impacts of any climate change. In addition, anthropogenic demands and varied uses have now left a very clear impression on the aquatic scenario with distinguishable marks of past two decades or more of activities. The estuarine system is currently subjected to a systems approach methodology to unravel the environmental features that has a bearing on the coastal seas. The steps covered include (1) periodic update on embank features (2) land use and practices in hinterland development (3) water resources and management plans (4) hydrological impact assessment (5) assessment of geomorphologic features (6) study of biogeochemical processes (7) identifying sensitive variables and (8) prospective planning and developmental measures. The scenario of the Cochin estuary on the tropical maritime boundary of southwest coast of India is drawn up as an illustrative case study to impress the complexities of these coastal environments.

ORGANIC CONTAMINANTS AND HEAVY METALS IN THE CONWY ESTUARY, NORTH WALES

Yang P Liu, JUN L ZHOU, Tim Dunn School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey LL59 5EY, UK

The Conwy Estuary is one of the largest and most westerly of the major estuaries of the North Wales coast, and drains an area of about 660 square kilometres from its source at Llyn Conwy in the mountains of Snowdonia. The estuary has rarely been studied for the presence of organic and inorganic contaminants, which may arise from the surronding farming and mining activities, and sewage discharges. The present project aims to fill in gap in our knowledge by determining the levels of heavy metals and polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), organochlorine insecticides in water, suspended particulate matter and sediments. Results show the levels of heavy metals and organic contaminants in water are seasonally dependent, with high levels in summer and relatively low levels in winter. Metal levels suggest strong influence from mining activities, while PAH levels indicate the importance of river and sewage inputs as well as atmospheric deposition. Contaminant levels in sediments exhibit homogeneous distributions suggest strong circulations of sediment population within the estuary. The ratios of individual PAHs in sediment point to the dominance of inputs by urban activities. Finally the results are incorporated into the Estuarine Contaminant Simulator (ECoS) for simulation and prediction purpose.

BIOGEOCHEMICAL LOADING VIA GROUNDWATER DISCHARGE TO ESTUARIES: BARATARIA BASIN, LOUISIANA (USA)

Jaye E. CABLE (Department of Oceanography & Coastal Sciences, Coastal Ecology Institute, Louisiana State University, Baton Rouge, Louisiana, USA 70803, email: jcable@unix1.sncc.lsu.edu) L.V. Inniss (Institute for Environmental Studies and Department of Oceanography & Coastal Sciences, Louisiana State University, Baton Rouge, Louisiana, USA 70803; email: linniss@unix1.sncc.lsu.edu) E.M. Swenson and R.E. Turner (both at Coastal Ecology Institute, Louisiana State University, Baton Rouge, Louisiana, USA 70803)

Submarine groundwater inputs to marine and fresh waters are receiving increasing attention within the United States and other countries as techniques are developed to better assess this elusive component of hydrologic budgets. Techniques that have been applied to quantify this flow include seepage meters, piezometers, and naturally occurring tracers. Several studies have demonstrated the importance of groundwater inputs to estuaries and coastal waters. In fact, these subsurface flows to estuarine surface waters can be surprisingly high. Biogeochemical budgets in estuaries often neglect groundwater inputs due to the difficulty associated with quantifying this input. The overall objective of this research is to contribute to our understanding of nutrient inputs to Barataria Basin via subsurface waters using the natural tracers, 222Rn (t1/2 = 3.83 days) and 226Ra (t1/2 = 1620 years). A geochemical mass balance of these tracers, in conjunction with standard hydrological techniques, provides an estimate of the magnitude of groundwater inputs to the water budget of this important estuarine watershed. Nutrient concentrations (N, P) measured at each station during the study provide an assessment of the nutrient loading from groundwaters to surface waters in the basin. Key questions include (1) what are the regional magnitudes and variations (temporal and spatial) of groundwater inputs to the estuary; and (2) how does temporal variability in groundwater input affect the nutrient loading to wetlands and lakes within the Barataria Basin?

P09/L/04-A2 1110

LINKING OFFSHORE IMPACTS TO MAINLAND WITHDRAWALS FROM REGIONAL AQUIFERS

Sydney T. Bacchus (Institute of Ecology, University of Georgia, Athens, Georgia, 30602-2202; e-mail: sbacchus@arches.uga.edu)

Adverse impacts to surface resources beyond the points unsustainable groundwater withdrawals from the Floridan aquifer have been documented throughout Florida. Unsustainable withdrawals from the same regional karst aquifer on the mainland of southeast Georgia have resulted in an estimated decline in the potentiometric surface of approximately 9 m on Cumberland Island. The majority of this largest, barrier island off the coast of Georgia was designated as a National. Seashore in 1972, with 3,600 ha of the federally owned tract identified as a "Wilderness Area", to "preserve the scenic, scientific, and historical values" of this natural resource. A ground reconnaissance conducted in the vicinity of the interior "Wilderness Area" wetlands on Cumberland Island, where the greatest potential for adverse impacts related to groundwater withdrawals was predicted to occur, revealed extensive environmental damage and sinkhole-like depressions.
Groundwater discharges from submarine springs and seeps are known to have decreased due to groundwater mining on the mainland, but quantification is difficult. The hypothesis is proposed that the documented damage to the National Seashore, in addition to large scale damage to estuarine and marine resources are linked to wide-spread fluid extraction throughout the Atlantic and Gulf Coastal Plains. Detailed, multidisciplinary investigations are recommended to determine the magnitude and extent of the damage and what corrective measures can be taken.

P09/L/01-A2 1130

BAROTROPIC CIRCULATION IN BAHÍA BLANCA ESTUARY (ARGENTINA). 1: TIDAL RESPONSE

Elbio D. PALMA (Dpto. de Física, Universidad Nacional del Sur. Avda. Alem 1253. (8000). Bahía Blanca)

The Bahía Blanca Estuary lodges in its margins a major petrochemical industrial park, a thermoelectric plant, and an important deep-water harbor system. A better understanding of the physical properties of the estuary will certainly help in solving the pollution and dredging problems of the region. In this study the tidal wind driven response of the estuary is analyzed with a finite difference two-dimensional barotropic model which has an embedded algorithm that handles tidal flat covering and uncovering. The model is verified by comparing observed and computed water elevations in some stations. The model results show that the incident tidal wave from the Atlantic is delayed considerably as it enters the estuary channels. The wave amplitude is amplified towards the head, with channel convergence prevailing over bottom and lateral friction A comparative study between sea surface elevation and currents lag confirms the existence of a standing wave in the main navigation channel. Experiments with the prevailing NW winds show minor modifications of surface elevations in the outer estuary and of tidal currents in the inner main channel. The simulation with the strongest SE winds ('sudestadas') produce the highest sea level changes in coastal areas, with important consequences for harbor activities.

P09/L/02-A2 1135

BAROTROPIC CIRCULATION IN BAHÍA BLANCA ESTUARY (ARGENTINA). 2: RESIDUAL CURRENTS

Elbio D. PALMA (Dpto. de Física, Universidad Nacional del Sur. Avda. Alem 1253. (8000). Bahía Blanca)

Tidally driven residual circulations are persistent features that contribute to the overall long-term distribution and transport of water properties. In this study we develop a depth-averaged model that includes tidal flats covering and uncovering to examine the residual circulation in Bahía Blanca estuary (Argentina). The model is integrated with appropriate boundary conditions to study the residual through-flow and the generation of residual eddies. The qualitative nature of the residual gyres is consistent with those discussed by several authors for similar coastal locations. Sensibility of the results to spatial resolution and horizontal mixing parameters are also analyzed by numerical experimentation. The dominant physical mechanism is explained by transport of vorticity from the oscillating flow to the mean field by barotropic rectification of the tidal wave. Finally, the effects of the dominant winds on the residual currents are discussed. The results stressed the importance of the open boundary treatment when studying wind driven residuals.

P09/L/03-A2 1140

MODELLING OF THE VERTICAL CIRCULATION IN QUEQUEN HARBOR (ARGENTINA)

Elbio D. Palma1 and G.M. E. Perillo2,3 (1Dpto. de Física, Universidad Nacional del Sur. Avda. Alem 1253. (8000). Bahía Blanca.2Instituto Argentino de Oceanografía Florida 400 Edificio E1. (8000) Bahía Blanca. Argentina3.Dpto. de Geología, Universidad Nacional del Sur. San Juan 870, 8000 Bahía Blanca, Argentina).

It has been observed that the vertical circulation in Quequén Harbor is strongly influenced by a steep bathymetric slope (step) located at the junction of the main harbor with the river. In this study a numerical model is used to examine the dynamics induced by tides and freshwater discharge in the system and to investigate the influence of the step on the circulation. Residual currents and salinity distribution obtained with the model show a two-layer circulation pattern where relatively low salinity water flows out at the surface and compensating high salinity waters from the shelf flows at the bottom. However, the model results also show that the presence of the steep slope can generate internal waves that modified the two-layer circulation mode. Sensibility experiments conducted changing the step position and depth confirms its strong influence on the harbor dynamics. During slack water time the model results show a re-circulation pattern at the base of the step. Further numerical experiments including passive tracers in the model show that this re-circulation modifies the vertical distribution of dissolved and suspended estuarine constituents.

P09/E/01-A2 1145

THE INFLUENCE OF THE TIDES ON THE CIRCULATION OF A TWO-SILLED FJORD

Michael W. STACEY (Department of Physics, Royal Military College of Canada, Kingston, Ontario, K7K 7B4, Canada. Email: stacey-m@rmc.ca) Yves Gratton (INRS-Oceanologie, 310 Allee des Ursulines, Rimouski, Quebec, G5L 3A1, Canada. Email: yves_gratton@uqar.uquebec.ca)

A laterally integrated, two-dimensional numerical model has been used with observations of velocity, temperature and salinity to study the influence of the M2 tide on the circulation in the Saguenay Fjord. The fjord has two sills, an outer sill (approx. 30 m deep) near its mouth,and an inner sill (approx. 60 m deep) about 20 km further up-fjord. The inner sill separates the inner and outer basins of the fjord. Both basins are about 250 m deep. The fjord is highly stratified, so vigorous internal motions are generated by the interaction of the tide with the sills of the fjord. The M2 tidal velocity near the surface, and over the deepest part of the outer basin, can be greater than 1 m/s.
The M2 tide has a very significant influence on the sub-tidal circulation because much of the energy associated with the tidally-generated internal motions is dissipated in the outer basin, so there is significantly more vertical mixing there than in the inner basin. The resulting horizontal pressure gradient causes a significant (10-20 cm/s) mean bottom flow of water from the inner into the outer basin across the inner sill. Upon entering the outer basin, this water sinks almost to the bottom. This 'reverse renewal', caused by the excessive tidal mixing in the outer basin, is evident in both the observations and the simulation.
According to the numerical model, M2 tidal energy is withdrawn from the surface tide at a rate of about 50 MW. The rate of withdrawal would be about five times less if the fjord were unstratified. Most of the energy withdrawn from the surface tide is fed into the internal tide.

PROCESSES AND CIRCULATION AT THE SHELF SLOPE (1)

Introduction **0900**

John JOHNSON

P10/E/23-A3 Invited **0910**

FORCED TRANSPORT ACROSS THE CONTINENTAL SLOPE

John HUTHNANCE (CCMS Proudman Oceanographic Laboratory, Bidston Observatory, Birkenhead, Merseyside L43 7RA, UK)

Ocean-shelf exchange is of interest as a component of the global cycling of nutrients and organic carbon (for example) and specifically for the fuelling of high primary production in shelf seas. Several ocean margin experiments concerned with this question have estimated significant cross-slope fluxes, especially down-slope export of particulate matter. However, large-scale flow across the continental slope is inhibited by geostrophy, and recent studies have suggested "shut-down" of the up- or down-slope Ekman transport below unforced along-slope flow.
External forcing appears to provide a means of resolving this apparent contradiction via sustenance of cross-slope circulation (in an up-welling or down-welling sense) including a bottom Ekman layer. The oceanic density field and associated pressure gradients, as well as winds, may provide such forcing. A parallel question is the form of boundary condition that the shelf and slope provide for ocean circulation.
These questions are explored with semi-analytic and fully prognostic numerical models. The models also indicate the importance of a non-uniform slope and of the coast which respectively aid and hinder cross-slope circulation.

P10/W/08-A3 **0950**

FLOW STRUCTURE AND SEASONALITY IN THE HEBRIDEAN SLOPE CURRENT

ALEJANDRO J. SOUZA (Centre for Coastal & Marine Sciences, Proudman Oceanographic Lab., Bdiston Observatory, Birkenhead L43 7RA, UK, email: ajso@ccms.ac.uk) John H. Simpson, M. Harikrishnan and J Malarkey (all at School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey LL59 5EY, UK).

We report on new determinations of the intensity, structure and variability of the slope current based on the 16 months of observations with ADCPs and conventional current meters on a cross-slope section at the Hebridean shelf edge during the SES programme.
After removal of the tidal signals, the mean flow over the upper slope is found to be closely parallel to the topography with speeds of ~20 cms-1. The flow extends down to depth of 500 m and is predominantly barotropic especially in winter when the flow is practically uniform between 350 m and the surface. In summer, there is a significant baroclinic component with a pronounced maximum in current at a depth of about 200 m but more than 80% of the kinetic energy is in the barotropic component. Flow in the core of the current is highly persistent with the Neumann's steadiness St > 0.8 in summer. The cross-slope profile of sea surface elevation, computed from the mean barotropic currents, shows a consistent relation to seabed topography through the seasonal cycle. Long term averages of the cross-slope components are generally small (~2cms-1) with some indication of persistent down-slope flow in the bottom Ekman layer.
Measurements with shipboard ADCP on sections at intervals along the slope show a high degree of continuity in the structure of the flow. The core of the flow appears to be related to a weak positive salinity anomaly and a depression of the 9.5_C isotherm near the shelf, but there is no strong correlation between the core of the slope-current and the core of the salinity anomaly. It is proposed that this may be due to differences in the cross-stream diffusion of salt and momentum which have different boundary conditions at the slope.
The observations suggest JEBAR as possible forcing mechanism for the slope current, but care should be brought to this assumption as other constrains, like homogeneous vorticity can produce a similar cross-shelf structure of the slope current.

P10/L/03-A3 **1010**

COASTAL CURRENTS DRIVEN BY WIND AND ALONGSHORE GRADIENT IN WINDCURL

DR LIE-YAUW OEY (Princeton University, Atmospheric & Oceanic Sci Program, Sayre Hall, Forrestal Campus, Princeton University, Princeton, NJ 08544, NJ 08544 USA. email: lyo@splash.princeton.edu)

When wind distribution along a coast is anisotropic, such that its cross-shore scale is smaller than its alongshore scale, the forced Kelvin wave consists of forcing by both the wind and alongshore gradient of the windcurl. The resulting evolution of the current on both the f-plane and beta-plane will be discussed, and ideas are applied to the observed seasonal variation of the coastal currents off the Southern California Bight, USA.

P10/W/09-A3 Invited **1050**

TRANSPORT AND RECIRCULATION IN UPWELLING FILAMENTS

E.D. BARTON, E. Navarro Perez, R. Torres Almarza (all at School of Ocean Sciences, University of Wales, Bangor, Menai Bridge, Anglesey LL59 5EY, UK, Email: oss041@bangor.ac.uk)

The offshore flow in upwelling filaments represents a plausible pathway for exchange between continental shelf and oceanic waters, mainly but not exclusively on the Eastern Boundaries of the oceans. However, compensating and possibly continuous return flows may result in no net offshore transport of nutrients or biogenic material. Two recurrent filaments, near 28N and 41N in the NW African and Iberian upwelling regimes, are examined to investigate the nature of the flow. One filament occurs in a relatively steady, possibly year round upwelling, while the other is located in a region of seasonal and intermittent upwelling. Both systems exhibit similar structure, despite having possibly different formation mechanisms, and both are associated with a well defined return flow on their equatorward flank. However, the time scales for circulation through the filament and return are significantly different in each location (7 and 20 days, respectively). This has clear implications for the transport of any non-conservative property advected around the system. In the NW African case, there is evidence that the filament interacts with offshore eddies generated by the Canaries archipelago to produce a net enrichment of island waters.

P10/W/12-A3 **1130**

MODELLING THE CAPE GHIR FILAMENT

Ian STEVENS and John Johnson (both at School of Mathematics, University of East Anglia, Norwich, NR4 7TJ,UK, email: i.stevens@uea.ac.uk)

Satellite imagery reveals the presence of a cool filament extending offshore from the coast of Morocco at Cape Ghir out into the Atlantic Ocean to the north of the Canary Islands. The filament appears to be a permanent feature with a seasonal variation in its zonal extent which is maximum in late summer.
A primitive equation model at 1/12° resolution covering the region between the Gulf of Cadiz and the Nort West African coast and including the Canary Islands has been constructed to investigate the generation mechanism of the filament.
The model reproduces seasonal variations in the surface temperature signal of the filament which compare well with the satellite observations, and also provides a description of the vertical structure of the hydrology and velocity field. Anticyclonic and cyclonic eddies trapped to the north and south of the Cape Ghir Plateau are produced in the model and these may play a role in the generation of the filament.

P10/W/05-A3 **1150**

STRATIFICATION PATTERNS AND PROCESSES ON THE INNER CONTINENTAL SHELF OF THE MIDDLE ATLANTIC BIGHT

John BRUBAKER (VIMS, School of Marine Science, College of William & Mary, Gloucester Point, Virginia, 23062, USA. Email: brubaker@vims.edu)

Patterns of density stratification and dynamic stability over the inner shelf in late summer to early autumn have been investigated in a field program in the Mid-Atlantic Bight off the coast of North Carolina. Temperature, salinity, and velocity data sets from repeated shipboard surveys over a grid of stations and from an array of moored instrumentation provided complementary perspectives. In this inner shelf environment, stratification was influenced significantly by variations both in temperature and in salinity. The relative influence was quantified through computation of the separate thermal and haline contributions to the potential energy anomaly integral, which compares the potential energy of the observed, stratified water column to the potential energy it would have if it were well mixed. In August, stratification at offshore distances < 10 km was due primarily to vertical salinity structure, whereas at distances > 15 km thermal influence was usually dominant. By October, the role of thermal structure had been reduced drastically. In addition to the vertically integrated energy measure for characterizing the water column as a whole, local stratification and stability were examined in terms of buoyancy frequency and gradient Richardson number estimates. Various spatial configurations were observed, with a thermocline and halocline sometimes distinct and sometimes merged. In August, localized velocity shear layers often coincided with sharply defined pycnoclines. With respect to Richardson number values, these stratified shear flows were usually stable, although the stability was often only marginal and some instances of likely instability in limited spatial regions were observed. In October, the regions of low Richardson number were more extensive. Key physical processes underlying the variability of stratification include fresh water influence from the Chesapeake Bay outflow and wind-driven currents, particularly at the synoptic scale on which upelling and downwelling circulation patterns redistributed the buoyancy associated with the Bay plume.

P10/E/10-A3 **1210**

OCEANIC INTERNAL SOLITARY WAVES:AN ANALYTICAL MODEL FOR KDV SOLITON PACKETS

John R. APEL (Global Ocean Associates, P.O. Box 12131, Silver Spring, MD 20853, USA; 1-301-460-7018 (V); 1-301-460-9775 (F); e-mail: globocen@erols.com

A new analytical model for oceanic internal solitons has been constructed that is based on (a) an approximate "dnoidal" solution to the Korteweg-De Vries wave equation, and (b) solutions to the Taylor-Goldstein equation for the vertical structure function. A finite-length wave packet results that has most of the salient properties of solitons generated at continental shelf breaks and oceanic sills: rank-ordered non-linear oscillations; a packet that propagates at speeds above the long-wave linear speed; increasing numbers of oscillations and packet lengths as time goes on; and a long-term depression of the pycnocline at the rear of the packet. The packet properties derive from imposition of a shocklike initial condition which evolves into a nonlinear undulatory internal bore that decays toward a linear state at its trailing edge. Input data include the vertical density and background velocity profiles, and specification of a numerical amplitude. The resultant solitons have properties that agree quantitatively with observed packets in the New York Bight and the Sulu Sea. The solution is extended to the full cycle of the internal tide by modeling the recovery of the "solibore" trailing edge to its equilibrium state over the semi-diurnal tidal cycle. The theory connects a wave number scale ko with the amplitude eta; from knowledge of the density and background velocity fields, and the variation of wavelengths within the packets, it is possible to construct the entire subsurface hydrodynamic field with the model. The wavelength variations come most conveniently from satellite imagery such as that from synthetic aperture radar. Thus from density data (either concurrent or historical) and a SAR image, one may arrive at reasonable estimates of the internal hydrodynamics. Predictive models can follow from the formulation. Based on a collection of images gathered from around the world, a global atlas of internal solitons is being prepared for publication.

PROCESSES AND CIRCULATION AT THE SHELF SLOPE (2)

P10/W/18-A3 Invited **1400**

RECENT DEVELOPMENTS IN WIND-FORCED UPWELLING AND DOWNWELLING

John MIDDLETON (School of Mathematics, University of New South Wales, Sydney 2052, Australia, Email: john.middleton@unsw.edu.au)

A numerical study is made of the dynamics of the circulation that arises from forcing by a steady, uniform alongshore wind over a uniform zonal shelf in the southern hemisphere. Both upwelling and downwelling favourable winds are considered.
In the former case, the results show that most of the upwelling is confined to the region inshore

of the shelfbreak. Over the slope and within the region of wind-forcing the circulation is found to be dominated by the growth of both an anticyclonic and a cyclonic eddy, an offshore flow, and downwelling. The results are fundamentally different to the upwelling described by 2-dimensional models or by 3-dimensional linear dynamics. Two new mechanisms related to the surface mixed layer are identified as being responsible for these features of the upwelling circulation. First, the offshore advection of alongshore momentum within the surface mixed layer (SML) is shown to accelerate the alongshore current near the eastern end of the region of wind-forcing leading to a sharpening of the cross-shelf gradient of sealevel, and an excess in the alongshore transport. This excess transport acts to raise sealevel, leads to downwelling below the base of the SML and the growth of the anticyclonic eddy. A simple scaling is given to show that the nonlinear effects will be important for narrow, strongly stratif ied shelves. A second important effect is argued to result from the geostrophic cross-shelf flow that is associated with the alongshore gradients of density within the SML.
The downwelling circulation obtained by simply reversing the sign of the wind stress is also examined. Over the first 10 days, when the system is largely linear, the circulation is simply the reverse of that found in the upwelling case. However, after this time, the downwelling and upwelling circulations are notably different, and the former is dominated by the development a bottom mixed layer (depth 70m) rather than the SML. Through thermal-wind shear, an Undercurrent (UC) over the slope evolves, the bottom Ekman transport becomes small and negative leading to the detachment of flow near the shelf break, localised spreading of isopycnals and further intensification of the UC. Finally, some recent modelling developments are presented for the seasonal circulation within the Great Australian Bight. The models are nested inside the Semtner-Chervin 1/4 degree output, and contain 150X60 cells in the horizontal with 40 sigma cells in the vertical.

P10/W/26-A3 1440

INTERANNUAL CHANGES IN THE EAST AUSTRALIAN CURRENT AS INFERRED FROM INFRARED SATELLITE IMAGERY

W.J. EMERY (CCAR Box 431, U. Colorado, Boulder, Co., 80309 USA) and J. Wilkin (Univ. of Auckland, SEMS, Tamaki Campus, Private Bag 92019, Auckland, New Zealand)

A five-year time series of infrared satellite images is used to compute surface currents using the Maximum Cross Correlation (MCC) technique in the area off southeast Australia. All pairs of images between 4 and 24 hours separation are used to compute surface currents. A relaxation step is added to the selection of the maximum correlation greatly reducing the errors in selecting the correct end point of the vectors. In addition next neighbor filtering can now be done in time as well as in space also improving the resulting vector velocity field. The need to prefilter cloudy pixels is a limiting factor in the application of the MCC technique. The MCC surface current fields are then to mapped using optimum interpolation (OI) constrained to yield a surface stream function resulting in a smooth surface current field dominated by eddies and variable mean flow. These OI current maps are used to compute Empirical Orthogonal Functions (EOFs) of the East Australian Current region. These EOFS characterize both seasonal and interannual variations in the surface currents. Wavenumber/frequency spectra are used to find the fundamental time and space scales characteristic of the East Australian Current region.

P10/L/06-A3 1500

THE RESPONSE OF SEMI-ENCLOSED SEAS TO SYNOPTIC ATMOSPHERIC FORCING

Christopher N.K. MOOERS, HeeSook Kang, and Lianmei Gao (OPEL/RSMAS,University of Miami,4600 Rickenbacker Cswy., Miami, FL33149-1098, USA, email: cmooers@rsmas.miami.edu, hkang@rsmas.miami.edu, lgao@rsmas.miami.edu)

Semi-enclosed seas are under the influence of atmosheric forcing(wind stress,surface pressure,heating/cooling,and evaporation/precipitation)on a variety of space and time scales from mesoscale to synoptic scale to intra-seasonal,seasonal/annual,inter-annual,and so forth. Here, the primary interest is in the oceanic response to synoptic scale forcing. Because of the joint effects of Earth's rotation, ocean density stratification, and continental margin topography, the response of semi-enclosed seas to synoptic forcing can be rich, ranging from transient coastal upwelling or downwelling, to coastally trapped waves, storm surges, transient jets and fronts, transient surface and bottom mixed layers, convection/ventilation, and so forth.
Numerical simulations (using POM) of the response of the Japan(East)Sea to wintertime extratropical cyclone/cold front outbreaks, and the Intra-Americas Sea to summertime tropical cyclones, are used as examples. The synoptic atmospheric forcing (with mesoscale resolution) utilized is provided by relatively new sources; e.g., a spaceborne scatterometer (NSCAT) and a mesoscale atmospheric model(MM5). By comparing with the response to more conventional,lower-resolution atmospheric forcing fields, the sensitivity of semi-enclosed seas is illustrated. Conversely, the space-time-amplitude resolution and accuracy requirements of atmospheric forcing for quality simulations of semi-enclosed seas circulation are beginning to be better defined by these response studies.
Looking ahead, the new sources of synoptic atmospheric forcing inform- ation(with mesoscale resolution)offer the potential for driving simulation and predictive models of circulation in semi-enclosed seas with higher accuracy on a routine(operational)basis.

P10/E/17-A3 1520

CIRCULATION PATTERNS OVER THE PETER THE GREAT BAY SHELF AND ADJACENT JAPAN SEA AREA

Vladimir Ponomarev, and Olga TRUSENKOVA (both at Pacific Oceanological Institute, 43 Baltiyskaya, Vladivostok, 690041, Russia, e-mail: archer@linkor.ru, ponomarev%dan86@poi.marine.su)

The dynamic processes associated with synoptic wind forcing and generation of topographic eddies and streamers over the Peter the Great Bay shelf and adjacent Japan Sea area are studied. The strong northern winds are typical for a cold season over the studied sea area. These winds generate upwelling and intensive water exchange between the Bay and open sea area. Satellite and CTD observations show the eddy structure of upwelling and synoptic scale multiple fronts over the shelf and continental slope. We simulated the circulation patterns in this area using the MHI numerical model developed by Naum Shapiro (Marine Hydrophysical Institute, Sebastopol, Ukraine, 1992-1998). It is the layered model based on the primitive equations and free surface boundary condition; temperature and salinity within layers and layer thickness are functions of time and horizontal coordinates. Interfaces between layers are allowed to bend up and down and layers themselves can degenerate by acquiring negligible thickness. This makes the MHI model an appropriate tool for simulation of synoptic scale vertical circulation. Numerical experiments were performed under forcing of synoptic north-western wind characterized by a strong jets directed along the axis of the Peter the Great Bay. Synoptic-scale dipole circulation patterns and streamers were obtained over the continental slope, associated with strong upwelling in the cyclonic eddy and downwelling in the anticyclonic one. Evolution of these structures and the Peter the Great current system was shown under alternative wind forcing.

COASTAL PROCESSES INVOLVED IN THE FORMATION OF ANTARCTIC BOTTOM WATER

Ann-Marie M. WONG and Jason H. Middleton (School of Mathematics, University of New South Wales, Sydney, AUSTRALIA)

Antarctic Bottom Water (AABW) is the dense water mass found at the bottom of the ocean basins around the world. The major sources of AABW are the Weddell Sea and the Ross Sea, both of which are characterised by wide continental shelves and land barriers, confining the circulation of the water on the shelf so that it becomes very saline. This shelf water forms an integral part of AABW.
The region off the coast of Wilkes Land has been identified as a source of AABW. In the past this region was not considered as a significant source of AABW but more recent research suggests otherwise. Wilkes Land does not have the land barrier confining the circulation to the shelf which plays a significant role in the circulation in the Weddell Sea and Ross Sea. The region off the coast of Wilkes Land is characterised by deep depressions on the shelf, strong katabatic winds and polynyas which are believed to contribute to the formation of AABW.
A numerical modelling study of the coastal processes off Wilkes Land is being undertaken using the Princeton Ocean Model (POM). The model has been configured to capture the essential features of this region including the deep reverse sloping shelf, brine production, strong katabatic winds and coastal trapped waves. The effects of these factors on the formation of AABW are analysed from the model results.

P10/W/19-A3 1620

CHARACTERISTIC PATTERNS OF CIRCULATION OFF THE COAST OF CALIFORNIA

C. D. WINANT (Scripps Institute of Oceanography, Centre for Coastal Studies-0209, 9500 Gilman Drive, La Jolla, CA 92093-0209. USA. E-mail: cdw@coast.ucsd.edu)

The ocean circulation along the central and southern California coast is described in terms of a few characteristic flow patterns based on a five- year set of moored observations, drifter releases, and ship-borne surveys. The observations were carried out over the Pacific continental shelf north of Los Angeles for a distance of approximately 300 km. The characteristic patterns are similar to the synoptic patterns used by meteorologists to forecast weather. A cyclonic eddy located in the western end of the Santa Barbara channel is the most persistent feature of the observations and is present in all patterns. In spring and summer, when winds are persistently equatorward and upwelling favorable, the current pattern is equatorward as well. Whereas in the fall and winter, when the equatorward winds have relaxed, currents shift to poleward. Two indices of forcing, the local wind stress and the alongshore pressure gradient, appear to be useful predictors of the circulation pattern.

P10/W/17-A3 1640

SUMMER MARINE BOUNDARY LAYER DYNAMICS AROUND PT CONCEPTION, CALIFORNIA

Clive DORMAN (Center for Coastal Studies, ScrippsInstitution of Oceanography, University of California San Diego, La Jolla, CA 92092-0209, USA, email: cdorman@ucsd.eduORNIA)

A climatology is based upon a net of twenty four surface stations on land, islands, buoys and platforms around the Santa Barbara Channel/Santa Marina Basin in Southern California. Radar profiler and soundings sampled the upper air. Marine layer winds accelerate around Pt Conception to reach a maximum in the western mouth of the Santa Barbara Channel, then deaccelerate toward the east. This wind speed maxima is also one of the two monthly mean,summer wind speed maxima along the west coast of the United States. A Sea level pressure is lowest on the north side of the channel and on the eastern end. An air temperature inversion base in the Southern California area is lowest and strongest in the western mouth of the Santa Barbara Channel. Stratus clouds are a minimum in the western portion of the Channel. The low level atmospheric structure in the vicinity of the Santa Barbara Channel is explained as a transcritical expansion fan in the marine boundary layer.

OBSERVATIONS AND SIMULATIONS OF THE CALIFORNIA CURRENT

Robert L. HANEY (Department of Meteorology, Naval Postgraduate School, Monterey, CA 93943-5114, USA, email: haneyrl@met.nps.navy.mil) David E. Dietrich (Center for Air Sea Technology, Mississippi State University, Stennis Space Center, MS 39529, USA, email: dietrich@nmia.com) Robert A. Hale (Department of Meteorology, Naval Postgraduate School, Monterey, CA 93943-5114, USA, email: hale@met.nps.navy.mil)

Major observational programs in the California Current (CC) during the last 15 years have greatly increased our knowledge of the quantitative nature of this important eastern boundary ocean current. In response to strong upwelling favorable winds in spring, a surface intensified baroclinic equatorward jet, with cold offshore-directed filaments and unstable frontal eddies, develops next to the coast. The jet moves offshore during summer and fall, and is replaced by a poleward Davidson Current next to the coast in winter. There is also a seasonal signal and limited offshore propagation (to only about 128W) of surface eddy kinetic energy (EKE), with the decrease of surface EKE west of 128W attributed to an unspecified dissipation process. To help interpret the new observations, long term simulations of the CC are carried out using the DieCAST regional model. In most of the simulations, the wind stress is prescribed from monthly climatology, while the buoyancy flux is computed by damping to the mean annual cycle of temperature and salinity at the surface. The simulations reproduce the main features of the annual cycle described above, however the decrease of surface EKE west of about 128W in the simulations is due to the vertical redistribution of EKE to the deep ocean, not dissipation. Adding a realistic wind enhancement offshore of each coastal headland produces both local and remote changes to the above annual cycle.

USE OF MMS/SCRIPPS OCEANOGRAPHIC DATA FOR OIL SPILL RISK ANALYSIS ANDOIL SPILL RESPONSE IN THE SANTA BARBARA CHANNEL-SANTA MARIA BASIN AREA

David R. Browne

In 1991, the Minerals Management Service (MMS) entered into a Cooperative Agreement with the State of California-Scripps Institution of Oceanography (Scripps) to conduct physical oceanographic studies to determine potential environmental impacts of offshore oil and gas activities in the Southern California Bight. The result is the Santa Barbara Channel-Santa Maria Basin (SBC-SMB) Circulation Study in the primary area of active federal oil and gas

leases. Field measurements extend from April, 1992, to November, 1999, with the objective of determining characteristic flow fields and their forcing mechanisms in the SBC-SMB area for MMS oil spill risk analysis and strategic planning purposes. Six characteristic surface circulation flow patterns identified through the SBC-SMB Circulation Study are discussed in terms of their relative impact on oil spill transport. This background knowledge of characteristic flow patterns, together with real-time acquisition of currents, winds, satellite imagery, and surface drifter tracks from the study's field array is proving helpful to industry and agency tactical oil spill response efforts. During actual oil spills in the SBC-SMB area, real-time estimates of synoptic flow patterns have been used to predict, with reasonable accuracy, oil spill trajectories in this complicated oceanographic environment. Trajectory prediction performance as a result of using real-time and climactic data in past actual oil spills and oil spill drills is presented.

P10/L/01-A4 0930

A CASE STUDY OF BORA-DRIVEN CURRENTS AND PO OUTFLOW SPREADNG OVER THE ADRIATIC SHELF (16-20 JANUARY 1987)

Gordona Beg PAKLAR (Institute of Oceanography and Fisheries, Set. I. Mestrovica 63, 21000 Split, Croatia, email: beg@jadran.izor.hr), Vlad Isakov and Darko Koracin (both at Desert Research Institute, P.O. Box 60220, Reno, NV 89506-0220, USA, email: darko@dri.edu), Vassilliki Kourafalou (National Centre for Marine Research, Elliniko, Athens 166-04, Greece, email: villy@erato.fl.ncmr.gr), Mirko Orlic (Andrija Mohorovicic Geophysical Institute, Faculty of Science, University of Zagreb, Horvatovac bb, 10000 Zagreb, Croatia, email: orlic@olimp.irb.hr)

The bora over the Adriatic sea induces strong transient currents whose horizontal variability is mainly controlled by an orographically-induced wind-curl effect. Until now, numerical models with resolution fine enough to resolve the alongshore variability in the bora wind field were forced with suddenly applied climatological wind, and inertial effects were not considered. In the present study we use the space- and time-varying hourly winds simulated by Mesoscale Model 5 with 9 km resolution to analyze the bora wind episode of 16-20 January 1987 and to reproduce its influence on the sea with Princeton Ocean Model. Infrared (IR) satellite imaged taken after the long lasting bora event reveal a cyclonic gyre traced by the Po River cold water. Although the bora wind, being of the NE direction, may be expected to induce downwelling on the western Adriatic coast, due to its alongshore variability the bora instead drives the Po River water away from the coast. The Po River was introduced in our model as an extra volume in the continuity equation and, moreover, was assumed to have zero salinity and 5 degrees C lower temperature than the sea water. The Advanced Very High Resolution Radiometer (AVHRR) sea surface temperature measured on 9 January was used to initialize the model, whereas temperature was assumed to be vertically uniform in accordance with some simultaneous bathythermograph measurements. AVHRR sea surface temperatures of 21 and 22 January were used to verify the model results. Initial salinity fields were obtained via a 10 days simulation, with the river discharge being the only forcing and neglecting the temperature changes. The results of the numerical simulations with space- and time-varying wing show current field resembling the cyclonic gyre visible on IR satellite images. Modeled sea surface temperatures show a smaller cyclonic gyre with lower temperature gradients than observed. In order to explain the discrepancy, in our final numerical simulations we explore a positive feedback mechanism: Po- influenced cold water enhance the stability of the overlaying atmosphere and locally reduce the wind stress which, in turn, reinforce the wind-curl effect over the Northern Adriatic.

P10/W/27-A4 0950

INTERNAL KELVIN WAVES OBSERVED AND MODELLED IN THE ZADAR AND PA_MAN CHANNELS (EAST ADRIATIC)

Ivica VILIBIC (Hydrographic Institute of the Republic of Croatia, Zrinsko Frankopanska 161, 21000 Split, Croatia, email: dhi-oco@dhi.tel.hr)

An experiment was organised during summer 1994 in the Zadar and Pa_man Channels (50 km long, 2-7 km wide, 8-50 m deep), placed in the inner Croatian waters. The experiment comprised 29 STD stations and 7 current-meter moorings (current-meters in the surface and bottom layers). Due to vertical stratification, various baroclinic processes were detected. An oscillation with 4-day period and 10 cm/s maximum current amplitude was extracted from the data, being parallel with the coastline and having bottom current which opposes to the surface one. Consequently, it is related to internal Kelvin waves, as the internal Rossby radius was a slightly lower than the channel width in its greater part. The waves were modelled in two ways: (1) using two-dimensional two-layer linear analytical model of a rectangular bay, imposing nodal line at the mouth and radiation condition on its shallowest part (head), and (2) using one-dimensional two-layer defant-like model of a bay which allowes for the variable topography. The first model successfully reproduced the phase changes in the channels, energy loss throughout the head and inclination of the current vector close to the mouth, while the second gives a more realistic along-channel distribution of the currents, being largest exactly where they are observed. The oscillation has a respectable horizontal transport for such small channel area (maximum about 5E8 m3/cycle), therefore, this should be taken into account, especially if the area is prone to the industrial pollution.

P10/E/02-A4 1010

THE CONTRIBUTION OF MIXING PROCESSES TO 3-D CIRCULATION IN THE SHALLOW ARABIAN GULF

CHERYL ANN BLAIN (Ocean Dynamics and Prediction Branch, Oceanography Division (Code 7322), Naval Research Laboratory, Stennis Space Center, MS 39529-5004,
Email: blain@nrlssc.navy.mil)

Within the Arabian Gulf, mixing over the water column is achieved by way of three primary forcings: tides, winds, and evaporation. The contribution of each of these mechanisms to the 3-D, seasonal mean circulation is presented. Numerical simulations of the nonlinear, 3-D shallow water dynamics are achieved through application of the Dartmouth finite element coastal ocean model. This free surface, 3-D circulation model includes tidal dynamics, wind and buoyancy
driven flows, and level 2.5 advanced turbulence closure. An examination of mixing dynamics at both basin and localized scales is possible due to the variable grid resolution employed. Diagnostic (prescribed mass variable fields) and prognostic (with advection and mixing of the mass variables) computations in combination with the modularity of the model allow forcing mechanisms to be considered independently and together in this study of mixing over the shallow shelf water. Asymmetry of the shelf bathymetry between the bounding coasts of the Gulf lend additional complexity to the mixing and circulation patterns present.

P10/E/12-A4 1050

BOILS AND EDDIES IN TIDAL FLOWS

W.A.M.NIMMO SMITH, S.A.Thorpe and A.Graham (School of Ocean and Earth Science, Southampton Oceanography Centre, European Way, Southampton SO14 3ZH, UK.)

The processes which lead to dispersion by tidal flows in shelf seas are poorly understood, in spite of their great importance in the spread of oil spills and the distribution of sediment, phytoplankton blooms or larvae. Here we describe acoustic and visual observations of large 'boils', regions of local upwelling, in strong quasi-steady tidal currents in the well-mixed and unstratified southern North Sea. The diameter of the boils is about equal to the water depth and at any one time they affect about 25% of the water surface. The typical time for which their effect persists at the surface is at least 7 min. Comparison of these observations with measurements reported in rivers and laboratory channels, the evident presence of sediment in the boils seen at the surface, and the frequent bifurcation of sediment patches, together offer strong evidence that the boils originate as turbulent bursts and ejections from the strongly sheared boundary layer near the sea bed, and that eddies appear after the erupting water reaches the surface. Buoyant material (oil) is pushed radially outwards and accumulates into filaments around the edges of the boils. The acoustic signal from the boils is strongest principally around their up-wind edge, pointing to an accumulation or increased production of bubbles in a region of convergence with associated wave steepening and breaking along this edge. A simple calculation shows that the effect of the boils on lateral dispersion of buoyant material is consistent with other observations. The boils contribute to surface renewal, and may therefore enhance the fluxes of gases between the atmosphere and the unstratified shelf-seas. They produce a patchy structure in, for example, the colour of the water surface which may bias the measured average values of sea-surface parameters detected by satellite or other 'remote' sensors.

P10/W/13-A4 1110

OBSERVED TIDAL MODULATIONS IN THE EASTERN NORTH SEA

Vibeke HUESS, Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark. Email: vh@dmi.dk Ole B. Andersen, Kort- og Matrikelstyrelsen, Rentemestervej 8, DK-2400 Copenhagen, Denmark. Email: oa@kms.dk

During 1997 the GEOid and Sea level Of the North Atlantic Region (GEOSONAR) project deployed an off-shore tide gauge station at Horns Rev, situated 60 km west of Esbjerg at the Danish North Sea coast. The pressure gauge was employed for 8 months, before disappearing. At the harbour of Esbjerg tide gauges have been deployed for many years. The objective of establishing the pelagic tide gauge station in the eastern North Sea was to identify the influence on the existing on-shore tide gauges by the local effects such as wind set-up and wave reflections. Additionally the pelagic gauge was positioned close to a TOPEX/Poseidon crossover as well as a ERS satellite ground track, and the sea level information provided by the station is used to validate the altimetry data. The aim of this presentation is to investigate the tidal and non-tidal variations observed by the near coastal and the on-shore tide gauge, respectively. The tides in this region are influenced by non-linear tidal effects, due to the non-linear shallow water processes. Besides the higher harmonics with amplitudes up to 6 cm (M4), annual modulations of the major ocean tide constituents apparently due to interaction with the wind driven effects are observed. These annual modulations change the amplitude of the major astronomical constituents by up to 20 % in amplitude (K1), whereas the largest constituent (M2) is only modified by 5 % in amplitude.

P10/W/22-A4 1130

THREE-DIMENSIONAL MODELING OF TIDAL CURRENTS AND SEASONAL CIRCULATION ON THE EASTERN SCOTIAN SHELF

Guoqi HAN and John W. Loder (both at Coastal Ocean Sciences, Fisheries and Oceans Canada, Bedford Institute of Oceanography, Dartmouth, Nova Scotia, B2Y 4A2, Canada,
Email: ghan@emerald.bio.dfo.ca)

Tidal currents and seasonal-mean circulation on the eastern Scotian Shelf are studied using a three-dimensional, nonlinear finite-element model with a level 2.5 turbulence closure scheme. Tidal currents are moderate over the outer shelf banks, and weak over the inner shelf except for the northeastern tip of the Shelf. The seasonal-mean circulation for four bimonthly periods (centered on February 1, May 1, August 1 and November 1) exhibits dominant and persistent southwestward nearshore and shelf-break currents, embedded with anticyclonic (cyclonic) gyres over outer-shelf banks (inner-shelf basins) and onshore/offshore exchange along cross-shelf trenches. The model transport of the nearshore and shelf-break currents shows prominent seasonal and alongshelf changes. The baroclinic component dominates the nearshore current, while the shelf-break current is sensitive to barotropic boundary inflows through Cabot Strait and on the southern Newfoundland Shelf. Tidal mixing plays an important role over the outer shallow banks, even though tidal rectification is generally weak in the entire region. The solutions are in approximate agreement with observed transports and currents for the primary flow features.

P10/L/05-A4 1150

INERTIAL OSCILLATIONS MEAR THE CRITICAL LATITUDE FOR DIUNAL RESONANCE

John SIMPSON, Tom Rippeth, (University of Wales, Bangor, School of Ocean Sciences, Menai Bridge, Anglesey, U.K., e-mail: j.h.simpson@bangor.ac.uk), Pat Hyder, Ian Lucas (Fugro Geos Ltd)

Oscillations at, or close to, the inertial frequency are widely observed in shelf seas where frictional damping is weak. In the vicinity of latitudes 30 deg. N and S, such motions may become significantly enhanced by a resonance in which the local inertial frequency coincides with that of diurnal forcing. Under these conditions, regular daily variations in wind stress tend to produce large anticyclonic motions which may extend throughout the water column as shown, for example in Craig (1989; Continental Shelf Research 9(4),343-358 and 9(11), 965-980)
In this contribution we shall examine new data sets from three low tidal energy locations close to the critical latitude including one in the southern hemisphere. The measurements have been made through the full depth of the water column with bottom mounted ADCP's and, in one case using HF radar to measure surface currents. At each of the locations we shall identify the vertical structure of the flow and the response to forcing by windstress in the diurnal and inertial bands. Analytical and numerical models of increasing subtlety will be used to elucidate an explanation of the characteristic surface to bottom phase shift observed in all three cases. In all three locations, we shall demonstrate that near-inertial motions make a major contribution to the total kinetic energy of the flow and must, therefore, be considered as an important candidate source for vertical mixing. Shear production of turbulent kinetic energy will be examined both directly from the observations and from the models of flow structure.

P10/W/02-A4 1210

A GENERALIZED SET OF EQUATIONS FOR COASTAL OCEAN CIRCULATION AND ITS APPLICATION TO THE EAST CHINA SEA

Shizuo FENG, Dexing WU, Hui Wang and Kai Wang (Institute of Physical Oceanography, Ocean University of Qingdao Qingdao, 266003, CHINA)

A turbulent closure three-dimensional nonlinear baroclinic coastal water system, in which tidal currents and a quasi-steady flow are dominant over the flow field and supposed to be of the same order of magnitude, is presented and examined. In view of dominant tidal currents, associated with tides as gravitational long waves, the scale analysis on the system reveals a small parameter characterizing and measuring the order of nonlinear convection, and using a perturbation approach with the small parameter the coastal water system is systematically treated. The inter-tidal transport equations for the tidally time-averaged concentration, temperature, salinity, turbulent kinetic energy and its dissipation rate are derived, in which the convective transport velocity is the sum of velocity of the dominant quasi-steady flow and the mass transport velocity and is termed a "generalized mass transport velocity". The generalized mass transport velocity as a solenoid can be viewed as a Eulerian field variable and the aggregate of such local velocities can be specified as a Eulerian field of flow of an incompressible fluid. A set of field equations governing the generalized mass transport velocity is derived and a turbulent closure problem for the coastal ocean circulation of which the velocity is embodied by the generalized mass transport velocity, nonlinearly coupled with the dominant tidal circulation through the eddy viscosity, is proposed and used to describe and understand the dynamics of the wind-, density- and tide-driven circulation and the inter-tidal transport processes. Based on the set of field equations, the nonlinear effects of the convection and the sea surface elevation of the quasi-steady flow on the circulation and, in particular, the dynamic mechanism of the nonlinear coupling between the tidal and the tidally time-averaged circulation are revealed and examined. Finally, a preliminary application of the proposed model to simulating the winter-time and the summer-time circulations in the East China Sea and to understanding their dynamics is briefly described and discussed.

MESOSCALE CIRCULATION ON THE SHELF (2)

P10/E/16-A4 1400

THE CONTRIBUTIONS OF NONLINEAR HYDRODYNAMIC PROCESSES TO WAVE-INDUCED NEARSHORE CIRCULATION

Mark Cobb (Sverdrup Technology, Inc. (ASGMS), MSAAP Building 9101, Door 136, Stennis Space Center, MS 39529, USA, Email: cobb@alaska.nrlssc.navy.mil) Cheryl Ann Blain (Ocean Dynamics and Prediction Branch, Oceanography Division (Code 7322), Naval Research Laboratory, Email: blain@nrlssc.navy.mil)

In the nearshore environment there are a number of nonlinear hydrodynamic processes (wave-current interactions, nonlinear bottom stress, advection, diffusion/dispersion, and tides) that play a significant role in determining the surface elevation and current velocity. A better understanding of nearshore circulation is crucial to problems concerning coastal zone management such as sediment transport, pollutant transport, water quality, and ship navigation. The contributions of each of these nonlinear processes are considered within the context of wave-induced nearshore flow. Three scenarios are investigated for the cases of a planar, colinear, and sinusoidal beach using a 2-dimensional finite element hydrodynamic model based on the shallow water equations, ADCIRC-2DDI. The three scenarios consist of applying a surface wave stress without wave-current interactions, including wave-current interactions through only the bottom stress, and examining both effects together. For each case, the nonlinear processes are analyzed both individually and collectively from offshore to nearshore and under varying wave conditions in order to determine their contribution to nearshore circulation. Within the context of this study, computed longshore currents were validated by comparison to measured values at Leadbetter Beach, CA in 1980.

P10/W/16-A4 1420

AN ASSESSMENT OF LOCAL COASTAL DYNAMICS OBSERVED WITH HIGH FREQUENCY RADAR

Colin Y. SHEN and Robert A. Fusina (Code 7250, Naval Research Laboratory, Washington, D. C. 20375 USA); Lynn K.Shay (Department of Meteorology and Physical Oceanography, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, Florida 33149 USA)

An assessment is made of the dominant processes governing the circulation in a 30 km by 40 km area off the coast of Cape Hatteras, North Carolina, where surface current velocity vectors have been obtained using shore-based high frequency radars in the High Resolution Remote Sensing experiment in 1993. Although the currents in this region are constantly under the influence of winds and tides, frequent intrusion of energetic flows into the area, apparently mostly of Gulf Stream origin, is shown to have a strong influence on the current variability. Analysis of vorticity and divergence shows that the flow intruding into the area is strongly rotational with positive vorticity. This rotational motion is not in geostrophic balance with the surface pressure gradient, and an inertial oscillation is often excited as a result, with vorticity and divergence oscillating 90° out of phase. On average, the geostrophic imbalance generates a net surface flow divergence which, in turn, induces negative vorticity that more than offsets the positive vorticity advected into the region. However, vertical viscous transfer of positive vorticity from subsurface to surface is shown to be required to complete the surface vorticity balance; the same energetic cyclonic shear flows that intrude into the area are suggested as the source of the subsurface vorticity, as these flows of Gulf Stream origin are known to be subducted under buoyant shelf water.

NEW DATA ON NONLINEAR INTERNAL WAVE EVOLUTION FROM OBSERVATIONS ON SHELF OF THE SEA OF JAPAN

Andrey SEREBRYANY (N.N. Andreyev Acoustics Institute, Moscow 117036, Russia, email: aserebryany@glasnet.ru)

The process of internal tide propagation on a shelf leading to generation of soliton-like internal waves was investigated by means of special field experiment which we carried out in the Sea of Japan. During period of 24 hours research vessel with towed temperature line sensor performed 10 non-stop repeated runs along a section oriented across the shelf. These measurements were supplemented with CTD zond survey along the section made just before and after the towing and 12-hour observation by line temperature sensor in the point of the section on shallow water made from ancored vessel after the towing and the survey. On the basis of the measurements we obtained the picture describing internal wave field evolution on a shelf. It was observed that generation of intense internal wave trains took place in the shallow water zone at a distance of 5-6 km from the shore. Observed intense internal waves are soliton-like. They propagated toward the shore. The most significant fact we found was connected with an interesting phenomena of alternative displacement up and down of the internal wave train as a "hole body" by long-period internal movements on the thermocline. This process leads to the strengthening of nonlinearity of internal waves and can create for them a radically new nonlinear effect.

P10/E/14-A4 1500

A NESTED BASIN/COASTAL CIRCULATION MODEL FOR EAST ASIAN REGIONAL SEAS

Peter C. CHU, S.L. Lu, and Y.C. Chen

A nested basin/coastal model is developed to study the east Asian regional seas and shelf processes. The Princeton Ocean Model (POM) with 23 sigma levels conforming to a realistic bottom topography is use for the study. The horizontal resolution is 1 deg by 1 deg for the Pacific basin module, and 0.25 deg by 0.25 deg for the coastal module including JES. The open boundaries for the coastal module are 150 deg E and 15 deg S. The model simulates realistic circulation pattern and thermohaline structure. Comparison between the model results with observations is also given.

P10/P/01-A4 1520

THE KUROSHIO EAST OF TAIWAN AND IN THE EAST CHINA SEA IN SUMMER 1997*

Yaochu YUAN (Second Institute of Oceanography, SOA, P O Box 1207, Hangzhou, 310012, China, email: yuanyc@zgb.com.cn); Yonggang Liu and Jilan Su (both at Second Institute of Oceanography, , SOA, P O Box 1207, Hangzhou, 310012, China, email: sujil@zbg.com.cn); Arata Kaneko (Department of Environmental Sciences, Faculty of Engineering, Higashi-Hiroshima 739, Japan, email: akaneko@ipc.hiroshima-u.ac.jp)

On the basis of hydrographic data obtained from two cruises during June and July of 1997, a modified inverse method is used to compute the Kuroshio east of Taiwan and in the East China Sea, respectively. It is found that: 1) The net northward volume transport (VT) of the Kuroshio through Section K2 southeast of Taiwan is about 37.5x106 during July of 1997. In comparison with VT of the Kuroshio through Section K2 during October of 1995 and May-June of 1996, this value of VT of the Kuroshio decreases obviously, i.e.: VT of the Kuroshio southeast of Taiwan decreases obviously during 1997 stronger El-Nino year. 2) There is not a branch of the Kuroshio east of Taiwan to flow northeastward to the region east of Ryuku Island during July and of 1997. 3) During July of 1997 there is an anticyclonic eddy east of the Kuroshio and a countercurrent east of this anycyclonic eddy. 4) There is an anticyclonic recirculating hyre south of Miyako Island and southeast of Okinawa Island during July of 1997. The net northward VT of the Kuroshio through Section PN in the East China Sea is about 26.3x106m3/s during June of 1997. 5) The comparison between the above computed results and the ADCP observed currents show that they agree quite each other.

P10/E/05-A4 1600

VARIABILITY IN PCYNOCLINE DIFFUSIVITY IN THE SEASONALLY STRATIFIED SHELF SEAS OF WESTERN EUROPE

T. P. RIPPETH (School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey, LL59 5EY, UK. M. E. Inall, SAMS, CCMS Dunstaffnage Marine Laboratory, PO Box 3, Oban, Argyll, PA34 4AD, UK.) J. H. Simpson (School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey, LL59 5EY, UK.) John Howarth (CCMS Proudman Oceanographic Laboratory, Bidston, Merseyside, L43 7RA, UK. Neil Fisher, School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey, LL59 5EY, UK.)

The determination of vertical mixing rates in the stratified water column is one of the key objectives of shelf sea Physical Oceanography with important applications in many aspects of Biological Oceanography. Recent developments in turbulence probe technology have allowed direct estimation of the vertical profile of dissipation, from which it is possible to determine the eddy diffusivity Kz via the Osborne relation; Kz = 0.2 E / N^2 ; E= energy dissipation rate; N= Brunt-Vaisala frequency.
In this paper we shall present observations of the vertical structure of the dissipation of turbulent kinetic energy, made using a Fly Profiler, over 25 hour cycles, at a number of contrasting thermally-stratified sites in the shelf seas of north western Europe. The dissipation observed in the pcynocline region varies from 10-6 Wm-3 at a low energy site in the northern North Sea station, to 10-2 Wm-3 at a station located near to the continental shelf edge during a period of intense internal wave activity. These direct measurements of E are combined with N^2 based on T and S measurements also made by the FLY, to estimate the diffusivity Kz.
The variability of the pycnocline Kz and its dependence on spatial differences in wind and tidal stirring at the contrasting sites will be considered along with the question of whether mixing rates in the stratified regime respond significantly to the springs-neaps cycle in the tidal flow.

CURRENT PROFILES DURING THE BREAKDOWN OF STRATIFICATION IN THE NORTH SEA

John HOWARTH (Centre for Coastal and Marine Sciences, Proudman Oceanographic Laboratory, Bidston Observatory, Birkenhead, Merseyside, L43 7RA, UK, email: mjh@ccms.ac.uk)

Two sets of current and temperature profile measurements have been made in the northern North Sea during the breakdown of stratification between September and November, in 1991 and 1998. At the two sites which were close together, about 20 miles apart, tidal currents were weak and water depths over 100 m so that the surface and benthic boundary layers were initially well separated. During both sets of measurements the thermocline substantially weakened and deepened as a result of heat loss at the sea surface. There was no exchange of heat downwards across the thermocline and by the end in neither case had the water column become fully mixed. The first set of current measurements have been analysed in terms of barotropic dynamics, inertial currents and near surface shear. The inertial currents were first mode baroclinic and were well modelled by a two-layer local wind driven model. Shears across the thermocline of 0.02 /s over 10 m were measured. Near surface shear was confined at most to the top 25 m even during the largest storms and was correlated with the wind stress. The largest shear between 2 and 25 m below the surface was 0.01 /s. During the second set of measurements turbulence dissipation measurements were also made. An interesting contrast between the two sets is that for the first the water column was homohaline whereas for the second there was a surface to bed salinity difference of more than 0.5.

SEASONAL EVOLUTION OF THE IRISH SEA COLD POOL GYRE

K.J. HORSBURGH and A.E. Hill (School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey. LL59 5EY U.K.)

An extensive cruise program in 1994,1995 and 1996 provided observations which describe the seasonal evolution of the three-dimensional density field in the western Irish Sea. A cold, dense pool flanked by strong, nearbed horizontal density gradients was present from May until October in 1995. The trajectories of 55 satellite-tracked Argos drifters demonstrated the existence of the cyclonic circulation pattern that constitutes the western Irish Sea gyre and defined the gyre's full spatial extent. Several distinct recirculation paths were observed and the implications for planktonic organisms of the seasonal variability in circulation is discussed. Drifter speeds were in good agreement with geostrophic calculations based on the density field. The dynamical significance of strong nearbed density gradients, or bottom fronts, is highlighted. The gyre is a special case of a class of intense, organised, density-driven flows in shelf seas and the ability of numerical models to properly simulate such baroclinic circulations is critical. The results of a primitive equation model are compared with the seasonal observations. The model reproduces well the spatial pattern of heating, the residual flows and furthermore provides some new dynamical insights into shelf sea frontal processes.

P10/E/08-A4 1700

FRONTS AND WATER MASSES IN THE NORTHERN SOUTH BRAZIL BIGHT

Belmiro M. CASTRO and Luiz B. Miranda (both at Oceanographic Institute, University of Sao Paulo, Praca do Oceanografico, 191, 05508-900, Sao Paulo, SP, Brazil, email: bmcastro@usp.br)

Data from seven consecutive seasonal (summer/winter) hydrographic cruises are used to study the seasonal stratification cycle in the northern part of the South Brazil (23.4S-23.7S). Three shelf regions have been identified: Inner Shelf (IS), Middle Shelf (MS) and Outer Shelf (OS).
The IS outer limit changes seasonally: it reaches the 20-40 m isobath during summer (10-30 km from the coast) and the 50-70 m isobath during winter (40-80 km from the coast). The IS Coastal Water is separated from the lower layer MS South Atlantic Central Water (SACW) by a bottom thermal front. The presence of the SACW is associated with intrusions towards the coast of slope waters. The intrusion scale is larger during summer than during winter due to seasonal changes in the wind forcing. The MS extends offshore to the 70-90 isobaths (60-80 km from the coast) during summer, being very narrow during winter. The main characteristic of the MS is the high stratification during summer, due to the presence of a seasonal thermocline. Estimates for the thermodynamical and dynamical processes able to vertically mix the water column show that were not for the SACW intrusions during summer the MS would be almost homogeneous, not presenting the dominant seasonal thermocline. The MS is separated from the OS by a surface saline front which is located in the transition region between two upper layer water masses: the MS Coastal Water and the Tropical Water. The latter is one of the two water masses transported by the Brazil Current in the region, the other being the lower layer SACW. The OS extends from the surface saline front to the shelf break. Stratification in the OS does not vary much during the year, being a thermocline present all the time.

P10/E/15-A4 1720

THE INFLUENCE OF PATOS-MIRIM LAGOON DISCHARGE ON THE THERMOHALINE REGIME OF THE SOUTH BRAZILIAN SHELF

Peter O. ZAVIALOV (Shirshov Institute of Oceanology, Moscow, Russia, email: zavialov@mi.ras.ru)
Osmar O. Moller Jr (University of Rio Grande, Rio Grande, Brazil, email: osmar@calvin.ocfis.furg.br)

Patos-Mirim lagoon is a large choked freshwater lagoon connected to Southwestern Atlantic through a narrow and relatively deep Rio Grande channel. It is known that the discharge from the lagoon contributes significantly into the regional heat and mass budgets (e.g. Zavialov et al., 1998, J. Phys. Oceanogr., 28, 545-562) and is among principal factors controlling the thermohaline regime of the southern Brazilian shelf. However, the Patos-Mirim plume has never been mapped in detail. A helicopter/ship CTD survey of the inner shelf south of the estuary was conducted in September, 1998. Profiling was performed simultaneosly by the helicopter and the Brazilian R/V "Comandante Varela". The total number of CTD stations was 21. The collected data revealed extremely stable salinity-controlled stratfication within the plume which largely suppressed vertical mixing. Despite of the initial southward momentum of the plume waters, south of the estuary the thermohaline signature of the plume is observable only within a distance of 5-15 km from the and separates from the coast. Thus the hypothesis that relates low salinity values observed on the inner southern Brazilian shelf south of Rio Grande to Patos-Mirim discharge is not supported by our data. Rather, this low salinity belt can be related to Plata river discharge transported by a northward coastal current.
Analysis of local historical data revealed anomalously strong secular warming trend of SST (up to 1.6 degrees C per 100 years) in the area adjacent to the estuary. This may be related to a human impact upon the freshwater discharge from the lagoon.

SIMPLIFYING PELAGIC BIOLOGY FOR COUPLED MODELS

TETT, P.1, Wild-Allen, K.1 & Wilson, H.2,1 1. Department of Biological Sciences, Napier University, Edinburgh, U.K. 2. School of Ocean Sciences, University of Wales, Bangor, U.K.

Marine pelagic ecosystems contain many hundreds of species and very large numbers of individuals. Although the life of each individual and the dynamics of each population can be described by a small set of rules, marine ecologists have achieved no consensus about a way to model system dynamics. There is no ecological equivalent of physical oceanographers' basic hydrodynamic equations. Nethertheless, models must simplify the complexity of real marine pelagic ecosystems. But how much? A series of biological models with increasing numbers of state variables will be used to discuss necessary complexity and to illustrate biogeochemical (element-conserving) and ecological (semi-freely dynamically interacting) models of the marine microplankton, defined as all organisms less than 200 µm. One end-point of the series is a model with two microplankton compartments, which is able to represent the annual sequence from Spring, diatom-dominated plankton to a Summer Microbial Loop community. This model has been coupled to a depth-resolving physical framework which includes deposition to and resuspension from the sea-bed. Simulations will be shown for sites in the North Sea, and compared with observations.

P10/W/23-A5 0930

A COUPLED PHYSICAL-BIOLOGICAL MODEL FOR THE SEASONAL CYCLES OF CHLOROPHYLL AND NUTRIENTS IN THE FIRTH OF CLYDE

JAE-YOUNG LEE and Paul Tett (Department of Biological Sciences, Napier University, 10 Colinton Road, Edinburgh EH10 5DT, UK, Email: j.lee@napier.ac.uk and p.tett@napier.ac.uk)

The Firth of Clyde, located on the west coast of Scotland, receives anthropogenic nutrients from the discharge of the Clyde and other rivers draining much of agricultural and industrial western central Scotland. As a result of these discharges, the Firth of Clyde is enriched in nutrients from agricultural fertilisers and domestic sewage.
A coupled physical-biological model has been constructed to aid understanding of the effects of these nutrients on the biota and oxygen demand. The physical model consists of a set of compartments with turbulent and advective exchanges driven dynamically by density differences and supplies of turbulent kinetic energy. It is forced by freshwater discharge to the Firth of Clyde, meteorology, and boundary conditions in the North Channel. The model was used to quantify the effect of various physical processes during the seasonal cycle, and extended to construct a budget of nutrients for the Firth.
The biological model divides organic particulates into microplankton (phytoplankton plus bacteria and protozoa) and detritus. It has two microplankton compartments, a diatom dominated (or 'diatomy') compartment and a small-cell dominated (or a 'flagellatey') compartment. It cycles carbon, nitrogen and silicon through microplankton, defecated-detritus, phyto-detritus, mesozooplankton and dissolved nutrients compartments.
Climatologically- and meteorologically-forced simulations of several seasonal cycles were compared with historic data, for dissolved oxygen, dissolved nutrients and chlorophyll, in the Firth of Clyde with the aim of using the model as a tool to predict the effects of the perturbations induced by Man or Nature. The importance of coagulation processes for the termination of diatom spring-bloom in the region has been investigated.

P10/W/15-A5 0950

MODELLING THE AGGREGATION AND SEDIEMNTATION OF PLANKTON

WILD-ALLEN, Karen (Dept. of Biologial Science, Napier University, Edinburgh, UK, Email: k.wild-allen@napier.ac.uk)

Variations in aggregation parameters were found to influence the functional group dominance of a mixed population of marine microplankton in a model system. The model cycles organic carbon, nitrogen and silica through microplankton, detritus and dissolved nutrient pools in a 1-D depth-resolving framework forced by turbulent diffusivity. The microplankton are modelled as two mixed populations of pelagic micro-organisms (<200 µm) which include photo-autotrophic micro-algae, cyanobacteria and heterotrophic bacteria and protozoa. One population is dominated by diatoms and includes silica dynamics, and the other by flagellates. This formulation allows a full range of pelagic micro-organisms to be modelled in a computationally efficient manner. Detritus is generated as a by-product of zooplankton grazing and by aggregation of diatom-type microplankton into phytodetritus which sinks rapidly (100m/day). Seasonal cycles of biomass show Spring and Autumn blooms with a shift from diatom to flagellate dominated communities as aggregation parameters increase. At higher rates of aggregation the Autumn bloom is larger and increasing amounts of nutrients in the euphotic layer remain unused. These results demonstrate the influence of aggregation processes in all parts of the pelagic system. This is important in relation to change in species balance in eutrophication, and in the export of organic material from the oceans surface.

P10/W/28-A5 1010

THE ROLE OF TURBULENCE IN DRIVING PRIMARY PRODUCTION AT SHELF SEA FRONTS

Jonathan SHARPLES, (Southampton University School of Ocean and Earth Science, Southampton Oceanography Centre, Empress Dock, Southampton, SO14 3ZH, UK,
email: j.sharples@soc.soton.ac.uk)

Shelf sea, or tidal mixing, fronts mark the physical transition between mixed and stratified water columns during summer in temperate shelf seas. These fronts are also known to be regions of enhanced primary productivity compared to the mixed and stratified waters on either side. This productivity requires an input of new nutrient (nitrogen) into the photic zone at the front, but the mechanisms behind this nutrient supply are not yet well understood. A simple model of the physical structure of a front, using a turbulence closure scheme to describe the temporal and spatial variability of vertical turbulent exchange, has been coupled to a model of primary production to simulate possible nutrient supply mechanisms. Two processes are investigated: nitrogen supply through the weakening stratification associated with the front, and spring-neap variability of frontal position leading to a fortnightly replenishment of surface nitrogen within the transition zone. The basic result shows that consideration solely of the cross-frontal change in vertical turbulent mixing is sufficient to explain typical observations of phytoplankton biomass, with both surface frontal and sub- surface thermocline concentrations being predicted. The addition of spring-neap tidal variability results in fortnightly pulses of frontal productivity and biomass, again similar to available observations. The model results are then used to further investigate nitrogen fluxes, nitrogen uptake, and phytoplankton growth rates within the front, leading to two important conclusions. First, for a phytoplankton with a deep critical depth, the vertical flux of nitrogen into the frontal photic zone is dominated by the flux of algal nitrogen rather than the direct physical mixing of dissolved inorganic nitrogen. This could help explain why recent estimates of dissolved nitrogen fluxes at a front are less than the estimated nitrogen requirements of the frontal productivity. Second, the total annual production at a front is altered significantly when spring- neap variability in the tidal mixing is included. For a phytoplankton with a deep critical depth, total production is predicted to be 20% less with a spring-neap cycle. For a phytoplankton with a shallow critical depth, total annual production with a spring-neap cycle increases by 50%. Consequences of these results for the design of experiments aiming to quantify annual production in shelf waters will be discussed. The conclusions can also be applied to ocean fronts in general, rather than being limited to tidal mixing fronts in shelf seas.

P10/E/06-A5 1050

HORIZONTAL TRANSPORT OF MARINE ORGANISMS RESULTING FROM INTERACTION BETWEEN DIEL VERTICAL MIGRATION AND TIDLA CURRENTS OFF THE WEST COAST OF VANCOUVER ISLAND

C.L. SMITH (Institute of Ocean Sciences, Sidney, B.C., Canada, email: smithcl@dfo-mpo.gc.ca)A.E. Hill (School of Ocean Sciences, University of Wales, Bangor, Wales, U.K.) M.G.G. Foreman (Institute of Ocean Sciences, Sidney, B.C., Canada) M.A. Peña (Institute of Ocean Sciences, Sidney, B.C., Canada)

This paper examines horizontal transport of marine organisms, resulting from the interaction between diel vertical migration (DVM) and numerically generated tidal and buoyancy currents

for the continental shelf and slope off Vancouver Island, Canada. DVM behaviour is simulated by migrating particles which are in the surface layer at night and near the bottom during the day. Eight tidal constituents, the tidal residual and typical summer buoyancy flows are calculated for the region using a 3-D barotropic finite element model. The interaction of these tides with migrating particles is investigated using the finite element model and Lagrangian particle tracking techniques in spatially heterogeneous tidal and buoyancy flows. DVM-tidal interaction alters the horizontal distance particles travel compared to non-migrating particles. We show that the K1 tidal constituent dominates transport patterns, producing regions of convergence and divergence, and on and offshelf transport along the continental shelf. During April and May, particles are transported from offshore onto the southern shelf and into Juan de Fuca Strait. From June to October, this pattern is reversed and there is a general offshore migration of particles. As the K1-DVM beat period is exactly 1 year, these patterns are reversed 6 months later, and do not change from year to year. When a typical summer buoyancy flow is included, the effect of DVM-tidal interactions is reduced, with buoyancy flow dominating transport of particles over most of the domain. However, cross shelf transport resulting mostly from K1-DVM interaction is shown to be important in the southern shelf in the La Perouse Bank area. This process may provide a partial explanation of observed changes in seasonal and interannual zooplankton biomass in the region.

P10/E/09-A5 1110

STARTING OF PHYTOPLANKTON SPRING BLOOM IN THE NORTHERN NORTH SEA (FLADENGROUND)

DILEC H.TOPCU, Birgit Mieding, Uwe H.Brockmann, Venugopalan Ittekkot (all at University of Hamburg, Centre for Marine and Climate Research, Inst. for Biogeochemistry and Marine Chemistry, Martin-Luther-King-Platz 6, 20146 Hamburg, Germany, e-mail: fg8z001@public.uni-hamburg.de)

In the Fladenground in 1976 the start and development of the phytoplankton spring bloom was studied in the frame of an international project (FLEX'76). In March/April 1996 the starting conditions of the blooming were investigated again. Along a transect from the German Bight to the Fladenground different blooming situations were found: blooming in the shallow German Bight and nutrient reduced water masses originating from the continuous production on the Doggerbank, interrupted by vertically mixed water masses without blooming indications. Only in the Fladenground chlorophyll maxima, reaching 0.15 (g/L, developed in depths between 10 and 40 m, showing during a 4 days lasting drift experiment diurnal variation, coupled with a weak vertical temperature gradient of 0.01 to 0.40C, and decreases of nitrate and silicate, and increase of particulate carbon and phosphorus, relecting the start of net production and the beginning of phytoplankton spring bloom. During this situation also a fluctuation of dissolved total amino acids (0.05 to 4 (mol/L) and to some degree also of DON (3 to 8 (mol/L) was observed, indicating the modification of water chemistry right up from the beginning of spring bloom.

P10/E/07-A5 1130

CONVERSION OF NUTRIENT ELEMENTS N AND P IN THE ELBE RIVER PLUME, GERMAN BIGHT

UWE H.BROCKMANN, Thomas Raabe, Andreas Starke (all at University of Hamburg, Centre for Marine and Climate Research, Inst. For Biogeochemistry and Marine Chemistry, Martin-Luther-King-Platz 6, 20146 Hamburg, Germany, e-mail: brockmann@rrz.uni-hamburg.de)

In the German Bight within the propagating river plume of the Elbe during summer 1994 and spring 1995 drift experiments were performed in order to study the conversion of nutrients, dissolved and particulate organic matter. In spite of moderate changes of the water masses, marked by the drifter, the succession of nutrient uptake, formation of particulate matter in the mixed layer and modification of the dissolved organic fraction of N and P could be followed. The drift experiments lasted 9 and 10 days and were accompanied by repeated investigations of the surrounding area. By this, the extension of the river plume and the regional representativity of the development in the drifting field could be identified. During spring at the central drift station nitrate decreased with 2.5 (mol/l d, partly compensated by an increase of 1.8 (mol/l d PN, phosphate decreased by 0.05 (mol/l d coupled with an increase of 0.03 (mol/l d of PP. Due to the accelerated remineralisation during summer there was a net nitrate decrease of 0.04 (mol/l d observed but an PN increase of 0.11 (mol/l d. Phosphate decrease (0.02 (mol/l d) was larger than the PP increase (0.002 (mol/l d) at this time. However, in the bottom water increases of nutrients were observed, especially for phosphate. During summer nutrient concentrations in the bottom layer were higher than in the mixed layer, reflecting the more important regeneration mode during this season. Mainly during spring the conversion rates at the drift station in the river plume corresponded to overall net conversion in the German Bight.

DYNAMICS OF FINE SEDIMENTS IN SHELF SEAS: OBSERVATIONS, PROCESSES AND MODELLING

Juergen Suendermann (Zentrum fuer Meeres- und Klimaforschung, Universitaet Hamburg, Troplowitzstr. 7, 22529 Hamburg, Germany, email: suendermann@ifm.uni-hamburg.de

The global change of our environment is a consequence of variable matter fluxes between land and ocean. An essential part of these fluxes is represented by the transport of suspended particulate matter (SPM). SPM consists of anorganic and organic constituents, and its dynamics is determined by physical and biological processes and their interactions. Field observations show a distinct dependency of SPM concentrations on currents and waves as well as on input from rivers and land. The key processes of SPM transport are sinking, deposition and resuspension. They are controlled by the current regime (advection, turbulence, orbital motion) and by biological factors as aggregation, filtration or bioturbation. A high-resolving 3D Lagrangean tracer model will be presented containing all these components. The time scale covered ranges from hours to years. The model is applied to the North Sea, to the Bohai Sea (China), to the German Bight and to the river Elbe. The numerical results are discussed and interpreted against observational data of SPM concentrations and bottom sediments.

P10/W/01-A5 1420

APPLICATION OF A 3-D HYDRODYNAMIC-WATER QUALITY COUPLED MODEL TO KOREAN WATERS IN THE YELLOW SEA

CHANG S. KIM (Korea Ocean R&D Institute, Coastal Engineering Division, 1270 Sadong, Ansan, 425-170, South Korea. Email: surfkim@kordi.re.kr)

A 3-D hydrodynamic-water quality coupled model is used to simulate the impact of river discharge, nutrient loads and dynamic forcings on the variability of coastal waters. The model consists mainly of two modules; hydrodynamics and water quality parts. Both modules are directly coupled in computation scheme. The hydrodynamic model is originated from the Blumberg-Mellor algorithm and extended at Virginia Institute of Marine Science, USA to include further processes such as tidal flat, etc. The water quality module has been adapted from the CE-QUAL-ICM developed by the WES of US Army Corps of Engineers. The module deals with 25 state variables including temperature, salinity, DO, nitrogen, phosphate, suspended matter, etc. The coupled model has been applied to the waters of Kyunggi Bay, where rivers flow in with terrain nutrient loads. The model uses the curvilinear grid system with grid size ranging from 200 m to 9 km. The study area shows the maximum tidal range of approximately 11 m and wide tidal flats. This study shows the result of the model implementation for the water quality prediction in macro-tidal coastal and shelf waters off Korea.

P10/E/13-A5 1440

PROCESSES CONTROLLING THE DISTRIBUTION OF SOLID RUN-OFF OF THE TUMANNAYA RIVER (PETER THE GREAT BAY, JAPAN SEA)

Alexander Moshchenko, Konstantin Feldman (both at Institute of Marine Biology, Russian Academy of Sciences, Far-Eastern Branch, Palchevskogo str., 17, 690041 Vladivostok, Russia, email: inmarbio@mail.primorye.ru). Gennady YURASOV, Nikolay Vanin (both at Pacific Oceanological Institute, Russian Academy of Sciences, Far-Eastern Branch, Baltiyskaya Str., 43, 690041 Vladivostok, Russia, email: pacific@online.marine.su)

The region studied extent is 30 km offshore and 35 km northward from the mouth of the Tumannaya River. It includes the territory of the Far Eastern State Marine Reserve. Presumable economical development of the Tumannaya River mouth area requires to study how to minimize possible anthropogenic impact on environs. That's why the processes defining natural sedimentation in the coastal area are to be important for understanding of possible unfavorable consequences for the region. Bottom sediments of the region studied are presented by a complex of terrigenic deposits from coarse sands to aleurites-pelites. The content of fine fractions varies from 1 to 45%. Their distribution have distinctive contagious character. Along with that the spots of aleuro-pelites prevailing are found closely to the mouth of the Tumannaya River and at 20-25 km off north-eastward. Results of numerical modeling of circulation on a basis of shallow water equations and instrumental observations reflect in whole the features of sediments distribution. Due to monsoon climate the maximal values of solid run-off of the Tumannaya River are observed during summer period, when the winds of the southern routes are prevailed. The schemes of circulation are defined mainly by the bottom relief features and the wind direction. For the south-western winds the transportation of suspensions and pollutants occurs north-eastward along the coastline. During the south-eastern winds an anticyclonic eddy is formed over the northern part of the region studied that also produces favorable conditions for sedimentation northward from the mouth of the Tumannaya River. But most unfavorable consequences for Marine Reserve should be expected in summer season during moderate and strong south-western wind.

P10/E/18-A5 1500

INFLUENCE OF CLIMATIC AND OCEANOGRAPHIC PROCESSES ON FORMATION OF COASTAL SUBWATER LANDSCAPES AND CONDITION OF BENTHOS (BLACK SEA)

Alexei PETROV ,Vladimir Shalyapin and Sergey Ignatyev (all authors at Institute of Biology of the Southern Seas, 2, Nakhimov av., 335011 Sevastopol, Ukraine, email: benthos@ibss.iuf.net)

The large-scale subwater landscape/ecological investigation have been made in 1993-96 along the coastal zone of SW Crimea at 0-40 m depth. In hydrological regime of this area role of breeze effect is very significant. Daily alterations in spatial pattern of wind currents define the unsteadiness of thermocline structure mostly revealed in early summer period. Such fluctuations impact on hydrological and biological peculiarities. To differentiate landscape facies, the data on hydrodynamics, seabed microrelief and slope, grain-size structure of bottom substrate as well as quantitative characteristics of phyto- and zoobenthos were used. As a result, 7 different bottom landscapes were distinguished. In the shallow (2-8 m depth) water areas with maximum hydrodynamic load (current velocities fluctuated 0.35 to 0.60 m/s) geomorphology were represented only by cliff and rocks sloping down at 8-14o and covered by Cystoseira spp. and mussels. Within 10-15 m depth a steepness of underwater slope reduced to 4-7o and velocity of wind currents to 0.12-0.23 m/s. Mosaic pattern of grounds promotes development of landscapes with high diverse in such groups of benthos as mobile predatory ectobionts and less abundant sessile filter-feeders. Sandy and silty grounds covered by meadows of eelgrass Zostera spp. Below 18-20 m depth, where the steepness does not exceed 1-2o and velocity of currents 0.03-0.05 m/s, a fine sand factions with admixture of shell debris and silt prevailed. Phytobenthos is scarce; in zoobenthos endobenthic suspension-feeders, epibenthic mobile deposit-feeders dominate. Comparative temporal analysis of landscapes patterns and condition of biota has manifested that about 15% of coastal rocky substrates covered earlier by brown algae and mussels have been destroyed due to anthropogenic eutrophication of water areas and hydrotechnical construction and replaced by cenoses wherein indicators of eutrophication (green algae) prevail. Biodiversity of soft-bottom macrobenthos also reduced and degradation of sensitive to eutrophication indicator species has been observed. The processes of mudding leads to expand a bottom areas covered with Zostera growth that contributes to accumulation of organic matter and formation of unfavorable oxygen conditions in such sites, gradual degradation of benthic assemblages associated with meadows of eelgrass.

P10/W/24-A5 1520

THE INTERACTION OF SHALLOW WATER AND COULOMB-DAMPED POROELASTIC BED

Mian Li (Institute of Mechanics, CAS, Beijing 100080, China, Email: rxzhu@mail.c-geos.ac.cn)

In many cases of coastal engineering, e.g., constructions of coastal structure and breakwaters, piple lines, etc., Correct estimations of the dynamic behavior of seabed and propagating water wave are very important. However, due to the fact that in most cases the seabed is permeable and deforming, and the water wave, in general, is nonlinear, the studies of the interaction between the water waves and seabed are very complicated.
Now the theory of shallow water waves has been applied and the seabed is regarded as compressible and deformable. Not only the wave propagation over coulomb-damped poroelastic bed has been considered, but also the porous pressure in the seabed take into account. Nonlinear shallow water equation of boussinesq type and nonlinear dispersion relation for shallow water are derived. It is found that wave damping is agreement with the experiments, as the coulomb friction between grains is considered. Porous pressure in sand and clay has been calculated. There is an extreme value of porous pressure in some depth of clay bed and the depth is compared with the resonant depth.

P10/E/11-A5 Poster **1600-01**

TIDAL AND SUBTIDAL CIRCULATION ON THE SOUTH BRAZILIAN CONTINENTAL SHELF

O. MOLLER Jr., D. Urbano Neto (both at Lab. Oceanografia Fisica, Depto. Fisica, Universidade do Rio Grande, 96201-900 Rio Grande, RS, Brazil; email: osmar@calvin.ocfis.furg.br)
P. Zavialov (Shirshov Institute of Oceanology, Moscow, Russia, email: zavialov@mi.ras.ru)

In order to characterize the water circulation and dynamics of Rio Grande do Sul continental shelf, time series of current and wind vectors covering a period from March to May of 1997 are analysed. A mooring station with two current meters that registered hourly values of current velocity and direction at the depths of 15 m and 45 m was deployed in the point 32 41'S, 51 27'W. The results indicate that the prevailing current direction was to NE despite of the predominantly NE winds. This indicates a geostrophic flow related to the cross shore density gradient and local sea surface elevation forced by freshwater discharge from Patos Lagoon and Plata River. The wind forcing resided mostly at the sinoptic time scale in the range between 3 and 10 days. The tidal influence was small.

P10/W/21-A5 Poster **1600-02**

NUMERICAL STUDIES OF UPWELLING OFF ZHEJIANG AND FUJIAN

Yiyong LUO and Guangyao YU Institute of Physical Oceanography, Ocean University of Qingdao Qingdao, 266003, CHINA

The waters off Zhejiang and Fujian in the East China Sea have anomalously low temperatures and high nutrients during summer. The contribution of tidal current, wind stress and Taiwan Warm Current (TWC) to the anomaly of temperatures and nutrients is individually discussed by using a three dimensional numerical model as well as field observations. The result reveals that there exists a tide-induced upwelling stripe off Zhejiang and Fujian, and its large ranges appear off Zhoushan Islands and north of Fujian where the tidal currents are strong and the variations of bottom topography are large. The result also shows that there exist wind-driven and TWC-driven upwelling stripes off Zhejiang and Fujian, and their ranges are more and more smaller from the south to the north. The computed largest upwelling, 0.0005cm/s for tidal current, occurs in upper layer (10-20m), 0.001cm/s for wind stress in middle layer (20-30m) and, 0.001cm/s for TWC in bottom layer (below 30m). The combination of tide-induced, wind-driven and TWC-driven upwelling provides the mechanism for producing the observed cold water anomaly off Zhejiang and Fujian. In addition, the source of these anomalous waters is discussed by using the Eulerian-Lagrangian method. Results show that the anomalous waters originate from Kuroshio subsurface waters climbing up the continental shelf northeast of Taiwan Island.

MODEL OF WATERS CIRCULATION ON A CONTINENTAL SHELF WITH THE HIGH SPATIAL RESOLUTION (ON AN EXAMPLE OF THE BARENTS AND KARA SEAS)

SEMYONOV G.A., Bezgreshnov A.M. (both at Arctic and Antarctic Research Institute, Bering st., 38, St.-Petersburg, Russia, 199397. E-mail: geosem@ecoshelf2.spb.org)

The calculation of currents on a grid with the high spatial resolution imposes, as a rule, restriction on the sizes of modeling area, that results in appearance of opened (liquid) borders of a model do-main. On opened borders the budget of a liquid either are unknown, that calls the inadequate results of computation of currents in shelf zones. The merging of global and regional model grids does not result in significant reduction of an error in the task of determine of the fluxes on borders of a grid with the high resolution. In order to prevent the specified above difficulties in simulation of circula-tion of waters and ice, and also for calculation of fluxes of solid substance and various pollutions for Barents and Kara seas the non-uniform model grid in spherical system of coordinates with a pole located in a point 65° N and 60° E was designed. The modeling area covers all Polar Ocean. The horizontal resolution of this grid varies from 4 km in a coastal zone up to 19 km in a strait be-tween Spitsbergen and Franz-Josef Land and reaches 120 km in Bering and Danish straits. The ver-tical resolution of the model grid is the 20 levels. For calculation of water circulation, fluxes of solid substance and pollutions is constructed the efficient numerical model. Step of integration on time can change from 0.5 till 12 hours. This model based on the complete equations of hydrother-modynamics of ocean with used of a hydrostatics and Boussinesque approximation with free sur-face, with registration of tidal component and parameterization of upper mixed layer. Also in model took into account the flux of energy from broken of superficial wind's waves.
The simulation of waters circulation in Barents and Kara seas for average year, for separate seasons and for differences state of atmosphere parameters are carried out. The analysis of water circulation in upper and bottoms layers of the specified seas is executed.

PROCESSES OF VERTICAL EXCHANGE IN SHELF SEAS (PROVESS)

John HOWARTH (Centre for Coastal and Marine Sciences, Proudman Oceanographic Laboratory, Bidston Observatory, Birkenhead, Merseyside, L43 7RA, UK, email: mjh@ccms.ac.uk)

Vertical exchanges are principally controlled by the water column's turbulence characteristics. Turbulence is generated at the sea surface, by winds and waves, and at the bed, by friction. At the pycnocline turbulence levels are reduced and vertical fluxes can be inhibited. Turbulence characteristics therefore depend on and affect the water column's thermodynamics and dynamics and their interaction with the sea bed and surface.
An aim of the project is to test turbulence closure models, which are commonly used to quantify fluxes in shelf sea environmental models of, for instance, heat, of particles and of nutrients into the photic zone. Of particular importance are fluxes across the thermocline and the determination of which processes control nutrient recycling in the benthic boundary layer where a key will be to distinguish processes in the water column from those in the fluff' layer formed by freshly deposited particulates, from those in the compacted sediment.
Measurements of turbulence dissipation rate throughout the water column and intensity over a wide frequency range, and of fluxes near the sea bed are being made at two contrasting sites in the northern North Sea. The first set of measurements were made during the autumnal breakdown of stratification in the northern North Sea in 1998 and the second, at a shallow high tidal energy site in the southern North Sea, will be in spring 1999. The project will contribute to the development of robust water column plankton shelf sea models tested over a range of turbulence environments.

USING SURVEYS OF AN UPWELLING JET NEAR A CAPE TO EVALUATE LAYERED MODELS OF JET SEPARATION

Andrew C. DALE and John A. Barth (both at College of Oceanic and Atmospheric Sciences, Oregon State University, 104 Ocean Admin Bldg, Corvallis, Oregon 97331-5503, USA,
E-mail: acd@oce.orst.edu)

During the upwelling seasons of 1994 and 1995 the coastal upwelling jet off Cape Blanco on the Oregon coast was surveyed using a CTD mounted on an undulating SeaSoar vehicle and shipboard ADCP. The observed fields show a tendency towards intensified upwelling in the lee of the cape accompanied by separation of the jet from the shelf and flow into the deep ocean. It is clear, from SST images, that these features are typical of the region. Layered models governed by potential vorticity conservation predict the evolution in structure of a coastal jet as it encounters gradual changes in topography, latitude and coastline curvature. The applicability of such models to the Cape Blanco region is investigated in the light of three dimensional dynamical fields derived from the survey data. A significant feature of the models is that when a jet passes a topographic anomaly (such as a constriction of shelf width) its structure can smoothly distort to a new downstream state. This happens when the flow is exactly critical to long coastal-trapped waves, a condition that is especially likely to be satisfied at some time by an upwelling jet as it evolves during the course of an upwelling season. Such a critical transition can lead to strongly enhanced upwelling in the lee of a cape and may be interpreted as jet separation. The likelihood of wave criticality is here determined by direct calculation of coastal-trapped wave phase speeds for the observed stratification and jet structure. The premise of potential vorticity conservation is also investigated for the alongshore scales of interest.

SHELF WAVES AS A CONTROL OVER THE FLOW, TEMPERATURE AND NUTRIENT SUPPLY IN SALDANHA BAY, SOUTH AFRICA

Grenville NELSON (Sea Fisheries, Department of Environmental Affairs, Cape Town.)

Saldanha Bay is a semicircular indentation on the west coast of South Africa centered on latitude 330 5'S with an area 1.41x108 m2 . A lightly dredged central channel drops from 12m at the centre of the bay to 40m at the mouth, which is some 6 to 7km wide. The adjacent narrow shelf supports the passage of energetic barotropic coastal-trapped waves, with a period of 5 to 6 days. The cross-shelf component of these waves acts to drive cold water into the bay below the wind influenced layer on the eastward phase. This is the dominant driving mechanism controlling temperature and nutrient supply and consequently primary productivity. The energetic six-day period waves appear to be forced by the synoptic pressure field over the southeast Atlantic. Also present in the spectra are less energetic waves at three and four days. These are the freely propagating coastally trapped waves generated locally by wind, and when their phase corresponds to that of the forced wave, the amplitude is great enough to produce a shelf water penetration of 4km into the bay. Under these conditions, upwelling favourable winds exacerbate the inward movement of bottom water, which is entrained into the surface layer in the shallowest parts.
Tidal flow, generally of little significance on this coastline, can be an important factor in this bay at the spring tide. A tidal lagoon of area 5.3x107m2 connects with the eastern part of the bay.

INDIRECT OBSERVATIONS OF DEIL MIGRATION ON THE HEBRIDEAN CONTINENTAL SHELF

T.P. RIPPETH and J.H. Simpson (School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey, UK, LL59 5EY.)

In this poster we shall consider the interpretation of measurements of vertical velocity and backscatter intensity, made using an acoustic doppler current profiler (ADCP) moored on the Hebridean Continental Shelf. The existance of vertically migrating scatterers is inferred from both the backscatter signal intensity and vertical velocity data, which indicates migration rates of 2-3 cm/s, and shows consistancy between the displacement deduced from the vertical velocity and the observed movement of scatterers from the near bed to the near-surface region, evident in temporal variations in the backscatter signal intensity. Independent evidence that the observed vertical velocities are largley due to movements of the acoustic scatterers relative to the water is obtained through comparison of the ADCP vertical velocity data with vertical velocities inferred from the movement of the thermocline. The close phase locking between the motion and sunset and sunrise times has led us to interpret the signal in terms of the deil migration of zooplankton. Although no biological samples were collected during this study, previous surveys of the area have identifed species of copepod and euphausiid that are known to migrate. The 12 days of data available show an initial period, during which there was a strong vertical migration signal, and a later period, during which the signal was not clear. By combining the observed vertical velocity and horizontal velocity components in a particle tracking model, it is demonstrated that the change in the migration signal may be a result of the advection of the patch of migrating zooplankton away from the ADCP, during the later part of the observational period.

ANALYSIS OF THE GEOMORPHOLOGICAL TRENDS FOR THE SOUTHERN CURONIAN SPIT LAGOONIC COAST

TATIANA A. DORMOLENKO, Boris V. Chubarenko (P.P.Shirshov's Institute of Oceanology of Russian Academy of Sciences, Atlantic Branch, Prospect Mira, 1, 236000, Kaliningrad, Russia,
E-mail: chuboris@ioran.kern.ru)

The Curonian spit is the largest (near 100 km) accumulative coastal macro-form in the South-Eastern Baltic and separates the Curonian lagoon from the Baltic Sea. It is mostly covered by forest but also has the areas of opening dune and the wetlands. The sand basis of the Curonian spit determines both the high velocity of shore-line shape changing and the instability of the vegetation free areas. The objective of this work consists in the quantification and analysis of the morphological trends of the Curonian spit lagoonic littoral from 1955 till 1994 years and assessing the influence of dune stripes on these trends. Practically important problem is the evaluation of the dune cells nourishment distribution downwards the underwater coastal slope and especially alongshore from open dune cells. Such knowledge is necessary for the optimization of trees planting program aiming to dunes fixation and for the using of the open dune stripes to compensate the shore erosion. The temporal variations (1955-1995) of the coastline, depths of 1, 2, 3 meters and underwater deposit volume were numerically appraised on the basis of comparative cartometric survey for the Curonian spit lagoonic coast. The analysis was executed for the set of sequential sites of the littoral, which were selected by coastline partition with a number of shore-normal cross-sections. The main geomorphological trends for the indicated above period were quantified. The shore-line of dune cells has promoted into lagoon and the littoral of these cells has got more shallow. The coastal line and littoral of the other cells have been eroded. The influence of dune nourishment on the stability of the coastline and littoral sites adjacent to dune cells was assessed. The trends in the alongshore and downwards sediment distribution were revealed.

OBSERVATIONS OS SEDIMENT RESUSPENSION AND TRANSPORT IN THE COASTAL AND BOTTOM BOUNDARY LAYERS OF LARGE LAKES WITH ACOUSTIC DOPPLER CURRENT PROFILERS

SALYOR, James H. and Gerald S. Miller (Both at: National Oceanic and Atmospheric Administration, Great Lakes Environmental Research Laboratory, 2205 Commonwealth Blvd., Ann Arbor, MI 48105; e-mail: saylor@glerl.noaa.gov)

Data from Acoustic Doppler Current Profilers (ADCP) deployed in the nearshore region of southeastern Lake Michigan provide evidence of sediment resuspension and the cross-shelf transport of these materials during episodes of winter wind storms. Significant increases (+20 dB) in echo intensity and current velocity correlate well with satellite imagery of a sediment-laden plume transporting material in a cyclonic flow around the basins perimeter. A decrease in echo intensity to near background levels following the resuspension event suggests that the larger particles settle out, leaving the very fine material that remains visible in satellite imagery for many days. In Lake Champlain, a long, narrow and deep lake that forms the boundary between the states of New York and Vermont, bottom sediment resuspension caused by surges and gravity currents in the density-stratified lake water has also been documented in acoustic profiler records. Although no concurrent measurements of Total Suspended Material have been achieved in either lake, the ADCP results show that resuspension events can be detected using these instruments. With calibration of sediment concentration and echo intensity at each site, it appears that quantitative values of sediment fluxes can be determined.

WATER MASS FORMATION PROCESSES

P12/W/03-A1 **0830**

SOME HISTORICAL, THEORETICAL AND APPLIED ASPECTS OF QUANTITATIVE WATER MASS ANALYSIS

Matthias TOMCZAK (School of Earth Sciences, The Flinders University of South Australia, GPOP Box 2100, Adelaide SA 5001,Australia, Email: matthias.tomczak@flinders.edu.au)

The concept of water masses is reviewed from the point of view of quantitative water mass analysis. A theoretical framework is presented which describes the life history of water masses in terms of formation, consolidation, ageing and decay. Water masses are described as physical entities and compared with their atmospheric counterparts (air masses). The classical temperature-salinity diagram is expanded into the mathematical concept of water types in an n-dimensional parameter space. Water types and their standard deviations are introduced as the foundation for quantitative water mass analysis. The relationship between parameter space and physical space is established through the definition of water type density. Mode Waters are discussed as regions in physical space with a minimum in water type density. Some unresolved issues of the structure of the oceanic thermocline are discussed in this context. The definition of water masses is extended to include water masses in the surface mixed layer where air-sea exchange processes continuously modify water mass properties. The paper concludes with a brief discussion of the representation of water masses and their evolution in numerical models.

SUBDUCTION RATES FOR THE SOUTHERN INDIAN OCEAN THERMOCLINE

J. KARSTENSEN and D. Quadfasel 1) Institut für Meereskunde, University of Hamburg, Germany 1) now at: NBIfAFG, University of Copenhagen, Denmark

Using a kinematic as well as a transient tracer/oxygen approach, the subduction rates for water into the southern Indian Ocean thermocline were calculated and compared. For both techniques, the rates were found to be of the same magnitude with respect to the error margins. Comparing Ekman and Ekman+lateral induced rates in density increments of the winter mixed layer, the side-by-side existence of Indian Central Water and Mode Water is evident. The total volume of subducted water into the permanent thermocline was found to be 32 Sv for the density range 25.3 to 26.9 kg/m_. This is comparable to recent estimates for the North Atlantic (27 Sv) and North Pacific (35 Sv) Ocean. However, the proportion of the lateral volume transport in the Indian Ocean (21 Sv) is twice as large compared to the northern hemisphere oceans (NA 9.5 Sv; NP 10.1 Sv). This is in agreement with the large volume of Mode Water, which can be found in the Indian Ocean. The formation of the Mode Water through mid-latitude convection is located south of the subtropical front, whereas its subduction in the thermocline is lateral, as a combination of the eastward flow field along the front combined with the southern tilting of the front. Relating the rates to tracer distribution in the winter mixed layer depth, enabled us to determine source tracer characteristics of the Mode and Central Water, respectively. The characteristics may be used for further mater mass mixing analysis.

TWO VARIETIES OF SUBTROPICAL LOWER WATER (SLW) IN THE SOUTH PACIFIC: THEIR ORIGIN AND DISTRIBUTION

Serguei SOKOLOV and Stephen Rintoul (both at CSIRO Marine Research and Antarctic Cooperative Research Centre, GPO Box 1538, Hobart, Australia, email: Serguei.Sokolov@marine.csiro.au and Steve.Rintoul@marine.csiro.au)

Two varieties of SLW are present throughout the western part of the South Pacific: a cool, fresh variety is situated north of New Zealand, and a warm, salty variety is found north of Fiji and the New Hebrides. New data from a roughly meridional WOCE section P11 along 155E between the Subtropical Front and Louisiade Archipelago at 12S occupied in winter 1993 help refine some details of the SLW origin and distribution in the region. The warm and salty northern variety of SLW is formed in the central South Pacific near the Society Islands where a surface salinity maximum coincides with a maximum in evaporation minus precipitation. The subsurface salinity maximum of the SLW in the western South Pacific is a result of these high salinity surface waters being carried west in the northern arm of the subtropical gyre and under-riding lighter, low salinity water produced by an excess of precipitation over evaporation in the western tropical Pacific. South of 25S on P11 the salinity maximum reaches the sea surface marking the northern boundary of the cooler, fresher, denser southern variety of SLW. The southern boundary of the southern SLW on P11 is marked by the strong near-surface horizontal salinity gradient associated with part of the Subtropical Front at 38S. The formation region of the southern type of SLW - the Central Tasman Sea - also coincides with a maximum excess of evaporation over precipitation. This region also experiences strong cooling by the atmosphere, driving winter convection. Deep mixing during winter increases the oxygen content of the surface layer. The water which feeds the formation zone of southern SLW is the northern variety of SLW. Cooling and evaporation convert about 5 Sv of northern SLW to southern SLW in the Tasman Sea. Ventilated SLW carried eastward by the EAC spreads around the subtropical gyre of the South Pacific and is driven northward beneath the Tropical Convergence zone by Ekman pumping (Morris at al., 1996). The high-oxygen southern SLW under-rides the newly formed northern SLW in the central Pacific. The two super-posed varieties of SLW are carried westward to the Coral Sea in the SEC along the northern flank of the subtropical gyre. Here the two components of SLW are separated by only 40-60 m in depth and become almost indistinguishable within the cyclonic gyre of the Coral Sea. The total net inflow of SLW into the Coral Sea in the neutral density layer between 23.6 and 26.8 is 32 Sv, with 10.1 Sv re-circulating in the Gulf of PNG and entering the Solomon Sea. The remainder of the SLW turns south to feed the EAC.

THE ORIGIN OF WATERS OBSERVED ALONG 137°E

Frederick BINGHAM (UNC-Wilmington, Wilmington, NC 28403 USA;
Email: binghamf@uncwil.edu) Toshio Suga and Kimio Hanawa (both at: Department of Geophysics, Tohoku University, Sendai 980-77 Japan; Email: suga@pol.geophys.tohoku.ac.jp)

Using the World Ocean Atlas data set, we examine the origins and flow paths of waters observed along 137°E section in the western North Pacific. The method of Bingham (1999) was used to trace waters from 137°E back through the subtropical gyre to their outcrops. We divide the water masses observed along this section into four zones. (1) There is a zone of waters that connect directly to areas of surface subduction, chiefly the water mass known as North Pacific Tropical Water. Working backward along geostrophic streamlines, we find the locations of the outcrops of these waters. Subducted waters are aged using this technique and found to be between 0.5 and 35 years old by the time they reach 137°E. For this subducted regime, waters on a given isopycnal observed along 137°E increase in age with decreasing latitude, with waters at the southern end of the section being 2-3 times older than waters at the northern end. (2) There is a recirculating zone, where waters do not have any direct contact with the surface. Some of these recirculating waters, particularly the North Pacific Intermediate Water are strongly influenced by surface processes outside the subtropical gyre, but are not subducted by Ekman pumping. (3) There are North Pacific Subtropical and Central Mode Waters, which have direct contact with the surface, but mainly through buoyancy forcing rather than Ekman pumping. And (4) there is a seasonal thermocline, where waters are strongly influenced by surface heating and cooling, and isopycnals can disappear during the winter. We use these generalizations to characterize water mass variability observed in the PR-1 hydrographic section along 137°E.

P12/C/JSP21/E/01-A1 **0950**

INTERPRETATION FOR THE FORMATION OF THE CFC MAXIMUM IN THE NORTH PACIFIC

Sachiko OGUMA, Yutaka Nagata(both at Marine Information Research Center, Japan Hydrographic Association, Tokyo 104-0061, Japan) Goro Yamanaka(Oceanographic Division, Meteorological Research Institute, Tsukuba 305-0052, Japan) Toshio Suga and Kimio Hanawa(both at Department of Geophysics, Graduate School of Science, Tohoku University, Sendai 980-8578, Japan)

Chlorofluorocarbon (CFC) maximum layers have been found in the broad area of the Subtropical North Pacific. By using the results which contain the distributions of current and temperature and its variation, obtained by an Ocean General Circulation Model (OGCM) developed by Yamanaka (1997), and by giving spatial (depending on surface temperature) and temporal variations of CFC at the sea surface, we calculate CFC distributions in the North Pacific, and compare them with the observed CFC distribution, especially in the cross-section along 30N. The main feature of the CFC distribution including its maximum layer is well reproduced. In order to find the source area of CFC maximum layer water, trajectory analysis is also made. It is shown that the CFC maximum layer water is originated near the bottom of the winter mixed layer near 39N of the central part of the North Pacific, along the line of outcrop of 25.8 sigma_theta isopycnal surface. However, the distribution derived from an assumption that the CFC concentration is simply advected along trajectories by keeping the values in the injected area is much different from that reproduced in our model which includes the effect of eddy-diffusion. Distribution of CFC concentration would depend not only on advection but also on eddy-diffusion. Using a simple box model checks the relative importance of the advection to diffusion. It is suggested that this ratio is different between in the upper half and in the lower half of the CFC maximum layer. The position of the CFC maximum layer may be located between the regimes where diffusion is dominant and where advection is dominant.

PHYSICAL MECHANISMS OF NORTH PACIFIC INTERMEDIATE WATER FORMATION

Nikolai A. MAXIMENKO (Shirshov Institute of Oceanology, Russian Academy of Sciences, 36, Nahimovskii prospect, Moscow 117851, Russia, email: maximenko@stream.sio.rssi.ru)

Results of isopycnal analysis of mean distribution of seawater properties in the North Western Pacific along with the propagation of seasonal signal point at the western part of the Kuroshio Extension as a formation area of the North Pacific Intermediate Water (NPIW). In addition to critical analysis of conventional theory of dominant role of lateral mixing, some new hypotheses are forwarded. Among them are: cabbeling and frontal convection, density-driven intrusions, geostrophic adjustment both in the confluence zone of subarctic and subtropical watermasses and downstream the current (due to dissipation of its zonal momentum), non-turbulent vertical transfer of zonal momentum (wave radiation and baroclinic interaction, resulting in "form drag"- type effects), interaction between thermocline and deep circulation. In all the cases specific forcing may appear in NPIW layer, making it drifting ageostrophically equatorward. Developed is a scheme of measurements and historical data reanalysis that may verify the importance of this physical mechanisms.

Presiding Chair: Matthias Tomczak (FIAMS, Flinders University)

Introduction 1030

P12/W/15-A1 Poster 1030-01

VARIABILITY OF THE NORTH ATLANTIC WATER MASS STRUCTURE AND CIRCULATION

S.A.DOBROLIUBOV (Department of Oceanology, Moscow State University, Vorobievy Gory, Moscow, 117234, Russia, e-mail: dobro@ocean.geogr.msu.su), A.V.Sokov and V.P.Tereschenkov (both at P.P.Shirshov Institute of Oceanography, Nahimovskiy pr., 36, Moscow, 117851, Russia, e-mail: boba@gulev.sio.rssi.ru)

Interdecadal changes of thermohaline characteristics and circulation of the intermediate and deep waters in the North Atlantic are considered. The results are based on the comparison of the Russian 1997 survey of 60N and WOCE AR5 with historical data. Significant changes of intermediate and deep waters T,S properties are found, accompanied by changes of the cross section mass, heat and freshwater fluxes. The earlier determined intensification of the Meridional Overturning Circulation (MOC) in the 80-s is confirmed. The MOC strengthening is accompanied by the rapid decrease of the recirculation flows and the formation of the well-defined two-layer structure of the MOC. The derived changes of the thermohaline structure suggest that at the phase of intensified MOC the preferable direction of the Labrador Sea Water spreading is north-east into the Irminger Basin, while at the period of reduced MOC the LSW flows preferably to the east and south-east. Enhancement of the southward freshwater transport in the Denmark Strait was closely correlated with the intensification of the northward meridional heat transport; the latter varied from 0.28 PWt to 0.38 PWt at 60N.

P12/W/16-A1 Poster 1030-02

INTERDECADAL CHANGES OF MASS AND MERIDIONAL HEAT TRANSPORT IN THE NORTH ATLANTIC

A.V.SOKOV, V.P.Tereschenkov (P.P.Shirshov Institute of Oceanography, Nahimovskiy pr., 36, 117851, Moscow, Russia; e-mail: sokov@gulev.sio.rssi.ru) and S.A.Dobroliubov (Department of Oceanology, Moscow State University, Vorobievy Gory, Moscow, 117234, Russia, e-mail: dobro@ocean.geogr.msu.su)

Estimates of meridional mass and heat transports across the planes of transatlantic hydrographic sections along 24.5N, 36N, 48N and 59N (computed for the three time periods 1957-1962, 1981-1982 and 1991-1993) are considered. The intensity of the Meridional Overturning Circulation (MOC) didn't change significantly at 59N during the whole time period. While remarkable changes were detected to the south from 59N. Strengthening of MOC occurred at 48N and 36N in 1981-82 (19Sv and 20Sv respectively) against 14Sv and 12Sv in 1991-93 and 9Sv and 8Sv in 1957-59. Intensification of MOC at 24.5N is less profound. The results demonstrate negative correlation between the variability of MOC and Labrador Sea Water (LSW) production rate. The MOC intensification observed in 1980s corresponds to the increase of the mass transport in the Denmark Strait Overflow waters (DSOW) layer at 59N and is accompanied by the increase of the Antarctic Bottom Water (AABW) transport at 24.5N and its upwelling in the area between 24.5N and 36N. During the weak MOC (in the 1990s) the LSW production reached its maximum, the transport of DSOW reduced and the AABW penetrated further to the north than 36N.

P12/W/12-A1 Poster 1030-03

INTERANNUAL VARIABILITY OF THE UPPER OCEAN CIRCULATION AT 36N IN THE ATLANTIC OCEAN

V.P.TERESCHENKOV (P.P.Shirshov Institute of Oceanography, Nahimovskiy pr., 36, Moscow, 117851,Russia, e-mail: boba@gulev.rssi.sio.ru) and A.V.Arkhipkin (Department of Oceanology, Moscow State University, Vorobyivy Gory, Moscow, 117234, Russia, e-mail: arkhip@ocean.geogr.msu.su)

Interannual changes of the ocean steric height at 36N in the Atlantic ocean are considered. The study is based on the temperature and salinity observations in the upper 2000m layer collected by repeated surveys of the cross-ocean hydrographic section during 1972-1984 time period. Variability of the upper layer steric height is inspected in terms of water mass properties variability. Special attention is paid to the evolution of subtropical (18 degree) and subpolar mode waters and Mediterranean waters, regarding their remote relation to the changes of the atmospheric conditions over the sites of their origin. The changes of the upper ocean zonal pressure gradients are discussed in sense of North Atlantic circulation features, such as Gulf Stream, its recirculation jets and Azore Current.

P12/E/01-A1 Poster 1030-04

WATER MASS, TEMPERATURE, SALT AND HEAT EXCHANGE OF ANTARCTIC AND NORTH ATLANTIC BASINS

ANISIMOV M.V., Ivanov Yu.A., Lebedev K.V. and M.M. Subbotina P.P.Shirshov Institute of oceanology, 117851,Nakhimovsky pr.36, Moscow, Russia, Tel.: (095)124-7729; fax: (095)124-5983; e-mail: MMS@sio.rssi.ru, MVA@sio.rssi.ru

On the base of ocean general circulation model with using of climatological massive (Levitus, 1994), we calculated temperature, salinity, density, free surface level and current fields in the North Atlantic and Arctic basins. We defined the integral mean annual and mean seasonal characteristics of water mass, salt and heat transports. Also we fulfilled the analysis of inter seasonal redistribution of water mass, salt and heat transports for climatic seasons. Estimates of climate averaged variability of integral transports were made.

P12/E/06-A1 Poster 1030-05

THE SPREADING OF RED SEA OVERFLOW WATERS IN THE INDIAN OCEAN

LISA M BEAL and Amy Ffield (Lamont-Doherty Earth Observatory, Palisades, NY 10964, USA. Email: lbeal@ldeo.columbia.edu)

As a result of its remarkably high salinity and low oxygen content, remnants of Red Sea Waters (RSW) have been identified in the southwest Indian Ocean, over 50f south of their source. Here we describe the mean pathway for the spreading of RSW throughout the Indian Ocean. A comprehensive set of observations is used, taken from the National Oceanographic Data Center archives and from the World Ocean Circulation Experiment Hydrographic Program for the Indian Ocean. The analysis suggests that the large scale salinity and oxygen distribution of the Indian Ocean is stationary at intermediate depth, indicating that there is little monsoon or interannual variability. From property maps the spreading of RSW appears to be favoured along the western boundary, particularly south of the westward flowing South Equatorial Current, where there is a clear tongue of RSW spreading through the Mozambique Channel and into the Agulhas Current. The property distributions imply a predominantly diffusive mixing regime in the ocean interior with a stronger advective component at the western boundary. The evidence for a long-time-mean pathway for RSW into the Agulhas Retroflection region suggests a consistent supply of saline intermediate waters which may be captured in Agulhas Rings and exported to the South Atlantic. A quantitative estimate of the transport of RSW in the Agulhas Current at 32S suggests that almost all of the Red Sea outflow waters end up in the WBC.

P12/E/02-A1 Poster 1030-06

WATERMASS STRUCTURE AND TRANSPORT IN THE INTERMEDIATE LAYERS OF THE SOUTH INDIAN OCEAN

BENNY N. PETER & Vimal Kumar (Department of Physical Oceanography, Cochin University of Science & Technology, Fine Arts Ave, Cochin, India 682016, email: benny@md2.vsnl.net.in)

The watermass assembly in the intermediate layers of the South Indian Ocean and its exchange with the Antarctic Ocean(at 32 degree south) is described in the present study. The hydrographic data procurred from the National Oceanographic Data Cente, washington, USA and National Research Institute of Far Seas Fisheries, Shimizu, Japan are used. Isanosteric Analysis is employed to identify the watermass movement. The distribution of potential temperature, salinity and depth on 140, 120, 100, 80, 60 cl/ton surfaces are presented. The method introduced by Montogomery and Stroup(1962), depicting the transport in the T-S diagram, is adopted to quantify the watermass exchange. The watermasses in the South Indian Ocean is much influenced by the Indonesian Throughflow, even in the intermediate layers. Also, the cross equatorial spreading is weakened towards deeper levels. The intrusion of Antarctic waters are more confined to the central part, while the return flow is taking place near the continential boundaries. The Indonesian Throughflow adds more low saline cool water to the South Indian Ocean. The thermohaline front which seperates the cool, less saline Pacific and saline, warm Indian waters is weakened with respect to depth. In the intermediate layers a net southward transport of 5.84Sv is observed. The major contribution of low saline Antarctic Intermediate Water towards north is confirmed from the flux distribution in the T-S diagram.

P12/E/07-A1 Poster 1030-07

WATER MASSES OF COASTAL REGIONS OF THE FAR-EASTERN (THE JAPAN, OKHOTSK, AND BERING) SEAS

Gennady YURASOV (Pacific Oceanological Institute, Russian Academy of Sciences, Far-Eastern Branch, Baltiyskaya Str., 43, 690041 Vladivostok, Russia, email: pacific@online.marine.su) Yury Zuenko (Pacific Fishery and Oceanography Research Institute, Shevchenko Alley, 4, 690600 Vladivostok, Russia).

General principles of water mass analysis based on statistical methods are applied to all listed seas. Materials of the long-term seasonal surveys of coastal regions are examined for this purpose. Using proposed technique a classification of water masses and types of water vertical structure was conducted.
Influenced by the same formation mechanism at all seas the water masses produce an estuaric (at the Okhotsk Sea only), coastal, shelf and subarctic types of the vertical structure. All of them have their attributed stratification degree and characteristics of water masses. In the regions of complete tidal mixing the water masses are homogenous from the sea surface to the bottom. The same named water masses for each of the listed seas are differed each other by values of their parameters (temperature, salinity, depth) and sizes of their extension. During winter season at all three seas the water masses of higher density are being formed. As a result of convection and mixing these waters ventilate deep layers. Particularly this mechanism develops at the Japan Sea where the shelf is of insignificant extent. It is supposed that the higher density waters of the Okhotsk Sea ventilate the layer of lower salinity in the North Pacific Ocean.

A THREE-LAYER MODEL FOR THE STUDY OF TIDALLY INDUCED DENSITY CURRENTS

Rainer Weigle, Peter BRANDT, and Angelo Rubino (Institut für Meereskunde, Universität Hamburg, Troplowitzstr. 7, D-22529 Hamburg, Germany, Email: brandt@ifm.uni-hamburg.de)

The dynamics of tidally induced internal waves is investigated by using a numerical three-layer model based on the weakly nonlinear, weakly non-hydrostatic Boussinesq equations. Numerical solutions of the three-layer Boussinesq equations are compared with analytical solutions of different equations describing internal solitary waves in a two-layer system. In contrast to the two-layer models, the three-layer model is capable of describing the evolution of sub-surface jets. As a result of the three-layer model these jets develop undulations that finally disintegrate into internal solitary waves. Several characteristics of these waves, like e.g., wave amplitude and distance between the first two solitary waves of a wave train are studied as a function of the initial jet velocity and the stratification. Results of the numerical simulations are compared with results of high resolution in-situ measurements carried out north and south of the Strait of Messina, in the European Mediterranean Sea. Implications of the presented study for a possible inversion of sea surface manifestations of oceanic internal waves into characteristics of the interior ocean are discussed.

GROWTH MECHANISM OF TOPOGRAPHIC INTERNAL WAVES GENERATED BY AN OSCILLATORY FLOW

Tomohiro NAKAMURA and Toshiyuki Awaji (Department of Geophysics, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan, Email: nakamura@kugi.kyoto-u.ac.jp)

A new amplification mechanism for topographic internal waves generated by tidal flow is presented to reveal the unknown growth processes of the internal waves in the Kuril Straits (about 47N in the North Pacific) reported by Nakamura et al. (1998). Accordong to their investigation, the nature of the wave properties is determined by the nondimensional parameter (k U0)/sigma_f, where k is the curvature of topoguraphy, U0 is the flow speed amplitude, and sigma_f is the frequency of tidal flow, through which the topographic internal waves can be classified into the three wave types; (1)unsteady lee waves (k U0/sigma_f >> 1), (2)mixed tidal lee waves (k U0/sigma_f \sim 1), and (3)internal tides (k U0/sigma_f << 1). Notably, their numerical model showed that the growth processes of the first two waves were quite different from those predicted by conventional internal wave theories, thus suggesting the presence of another criterion for wave amplification. For this issue, our theoretical investigation based on the ray tracing of individual waves generated at various time reveals the following interesting facts. Unsteady lee waves are always amplified when the maximum frequency is sufficiently smaller than the buoyancy frequency (i.e., sigma_f << k U0 << N), because their phase speeds and amplitudes are equal

and proportionate to the tidal flow speed at their generation, respectively. Fast mixed tidal lee waves are also effectively amplified as well as unsteady lee waves, when the rotation effect is significant (i.e., f \sim sigma_f \sim k U0 << N). Accordingly, amplification of unsteady lee waves and fast mixed tidal lee waves can occur even if the conditions indicated by previous theories (i.e., the critical slope and the critical Froude number) are not satisfied. Since our theoretical model covers generation and amplification processes of topographic internal waves in a broader parameter range than before, it may contribute to a better understanding of the Boundary Mixing processes.

WATER MASS, TEMPERATURE, SALT AND HEAT EXCHANGE OF ANTARCTIC AND NORTH ATLANTIC BASINS

Anisimov M.V., IVANOV Yu.A., Lebedev K.V. and SUBBOTINA M.M. P.P.Shirshov Institute of Oceanology

On the base of ocean general circulation model with using of climatological massive (Levitus,1994) we calculated temperature, salinity, density, free surface level and current fields in the North Atlantic Antarctic basins. We defined the integral mean annual and mean seasonal characteristics of water mass, salt and heat transports. Also we fullfiled the analysis of interseasonal redistribution of water mass, salt and heat transports for climatic seasons. Estimates of climate avereged variability of integral transports were made.

Presiding Chair: Bernadette Sloyan

WATER MASS CLIMATOLOGY

WORLD OCEAN THERMAL STRUCTURE

Peter C. CHU, Chenwu Fan, and Hui Liu

We used gradient criteria to establish a global ocean mixed layer depth (MLD), thermocline depth (THD), and thermocline strength (THS) data sets from the National Oceanographic Data Center (NODC) 4.5 million temperature profiles. The annual cycles of MLD, THD, and THS of the world ocean are described based on climatological monthly-mean MLD fields. The interannual variabilities of MLD, THD, and THS are obtained from zonally averaged monthly mean fields as well as the latitudinally averaged (10 deg N and 10 deg S) monthly mean fields. The ocean interannual thermal variability is closely related to El Nino, North Atlantic Oscillation (NAO), and Great Salinity Anomaly in the Arctic regions.

WATER MASS CHANGES IN THE SCOTIA SEA

David P. STEVENS (School of Mathematics, University of East Anglia, Norwich NR4 7TJ, email: D.Stevens@uea.ac.uk) Karen J. Heywood (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, email: k.heywood@uea.ac.uk)

In March-April 1999 two South Atlantic WOCE sections, A21 (Drake Passage) and (part of) A23 (35 degrees west), will be reoccupied as a component of ALBATROSS (Antarctic Large-scale Box Analysis and The Role Of the Scotia Sea). WOCE section A21 was occupied in February 1990 and section A23 was occupied in March 1995. Early results from ALBATROSS will be presented. In particular we will focus on an analysis of differences between ALBATROSS and the earlier WOCE sections. Both the WOCE and ALBATROSS data include a full suite of chemical tracers (such as CFCs and nutrients) as well as traditional hydrography. Assessments will be made of the role of the observed water masses in climate variability.

WATER MASS CHANGES IN THE NORTH AND SOUTH PACIFIC OCEANS BETWEEN THE 1960'S AND 1985-94, IMPLICATIONS FOR CLIMATE CHANGE

Annie P.S. WONG (IASOS, University of Tasmania, GPO Box 252-77, Hobart, 7001, Australia), Nathaniel L. Bindoff (Antarctic CRC, GPO Box 252-80, Hobart, 7001, Australia,
email: N.Bindoff@utas.edu.au) and John A. Church (Antarctic CRC and CSIRO Marine Research, GPO Box 1538, Hobart, 7001, email: john.church@marine.csiro.au).

Comparisons have been made along five modern hydrographic sections with historical data to investigate water mass changes in the North and South Pacific Oceans. The five modern hydrographic sections were sampled in the decade 1985-94, while the historical data were mostly from the 1960s.
Below the seasonal mixed layer, statistically significant temporal differences in temperature and salinity have been detected in the water masses that occur in the top 2000 dbar of the water column. These differences in water mass property changes are assumed to result from changes in sea surface conditions at the formation regions.
Of the observed temporal differences, the ones with largest scale are from the shallow salinity maxima of North Pacific Subtropical Water (NPSTW) and South Pacific Subtropical Water (SPSTW), and the intermediate salinity minima of North Pacific Intermediate Water (NPIW) and Antarctic Intermediate Water (AAIW). The two salinity maxima, NPSTW and SPSTW, also show signs of salinity increase, while the two salinity minima, NPIW and AAIW, have become warmer and fresher. Since NPSTW and SPSTW originate under the high evaporative cells of the central North and South Pacific, and NPIW and AAIW acquire their properties near the polar gyres, these changes in the ocean interior imply an increase in evaporation over the mid-latitudes, and an increase in precipitation over the high-latitudes regions in both hemispheres. Taken together these results imply a strengthening of the hydrological cycle over the North and South Pacific Oceans. Output from coupled climate model for increasing atmospheric CO2 level show that the model ocean responds with a warming of the water column. Superimposed on this background warming trend is a decrease in salinity in the salinity minima of the Pacific (AAIW and NPIW) which corresponds to near-surface freshening where their respective isopycnals outcrop. Hence the freshening signature that has been detected in NPIW and AAIW from observational data is qualitatively consistent with the results from this climate model for increasing atmospheric CO2.

WATER MASSES IN MODELS

P12/W/23-A1 **1400**

WATER MASS ANALYSIS IN OCEAN MODELLING

Matthew H. ENGLAND, Centre for Environmental Modelling and Prediction (CEMAP), The University of New South Wales, Sydney NSW 2052, Australia email: M.England@unsw.EDU.AU

Water mass analysis forms a vital component of ocean model assessment. I will present an overview of the fidelity of models in the context of the global scale water masses, summarising the key processes and parameterisations required for large-scale simulations of water mass renewal. I will also outline how ocean modellers try to verify water mass formation processes in global ocean simulations. Proxy model diagnostics of ventilation rates, such as "age" and age distributions, will also be discussed in the context of ocean model assessment.

P12/W/05-A1 **1420**

USE OF PASSIVE TRACERS TO ANALYSE WATER MASSES IN CONTROL AND TRANSIENT CO2 SIMULATIONS

Siobhan P. O'FARRELL, CSIRO Atmospheric Research Aspendale, 3195, Australia. email : Siobhan.O'Farrell@dar.csiro.au

Due to the high frequency component of atmospheric forcing, the ocean response when coupled to an atmospheric model differs from that seen with imposed surface boundary conditions. In particular, the rates of convection, depth of mixed layer, and meridional overturning rates are altered at high latitudes under coupled conditions. A passive tracer has been used in the ocean model to explore differences between spin up and coupled experiments as an analogue to some of the chemical species that are regularly measured on ocean hydrographic sections. There are two versions of the ocean model, a version with standard horizontal diffusion and a second with the Gent and McWilliams eddy mixing. Simulations with both ocean versions have included tracers for 50 years in the coupled ocean atmosphere model and in ocean-only runs. The tracer output is discussed in terms of water masses for individual ocean basins.
Additionally, there are 50 years of tracer data from a transient CO2 experiment with the coupled model. The tracer was released at a time when the CO2 level is held constant in the atmosphere at double the value of the control simulation, after the ocean adjustment to the new surface conditions has slowed. A further set of passive tracer data is now being gathered in a transient simulation, as CO2 is increased from 1880 levels to those projected for the end of the next century. Both these tracer data sets will be used to examine how different water masses in the ocean are responding to the climate change signal.

RENEWAL AND MODIFICATION OF ANTARCTIC INTERMEDIATE WATERS

Bernadette SLOYAN, Alfred Wegener Institute for Polar and Marine Research, Postfach 12 01 61, D-27515 Bremerhaven, GERMANY

Subantarctic Mode water (SAMW) and Antarctic Intermediate water (AAIW) are characterized by a dissolved oxygen maximum and salinity minimum north of the Antarctic Polar Front zone (APF). These water masses move eastward with the Antarctic Circumpolar Current (ACC) and northward into the adjacent Atlantic, Indian and Pacific subtropical Oceans. Along this circulation path significant property changes occur to both water masses. Many mixing mechanisms and their principal location, which results in the observed property changes, have been suggested.
Estimates of interior and air-sea diapycnal fluxes for the southern oceans, across neutral surfaces identifying SAMW and AAIW, are derived from basin-scale budgets of mass, heat and salt using a box inverse model. The diapycnal fluxes quantify mixing occurring in the subtropical oceans and across the APF. The inferred fluxes help us explain the property changes in SAMW and AAIW observed across each ocean basin.

ZONAL FLUXES IN THE DEEP LAYERS OF THE SOUTH ATLANTIC

Michael VANICEK (Department of Marine Physics, Institut fuer Meereskunde Kiel, Duesternbrooker Weg 20, 24105 Kiel, Germany, email: mvanicek@ifm.uni-kiel.de) Gerold Siedler (Department of Marine Physics, Institut fuer Meereskunde Kiel, Duesternbrooker Weg 20, 24105 Kiel, Germany, email: gsiedler@ifm.uni-kiel.de)

The circulation of the North Atlantic Deep Water (NADW) in the South Atlantic is determined from hydrographic, nutrient, and tracer data from WOCE and other high quality pre-WOCE sections using a linear box-inverse model. Multiple linear regression, which makes use of the correlation between different parameters, is applied to infer the missing parameters in the bottle data set. This interpolation technique also enables us to include the nutrient and tracer measurements in the inverse model with a spatial resolution of the corresponding CTD data. The data define a set of 126 closed boxes on which conservation requirements are imposed. A detailed water mass analysis is performed, incorporating the tracer information from the whole South Atlantic, to determine the vertical boundaries of these boxes. As a result the water column is divided into 11 layers which are defined by neutral densities. Constraints for the inverse model are an integral meridional salt and phosphorus transport, the overall salt and silica conservation, as well as flow conditions inferred from moored current observations. The results are analysed with an emphasis on the zonal spreading of the NADW. A clear meridional separation in the direction of the zonal NADW transports can be observed. Quantitative estimates are given.

MEAN CIRCULATION AND TURBULENCE IN THE EASTERN NORTH ATLANTIC, FROM A REGIONAL NUMERICAL MODEL

Thierry PENDUFF (Laboratoire des Ecoulements Geophysiques et Industriels, BP53 38041 Grenoble Cedex 9, France, email Thierry.) email: Penduff@hmg.inpg.fr Alain COLIN DE VERDIERE (Laboratoire de Physique des Oceans, Universite de Bretagne Occidentale, BP 809, 29280 Brest cedex, FRANCE, email: acolindv@univ-brest.fr) Bernard BARNIER (Laboratoire des Ecoulements Geophysiques et Industriels, BP53 38041 Grenoble Cedex 9, France,
email: Bernard.Barnier@hmg.inpg.fr)

An eastern North Atlantic regional configuration of SPEM model is used to study the general circulation in the basin, the mesoscale turbulence, and the interactions between these two

scales. Contrary to previous studies, and to ensure consistency between lateral forcing and inner dynamics, the velocity field along the wide open boundaries is largely determined by the model itself. This approach can therefore be considered as a prognostic alternative to inversions; after stabilization, the general circulation is qualitatively and quantitatively close to available data. It is shown that in the North Atlantic Current, baroclinic instability generates eddies that in turn strengthen the mean flow, and that these processes are intensified on the polar side of the fronts; avaliable data seems to confirm this features.

INFLUENCES ON NEAR-SURFACE VELOCITY FIELDS DUE TO STRONG VERTICAL MIXING IN THE INDONESIAN SEAS

Masatora IIDA, Toshiyuki Awaji, Yoichi Ishikawa, Kazunori Akitomo, Teiji In, Nobumasa Komori, Takaki Hatayama, Tomohiro Nakamura (Department of Geophysics, Graduate School of Science, Kyoto University, Kitashirakawa-Oiwake, Sakyo, Kyoto 606-8502, Japan,
email: iida@kugi.kyoto-u.ac.jp), and Bo Qiu (Department of Oceanography, University of Hawaii at Manoa, 1000 Pope Rd., Honolulu, Hawaii 96822, U.S.A., email: bo@iniki.soest.hawaii.edu)

Impacts of strong vertical mixing caused by tidal mixing in the Indonesian Seas are investigated with emphasis on how much this regional mixing has influences on the near-surface velocity fields over the Pacific and Indian Oceans by using an extended reduced gravity layer model, which is basically similar to that of McCreary and Kundo (1989) but is widely extended. Our reduced gravity layer model has dynamically two and thermodynamically three active layers. The first dynamical layer has two thermodynamical layers; the upper one is called the 'mixed layer' which includes a bulk mixed layer model based on Kraus-Turner thermodynamics, and the lower one is called the 'fossil layer'. Within this layer, no vertical temperature gradients exist but horizontal gradients do. This means that density can vary within the layer. In addition, our layer model can deal with vertical heat / momentum exchanges due to entrainment / detrainment.
Using this layer model, we have performed two numerical experiments with and without strong vertical mixing in the Indonesian Seas. Comparison between both results revealed many interesting facts about the influences of the regional vertical mixing on the near-surface velocity fields of the equatorial Pacific and Indian Oceans. For example, the South Equatorial Current in the Pacific Ocean is much intensified, leading to the significant increase in transport of the South acific water into the Indonesian Seas. This is very consistent with the observational result revealed by Ffield and Gordon (1992). Our detailed analysis showed that such an increase in the volume transport of the South Pacific Water flowing into the Indonesian Seas is associated mainly with the occurrence of upwelling Kelvin waves in the western equatorial Pacific due to the effect of strong vertical mixing in the Indonesian Seas and their propagation along the equator.

P12/W/21-A1 **1620**

THE EFFECT OF THE SUBTROPICS ON THE TROPICAL SALINITY FIELD

Masami NONAKA (Institute of Low Temperature Science, Hokkaido University, Sapporo 060-1809, Japan, Email: nona@lowtem.hokudai.ac.jp) Kensuke Takeuchi (Institute of Low Temperature Science, Hokkaido University, Sapporo 060-1809, Japan, Email: takeuchi@lowtem.hokudai.ac.jp)

In higher latitudes, more saline water compared with that in the tropics is supplied through the sea surface and is advected to the tropics by the ocean circulation connecting the subtropics and the tropics. Using a ocean general circulation model (GCM) which has realistic topography and is forced by the climatological data, we examine the effect of water directly transported to the tropics on the tropical salinity fields and the reason for the discrepancy between the salinity and tritium fields' properties: Tritium indicates an interior route to the equator in the Northern Hemisphere, but high salinity water does not indicate it. The results of our GCM show that the water subducted into the subsurface from the high sea surface salinity (SSS) regions in the subtropics is advected to the tropics, forming a high salinity tongue. In the Southern Hemisphere, the high salinity tongue extends directly to the equatorial region, but in the Northern Hemisphere it extends to the western boundary. In the Northern Hemisphere, water subducted from the low SSS region in the eastern part of the subtropics and water whose salinity is lowered by mixing with the eastern low salinity water extend to the equatorial region through the interior ocean, forming a low salinity tongue. The ocean circulation in our GCM follows an interior route from the North Pacific to the equator, consistent with the subsurface tritium field, and, at the same time, reproduces the properties of the subsurface tropical salinity field. Because the northern interior route transports only low salinity water, the northern high salinity tongue does not follow an interior route and is discrepant from the tritium fields. The discrepancy is caused by the difference of the sea surface distribution: High SSS exists in the western boundary exchange window in the Northern Hemisphere, while sea surface tritium has its maximum near the eastern boundary within the interior exchange window. Here, water subducted from the western boundary (interior) exchange window is transported to the equatorial region through the western boundary region (the interior ocean) in the subsurface layer.

P12/W/18-A1 **1640**

WATER MASS TRANSFORMATIONS IN THE NORTH PACIFIC OCEAN

Dr Maxim YAREMCHUK, International Pacific Research Center

A dynamically consistent state of the North Pacific ocean has been obtained by the variational assimilation of climatological data into a non-linear steady state circulation model. The assimilated data include Da Silva heat, freshwater and momentum fluxes at the ocean surface, WOCE hydrology, five year (1992-1997) mean Topex-Poseidon altimetry and MEDS surface drifter trajectories, averaged over the period 1990-1996. Advective balance residuals in the optimized fields of potential temperature and salinity are treated as transformation rates of waterproperties caused by local diffusive and mixing processes. Statistical analysis of these "elementary"transitions in the temperature-salinity space provides their decomposition into thetransformation rates between the basic water masses of the North Pacific ocean. The analysis shows in particular, that North Pacific Intermediate Water (NPIW) plays a central role in the water mass balance of the region. Isopicnal flow patterns indentify intensive NPIW divergencies east of Southern Kuril Islands and Hokkaido. A much weaker possible source of NPIW is locatedin the Alaska Gyre. Zonal mean circulation of the optimal state exhibits 8.5 Sv of the deepwaters inflowing from the south which are then involved into the meridional upwelling of 14 Sv between 30-50N. A weaker (5 Sv) overturning cell exhists north of 50N which is driven by the downwelling of the north Bering Sea waters.

REGIONAL WATER MASS STUDIES

P12/W/09-A1 **1700**

ORIGIN OF DEEP AND BOTTOM WATER IN THE SOUTHWEST PACIFIC

Serguei SOKOLOV and Stephen Rintoul (both at CSIRO Marine Research and Antarctic Cooperative Research Centre, GPO Box 1538, Hobart, Australia, emails: Serguei.Sokolov@marine.csiro.au and Steve.Rintoul@marine.csiro.au)

The majority of the hydrographic stations occupied in the Tasman/Coral Sea have been shallow (<1500 m deep). As a result, there has been little discussion of the deep circulation. Recent high quality deep hydrography,including WOCE P11, helps refine some details of the deep water circulation in the region. According to P11 data, there are two major sources of the deep water in the Coral and Solomon Seas: the "southern" source supplied from the East Australian Basin and the "eastern" source entering the Coral Sea from the east. About 3 Sv of deep water is carried into the Coral Sea by a deep western boundary current in the Cato I. Trough from the Tasman Sea, and about 6 Sv (relative to the bottom) of deep and bottom water recirculate in the Coral Sea across P11. The deep and bottom water entering the Coral Sea from the east are derived from the CDW spreading north from the ACC as a western deep boundary current along the Tonga-Kermadec Ridge, through the Samoa Passage, and finally across the equator to the North Pacific. While the densest water in the boundary current is prevented from spreading to the west by topography, lighter CDW spreads west in the East Mariana Basin and also supplies deep water to the eastern Coral Sea and the Solomon Sea. The deep waters in the Solomon Sea are horizontally homogeneous throughout the basin, and the theta-S curves found for the New Britain Trench and near the northern entrance to the Solomon Sea at the Vitiaz Strait, St. Georges Channel and the Solomon Strait are almost identical to those found in the South Solomon Trench. This is a clear indication that the deep waters in the Solomon Sea enter from the east. The CDW entering from the east is cooler and fresher than water entering the Coral Sea from the East Australian Basin. The distribution of silica in the South Pacific also supports this view. CDW entering the Pacific from the Southern Ocean is initially low in silica (<90, see e.g. Schmitz, 1996), while North Pacific DW can have values as high as 180. The low silica in the Coral Sea Basin is an indicator of the "southern"source of deep water supplied from the Tasman Sea, while the higher values in the eastern part of the Coral Sea reflect deep water inflow derived from the "eastern"source.

P12/W/17-A1 **1720**

STRAIT OF SICILY WATER MASSES

Alex WARN-VARNAS (Naval Research Laboratory at Stennis, USA, email: varnas@nrlssc.navy.mil), Allan Robinson, Jurgen Sellschopp, Wayne Leslie, Pat Haley, Carl Lozano, and Steve Piacsek

We have derived a water mass model for the Strait of Sicily, based on 1994 and 1995 cruise data. The model consists of seven water masses, suggested by the measured shapes of the vertical temperature and salinity profiles. The core of the Atlantic water is distributed below the surface as a shallow layer, in a depth range of 40 to 100 meters, with a salinity minimum. Upper and surface layers above and a mixed region below cap it. At the bottom Levantine water is present with a transition region above. Between the mixed and transition region there is, on occasion, a fresher water layer. The structure and statistics of the water masses is analyzed in terms of their temperature, salinity, and depth parameters. Objective analysis of the temperature, salinity, and depth parameters is performed in latitude and longitude. The water masses are tracked in terms of their parameter signatures. Changes in temperature and salinity distributions are interpreted. 2-D ellipses that represent the water masses, in terms of mean and standard deviation, are derived in a space of temperature, salinity, and depth. Their axes are the standard deviations of parameter space ranges.The areas of the ellipses are compared against the temperature and salinity distributions. The water mass composition ratios are computed and analyzed. Hypotheses and mechanisms for the origin and mixing of water masses are suggested. The temporal and spatial variability of the volume flows associated with the major water masses is studied via high horizontal resolution, 5km, and 64 level ocean model using 6-hour forcing and an embedded mixed layer.

REVIEW OF HYDRAULICS AND HYDRAULIC CONTROL IN THE OCEAN

Larry Pratt (Woods Hole Oceanographic Ins., Woods Hole, MA. 02543, USA. email: lpratt@whoi.edu)

A review of recent progress in understanding the hydraulics of straitand sill flows is given. Areas of interest include hydraulic control in the presence of continuous stratification, linking controlled flows to forcing and dissipation in upstream and downstream basins or marginal seas, hydraulic jumps and bores, rotation, and time-dependence. Also mentioned will be some longstanding problems whose importance is widely recognized but which have proved difficult to understand. These include hydraulic control in the presence of rapidly fluctuating currents, the presence of critical layers in 'hydraulically critical' flow, and the role of friction in rotating, hydraulically-driven flows. Finally, I will review two classes of hydraulic problems having well-developed theories but, at present, little or no observational support. These are coastal hydraulics and potential vorticity hydraulics.

P14/E/04-A4 Invited **1040**

CIRCULATION IN STRAITS – A REVIEW OF RECENT OBSERVATIONAL STUDIES

Stephen P. MURRAY (Coastal Studies Institute, Louisiana State University, Baton Rouge, Louisiana 70803, USA, email: smurray@unix1.sncc.lsu.edu)

The important role of sea straits in controlling exchange between marginal seas and ocean basins and between adjacent ocean basins is well established, but in the last 20 years, modern instrumentation has provided a new depth of insight into the controlling processes. The Gibraltar Experiment (1985-86), for example, allowed a vast improvement in the determination of mass and salt transport between the Mediterranean and the Atlantic Ocean, leading to a significant revision in the Mediterranean evaporation rate. The Experiment also determined that as much as one-half of the exchange across the Gibraltar sill is controlled by

tidal covariance (Bryden et al. 1994). Additionally, barotropic fluctuations caused by atmospheric pressure differences between the basins can cause transport fluctuation as much as 1 Sv--as large as the mean flow. A recent study in the Bab el Mandab Strait (linking the Red Sea and Indian Ocean), employing moored ADCPs, has documented the seasonal transport cycle of the two-layer regime that is present most of the year and the three-layer regime that prevails in summer. Highly energentic low frequency fluctuations in the transport are largely controlled by direct wind driving, producing both barotropic and baroclinic responses. A strong (0-0.8 Sv) seasonal modulation in the deep high density outflow is related to the annual cycle of the winds in the Arabian Monsoon but the controlling dynamics remain unclear. In addition to the above settlings forced by thermohaline, wind, andatmospheric pressure effects, other straits (e.g. in the Indonesian Archipelago) are controlled by inter-ocean basin sea level differences at the seasonal scale and coastal Kelvin waves at the intraseasonal line scale. These and other examples from the Bosphorus and Straits of Otranto, of Sicily and Hormuz, are discussed, compared, and summarized in terms of regional forcing mechanisms.

P14/W/14-A4 Invited 1140

ASPECTS OF STRAIT DYNAMICS STUDIED BY NUMERICAL LAYERED MODELS

Angelo RUBINO and Peter Brandt (both at the Institut für Meereskunde, Universität Hamburg, Troplowitzstr. 7, Hamburg, Germany, Email: rubino@ifm.uni-hamburg.de) Stefano Pierini (Dipartimento di Fisica, Università dell'Aquila, Via Vetoio, I-67010 Coppito (l'Aquila), Email: pierini@cds.unina.it)

Different multi-layer numerical models are employed for the study of three straits of the western Mediterranean Sea: the Strait of Gibraltar, the Strait of Sicily, and the Strait of Messina. The Strait of Gibraltar, that connects the Mediterranean Sea and the Atlantic Ocean, is investigated with the help of two different two-layer models. By using a one-dimensional, nonlinear, weakly non-hydrostatic model the generation and propagation of internal bores caused by the interaction of the barotropic tide with the Camarinal Sill and their disintegration into trains of internal solitary waves is simulated. The results are compared with different remote sensing data. By using a nonlinear, hydrostatic, two-dimensional boundary-fitted coordinate model, two-dimensional aspects of the strait dynamics induced by topography and earth rotation are simulated. In particular, it is shown that within the strait different areas in which the flow is supercritical exist, characterized by a complex temporal evolution. The Strait of Sicily, that connects the western and eastern Mediterranean basins is investigated with the help of a nonlinear, hydrostatic three-layer model. The layers represents waters of Atlantic origin, the Levantine intermediate water, and deep waters of the Mediterranean Sea. Quasi-stationary circulation patterns representing aspects of an idealized thermohaline circulation are produced by steady fluxes imposed at the open boundaries. The model is capable of capturing several features of the observed circulation in the area of the Strait of Sicily. The Strait of Messina, that connects the Tyrrhenian and Ionian seas, is investigated with the help two different models. The first model is a one-dimensional, two-layer coupled model. In the region of the strait sill the complex interaction of the lower layer with the topography induced by a strong barotropic tide is simulated by using a frontal model that, due to a numerical technique for the treatment of movable lateral boundaries, is capable of describing the dynamics of water layers having a localized extension. Outside the sill region the disintegration of the internal tidal bores produced in the sill region into trains of internal solitary waves is simulated by coupling to the generation model a nonlinear, weakly nonhydrostatic model. The results are compared with high-resolution in-situ and remote sensing data. The second model is a three-layer, nonlinear, weakly non-hydrostatic model. Using this model, the observed jet-like structure of the tidal flow outside the sill region is simulated.

P14/E/02-A4 Invited 1210

ENTRAINMENT BY OVERFLOWS AND DENSITY CURRENTS, A REVIEW

JAMES F. PRICE, Woods Hole Oceano. Inst., Woods Hole, MA, 02556 USA (email: jprice@whoi.edu)

Simulation of past or future climate will require ocean general circulation models (OGCMs) having comprehensive physics, and including a realistic treatment of the most important marginal sea overflows. This presents a considerable challenge since the scales and dynamics inherent to marginal sea overflows are different from that of the general circulation over most of the open ocean. Overflows are density-driven bottom currents that have small vertical scales, being typically about 100-200 m thick, and currents that are O(1 m s^{-1}). As they Descend into the ocean they may mix intensely with overlying oceanic water, typically doubling their initial transport and diluting their tracer properties. Because of these distinctive scales and dynamics, realistic marginal sea-ocean exchange and deep water production do not arise spontaneously in large-scale OGCMs, even those with the greatest resolution. Consequently, it will be necessary to parameterize marginal sea processes in OGCMs. The aim of this review will be to describe what an ideal parameterization should do, and to consider some candidates.

HYDRAULIC CONTROL IN THREE-LAYER EXCHANGE FLOWS AND APPLICATION TO THE BAB AL MANDAB

David SMEED and Gregory Lane-Serff, Southampton Oceanography Centre, University of Southampton, Southampton. SO14 3ZH UK.

There is a strong seasonal variation of the flow in the strait of Bab al Mandab. In winter dense salty water leaves the Red Sea and fresher surface water enters the Red Sea from the Gulf of Aden. In the summer the outflow of dense salty water Is much reduced, the direction of flow in the surface layer is reversed and a sub-surface layer of cool fresh water enters the Red Sea between the two outflowing layers. A model of hydraulic control in three-layer exchange flows has been developed. The model predicts the observed flow regimes and supports the hypothesis that upwelling, dependent upon the monsoon, in the Gulf of Aden is primarily responsible for the seasonal variation. The model has applications to other strait and sill flows. The problem has been examined further in a series of laboratory experiments. Measurements of the exchange fluxes and interface heights agree well with the model predictions.

P14/W/05-A4 1420

THE CONTINUOUS DYNAMICAL MODES OF THE BAB AL MANDAB AND THEIR HYDRAULIC INTERPRETATION

Heather E. DEESE (Woods Hole Oceanographic Ins., Woods Hole, MA, 02543, USA, email: hdeese@mit.edu); Larry J. Pratt (Woods Hole Oceanographic Ins., Woods Hole, MA, 02543, USA, email: lpratt@whoi.edu); Steve Murray (Coastal Studies Institute, Louisana State University, Baton Rouge, LA, USA, email: smurray@lsuvax.sncc.edu); William Johns (RSMAS, University of Miami, Miami, FL, USA, email: johns@ibis.rsmas.miami.edu)

The continuous dynamical modes of the exchange flow in the Bab al Mandab are computed in an attempt to assess the hydraulic character of the flow at the sill. Hydrographic and direct velocity measurements taken from April to November of 1996 using moored CTDs and a bottom-mounted ADCP are first used to construct monthly mean density and velocity profiles. Next, an extended version of the Taylor-Goldstein equation is solved for the phase speeds and vertical structures of the first and second internal long wave modes. The 'extended' equation takes cross-strait topography into consideration. The sill flow is found to be subcritical during each month, but it hovers near a critical state with respect to the second internal mode during the non-summer months. A series of calculations using idealized velocity and buoyancy frequency profiles are presented to illustrate the effects of the topography on the vertical modes. Wave speeds are also calculated for a variety of instantaneous conditions at the extremes of the tidal cycle. The results indicate that the tides often push the flow into a critical or supercritical regime with respect to the second mode and, somewhat less frequently, with respect to the first mode. We can only speculate on the connection between classical hydraulic control and the observed intermittent critical and supercritical conditions. A series of calculations using idealized velocity and buoyancy frequency profiles are also presented to illustratethe effects of the topography of the vertical modes.

INVESTIGATING THE FEEDBACK BETWEEN STRAIT EXCHANGE AND WATER FORMATION USING A HYDRAULICALLY CONTROLLED BOX MODEL OF THE MEDITERRANEAN

Stephan MATTHIESEN and Keith Haines (Dept. Meteorology, Univ. Edinburgh, James Clerk Maxwell Building, Edinburgh EH9 3JZ, UK, email: stephan@met.ed.ac.uk and kh@met.ed.ac.uk)

We have built a 2 layer model consisting of a hydraulically controlled strait coupled to a 2 box model of the Mediterranean. This is the simplest system that can respond to changes in the strait flow. Unlike most previous models which have assumed maximal exchange at all times, our model also allows the exchange to become submaximal. A wide range of strait cross sections can be accommodated in the model. For the maximal regime, the model includes a hydraulic jump towards the Mediterranean with the possibility of mixing.
The model is used to investigate the feedback between the water formation processes in the basin and the strait dynamics and the relevant timescales. We discuss the implications of the fact that the adjustment time for salinity changes is of the order of decades, while the adjustment time for water budget changes are of the order of years.
This study also addresses the stability of the maximal and submaximal regimes for different situations. In most cases, the water formation rate inside the basin determines whether the strait flow is maximal or submaximal. When mixing in the hydraulic jump is included, the system can exhibit stable multiple equilibria for the same net evaporation over the basin, where one state is submaximal with weak mixing, and the other maximal with strong mixing. Comparisons with GCM simulations are also shown.

LARGE AMPLITUDE INTERNAL WAVES IN THE STRAIT OF GIBRALTAR

Harry L. BRYDEN and Brian A. King (both at Southampton Oceanography Centre, Southampton, SO14 3ZH UK, email: h.bryden@soc.soton.ac.uk or b.king@soc.soton.ac.uk)

Large amplitude internal waves are generated close to the time of high tide at or near the sill in the Strait of Gibraltar, particularly during strong Spring tides. We examined the subsurface characteristics of these large amplitude waves using new technology including calibrated, three-frequency backscatter profiles from an EK500 and accurate velocity profiles from shipboard ADCP measurements combined with three-dimensional differential GPS navigation as well as using a slowly-towed CTD package to measure the hydrographic properties of the interface between inflowing Atlantic water and outflowing Mediterranean water. In the early morning hours of 4 successive days over Easter weekend 1998, 100 m amplitude waves propagated eastward past the nearly stationary ship at locations east of the sill. Maxima in the vertical profiles of backscatter, particularly at 38 kHz, provided dramatic, real-time portraits of the waves. The maxima in backscatter, however, appear to be a feature of the Mediterranean layer and not a feature of the interface as the maximum lies 20 m below the 38-isohaline; furthermore, the backscatter maximum appears to evanesce before the complete wave train has passed so it is an unreliable indicator of the waves. More robust signatures of the waves are measured by the shipboard ADCP: upward and downward vertical velocities as large as 50 cm s-1 are an outstanding feature of the waves and the depth of the maxima in the vertical shear of the eastward current from the ADCP tracks the lower part of the interfacial region (salinity of about 37.7) for much longer periods than does the backscatter.
On 14 April the large amplitude waves are observed at two alongstrait locations separated by 15 km and 2 hours implying an eastward propagation speed of about 2 m s-1. As the waves propagate over 15 km, their amplitude, maximum vertical velocity, and maximum steepness decrease by about 30% from 120 m to 80 m, from 50 to 35 cm s-1, and from 0.7 to 0.5. As a measure of nonlinearity, horizontal advection accounts for about half of the local time changes in interface depth while vertical velocity accounts for the remainder.

P14/W/12-A4 1520

GROWTH MECHANISM OF TOPOGRAPHIC INTERNAL WAVES GENERATED BY AN OSCILLATORY FLOW

Tomohiro NAKAMURA and Toshiyuki Awaji (Department of Geophysics, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan, Email: nakamura@kugi.kyoto-u.ac.jp)

A new amplification mechanism for topographic internal waves generated by tidal flow is presented to reveal the unknown growth processes of the internal waves in the Kuril Straits (about 47N in the North Pacific) reported by Nakamura et al. (1998). Accordong to their investigation, the nature of the wave properties is determined by the nondimensional parameter (k U0)/sigma_f, where k is the curvature of topoguraphy, U0 is the flow speed amplitude, and sigma_f is the frequency of tidal flow, through which the topographic internal waves can be classified into the three wave types; (1)unsteady lee waves (k U0/sigma_f >> 1), (2)mixed tidal lee waves (k U0/sigma_f \sim 1), and (3)internal tides (k U0/sigma_f << 1). Notably, their numerical model showed that the growth processes of the first two waves were quite different from those predicted by conventional internal wave theories, thus suggesting the presence of another criterion for wave amplification. For this issue, our theoretical investigation based on the ray tracing of individual waves generated at various time reveals the following interesting facts. Unsteady lee waves are always amplified when the maximum frequency is sufficiently smaller than the buoyancy frequency (i.e., sigma_f << k U0 << N), because their phase speeds and amplitudes are equal and proportionate to the tidal flow speed at their generation, respectively. Fast mixed tidal lee waves are also effectively amplified as well as unsteady lee waves, when the rotation effect is significant (i.e., f \sim sigma_f \sim k U0 << N). Accordingly, amplification of unsteady lee waves and fast mixed tidal lee waves can occur even if the conditions indicated by previous theories (i.e., the critical slope and the critical Froude number) are not satisfied. Since our theoretical model covers generation and amplification processes of topographic internal waves in a broader parameter range than before, it may contribute to a better understanding of the Boundary Mixing

processes.

P14/E/10-A4 1540

FLOWS IN THE SILL REGION OF THE CLYDE SEA.

Rik MIDGLEY & John Simpson (School of Ocean Sciences, University of Wales, Bangor, Gwyned LL57 2DG, U.K. email: oss088@sos.bangor.ac.uk)

Observations of the vertical structure and currents in the Clyde Sea over a seasonal cycle identified the sill as a region of major uncertatinty. At times when the cross-sill density difference was maximum, the rate of exchange was below average, indicating that other forces control exchange. Renewal was generally episodic, indicative of wind induced exchange, and in the summer, when horizontal gradients were minimal, persistently high rates of exchange were observed.
New observations in the sill region in 1995 were used to construct a dynamical schematic of the structure. In March, a rapid cross-sill exchange (flows ~10 cm-1), which appeared to be essentially estuarine, and influenced by rotation, was observed. In contrast, in September cross-sill flows were observed to be relatively weak and spatially complex. A 3-dimensional model was used to confirm that changes in wind direction could substantially increase or diminish exchange by enhancing or blocking the estuarine circulation, and the summer time retreat of the front at the mouth of the Clyde, due to low freshwater inflow, could enhance exchange by increasing the availability of saline water over the sill.

MODELING OF MEDITERRANEAN OUTFLOW IN THE BLACK SEA. DEPENDENCE ON TOPOGRAPHY

Elissaveta PENEVA and Emil Stanev (both at Dept. of Meteorology and Geophysics, University of Sofia, Sofia 1126, Bulgaria, email: elfa@phys.uni-sofia.bg,stanev@phys.uni-sofia.bg)

Numerical simulations of Mediterranean outflow in the Black Sea using reduced gravity model with horizontal resolution of 600 m have been carried out. The Mediterranean water spreads in the neighbouring Black Sea as gravity plume accelerated by the the large density contrasts and topography slopes. This process is of major significance for the deep and intermediate water mass formation in the Black Sea. A number of numerical experiments have been run in attempt to better understand the topographic control of the current. In the refference experiment we use realistic topography and the model is tuned to adequately simulate the observed characteristics of gravity currents. Idealistic topography H=H(y), consisting of Bosphorus exit, shelf, continental slope and abyssal plain, is constructed in such a way that the geometric parameters of topography elements (slope and length) are comparable to the real ones. In order to investigate the impact of roughness on the gravity current simulations are carried out with idealistic but rough topography with roughness characteristics similar to observed ones. Additional experiments with deviating element in north-western direction after Bosphorus exit were run too in order to study the effects of Bosphorus underwater extention. The results show that the entrainment rate reaches its maximal values over the continental slope due to the acceleration of the plume. The roughness affects both entrainment rates and dispersive properties of the model. It was also found that the presence of Bosphorus underwater channel in north-western direction is quite significant for the dynamics of gravity currents.

P14/E/05-A4 1640

FLOW AND MIXING IN THE BOSPHORUS

Michael GREGG (University of Washington Seattle, WA 98105 USA); Emin Ozsoy (Middle East Technical University Erdemli, Turkey)

Current meter moorings and high-resolution surveys during late summer of 1994 in the Bosphorus revealed important details of the exchange flow between Mediterranean and Black Sea waters. We conducted the surveys with a narrowband ADCP, a high-frequency acoustic backscatter system, and a microstructure profiler carrying a CTD. The flow was quasi-steady and mixed most vigorously south of the principal contraction in the strait. The mixing was demonstrated by trains of billows,density overturns, high dissipation rates, and rapid thickening of the interface between the surface and bottom layers. Nevertheless, composite Froude numbers were much less than critical through the Contraction and may have been critical only several kilometers south of the Contraction, when the surface layer became too thin and shallow for us observe its speed.

THE BOSPHORUS STRAIT MIXING AND THE DENSE WATER OUTFLOW ON THE BLACK SEA SHELF: EXPERIMENTS AND MODELLING

Emin OZSOY (Institute of Marine Sciences, Middle East Technical University, P.K. 28 Erdemli - Icel 33731 Turkey, Email: ozsoy@ims.metu.edu.tr), Daniela Di Iorio (NATO SACLANT Undersea Research Centre Fine Scale Acoustics and Oceanography Group, Viale S. Bartolomeo 400, 19138 La Spezia (SP), Italy, Email: daniela@saclantc.nato.int), Michael Gregg (College of Ocean and Fishery Sciences, 522 Henderson Hall, University of Washington, 1013 NE 40th Street Seattle Washington 98105-6698, Email: gregg@apl.washington.edu), Sciences, 522 Henderson Hall, University of Washington, 1013 NE 40th Street Seattle Washington 98105-6698, Email: gregg@apl.washington.edu), Jan Backhaus (Institute for Oceanography, University of Hamburg, Troplowitzstr. 7, D-22529, Hamburg, Germany Email: backhaus@dkrz.de).

The exchange and mixing of waters from the Black Sea and the Mediterranean Sea occurs throughout the Turkish Straits, and intensively in the Strait of Bosphorus. Entrainment and mixing processes are studied through the Bosphorus, and on the Black Sea continental shelf / slope, based on the historical data base and the high-resolution intensive data sets obtained in 1994 and 1996. The changes in water properties along the Strait and in the outflow regions are characterized by distinct entrainment / mixing regimes, such as near the southern end of the Bosphorus, within the northern reach of the Strait and across the northern sill and the shelf region. A reduced gravity model of the dense bottom current is employed to study the flow across the northern shelf and to the continental slope. The flow is shown to be very sensitive to chosen parameters, to the environmental conditions in the Black Sea, and especially to the accurate representation of the bottom topography. High resolution, improved topographical data constructed from adcp and swath echosounder measurements are used to improve model predictions. Measurements of hydrographic and current features are used for verification of the results.

P14/W/15-A4 1720

A COMPARISON OF LARGE EDDY SIMULATIONS WITH OBSERVATIONS FROM THE CENTRAL CONTRACTION IN THE STRAITS OF BOSPHORUS

HARVEY SEIM, Skidaway Institute of Oceanography, Savannah, Ga 31411, USA, email: seim@skio.peachnet.edu Kraig Winters, Applied Physics Laboratory, University of Washington, Seattle, WA, USA and Centre for Water Research, University of Western Australia, Nedlands, Australia, email: winters@cwr.uwa.edu.au

Large eddy simulations of an internal hydraulic control at a contraction are found to support both maximal and submaximal exchange flows. The model results are compared with observations collected from intensive shipboard sampling by Gregg and Oszoy of the central contraction in the Straits of Bosphorus. A two layer decomposition of both the model results and the observations facilitates comparison with two-layer inviscid hydrostatic theory. A three layer decomposition, in which the upper and lower layer are well-mixed and the third layer comprises the interface between them, highlights the extent and location of mixing between layers. The comparison suggests the flow in the contraction is submaximal exchange, and that this can occur without flooding other hydraulic controls along the Strait, but that this configuration still generates copious mixed fluid.

ROLE OF DENSITY CURRENTS IN STRAIT DYNAMICS AT COCHIN INLET- SOUTHWEST COAST OF INDIA

K. J. AJITH and A.N. Balchand (Department of Physical Oceanography, Cochin University of Science and Technology, Fine Arts Avenue, Cochin 682 016, INDIA. email: oceans @md3.vsnl.net.in)

The shores of the tropical regions are embedded with tidal inlets that are grouped under straits as the dynamics of these inlets mimic flow patterns similar to that which occur in larger straits. As these inlets serve as openings of estuaries in many instances, the dynamics of two layer exchange present a vivid analytical situation brought about by the circulation of coastal waters vs. inland runoff. Also the physical configuration of the inlet controls the amount of exchange between the protected embayment and the coastal sea. The southwest coast of India, often a region of many geomorphologic features is no exception, where Cochin inlet (9˚58'N, 76˚14'E), provides an insight on the strait dynamics. This paper elucidates information on the inflow and outflow transport rates by density currents due to the change in sigma-t with appreciable salinity differences. A monthly sigma-t analysis at Cochin inlet authenticates the variation in density currents with seasonal changes in mixing. The tidal conditions and freshwater influence is also considered while analysing the strait dynamic features of this tropical tidal inlet. The study also covers aspects on the influence of land sea exchange of material and the role of inlet hydraulics in the protection of the embayment.within.

A 3-LAYER HYDRAULICALLY CONTROLLED BOX MODEL OF THE RED SEA AND BAB AL MANDAB STRAITS

David COBBY (ESSC, Univ. Reading, Harry Pitt Building, 3 Early Gate, Reading RG6 6AL, UK, email: dmc@mail.nerc-essc.ac.uk) Keith Haines and Stephan Matthiesen (Dept. of Meteorology, Univ. Edinburgh, James Clerk Maxwell Building, Edinburgh EH9 3JZ, UK, email: kh@met.ed.ac.uk and stephan@met.ed.ac.uk)

We have built a 3 layer model for the Red Sea in which the inflow and outflow of the layers is controlled hydraulically. The Bab al Mandab Strait connecting the Red Sea to the Gulf of Aden exhibits a 2 layer anti-estuarine exchange in winter which becomes a 3 layer flow in summer under the influence of summer Monsoon winds which raise an intermediate water mass up in the Aden Gulf, which then penetrates into the Red sea. The main control for the hydraulic flows is taken at a sill and narrows which are assumed coincident. Other controls and associated hydraulic jumps are detected by their influence on the flow rates.
Our model simulates the full seasonal cycle of flow as the Gulf of Aden intermediate water level is raised and lowered outside the straits. The layers inside the Red Sea exchange water through mixing and E-P water conversions and maintain both mass and salt budgets. The results are compared to observations from both current meter in the strait, layer thicknesses and sea level changes. The impact of the summer season 3-layer flow on the average properties of the waters inside, and emerging from, the Red Sea is discussed.

P14/W/01-A4 Poster 1400-03

CONTROL OF CONVECTIVELY DRIVEN EXCHANGE FLOW IN A SILL-ENCLOSED SEA

TIMOTHY D. FINNIGAN and Gregory N. Ivey (both at Department of Environmental Engineering, Centre for Water Research, University of Western Australia, Nedlands, WA 6907, Australia email: finnigan@cwr.uwa.edu.au)

Flux of buoyancy through the surface of a semi-enclosed or marginal sea, due to cooling or evaporative processes, generally results in a circulation within the sea and an exchange of fluid with the adjoining water body (ocean). The Red and Mediterranean Seas are well known examples of systems exhibiting this type of circulation. We describe laboratory experiments of the flow in an idealized semi-enclosed sea, with a configuration similar to the natural examples, where the sea is uniform in width and separated from an ocean by a shallow sill. Steady withdrawal of buoyancy by cooling at the sea surface results in turbulent convection and an associated lateral buoyancy gradient across the sill. A mean flow is thus driven into the sea near the surface becoming progressively more dense as it traverses the length of the sea before turning 180 degrees and flowing back out of the sea at depth. This circulation persists above a deep stagnant layer trapped behind the sill.
The net effect of the surface buoyancy flux is reflected in the density of the lower outflowing layer at the sill. The two-layer exchange at the sill is hydraulically controlled and thus coupled with the surface buoyancy forcing through the density signature in the lower layer. The hydraulic control, the mean flow, and the mixing are linked in a complicated non-linear feedback loop. We present observations of the mean and turbulent fields, obtained through particle tracking methods, and interpret the effect of mixing on the control condition and the outflow density and volume flux. In addition, the long-term erosion of the deep stagnant layer is described and related to the geometric scales of the sea and the buoyancy forcing.

EVOLUTION OF SALINATION OF THE BLACK SEA DURING HOLOCENE

Mehmet Karaca, Eurasia Inst. of Earth Sciences, ITU Maslak 80626 Istanbul Turkey, Achim Wirth and Michael Ghil, Dept. of Atmospheric Sciences and Inst. of Geophysics and Planetary
Physics, UCLA Los Angeles, CA 90095 USA

The evolution of the Black Sea's salinity after the opening of the Bosporus about 7500 years

ago is investigated using a simple two-box model. The model consists of watermass and salt conservation equations, allows for changes in thermocline depth. The paleoceanographic box model is forced by the present-day Mediterranean inflow and outflow, and atmospheric forcings. Analytic solutions for the evolution of the box volumes are given. Model salinities reach 90% of their present -day values in both boxes about 2,500 years after the opening of the Bosporus. The evolution of salinities is shown to be almost independent of the evolution of the box volumes and the results are shown to agree with the existing paleoceanographic proxy records.

SILLS AND INTERNAL BORES

Gregory LANE-SERFF (School of Ocean and Earth Science, University of Southampton, Southampton Oceanography Centre, Southampton, SO14 3ZH, UK, email: gfl@soton.ac.uk)

Flows through straits and over sills are often strongly modulated by the tide. Basing calculations on mean conditions and treating the flow as steady may significantly underestimate the mixing that takes place in straits. A common feature of tidally modulated strait flows is the generation of internal bores. It is important to determine how much of the mixing takes place during transient events (such as the passage of an internal bore and its associated internal waves) compared with the mixing that occurs at other times. A striking example of a tidally generated internal bore is that in the Strait of Gibraltar, where the interface between the outflowing Mediterranean water and the inflowing Atlantic water can oscillate by 100 m or more in the vertical over periods of only a few minutes as the bore passes. Oceanographic measurements of the internal bore in the Strait were recovered during a cruise in 1998 led by Dr H L Bryden, using acoustic backscatter, ADCP and an oscillating CTD package. The simultaneous use of these different types of observations allows a comprehensive description of the internal bore to be made.The flow in a two-layer system with a combination of sill and internal bore is also analysed mathematically using shallow water equations and hydraulic control theory. The theory gives predictions for the dependence of bore speeds and layer depths on the initial stratification and the net flow through the strait. The same system is modelled in the laboratory using tanks of saline solution of different density. The laboratory experiments are recorded on a video system and processed to give quantitative information about the flow. The laboratory experiments also give information about the character of the bore, whether it is abrupt or marked by a series of internal waves (undular bore). For the undular bores, the experiments give the amplitudes and wavelengths of the waves. The results from all these methods of investigating unsteady flow through straits are compared, and we outline directions for future research.

QUASI-STATIONARY TWO-LAYER EXCHANGE FLOWS THROUGH LONG STRAITS

Vladimir MADERICH (Institute of Mathematical Machine and System Problems NASU, Glushkova pr. 42, Kiev 252187, The Ukraine. Email: vlad@maderich.pp.kiev.ua)

Quasi-stationary water exchange through the narrow strait with two-layer flow structure and net barotropic transport was investigated both experimentally and theoretically. The experimental facility consisted of the tank that was divided on two basins, connected by a shallow and narrow rectangular channel. One basin was heated at the bottom. Another basin was cooled at the top. The results of measurements were given for the short, intermediate and long straits in dependence on the magnitude of the net barotropic transport. The measured depths of interface and volumetric flow rate in the laboratory analog agree reasonably well with computed by a laminar hydraulic model that based on the principle of maximal exchange. The influence of the sills placed inside of the long strait, on the exchange was studied. The results showed strong influence of the position of sill on the exchange in the long straits. These results have been extended on the sea straits with predominated turbulent bottom and interfacial friction. Finally, the response of the chain of the seas connected by the long straits to the seasonal variations of the freshwater budget was investigated for the case Black Sea - Bosphorus - Marmara Sea - Dardanelles - Mediterranean Sea. The one-and-a-half-dimensional sea models supplemented the strait models. The computations showed a complicated response of exchange flows and level in adjacent seas on the seasonal forcing.

TRANSFORMATION OF ATLANTIC WATERS IN THE BARENTS SEA AND THEIR FLOW TO THE EURASIAN BASIN THROUGH ST. ANNA TROUGH

URSULA SCHAUER (Alfred-Wegener-Institut fuer Polar- und Meeresforschung, D-27515 Bremerhaven, Germany, email: uschauer@awi-bremerhaven.de Bert Rudels (Finnish Institute of Marine Research, FIN-00931 Helsinki, Finland) Harald Loeng (Institute of Marine Research, N-5024 Bergen-Nordnes, Norway)Robin Muench (Earth & Space Research, Seattle, WA 98102-3699 USA) Jim Swift (UCSD Scripps Institution of Oceanography, La Jolla, CA 92093-0214, USA)

The ventilation of the Arctic Ocean basins is largely associated with the input of water from the Barents and Kara Seas. Using hydrographic observations, made in the Barents Sea and along the shelf edge of the Kara Sea between 1991 and 1996, and time series of current, temperature and salinity from moorings in the eastern Barents Sea, we discuss the flow and the modification of the water masses between the western Barents Sea and the St. Anna Trough. The inflow of warm, saline Atlantic-derived water from the Norwegian Sea and the low salinity Norwegian Coastal Current feed a permanent eastward flow. An additional input of fresh water is melted ice which is advected from the central Arctic Ocean and the Kara Sea.These three water masses are modified through cooling and the freezing/melting cycle. Two distinct modes are formed, which leave the Barents Sea eastward and descend down the St. Anna Trough. The lighter mode is winter water of low salinity, thus confined to the upper layers, which leaves the Barents Sea seasonally at temperatures close to freezing point. The largest and most dense contribution consists in more saline but only moderately cold bottom water which is formed in the polynya west of Novaya Zemlya through highly brine-enriched water. Subsequent lateral mixing with warmer Atlantic water feeds a bottom-intensified flow throughout the year. At present conditions, both modes form a low salinity input of about 2 Sv to intermediate depths of the Arctic Ocean.

VARIATIONS IN THE MAIN KUROSHIO PATH SOUTH OF JAPAN

Yoshihiko SEKINE (Institute of Oceanography, Faculty of Bioresource, Mie University, 1515 Kamihamachou, Tsu Mie 514-8507 Japan.)

Characteristics of the variation in the Kuroshio path south of Japan is studied by use of the observational distance of the main Kuroshio path from Japanese Coast over the period of 1975 - 1993. It is pointed out that a large meander formed in 1975 has a larger distance from the Japanese coast from Murotomisaki (Muroto Pen.) to Daiohzaki (Daioh Pen.), while its distance from coast in east of Omaezaki (Omae Pen.) is small. In contrast to this, large meanders formed after 1980 show an opposite tendency to have short distances from coast from Murotomisaki to Shionomisaki (Shiono Pen.), while they have larger distance from eastern area of Omaezaki. It is also resulted from the correlation analysis of the distances of the main Kuroshio path from Japanese coast that the path pattern of the large meander path formed in 1975 has a tendency to shift westward, while that formed after 1981 has a tendency to shift eastward. It is shown that the flow pattern of the large meander path is different before and after 1980. It is also resulted that there exists one month (two months) time lag between sea level difference across Nishinoomote - Naze that represents the surface volume transport of the Kuroshio and distance of the main Kuroshio axis off Toimisaki (Murotomisaki), which indicates that an increase in current velocity of the Kuroshio occurs before formation of the small meander of the Kuroshio and its eastward shift. Some other results that give important suggestion on the Kuroshio path dynamics are also detected.

MODELLING STUDIES ON ASPECTS OF THE DYNAMICS OF THE STRAIT OF SICILY

S. PIERINI(Dipartimento di Fisica, Università dell'Aquila, Via Vetoio, I-67010 Coppito (l'Aquila) Italy, Email: pierini@cds.unina.it) A. Rubino (Institut für Meereskunde, Universität Hamburg, Troplowitzstrasse 7, D-22529 Hamburg, Germany, Email: rubino@ifm.uni-hamburg.de)

In order to describe aspects of the baroclinic dynamics of the Strait of Sicily a high resolution multi-layer model has been implemented in a central Mediterranean region including the Tyrrhenian and the Ionian Sea. Three layers have been considered representing waters of Atlantic origin (MAW), the Levantine Intermediate Water (LIW) and deep waters of the Mediterranean. Quasi-stationary circulation schemes representing the effect of an idealized Mediterranean thermohaline circulation are produced by steady fluxes imposed remotely along the open boundaries. In order to follow the evolution of the oceanic response, a norm in the space of the flow patterns in each layer is defined. Thus, by studying the temporal evolution of the "distance" between our numerical solution and the initial motionless state we identified an initial adjustment time of 1-2 months followed by a very slow evolution of the system in which dissipating mechanisms appear to play a major role. We therefore selected our quasi-stationary states just after the adjustment phase. Such states can be interpreted as possibledynamic scenarios of the seasonal variability. In the simulations an inflow of MAW and an outflow of LIW through the Strait of Sardinia, an outflow of MAW and an inflow of LIW through the Ionian boundary and an outflow of MAW through the Corsica channel are imposed, resulting in a vanishing total net transport in each layer within the basin. For realistic values of the imposed transports the model captures some of the main features of the observed circulation in the area of the Strait of Sicily, such as: (a) the separation of the Algerian current intotwo branches (one directed toward the Tyrrhenian and the other toward the strait) of relative intensity in agreement with observations; (b) a secondary bifurcation of MAW within the strait giving rise to a southward moving current which follows the Tunisian continental slope and to a current that, after flowing south-eastward along the southern Sicilian coast, travels northward as a coastally trapped current; (c) a bifurcation of LIW at the strait level leading to a main current directed toward the Strait of Sardinia and to a weaker current crossing the strait and bending eastward along the northern Sicilian coasts. Variations of the boundary fluxes in the MAW and LIW layers have also allowed to determine that the horizontal distribution of the MAW flow across the Strait of Sardinia does not exert a relevant influence on the circulation in the zone of interest, and that the bifurcation of the Algerian current strongly depends on the LIW transport, i.e. the Tyrrhenian branch of the MAW decreases as the LIW transport decreases.

A THREE-LAYER MODEL FOR THE STUDY OF TIDALLY INDUCED DENSITY CURRENTS

Rainer Weigle, Peter BRANDT, and Angelo Rubino (Institut für Meereskunde, Universität Hamburg, Troplowitzstr. 7, D-22529 Hamburg, Germany, Email: brandt@ifm.uni-hamburg.de)

The dynamics of tidally-induced internal waves is investigated by using a numerical three-layer model based on the weakly nonlinear, weakly non-hydrostatic Boussinesq equations. Numerical solutions of the three-layer Boussinesq equations are compared with analytical solutions of different equations describing internal solitary waves in a two-layer system. In contrast to the two-layer models, the three-layer model is capable of describing the evolution of sub-surface jets. As a result of the three-layer model these jets develop undulations that finally disintegrate into internal solitary waves. Several characteristics of these waves, like e.g., wave amplitude and distance between the first two solitary waves of a wave train are studied as a function of the initial jet velocity and the stratification. Results of the numerical simulations are compared with results of high resolution in-situ measurements carried out north and south of the Strait of Messina, in the European Mediterranean Sea. Implications of the presented study for a possible inversion of sea surface manifestations of oceanic internal waves into characteristics of the interior ocean are discussed.

MODELLING THE RIFT-VALLEY FLOW OF THE MID-ATLANTIC RIDGE

A.M. THURNHERR, K.J. Richards, and M.M. Lam (School of Ocean and Earth Sciences, Southampton Oceanography Centre, Southampton SO14 3ZH, UK)

The hydrography and flow field of the AMAR segments of the Mid-Atlantic Ridge (35 Deg 35' N - 36 Deg 45' N) were investigated by analysing CTD data from two hydrographic surveys, a set of LADCP profiles, and data from an array of moored current meters deployed for one year. The bathymetry of the rift valley can be approximated as a sequence of deep basins separated by shallow sills. Hydrographic sections across these sills show potential density contours consistent with unidirectional, hydraulically controlled, along-valley flow. This is supported by the current meter observations, which show unidirectional flow of order 0.1 Sv along the valley throughout the one year deployment. Based on the T/S characteristics of the rift-valley water as well as direct density observations, the flow is most likely fed by an inflow sill on the eastern valley wall of the southernmost basin of the segment.

Based on these observations a simple basin/sill model for the along-valley flow is constructed. Topics to be studied using this model include: the timescales of the flow; the nature and variability of its forcing; the most likely destiny of the rift-valley water; and the sensitivity of the flow to rift-valley processes, such as the localized hydrothermal density flux which occurs just upstream of one of the sills studied.

LATERAL CIRCULATION DRIVEN BY AN OVERFLOW

Jody M. KLYMAK and Michael C. Gregg (both at APL/U. of Washington, 1013 NE 40th St., Seattle, WA 98105; 206-543-1300; e-mail: jklymak@apl.washington.edu)

The importance of interfacial stress and entrainment on the dynamics of an overflow is generally recognized. Interfacial stress slows the overflow, while mixing dilutes it and makes it lighter. However, the importance of stress and mixing on the water above an overflow is not usually discussed.
Recent observations in Knight Inlet (B.C.) show that an overflow can drive strong recirculations. We believe that shear instabilities along the top of the overflow accelerate the overlaying water. This acceleration is local because it only occurs over the overflow, which creates a cross-channel divergence in the overlaying water. A matching pair of recirculations transport water across the channel to fill this divergence. These recirculations strongly affect the flow in Knight Inlet. For instance, they draw mixing ingredients into the flow laterally, they bias volume budgets, and they confuse determinations of the level of no-motion which has traditionally been used to define the vertical extent of an overflow.
We hypothesize that these recirculations are a general phenomena in supercritical flows. First, supercritical flows are often susceptible to shear instabilities which exchange momentum and fluid between the overflow and the overlaying water. In addition, supercritical flows are too fast to allow pressure signals to propagate back upstream. This means that the local acceleration in the lee of the sill cannot change the flow upstream of the sill crest, and the increased flow can only be supplied by circulation in the lee of the sill. Since the major overflows are almost all supercritical at some point, we expect that they all drive lateral recirculations.

MULTI-PHASE DISTRIBUTION OF ORGANIC MICROPOLLUTANTS IN XIAMEN HARBOUR, CHINA

J.L. Zhou (1), Z. Zhang (2), K. Maskaoui (2) and H. Hong (1) School of Ocean Sciences, University of Wales Bangor, Menai Bridge, Anglesey LL59 5EY, UK, (2) Environmental Science Research Centre, Xiamen University, Xiamen 361005, P.R. China

Abstract 2. Xiamen Harbour, In Xiamen Special Economic Zone of the People's Republic of China, was studied for its water and sediment quality, by determining the levels of 16 polycyclic aromatic hydrocarbons (PAHs), 12 polychlorinated biphenyls (PCBs) and 18 organochlorine insecticides in water, porewater and sediment samples from nine stations in the Harbour. Total PAH concentrations varied from 106 to 945 ng/l in water, 0 to 3548 ng/l in porewater, and 247 to 480 ng/g dry weight in surficial sediments. Total PCB levels varied from 0.12 to 1.69 ng/l in water, 2.67 to 34.80 ng/l in porewater, and 0 to 0.32 ng/g dry weight in sediments. The levels of all insecticides were in the range 6.60 - 19.56 ng/l (water), 11.93 - 78.53 ng/l (porewater), and 0 - 0.58 ng/g dry weight (sediment). The levels of total hexachlorocyclohexane (HCHs) in sediments varied from 0 to 0.14 ng/g dry weight, and those of total DDTs were in the range 0 - 0.06 ng/g dry weight. The micropollutants were present in higher levels in porewater than in surface water, due to the preference of these hydrophobic compounds for sedimentary phase than for water. Such a concentration gradient imply a potential flux of pollutants from sediments to overlying water. The levels of pollutants in sediments were one to several orders of magnitude lower than those in 1993, suggesting their decreased inputs in recent years and possible degradation over a period of time. Further work is needed to quantify the levels of these contaminants in suspended particulate matter, which are currently below the limits of detection.

TROPICAL REGIONS OF FRESHWATER INFLUENCE

ALEJANDRO J. SOUZA (Centre for Coastal & Marine Sciences, Proudman Oceanographic Lab, Bidston Observatory, Birkenhead, L43 7RA, UK email: ajso@ccms.ac.uk) and John H. Simpson (School of Ocean Sciences, Menai Bridge, Anglesey, LL59 5EY, UK).

The processes involve in the dynamics of Regions of Freshwater Influence (ROFIs) have been studied for some time in the first world countries, this has lead to basic understanding of this systems. But the Mayor ROFIs are located in tropical regions and predominatly third world countries in America, Asia and Africa, most of these systems are little studied and insitu data is scarce or non existant. The study of tropical ROFIS is of great importance to the global ecology as is here that there is great diversity of marine organisms live or develope, at the same time these regions are subject to important fisheries and in some cases are subject to large inputs of agreochemicals, as in the case of west Mexico and Mozambique. This calls for a knowledgable mangement of the Tropical ROFIs, which only be possible if the knowledge aquired in developed countries is transfered to underdeveloped countries.

MANGROVE DENUDATION AND ECOLOGICAL CHANGES IN A BAY-ESTUARY SYSTEM ON THE EAST COAST OF INDIA

Raman A.V., Frank Dehairs*, Chandramohan, P., Dipti Raut, Murthy, N.V. S. S., Rohini, T. and Satyanarayaiia, B. (Marine Biological Laboratory, Department of Zoology, Andhra University, Visakhapatnam-530 003, India, email: pcmavr@md2.vsnl.net.in) *Department of Analytical Chemistry (ANCH), Virje Universiteit Brussel, Pleinlaan 2, B-1050 Brussels, Belgium, email: fdehirs@vub.ac.be)

Kakinada Bay, a shallow (<5 m) bar-built water body on the east coast of India, underwent many topographical changes attributable to port expansion programmes and industrial development recently. The Bay which covers an area of approximately 132 sq.km. is surrounded by extensive estuarine areas with enormous mangrove vegetation mainly, Avicennia, Excoecaria, Rhizophora, Aegiceras, Lumnitzera, Ceriops and others. In recent years, there has been a spurt in shrimp farming activity in this area which resulted in the destruction of much of this vegetation, the impingement being very severe in some localities. Investigations during the last three years (1994-1997) revealed appreciable changes in water quality and organisms in the Bay and tributaries, Coringa and Gaderu, as a result of these activities. In Coringa-Gaderu region close to shrimp farms, a several fold increase in nitrate (max. 83.52 µg.at/1) and phosphate (max. 41.6 µg.at/1) levels was noticed. Several species of phytoplankton notably Navicula, Skeletonema costatum,
Pleurosigma angulatum and Nitzschia closterium occur here often in bloom proportions (8,000 cells/ml). Within the Bay, regions once supported dense assemblages of benthic organisms (molluscs) Anadara, Placuna, Tonna and Turritella have now given place to different species owing to changes in sediment nature. Over the years, population size of these species decreased as a result of over exploitation commercially. The paper purports to draw comparisons between this study with those conducted in 1959-1964 attributing changes to anthropogenic effects during the intervening years.

OVERTURNING LENGTH SCALE AS AN INDICATOR OF THE WASTEWATER NEAR FIELD

Vlado MALACIC (Marine Biological Station, National Institute of Biology, Piran, 6330, Slovenia, email: malacic@nib.si)

During a period of calm weather and stratified water column of a shallow (depth = 21 m) semi-enclosed sea, six surveys of the wastewater near-field of two adjacent submarine diffuser outfalls, with a low sewage ouflow rate (usually less than 220 l/s), were conducted with a fine-scale CTD probe. The survey area of 780mx740m was monitored with the free-falling probe at 30-31 stations. Vertical velocity of the probe was nearly constant, 1 m/s, and the data was retrieved at a frequency of 50 Hz, providing a vertical resolution of 2.5 cm.
When using a fine-scale CTD it has been observed that from the vertical distribution of 'virtual' displacements (Thorpe displacements) of particles with a sampled density, by which each particle would gain a statically stable position, the length scale of overturning events could be estimated, through an appropriate averaging process.
Within the turbulent wastewater field the fluctuations of temperature were of the order of 0.1˚C, and of salinity less than 0.05 psu, generating overturning. The vertical extent of the overturning events could well be determined using the maximum vertical displacement, or the Thorpe length scale. Both scales also indicate the thickness of the neutrally buoyant subsurface wastewater field. Distribution of these length-scales over the diffussors show a clear picture of the wastewater field(s) of a thickness smaller than 1m in windless, stratified conditions, which is otherwise hard to obtain without costly experiments (dye tracers).

PW1/P/03-A6 **1120**

OCEANOGRAPHIC PROCESSES AND IMPACT OF HUMAN ACTIVITY ON COASTAL EROSION:A CASE STUDY FROM KARNATAKA, INDIA

K S JAYAPPA (Marine Geology Faculty, Mangalore University, Mangalagangotri-574199, Karnataka, India, email: jayappa@mnglr.ernet.in)

Complex nearshore processes change continually and derive their energy from waves and currents. Variations in energy distribution within the surf zone cause transport of sediment alongshore and offshore. Beach erosion in Karnataka has become a severe problem since last two decades. It is estimated that out of 290 km, 80 km is vulnerable to erosion during SW monsoon. The factors which are responsible for erosion of this coast are: storm waves, tidal and longshore currents, wave refraction (all natural), construction of ports, harbours, breakwaters, seawalls, damming of rivers and sand mining (all man-made). Of these, the man-made erosion and steps taken for its prevention are important ones to be attended immediately. In recent years, coastal communities are inhabiting newly developed coastal landforms. Beach erosion is part of a cyclic process and maintains a seasonal balance between erosion and accretion, but in some cases net erosion or accretion takes place. Erosion of beaches could be minimised by preventing (1) human interference with coastal processes, (2) inhabitation of fragile zones, and (3) sand mining from beaches and estuaries. Seawalls which are used as erosion management tools, often complicate the erosion problem or shift the erosional sites to adjacent areas. In general, the cost of seawall construction and maintenance is greater than the value of the property saved. In some cases they have been destroyed by huge waves thereby recreational potentials of beaches are lost and posed a severe threat for shore-based fishing activity.

PW1/E/02-A6 **1140**

ON THE ISTRIAN COASTAL COUNTERCURRENT

Nastjenjka Supic (Centre for Marine Research, Rudjer Boskovic Institute, G. Paliaga 5, 52210 Rovinj, Croatia, email: supic@cim.irb.hr) Mirko ORLIC (Andrija Mohorovicic Geophysical Institute, email orlic@olimp.irb.hr) Danilo Degobbis (Centre for Marine Research, Rudjer Boskovic Institute, email: degobbis@cim.irb.hr)

By computing the relative (with respect to the 30 dbar surface) and absolute geostrophic currents and net transports from hydrographic data collected monthly to seasonally at six stations of the Po-Rovinj profile in the northern Adriatic, we demonstrate the existence of a descending current which usually appears in August along the Istrian coastal line and runs counter to the general Adriatic-wide cyclonic flow. We name it Istrian Coastal Countercurrent (ICCC). The current is found to be confined to the surface (of a 10 m depth) and coastal boundary (of a 10 km width) layers. Its mean relative speed is high, 7 cm/s (relative currents at the profile on average stay below 5 cm/s in winter and below 8 cm/s in summer), inducing a net geostrophic outflow near the Istrian coast. The ICCC was strong in 1968, 1977, 1983, 1984, 1988, 1989, 1991, 1992, 1996 and 1997, weak or absent in 1971, 1972, 1973, 1982, 1986, 1993, 1994 and 1995. Whenever the ICCC was well pronounced, a strong northerly flow was observed in the central part of the northern Adriatic profile, whereas a thick surface or subsurface layer of low density was found in the open waters off Rovinj. This points to a possible existence of a cyclonic gyre east of the Po delta and/or anticyclonic gyre off Rovinj. The existence of ICCC is confirmed by direct current measurements, which show that the descending coastal current was intense in 1977 and 1983, and that it did not develop in 1976, 1978 and 1987. The August intensity of the ICCC significantly correlates with the sea surface temperature (SST) recorded in preceding March in the northeastern Adriatic. Using a polynomial fit of the ICCC speed on the northeastern Adriatic SST a weak or non-existent ICCC is hindcasted for 1976 and 1987. It seems that a high intensity of ICCC coincides with oceanographic conditions which favour near anoxia or mucilage events, observed in 1988, 1989, 1991 and 1997.

PW1/W/03-A6 1200

INTERNAL WAVES AND ACOUSTIC FIELDS IN THE SHELF ZONE OF SEA

Vadim V. NAVROTSKY, Alexander N. Rutenko (Pacific Oceanological Institute, 43 Baltiyskaya Str., Vladivostok, 690041, Russia, email: navr@online.vladivostok.ru)

Some results of experimental investigation of internal waves and their influence on the characteristics of acoustic fields in the shelf zone of the Japanese Sea are presented. In our field experiments we used continuous signals with sinusoidal frequency modulation in the range 306- 328 Hz. Simultaneous measurements of acoustic parameters and water temperature fluctuations at different levels were made with the help of a measuring system, placed at distance of 250 m from the emmitor with the site depth of 38 m. It is shown, that intensities of acoustic signals with 4% difference of frequencies have rather different variations in time, sometimes in counterphase. The differences are maximum at levels, where the interference minimum is observed. Half-day tides cause 3 Hz displacements of the minimum in the interference structure of the measured acoustic field. The statistical analysis of temperature fluctuations at different levels was made. It was shown that in the range of short internal waves the most pronounced effects are due to resonant interactions of acouctic waves with sound velocity inhomogeneities, registered by temperature sensors. The main result of such interactions is redistribution of acoustic energy among normal modes with general flow of energy into higher modes and phase randomization.

PW1/E/01-A6 1220

ANTHROPOGENIC DISCHARGES INTO THE MOZAMBIQUE CHANNEL

U.ASWATHANARAYANA (c/o Ministry for the Coordination of Environmental Affairs, C.P. 1947, Maputo, Mozambique. Email: anarayan@zebra.uem.mz)

Mozambique Channel receives two kinds of anthropogenic discharges:
(1) Discharges (accidental or deliberate) from about 200 ships (mostly tankers) that pass through the Mozambique Channel daily - no discharge data is available in this regard, and (2) anthropogenic discharges from the coast - these are studied along four principal coastal towns from south to north, namely, Maputo, Beira, Quelimane and Pemba.
In the case of Maputo and Beira, the industrial discharges into the sea are due to the port, oil installations, food and beverage processing, batteries, edible oils and soaps,textiles, fishing and canning, tourism, animal farms, etc. Municipal sewerage, with human faeces, is discharged into the sea untreated, with the consequence that the seawater is heavily contaminated with E.Coli (x 1000/100 mL). In the case of Quelimane and Pemba, the industrial discharges into the sea are minimal, but the biological pollution of the sea is serious, as a good part of the population defaecate in the mangroves or on the beach. The human faeces get washed into the sea at high tide, and end up in fish which people consume. If there are cholera pathogens in the human faeces, cholera epidemic results. The cholera epidemic caused by ENSO-induced flooding along the east coast of Africa, killed an estimated 5000 people last year.

STABILITY AND MORPHOLOGY OF THE COASTAL CONTOURS FROM SEDIMENTOLOGICAL LIFTING IN THE FORTALEZA-CE AREA, BRAZIL

Prof Agenor Cunha da Silva

This work was generated from studies required to the Directorate of Hydrography and Navigation of the Brazilian Navy by the National Union State Secretariat of the Ministery of the Treasury in order to analyse the evolution of coastal features in the municipalities of Fortaleza, Aquiraz, Caucaia and São Gonçalo do Amarante, Ceará State, Brazil, with views to determine the real mean high water line to charge taxes. The mean high water line was referred initially by the mean sea level in 1831, and it must be corrected because of the possible changes in that line. It includes granulometry and analysis of the sediments collected along the coast, between September 28 and October 02, 1993. The stability and contours of Northeastern and Southeastern beaches of Ceará, Brazil were researched. In addition, the intensity and evolution of the coastal process were examined in order to make a diagnosis, with the use of sedimentology, of areas where the contour mobility may imply loss of accuracy in cartographic works.

PW1/P/02-A6 1420

THE FUTURE PROSPECTS OF OCEANOGRAPHIC RESEARCH IN THE MEDITERRANEAN AND RED SEAS BY THE SURROUNDING DEVELOPING COUNTRIES

S.H. SHARAF EL DIN, Oceanography Department, Faculty of Science Alexandiua University

POEM is a multi-national co-operative research program initiated and carried out by scientists in both the regional oceanography and the potential of the eastern Mediterranean to provide a laboratory basin for global processes. In the past, some of the developing countries surrounding the eastern Mediterranean shared with a limited efforts in the various studies. More recently, several developing countries such as Egypt, Israel, Lebanon, Syria and Libya started to increase their scientific activities in the eastern Mediterranean. In Egypt, a lot of studies have been done on the management of the Egyptian Mediterranean coastal areas. Recently, study of the effect of some environmental factors on the distribution of the phytoplankton in the banias region on the Syrian coast has been taken place, In Lebanon, a model was constructed as a useful tool for the rehabilitation, protection and development of the Lebanese coast. Also, the status and solution of Beirut Bay wastewater problem was studied extensively. In Lybia, the marine science activities were devoted more recently to the fisheries, pollution and coastal zone management.
In the Red Sea area, most of the work carried out in Suez, Bay, was mainly pollution and coastal zone management. In Aquba Gulf, most of the work done by a group of scientists from USA, Egypt and Israel. The project was mainly devoted to study the biological and environmental parameters in the Gulf. In the Red Sea, the research projects are still limited to the regional boundaries.

PW1/E/06-A6 1440

CZM AND THE COASTAL SEA: THE NEED TO ASSESS COASTAL ZONE VULNERABILITY AND APPLY LONG TERM STRATEGIC MEASURES

A. N. BALCHAND (Department of Physical Oceanography, Cochin University of Science and Technology, Fine Arts Avenue, Cochin 682 016, India, email: oceans@md3.vsnl.net.in)

The interaction between the land and oceans has been recognized as an important surface process of short and long term time scales. The dynamic properties and functional attribute of the coastal zone are the results of cumulative global environmental change - sea level changes, landscape alterations, marine ecosystem changes, trends in sedimentary behavioral patterns, hydrological factors and so forth. Of immediate concern is the coastal zone vulnerability arising due to climate change, subsidence and recession of coastlines, mining activities, water abstraction and large changes in wetland management. Study subjects often chosen relates to areas at change and related population at risk, agricultural production at change and ecosystem losses. The sensitive tropical coastal regions (mostly in low lying lands) which are highly productive and densely populated are currently threatened by above stated changes. Thus the need to assess coastal zone vulnerability based on information gathered on the physical environment, geomorphological setup, evaluation of varying trends of both natural and anthropogenic influences is relevant. The evaluation methodology shall aim at assessing the extent of damage already inflicted to the region, the response pattern, the remedial measures adopted and thus help us to deduce better understanding on the development of the fragile coastal sea. A suitable database covering land water uses and practices, development of wetlands, their functions and resources along with risk estimation and hazard evaluation would lead to the right application of long term strategic measures.

PW1/E/07-A6 1500

IMPACT OF RIVER DIVERSION IN SOUTHERN IRAQ ON THE HYDROBIOLOGY OF THE NORTHERN ARABIAN GULF

FAIZA AL-YAMANI Kuwait Institute for Scientific Research, P.O. Box 1638, Salmiyah-22017, Salmiyah, Kuwait.

The Arabian Gulf is a semi-enclosed body of water located in a climatically arid region with an average depth of 35 m, with a maximum depth of 120 m. Its only source of freshwater is seasonal and from the Shatt al-Arab in the north. High evaporation rates in excess of precipitation and river discharge result in high salinity (~ 42 psu). Frequent northwesterly winds mix the northern Gulf's shallow waters contributing to the resuspension of particulate matter and high turbidity from the silt-laden waters of the Shatt al-Arab. Freshwater enters the northern Gulf via the Shatt al-Arab, with an estimated annual discharge rate of 5 to 100 km3/yr. The Shatt al-Arab watershed and associated marshes are the main sources of nutrients that sustain a high productivity in the northern Gulf. Recently, Iraq completed its diversion of the Euphrates River to a man-made canal named the Third River which flows to the northwestern part of the Gulf. Additionally, more than 60% of the marshes in southern Iraq have been drained. Such developments as well as the ongoing Southeast Anatolia Project in Turkey, will exert a great impact, particularly in the northern Gulf. Comparison of recent data (1995-1998) with the earlier showed : a) a decrease in salinity in the northwestern Gulf to 25.60-33.00 psu, b) elevation of nutrients to higher ranges (6-15 mg-at/l nitrates, 0.4-0.9 mg-at/l phosphates, and 26-43 mg-at/l silicates). This is attributable to the impact of additional river runoff from the diversion. Additionally, higher turbidity levels (58-174 NTU), and higher phytoplankton biomass were recorded for the northern waters. Changes in the marine ecosystem resulting from alteration of flow regimes and water quality of the Shatt al-Arab waterway will probably have a major impact on the fishery resources of the northern Gulf. Especially the economically important species such as the shrimp-Metapenaeus affinis, the pomfret Pampus argenteus, and the suboor Tenualosa ilisha which are known to directly depend on freshwater inflow for spawning or nursery habitat. Additionally, indirect effects, operating through changes in the food web, may further impact population abundances, species diversity and imbalances amongst species.

PW1/W/01-A6 1520

THE HEAT BUDGET OF A TIDAL BAY

SHIGALLA B. MAHONGO Tanzania Fisheries Research Institute P.O. Box 9750 Dar es Salaam Tanzania

Atmospheric, sea surface temperature and sea level data were collected for a 23-day period at Chwaka bay (Zanzibar Island)in 1996. The data were used to calculate the turbulent fluxes of heat and moisture from a bulk aerodynamic method. The net radiative (long-wave and short-wave) heat fluxes were computed from records of incoming and outgoing short-wave radiation, and net all-wave radiation. An independent method was used to calculate the advective heat flux, and results conformed with a qualitative analysis of net surface heat flux in relation to the tidal phase, and to the water temperature variability. The effect of water-sediment heat conduction was basically a net transfer of heat from sediments to inundating water layers. The heat budget of the bay involves a near balance between heating by solar radiation, and cooling by evaporation and advective exchange with the open ocean. Maximum net surface heating occurs at around noon, while maximum net surface cooling takes place immediately after sunset.

CLIMATE CHANGE AND RADIATIVE FORCING BY ANTHROPOGENIC AEROSOLS: A SUMMARY OF CURRENT UNDERSTANDING

Joyce E. Penner (Department of Atmospheric, Oceanic and Space Sciences University of Michigan Ann Arbor, MI 48105, USA email: penner@umich.edu).

The Intergovernmental Panel on Climate Change (1996) published estimates for the direct and indirect forcing by anthropogenic sulfate, soot, and biomass aerosols which ranged from -0.2 Wm-2 to -2.5 Wm-2. It is important to decrease the uncertainty associated with this range of forcing because if the forcing is as small as suggested by the lower limit and if the temperature change experienced in the last 100 years is mainly from the warming caused by greenhouse gases, then the climate should be relatively insensitive to greenhouse gas increases. On the other hand, if the forcing is as large as -2.5 Wm-2, then climate sensitivity to anthropogenic forcing is probably at the higher range of estimates and some of the observed increase in temperature must be associated with natural variability. Since the 1996 report, a number of advances and assessments of both the direct and indirect forcing by anthropogenic aerosols are available. This talk will summarise our current understanding of both the direct and indirect forcing and summarise current model capabilities to assess this forcing.

MI01/W/12-A1 0945

COMPARISON OF THE VERTICAL DISTRIBUTIONS OF SULFUR SPECIES FROM MODELS PARTICIPATED IN THE COSAM EXERCISE WITH OBSERVATIONS

Ulrike Lohmann (Dept. of Physics, Dalhousie University, Halifax, NS, B3H 3J5, Canada, email: Ulrike.Lohmann@Dal.Ca) Len Barrie, Richard Leaitch, Yuhong Yi (all at Atmospheric Environment Service, Downsview, ON, M3H 5T4, Canada) Kathy Law (Dept. of Chemistry, University of Cambridge, Lensfield Road, Cambridge, CB2 1EW, U.K.) and modellers

The comparison of large scale models simulating atmospheric sulfate aerosols (COSAM) was conducted to increase our understanding of sulfate aerosols and precursors. Earlier model comparisons (Rasch et al. 1999) focussed on wet deposition measurements and sulfate aerosol concentrations at the surface. It was found that different models simulated sulfate surface concentrations which agreed reasonably well with observations, but the column burden or the concentrations aloft were very different amongst different models. Thus, in the COSAM exercise, one aspect is the comparison of sulfate aerosol and precursor gases above the surface. Vertical profiles from observations are available from the NARE experiment, which took place in August/September 1993 off the coast of Nova Scotia, Canada and from EMEFSII, which took place in March/April 1990 in Ontario. Results from the participating models (global climate models and chemical transport models) will be presented in this talk.

MI01/E/12-A1 1005

SIZE DISTRIBUTION AND COMPOSITION OF ATMOSPHERIC AEROSOL PARTICLES IN MARINE AND CONTINENTAL INFLUENCED AIR

Sabine GRUBER, Sabine Matthias-Maser and Ruprecht Jaenicke (Institute for Atmospheric Physics, University of Mainz, Becherweg 21, 55099 Mainz, Germany; email: gruber@mail.uni-mainz.de)

The atmospheric aerosol is an external mixture of various particle types including minerals, sea salt, soot, biological particles and others. The composition as well as the concentration of the aerosol particles have a vast impact on the formation, microp hysics and chemistry of clouds. For most numerical cloud simulations in marine air the particles are assumed to consist of sea salt only and hence to be 100 % water soluble. Recently it was shown that modelling marine clouds with a more realistic solubility of particles leads to noteworthy differences in the cloud droplet spectra. In this study, aerosol particles were collected size distributed on the island of Helgoland in the North Sea. The particles were investigated in a scanning electron microscope which was combined with an energy dispersive X-ray detector. Interpreting the morphology and elemental composition of each single particle, the particles were classified into different aerosol types. The size distributions for the various aerosol types were determined in the particle size range 0.2 µm < radius < 2.2 µm, for the tot and the biological aerosol even in the size range 0.2 µm < radius < 41.6 µm. It turned out that in marine influenced air masses only half of the particles consisted of sea salt while 17 % were calcium sulphates and 9 % biological particles. The remaini ng 25 % of the particles consisted of soil dust, particles derived from combustion processes and others. It is well known that both the calcium sulphates and the biological particles have marine sources.
Calcium sulphate is produced by fractionated cryst allisation of sea salt and biological particles like algae are spread into marine air by the bubble burst mechanism. Our measurements show that they are an important portion of the marine aerosol and therefore their existence should be taken into consider ation when simulating marine scenarios.

MI01/W/09-A1 1025

A SCHEME FOR MODELLING BLACK CARBON AND SULPHATE AEROSOLS IN GENERAL CIRCULATION MODELS

Øyvind SELAND and Trond Iversen Department of Geophysics, University of Oslo P.O.Box 1022 Blindern,0315 Oslo Norway

As a first step towards estimating the effects of aerosols on the earth's radiation budget, the spatial and seasonal distribution of the two aerosol components is calculated.The scheme is assigned to crudely take into account size distribution as a function of aerosol age. Aging is parameterised by coagulation processes, humidity processes and scavenging. In addition aging processes also describe the transition from elemental carbon with hydrophobic properties externally mixed with hygroscopic sulphate, to an internally mixed aerosol.
The scheme has been developed in a hemispheric transport model that uses analysed meterological data from the ECMWF. This was done to be able to validate the scheme by comparing the results with measurements from the same time period. The turnover times calculated in the hemispheric model were 1.8 days for sulphur dioxide, 3.7 days for sulphate and 3.7 days for black carbon. Some sensitivity tests were performed as well, showing that the results were very sensitive to changes in the parameterisation of below-cloud scavenging. To obtain global distribution of the components the scheme is now included in the NCAR CCM3 General Circulation Model.
Results from the calculations will be presented, and compared with available measurements, with the main emphasis on the results from the CCM3. Both seasonal,latitudinal and vertical variations of particle concentrations will be discussed.

THREE DIMENSIONAL MODELLING THE EVOLUTION OF THE DUST PARTICLE SIZE DISTRIBUTION DURING THE ACE-II FIELD CAMPAIGN

Peter R. COLARCO, Irina N. Sokolik, and Owen B. Toon (all at Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, CO 80309-0392, USA,
email: Peter.Colarco@Colorado.EDU)

The properties of mineral aerosols are highly variable in space and time, and are poorly understood. A major question is how the size distribution evolves as dust is transported downwind from its source region. The evolution of the size distribution is important for the assessment of direct radiative forcing by mineral dust and for satellite retrieval validations. We have incorporated an aerosol microphysical model into a three dimensional GCM to simulate dust emission and transport. Because the GCM is driven by assimilated meteorological fields, it can be used to simulate specific events and be tested against specific observations. Currently, the dust model includes an emission scheme to account for source strengths and locations, and a removal scheme to account for gravitational settling, dry deposition, and wet removal. We focus on the analysis of the time-dependent size distribution as Saharan dust is transported in the vertical and horizontal directions. The model is applied to the timeframe covered by the ACE-II experiment (mid-June through July, 1997). The model is able to reproduce dust optical depths and a plume shape in a good agreement with observations made by the AVHRR and TOMS instruments. The model results are also compared with observations made by ground based sun-photometers and other instruments from the ACE-II campaign. Future directions of this work are also discussed.

MI01/E/04-A1 1130

MODELLING MINERAL DUST IN AN AGCM: PARAMETRIZATION AND RADIATIVE FORCING

STEPHANIE WOODWARD and David L Roberts (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SY, UK.)

Mineral dust aerosol is produced primarily through the action of wind on bare soil, the largest sources being in the major deserts. Small dust particles may be carried great distances and are found throughout the troposphere. The quantity of dust in the atmosphere may be large enough for it to have an appreciable effect on the earth's radiation balance, through both shortwave and longwave forcings.
A dust parametrization has been developed for the Hadley Centre climate model, in which dust is produced when the surface friction velocity exceeds a threshold. The magnitude of the dust flux depends on the friction velocity, air density, vegetation cover,soil moisture and particle size distribution. Dust is transported as six model tracers representing different particle size classes. Deposition processes include below-cloud washout, and dry deposition due to turbulent mixing and gravitational settling. The radiative properties of dust have been incorporated into the model's Edwards-Slingo radiation code.
Model integrations have been performed with the new scheme, to compare modelled dust distributions with observational data and to estimate radiative forcing. Partial cancellation occurs between shortwave and longwave forcings, and the global mean net top-of-atmosphere forcing is further reduced by spatial averaging over areas of opposite sign. There are still many uncertainties, particularly associated with dust production and radiative properties and the sensitivity of modelled dust amounts to many variables. However, it appears that the radiative forcing due to mineral dust may be appreciable, particularly on a regional scale.

AN ILLUSTRATION OF THE TRANSPORT AND DEPOSITION OF MINERAL DUST ONTO THE EASTERN MEDITERRANEAN

Nilgun Kubilay (Institute of Marine Sciences, Middle East Technical University, P.O. Box 28, Erdemli-ICEL, 33731, Turkey, email: kubilay@ims.metu.edu.tr) Slobodan Nickovic (University of Malta, Foundation for International Studies, ICoD, St Paul Street, Valletta, Malta, email:nicko@icod.org.mt) Francois Dulac (Centre des Faibles Radioactivites, CNRS-CEA, F91198, Gif-Sur-Yvette Cedex, France, email:dulac@lsce.saclay.cea.fr)

The analyses of aerosol samples and deposition (wet) measurements during August 1991 - December 1992 at Erdemli (36°N, 34°E) located on the Turkish coast of the Eastern Mediterranean has shown higher dust concentration and total deposition during transitional seasons (spring and autumn) compared to summer and winter seasons. The data, complemented by three-dimensional (3-D) air mass back trajectories and satellite observations suggest that North African and Middle East desert derived dust particles are transported to the region during transitional seasons. Transport events in the last part of March 1992 and early October 1992 are studied through combined analyses of ground based and satellite observations and modelling results. It is shown that dust transport constitutes a large fraction of the annual atmospheric deposition in the eastern Mediterranean, with two deposition events of short duration accounting up to 30 % of the total annual flux. Therefore, the dissolved and particulate species associated with dust could be extremely variable in the mixing layer during large deposition events and could easily be missed in a short -- term sampling program. The possible impact of large pulses on biological productivity of the sea also warrants consideration.

COMPUTED SULPHATE AND NITRATE AEROSOL ATMOSPHERIC LOADING IN EUROPE

Krzysztof Olendrzynski, Svetlana Tsyro, Jerzy Bartnicki, Jan Eiof Jonson, and E.Berge (Meteorological Synthesizing Centre-West of EMEP, Norwegian Meteorological InstituteP.O.Box 34, Blindern, N-0313 Oslo, NORWAY)

Hazardous effects of atmospheric aerosols are numerous and appear on different time and space scales. The radiative forcing by aerosols is largest in industrial regions, but it can also have hemispheric and global effects. Estimations of radiative forcing rely primarily on aerosols concentration distribution calculated with chemical models and, thus, depend on the models adequate results. On the regional scale aerosols contribute to acidification and eutrophication of ecosystems, impaired visibility and adverse health effects. EMEP (Co-operative programme for monitoring and evaluation of the long range transmission of air pollutants in Europe) operates a 3-D Eulerian acid deposition model to compute concentration levels of nine sulphur and nitrogen components over Europe. The air concentrations and acidifying depositions derived from them when presented in a form of country-to-country budgets, provide a scientific basis for emission reduction negotiations under the UN Convention on Long-Range Transboundary air Pollution. The EMEP Eulerian model has twenty vertical layers (up to 100hPa) and horizontal resolution of ca. 50km x 50km. Input data include: official EMEP anthropogenic emissions of sulfur, nitrogen oxides and ammonia, as well as natural sulphur emissions; real-time meteorological data derived from a dedicated version of the Norwegian Weather Prediction Model (HIRLAM). No carbonaceous particles are included. The model has been applied to compute concentrations and column load of sulfate and nitrate aerosols in Europe in 1997. So far no information is given on the size distribution or number concentration. Neither photooxidation nor aerosol dynamics is accounted for. Both annual average mass concentration fields and column load of sulphate and nitrate aerosols are presented. The relative importance of sulphate and nitrate particles in the modelled aerosol burden in different European areas is also shown. Some examples are given of monthly/seasonal variation of aerosol loading in Europe. The computations have been compared with …

EULERIAN AND LAGRANGIAN PROCESS STUDIES DURING ACE-2: DO THEY GIVE A CONSISTENT PICTURE OF ANTHROPOGENIC AEROSOL EVOLUTION WITHIN THE MARINE BOUNDARY LAYER.

Frank Raes, Rita Van Dingenen, Commission of the European Communities, Environment Institute, 21020 Ispra (VA) Italy, Doug Johnson, Met. Research Flight Y24, Farnborough, Hampshire, UK, Colin O'Dowd, University of Sunderland Sunderland, UK.

The Aerosol Characterization Experiments of IGAC adopt both Eulerian and Lagrangian observation strategies. The latter is especially useful for process studies, as a single air parcel is identified and followed during its transport. Continuous observations at a fixed station will usually show a large variability which must mainly be ascribed to changes in the origin of the air masses. However, processes acting on these air masses upwind of the station, will also contribute to the observed variability. In this study we focus on measurements of sub-micron aerosol size distributions. On three occasions during ACE-2, an air parcel advecting within the MBL, was followed and sampled by aircraft. The observed changes in the size distribution during each of these Lagrangian experiments, reflected the importance of one process or another Additionally, a station on the NE coast of Tenerife continuously characterized air masses coming from various areas in Europe, from N. America, as well as the clean Atlantic and Arctic. Given that air parcels with a longer residence time over the oceans undergo more processing, information can be obtained about the relative importance of several processes acting on the size distribution. Both observation strategies are consistent in their conclusion that, once the aerosol is some 24 hrs away from its continental source area, changes in its size distribution are mainly governed by meteorological factors, notably dilution by entrainment, and a modulation of sea salt accumulation mode by wind speed. Collision of aerosols with clouds and/or coalescence of cloud droplets, with subsequent re-evaporations, and aqueous phase chemistry are second in importance. Nucleation of new aerosol particles, and growth by condensation were unimportant during the ~ 30 hrs of each Lagrangian experiment, and were not observed at the station either. The station measurements, which include timescales of 5-10 days and more, support the idea that a steady state between entrainment , aqueous phase chemistry and coalescence/precitation largely explains the size distribution of the clean MBL aerosol.

MI01/E/05-A1 1430

MODELLING CLOUD PROCESSING OF AEROSOL DURING THE ACE-2 HILLCLOUD EXPERIMENT.

MICHAEL J. FLYNN, Keith N. Bower and Thomas W. Choularton, Atmospheric Physics Research Group, Physics Department, University of Manchester Institute of Science and Technology, PO Box 88, Manchester, M60 1QD, UK.

The ACE-2 HILLCLOUD experiment used a hill cap cloud forming on the northern ridge of the island of Tenerife as a natural flow through reactor to study the response of cloud microphysics to the aerosol properties and gases in the airstream entering the c ud and to study the processing of aerosol and trace gases within the cloud.
A numerical model has been used to simulate the conditions observed during the field experiment, and to study the processes which may be taking place. The model incorporates gas phase chemistry of sulphur and nitrogen compounds upstream of the cloud, and he interaction of aerosol, precursor trace gases and oxidants within the cloud.
From this modelling study it can be concluded that in general in the remote environment the exchange of hydrochloric acid, nitric acid and ammonia between aerosol particles in the vicinity of cloud may be a very important mechanism in regulating the evol ion of the aerosol spectrum.
Further a much more linear relationship between cloud droplet number and aerosol number was observed and predicted by the model than has been reported in the past. The implications of this for the indirect effect will be explored.

MI01/W/14-A1 1450

NUMERICAL MODELLING OF THE MICROPHYSICAL AND RADIATIVE PROPERTIES OF A STRATOCUMULUS CLOUD STUDIED DURING ACE II

S. GHOSH and P.R. Jonas (Dept. of Physics,UMIST,Manchester M60 1QD, U.K)

The Aerosol Characterisation Experiment II was conducted from the 15 June to 23 July 1997 in the north-east Atlantic region. Although the air in the boundary layer originated from the Atlantic and the stratocumulus cloud was relatively `clean', on some days observations indicate the the possibility of advection of polluted continental air from Europe leading to some processing or modification of the aerosol and the cloud droplet spectrum. In this study we present results from an optimised three dimensional Large Eddy Simulation model (3D LES) which can distinguish between contaminated and clean clouds. We have also compared our model results with observations from the C130 aircraft for the 19th of July 1997 when the cloud was contaminated. The high resolution3D runs yield a realistic cloud showing convective cellular organisation and the layer averaged liquid water content (LWC) profile agrees remakably well with observations of the Johnson-Williams LWC. We have also calculated an optical depth map for this cloud covering a 10KmX2.5Km domain and we observe a great deal of variability in the optical depths and the mean and standard deviation of the modelled optical depths are in reasonable agreement with the limited observations available. Finally, we also performed 1D microphysical model runs (having a dynamical environment identical to the LES runs) with 0.1 ppb of HNO_3 since the maximum measured HNO_3 in the cloud samples are expected to be less than this value. We find that there is an increase of the droplet number concentration in the cloud interior of the 5 micron radius drops from 100/cm3 to 125/cm3. The number densities did not change for larger drops and the largest dropsize that was obtained was 10 microns. The model was insensitive to changes in the acid concentration for values less than 0.1 ppb. The results obtained from this study are in accordance with the generally accepted fact that the droplet concentration in clouds that are formed in or pass over polluted air, is higher than in clouds formed in clean air and that these clouds have a correspondingly lower droplet size. Because of the rapid decrease in droplet encounter rates and collection efficiencies as the droplet size is reduced, formation of drops of precipitation size is likely to be inhibited in such clouds.

MI01/W/18-A1 1510

ESTIMATING CLOUD DROPLET NUCLEATION FROM DIFFERENT AEROSOL COMPOUNDS IN A GCM

Ulrike Lohmann (Dept. of Physics, Dalhousie University, Halifax, NS, B3H 3J5, Canada, email: Ulrike.Lohmann@Dal.Ca) Johann Feichter (Max Planck Institute for Meteorology, Bundesstr. 55, D-20146 Hamburg, Germany) Julian Wilson and Frank Raes (both at Environment Institute, Joint Research Centre, European Commission, 21020 Ispra (VA), Italy)

Cloud droplet nucleation depends on the hygroscopicity and size of the aerosols as well as on the maximum supersaturation. Lohmann et al. (1999) introduced a prognostic equation for the number of cloud droplets into the ECHAM GCM. For droplet nucleation they assumed a uniform monomodal aerosol size distribution for the marine and continental aerosol. However, the different aerosol species considered (sulfate, sea salt and carbonaceous aerosols) have different typical mode radii and different van't Hoff factors and, thus, grow differently with relativehumidity and should be activated differentially. We will use Twomey's approach (N = c Smax**k) to estimate the number of cloud droplets being nucleated and link c and k to our simulated aerosol size spectrum. The maximum supersaturation is obtained from the updraft velocity and again from information about the aerosol size spectrum. Results using this approach will be compared to observational data taken during ACE2.

MI01/W/04-A1 1640

THE EFFECT OF AEROSOL AND CLOUD MICROPHYSICS ON THE ALBEDO OF MARINE STRATUS

Mark COUTURE, Richard Leaitch, and Cathy Banic (Cloud Physics Research Division, Atmospheric Environment Service Downsview, Ontario M3H 5T4, Canada, Email: couture@armph3.tor.ec.gc.ca), Henry Leighton and Dean Gilbert (Department of Atmospheric and Oceanic Sciences, McGill University, Montreal, Quebec H3A 2K6), Ray Hoff and Kevin Strawbridge (Centre for Atmospheric Research Experiments, Atmospheric Environment Service, Egbert, Ontario L0L 1N0)

The Radiation, Aerosol and Cloud Experiment (RACE) was based in Greenwood, Nova Scotia, Canada and conducted in late August and early September of 1995. Two instrumented research aircraft were used to make observations of aerosols and low stratiform cloud over the Bay of Fundy and the Gulf of Maine. Four cases of optically thin clouds in air with different aerosol particle number concentrations at cloud base are compared. Measurements of visible cloud albedo exhibit a strong dependence on the measured optical depth, which, in turn, correlates with the measured optical extinctions in the clouds. Within each case, the in-cloud extinction varies predominantly with the liquid water content. From case-to-case, differences in the in-cloud extinction are predominantly related to the differences in the droplet number concentrations. A link from aerosol/CCN to cloud droplet number concentrations through to optical depth is made. The cloud albedo increases by 25% for increases in the cloud-base aerosol number concentration from 80 to 265 cm-3. The observations are consistent with radiative transfer simulations of the cases.

MI01/E/03-A1 1700

IN SITU CHARACTERIZATION OF OPTICALLY THIN MIDLATITUDE CIRRUS CLOUDS BELOW THE TROPOPAUSE

Peter WENDLING, Franz Schröder, Ralf Meerkötter, Robert Baumann (all at Institut für Physik der Atmosphäre, DLR Oberpfaffenhofen, D-82234 Wessling, Germany, email: Peter.Wendling@dlr.de, Ralf.Meerkoetter@dlr.de, Franz.Schroeder@dlr.de, Robert.Baumann@dlr.de), and Jean-Francois Gayet (Laboratoire der Meteorologie Physique, Universite Blaise Pascal, 24 avenue des Landais, F-63177 Aubiere Cedex, France, email: gayet@opgc.univ-bpclermont.fr)

During the national CONTRAIL experiment in spring 1996 in situ characterization of upper tropospheric ice clouds including aerosols was performed with the german DLR research aircraft Falcon. The full instrumental detection range using both optical and nonoptical instrumental methods covered particle diameters from 0.01 - 800 µm (CN-counters: diameters > 10 nm; FSSP-300: 0.4 - 20 µm; FSSP-100ER: 5 - 100 µm; OAP-2DC: 20 - 800 µm; CVI(Counter Virtuel Impactor): 5 - 80 µm; Hallett-Type Replicator; 3 - 100 µm). Since optically thin cirrus has obtained considerable interest due to increasing air traffic and its possible influence on the natural high level cloud cover we present a selected case of our measurements which has been analyzed with special emphasis on the characterization of small ice crystals and µm-sized hydrated aerosols. We interprete this case as a typical well documented example for a developing cirrus in an atmospheric environment which is influenced by emissions from air traffic. By use of computations with a doubling-adding radiative transfer model we determined the influence of the measured cirrus cloud including the hydrated aerosol on the radiation budget of the atmosphere.

MI01/E/17-A1 1720

A POSSIBLE LINK OF AEROSOL AND CLOUDS RADIATIONS TO ASIAN SUMMER MONSOON AND ITS IMPLICATIONS IN LONG RANGE FORECAST

Toshiki IWASAKI (Geophysical Institute, Graduate School of Science, Tohoku University, Aoba-ku, Sendai, 980-8578, JAPAN, Email: iwasaki@wind.geophys.tohoku.ac.jp); Hiroto Kitagawa (Japan Meteorological Agency, Otemachi 1-3-4, Chiyodaku, 100-8122, JAPAN,
Email: kitagawa@naps.kishou.go.jp)

1. Systematic errors of radiation budgets of JMA's global NWP model compared with satellite-derived TOA radiation, JMA's global NWP model considerably overpredicts absorbed solar radiation and outgoing long wave radiation over the continent though it predicts well their global means. Such errors are thought to come mainly from underprediction of clouds over the land and omission of aerosol effects in our model. Thus, we enhance model cloud over the land and introduce both parameterization schemes of direct and indirect effects of aerosols.
2. Impacts of the modified parameterization scheme on forecasts of Asian summer monsoon. A series of one month forecast experiments for June, during which East Asian precipitation band migrates northward, has been performed to study systematic impacts of the modified parameterization scheme on Asian summer monsoon. The modified scheme reduces solar insolation over the land and suppresses heat low. As a result, the northward migration of East Asian fronts, the so-called Meiyu, Changma and Baiu, are considerably delayed. We can say that the model clouds and aerosols have significant impacts on forecast performance on Asian monsoon.
Total optical thickness of cloud and aerosols even over the continents is not well known. We need intensive validation studies with observations to refine the cloud diagnostic or prognostic schemes and aerosol schemes.
3. Influence of other physics schemes on forecast performance of Asian summer monsoon. The monsoon formation is related to many diabatic processes. The control model has a systematic error of delay in the seasonal march of East Asian monsoon. The modified scheme further delays the seasonal march, although it improves model radiation budgets. Thus, we are studying the impacts of other physical processes on Asian summer monsoon, particularly of deep cumulus convections.

MI01/W/05-A1 1740

AN EXPERIMENTAL EVIDENCE OF THE INDIRECT AEROSOL EFFECT ON CLIMATE

LOTHAR SCHÜLLER 1, Jean-Louis Brenguier 2, René Preusker 1, Jürgen Fischer 1 and Hanna Pawlowska 2, 1 Institut für Weltraumwissenschaften, Freie Universität Berlin, Fabeckstr. 69, 14195 Berlin, Germany, 2 Météo-France, (CNRM/GMEI), 42 av. Coriolis,,31057 Toulouse Cedex 01, France

The enhancement of the reflection of solar radiation as a result of light scattering at aerosol particles is referred to the direct effect of aerosols on climate, however, the indirect effect of aerosols on cloud microphysics and thus on reflected radiation leads to an overall cooling in the atmosphere, which is expected to be more important The Twomey effect is the chain of processes: anthopogenic aerosol production, increased number of cloud condensation nuclei (CCN), smaller but more numerous cloud droplets and a larger ability to reflect solar radiation back to the sky. To reduce the large uncertainties in quantifying the overall effect on the global radiation budget (estimates range between 0 and –1.5 Wm-2) more sophisticated observation techniques using radiance measurements from airborne instruments or satellites are required. In this study, we modified existing methods to derive cloud microphysical and optical properties from measurements in the visible and near infrared spectral range. The new approach is to focus on the cloud droplet concentration Nd rather to the cloud droplet radius as the most relevant parameter which determines the reflectivity of a cloud layer. Nd can be related directly to the changes in cloud microphysics, induced by an increase in cloud condensation nuclei (CCN), whereas the remotely sensed droplet radius is also dependent on the geometrical thickness of the cloud layer. Radiative transfer simulations of clouds with constant Nd and vertically variable droplet size has been performed to analyse measurements of the reflected radiation during the second Aerosol Characterisation Experiment (ACE 2) in 1997. The Twomey effect was clearly observed: a stratocumulus within an clean air-mass with low aerosol loading showed significant lower reflectivity than a stratocumulus of comparable vertical extension under a polluted environment. Coincidentally, the measured reflectance corresponds to the simulations calculated with lower res. higher droplet concentrations. The retrieved droplet concentrations agree with in situ measurements performed inside the cloud layers.

AEROSOLS AND RADIATION

MI01/E/07-A2 Invited 0930

AEROSOL SOLAR RADIATIVE FORCING OVER THE INDIAN OCEAN

V. RAMANATHAN, W.C. Conant, Xu Li-Jones, I.A. Podgorny, K. Rajeev, and S.K. Satheesh (all at Scripps Institution of Oceanography, University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093-0021, USA, Email: vramanathan@ucsd.edu)

The first field phase of the Indian Ocean Experiment (INDOEX), which was onducted during January to March 1998, collected aerosol chemical, microphysical and column radiative properties from the surface, ship and from satellites. These data were synthesized to obtain the surface and the column aerosol solar radiative forcing on regional scales over the Arabian sea, Bay of Bengal and the equatorial Indian ocean. The aerosol solar radiative forcing is defined as the change in the solar radiative fluxes due to the presence of the aerosols. The synthesis is based on a detailed erosol-radiation model that is consistent with the in-situ chemical data, vertical Lidar data and column spectral optical data. This model was used to obtain surface and top-of-the atmosphere radiative forcing and separate the contribution to the forcing from sulfates, soot, mineral dust, sea salt and nitrates.
Furthermore the model was also validated with satellite radiation budget data from CERES on board the TRMM satellite. This aerosol-radiation model was then used to develop bi-directional models for retrieving aerosol optical depths from the NOAA AVHRR satellite radiances. The retrieved optical depths were validated with ship and island sun-photometer optical depths over the Indian ocean. Lastly, the optical depths were combined with satellite radiation budget data and the aerosol-radiation model to obtain regional aerosol radiative forcing; these estimates are then compared with values determined directly from observations over selected locations.
It is shown that, during the north east monsoon period, significant amount of anthropogenic aerosol is transported from the sub-continent into the tropical Indian ocean, with aerosol visible optical depths (tv) ranging from about 0.3 in the Northern Arabian sea to values as high as 0.2 in the equatorial Indian ocean. Spatial gaps in the ITCZ are frequent enough that, aerosols are transported into the southern hemisphere tropical Indian ocean. The clear sky aerosol radiative forcing at the top-of-the atmosphere is about -2 W.m-2 per 0.1 increase in tv and about a factor of three larger in magnitude at the surface. Soot and mineral dust aerosols are the reason for the amplification of the forcing at the surface. The solar forcing values change in sign in the presence of clouds. The magnitude of the derived aerosol solar forcing values are separated into the contributions from the individual species and then compared with GCM predictions of the aerosol climate forcing.

MI01/W/22-A2 1000

IMPACT OF AEROSOLS ON THE SPECTRAL SOLAR IRRADIANCE AT THE SEA SURFACE DURING INDOEX

Meywerk, J. (Scripps Institute of Oceanography, 9500 Gillman Dr., 230 La Jolla, CA 92037 USA, Email: jens@fiji.ucsd.edu)

During the First Field Phase (FFP) of the Indian Ocean Experiment (INDOEX) in February and March, 1998, the spectral global and direct beam irradiance have been measured between 350 and 1050 nm wavelengths using a 512 channel, fixed grating, photodiode array spectroradiometer. A detailed analysis of the instrument's reliability, the absolute calibration, and the corrections for deviation from the cosine response are presented. For most of the spectral region the total uncertainty is shown to be less than 2%. The changes in spectral and 400-700nm integrated irradiance are investigated for the global, direct, and diffuse portion of the solar spectrum reaching the ocean surface. For the aerosols in the Indian Ocean area the solar spectrum reaching the sea surface has been considerably modified. Comparing spectra from very clean regions south of the ITCZ with those measured within the range of influence of the Indian subcontinent show not only strongly decreasing direct beam irradiance accompanied with increasing diffuse irradiance, but also a remarkable spectral signature due to the existing aerosols. The direct beam spectral maximum is shifted to longer wavelengths due to the aerosol influence on the solar radiation - a combination of scattering and absorption of these aerosols. By comparing highly aerosol contaminated measurements with clean air radiative properties an anthropogenic climate forcing for these aerosols of -10 W/m2 was found for the given region and time period. These observed changes in the spectral solar irradiance together with decreased totally available solar energy will probably change the biomass production of the ocean.

MI01/E/08-A2 1020

GLOBAL DIRECT RADIATIVE FORCING DUE TO MULTICOMPONENT ANTHROPOGENIC AND NATURAL AEROSOLS

Mark Z. JACOBSON (Dept. of Civil & Environmental Engineering, Terman M-13, Stanford University, Stanford, California 94305-4030, USA, Email: jacobson@ce.stanford.edu)

Results from the first global study of the solar plus infrared direct forcing due to the combination of all important anthropogenic and natural aerosol constituents in the atmosphere are discussed. Aerosol concentrations were constrained by observations to the greatest extent possible. In the presence of clouds, calculated tropopause forcings due to anthropogenic aerosols and all aerosols were -0.51±0.2 and -1.6±0.5 W m-2, respectively. Natural chloride and its hydrated water in sea spray caused a net forcing of -0.62±0.3 W m-2, greater than that of any other natural aerosol constituent. Sodium, potassium, calcium, and magnesium caused positive forcing due to their interactions with solids. SiO2(s) was the dominant forcing component in soil particles. Clouds reduced the magnitude of forcing of all aerosol constituents. The treatment of elemental carbon as core material enhanced the magnitude of its positive forcing. The treatment of UV absorption by organic material slightly reduced the magnitude of its negative forcing. The inclusion of only a few aerosol constituents in a climate model will cause errors in climate model predictions.

MI01/W/11-A2 1100

A NEW PARAMETERIZATION SCHEME FOR AEROSOL OPTICAL PROPERTIES AND CCN CONCENTRATIONS FOR USE IN GCMS.

Alf KIRKEVÅG, Trond Iversen, and Jon Egill Kristjansson (all at Department of Geophysics, University of Oslo, P.O. BOX 1022 - Blindern, 0315 Oslo, Norway)

The scheme which is outlined enables table interpolations to be carried out to yield the aerosol single scattering albedo, asymmetry factor, extinction coefficient and specific extinction coefficient. For supersaturated conditions, concentrations of cloud condensation nuclei (CCN) are estimated. Input parameters are: process attributed concentrations of BC and sulphate, ambient relative humidity or supersaturation, and a set of parameters determining the background aerosol size distribution and composition. The scheme is employed in a stand-alone version of the radiation module of the NCAR CCM3. Questions concerning CCN and the indirect effect will be addressed, but our main focus will be on direct effects from particulate sulphate and black carbon (BC), mixed internally and externally with the prescribed background aerosol.
Early results for hemispheric calculations for clear sky conditions in April show large regional differences. The direct forcing due to anthropogenic sulphate and fossil fuel BC ranges from -7 W/m^2 (cooling) in eastern Europe (and -3 W/m^2 in eastern USA), up to 1.7 W/m^2 (warming) near the large cities in western USA. Also areas (with high ground albedo) in North Africa, Asia and the Arctic experience some warming, up to 0.5 W/m^2. The results, especially in the Arctic, are somewhat sensitive to the background aerosol distribution. The sensitivities to assumed aerosol and cloud vertical distribution, relative humidity, time of year, and to assumptions on the treatment of added sulphate, BC and OC, will also be examined.

MI01/W/08-A2 1120

DIRECT FORCING BY SULPHATE AEROSOLS IN CLOUDY SKIES

ELEANOR HIGHWOOD (Department of Meteorology, University of Reading, UK)

Considerable uncertainty remains in the estimation of the direct climatic impact of aerosols. Reducing this uncertainty is a key aim of aerosol-climate studies. While much of the uncertainty arises from inadequate knowledge of the spatial and temporal distribution of aerosols, there is considerable variability in the methods of calculating radiative forcing itself. In particular, previous studies have disagreed on the importance of the direct radiative forcing in cloudy skies. Zenith angle dependence of radiative forcing is expected to be important where inhomogeneous cloud layers are present and this differs significantly between models, largely due to different treatment of the phase function. In this study the zenith angle dependency of aerosol forcing in two radiative transfer models is compared, initially for clear skies. the secon part of the study uses simple representations of inhomogeneous cloud layers to investigate the contribution to aerosol radiative forcing from cloudy regions in each model.

MI01/W/26-A2 1140

DETERMINATION OF THE AEROSOL SIZE DISTRIBUTION FROM SPECTRAL INTERPOLATED EXTINCTION COEFFICIENTS

Ghislain FRANSSENS (Belgian Institute for Space Aeronomy, Email: ghislain.franssens@oma.be)

We propose a new method to determine the aerosol size distribution from aerosol spectral extinction measurements. It is applicable to spherical particles and is based on the Anomalous Diffraction Approximation. Our method solves the spectral extinction interpolation problem and solves the inversion problem as a by-product. The extinction interpolation uses a linear combination of carefully designed basis functions, each possessing the correct spectral behaviour of an extinction function. The expansion coefficients are obtained by minimising a fitting cost function, using a Generalized Reduced Gradient Method, with constraints. The method has been specifically designed so that it can be applied to sparse and noisy data. A number of numerical test examples and applications to real data will be shown.

COMPARISON OF COMPUTED AND MEASURED OPTICAL PROPERTIES OF CONTINENTAL AEROSOLS IN WYOMING

Ziguang Han, Derek C. MONTAGUE, and Jefferson R. Snider (all at Department of Atmospheric Science, Box 3038, University of Wyoming, Laramie, WY 82071-3038, USA,
Email: montague@uwyo.edu)

Airborne observations of boundary layer (30 - 50 m agl) and free tropospheric aerosols (5400 m msl) were obtained using the Wyoming King Air, over the Green River Basin and Red Desert regions of southern Wyoming, USA, in late February and March, 1996. Light absorption and scattering extinction by aerosols were characterized using an aethalometer and a single wavelength (550 nm) nephelometer, respectively. Filter samples collected on board the aircraft, enabled the averaged mass loading and chemical composition of the aerosol to be determined, and hence its averaged refractive index to be estimated, for each flight. The refractive index values were used to carry out post-flight recalibrations of the measurements made with a Passive Cavity Aerosol Spectrometer Probe (PCASP) and a Forward Scattering Spectrometer Probe (FSSP), thereby allowing corrected particle size distributions and number densities to be determined, from which aerosol scattering extinction coefficients were computed, using Mie scattering theory, for comparison with the nephelometer data. In addition, combination of the scattering data with that for aerosol absorption, has allowed estimates of aerosol total extinction and single scattering albedo to be made, for both dry and wet aerosol. The scattering extinction coefficients have been examined in the context of both geographical location and altitude, as have correlations of the aerosol characteristic parameters with observed meteorological variables, local particulate sources, and measured trace gas mixing ratios. A summary of the results of these analyses will be presented.

AEROSOLS AND RADIATION

MI01/E/14-A2 Invited 1400

FUTURE SULPHATE AEROSOL DISTRIBUTIONS SIMULATED USING A CLIMATE MODEL

Margaret J Woodage and DAVID L ROBERTS (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SY, UK.)

The Hadley Centre climate model incorporates a fully-interactive sulphur cycle scheme which represents the emissions and large-scale advection of sulphur species, vertical transport by convection and boundary layer turbulence, and dry and wet deposition. Sulphur chemistry is parameterized using oxidant fields generated by a separate Lagrangian chemistry model (STOCHEM) as boundary conditions. The direct radiative forcing implied by the simulated sulphate aerosol distribution can be diagnosed using the model's radiation code, developed by Edwards and Slingo. In this study, the model will be used to investigate the impact of future changes in anthropogenic sulphur dioxide emissions, using recently devised emission scenarios. The sensitivity of the simulation to alterations in model parameterizations will also be explored.

MI01/W/25-A2 1430

REGIONAL STUDIES OF RADIATIVE FORCING OF SAHARAN DUST USING TOMS AND ERBE DATA

CHRISTINA HSU (Raytheon ITSS, Lanham, Maryland 20706, USA, email: hsu@wrabbit.gsfc.nasa.gov); jay Herman (Code 916, NASA/Goddard, Greenbelt, Maryland, USA, email: herman@tparty.gsfc.nasa.gov)

Climate forcing due to tropospheric aerosols has gained increasing attention in recent years. In order to understand the role of aerosols such as Saharan dust in the radiative balance, we have combined measurements of dust loading derived over both land and ocean from TOMS (Total Ozone Mapping Spectrometer) with measurements from ERBE (Earth Radiation Budget Experiment) of the top-of-the-atmosphere (TOA) upward flux. In doing so, we've been able to estimate the effect of Sharahan dust on the longwave and shortwave TOA fluxes. The changes in the TOA upward flux in response to the characteristics of aerosols will be discussed using these satellite measurements and radiative transfer model simulations. Since there is a significant change in the Saharan dust layer height from the winter to summer season, the observed effect of this altitude difference on the longwave TOA flux will also be addressed. Such studies are important in understanding the radiation budget on a regional scale.

MI01/E/20-A2 1450

BLACK CARBON AEROSOL IN THE ATMOSPHERE IN BEIJING

WANG GENGCHEN, Gu Zhifang, Kong Qinxin, Liu Guangren (institute of Atmospheric Physics, Academia Sinica,Deshenmenwai Road,100029,Beijing, China. email: wanggc@mimi.cnc.ac.cn); Emilenko Alexsander S. (Institute of Atmospheric Physics.Russian Academy of Sciences, 109017, Moscow, Zh-17 St. Pyzhevsky, 3, Russia)

Beijing, as one of the bigest cities in China, is seriously polluted at present time mainly by industrial emission and machine exhaust. The particulate carbon in the atmosphere is origined mainly by incomplete combustion of carbonic fuel and has a important effect on both air quality and physical, chemical and optical processes in the atmosphere. Concentration of the black carbon aerosol (BCA) and its variation characteristics in the atmosphere in Beijing are discussed in this paper. Measurement results obtained for the last 3 years show a quite large variation of BCA concentration in the atmosphere in dependence on intensity of emission sources and the meteorological condition. In favourable conditions, 0.1 ug/m3 of the BCA and 20 ug/m3 of the total suspended particles (TSP) are observed as their background values, respectively, for Beijing city, while under some unfavourable meteorological conditions, especially in period of the later autumn and early winter when the city hearting supply started,the daily average BCA is observed as high as 23 ug/m3 in the atmosphere. In the most case of BCA diurnal variation, two peaks of the BCA concentration are observed, that are: maximum BCA concentration appears in the local time intervals of 7h - 10h and 20h - 24h. Variation behaviours for both TSP and BCA are quite consistent, that demonstrate the same sources of TSP and BCA for Beijing at present time.

MI01/W/07-A2 1510

RADIATIVE FORCING OF VOLCANIC ERUPTIONS

Claudia TIMMRECK and Hans-F. Graf, (Max-Planck-Institut fuer Meteorologie, Bundesstr.55 Hamburg, D-20146 Germany, email: timmreck@dkrz.de, graf@dkrz.de)

Major volcanic eruption have significant impact on stratospheric and tropospheric climate and circulation. Enhanced radiative heating caused by the aerosol absorption of solar and terrestrial radiation changed stratospheric temperature and circulation.
Using the stratospheric mesospheric version of the Hamburg climate model MA/ECHAM4, we performed interactive and non-interactive simulation with prognostic volcanic aerosol. The volcanic aerosol is described with the global sulfate mass (SO4^2-), while for the radiative calculation a mean volcanic size distribution is assumed with a mode radius rm of 0.3 um and a standard deviation s of 1.5. For the current study, a sulfur cycle is coupled to the meteorological model, which takes into account the oxidation pathways of sulfur dioxide (SO2) and the removal processes of SO2 and SO4^2- in the troposphere.
Here model results for a Pinatubo like tropical and a major midlatiude eruption are presented. The climate effects of the two different volcanic disturbances will be discussed for the stratosphere and for the troposphere. The discussion includes the radiative forcing, the lifetime of the disturbance in the stratosphere and temperature effects in the lower troposphere. The model results will be compared to observations after the Mt. Pinatubo eruption (as example for a tropical volcano) and for the Laacher See (13.000 B.P) and the Katmai (1911) eruptions (midlatitude NH).

MI01/W/20-A2 1640

THREE-DIMENSIONAL SIMULATION OF STRATOSPHERIC AEROSOL

Claudia TIMMRECK, Johann Feichter and Hans-F. Graf, (Max-Planck-Institut fuer Meteorologie, Bundesstr. 55, Hamburg, D-20146 Germany, email: timmreck@dkrz.de, feichter@dkrz.de, graf@dkrz.de)

Stratospheric aerosol has various effects on the global climate system. It changes the chemical composition of the atmosphere due to heterogeneous reactions and disturbs the radiative balance.
Therefore, a sulfuric acid aerosol model has been implemented in the global climate model ECHAM4. This model treats the formation, the development and the transport of stratospheric sulfuric acid aerosol. The size distribution and the weight percentage of the aerosol is calculated dependent on the H2SO4/H2O-concentration, temperature and pressure in a size range between 3 10^-4 um and 6.2 um. Homogeneous nucleation, condensation (evaporation), coagulation, water-vapor growth, sedimentation and sulfur chemistry are included. The microphysical model is combined with a tropospheric sulfur cycle. This sulfur cycle treats the natural and anthropogenic emissions, chemistry, dry and wet deposition and chemistry of DMS, SO2 and SO4^2-.Globally and seasonally different SO2- and SO4^2- - sources for stratospheric aerosol can therefore taken into account.
Results of a multiyear simulation show that the stratospheric aerosol distribution is mainly determined by the aerosol flux from the troposphere.The formation of new particles through homogeneous nucleation takes place in the tropical lower stratosphere and upper troposphere and in polar spring. The aerosol surface area density and the aerosol mass concentration represent lower stratospheric background conditions quite well. Effective radius and aerosol mixing ratio agree with satellite and in situ measurements. The SO2 and H2SO4 concentrations are also in good agreement with observations.

MI01/E/22-A2 1700

A MESOSCALE STUDY OF A DESERT PLUME OVER WEST AFRICA AND EASTERN ATLANTIC : RADIATIVE IMPACT

Olivier CHOMETTE and Michel Legrand (Laboratoire d'Optique Atmosphirique, Universiti des Sciences et Technologies de Lille, 59655 Villeneuve d'Ascq, France, email: legrand@loa.univ-lille1. fr); Guy Cautenet and Frediric Pradelle (Laboratoire de Mitiorologie Physique, Universiti Blaise Pascal, 63170 Aubihre, France, email: cotenet@opgc.univ-bpclermont.fr)

Desert dust is generated by wind erosion of the unprotected arid surfaces of the Saharan desert and its borders. About 0.7 GT (d'Almeida-1985) of Saharan dust is mobilized each year in this way. Then dust is transported over large distances, as far as America and Europe. At last it settles by gravitation (dry deposit) or after being scavenged by rain (wet deposit).
The spatial extension and the high frequency of occurrence of dust plumes is such that they have a significant effect on the global climate through their direct impact on the radiative budget of the Earth-Atmosphere system.
The simulation of mobilization, transport and deposition of dust, and of its radiative impact has been carried out. The model used is the CSU RAMS for the mesoscale transport, in association with a new physical dust emission scheme, a dry deposition module, and a radiative code. We present results for a case study which occurred at the beginning of May 1997. Dust was generated by sources located in the Western Sahara and transported westwards up to the Atlantic Ocean, beyond the Cape Verde Islands. The radiative impact is especially addressed in the presentation. Validations are made through remote sensing measurements acquired from the ground by sunphotometry and from space by satellite data (with both land and ocean coverages).

MI01/W/19-A2 1720

PREDICTION OF AEROSOL OPTICAL PROPERTIES FROM PHYSICAL AND CHEMICAL MEASUREMENTS IN CANBERRA, AUSTRALIA

YOSHITERU IINUMA and Gail P Box (both at Atmospheric Group, School of Physics, The University of New South Wales, Sydney, NSW, 2052, Australia, e-mail: iinuma@newt.phys.unsw.edu.au, gpb@newt.phys.unsw.edu.au) John Gras, Melita Keywood and Greg Ayers (all at CSIRO Atmospheric Research, PMB1, Aspendale, Vic, 3195, Australia, e-mail: john.gras@dar.csiro.au, mzk@dar.csiro.au, greg.ayers@dar.csiro.au)

Detailed information on the optical properties of aerosol particles is essential for assessing or predicting the effects of aerosol on air quality and visibility degradation. Successful prediction of aerosol refractive index using observed or modelled size-resolved chemical composition data is a key step towards the determination of extinction of light by aerosol particles. Properties of the winter aerosol in Canberra, Australia were measured during a field campaign in 1997 using a suite of instruments. These included a PMS ASASP-X laser size spectrometer for number concentration, nephelometers for the integrated scattering coefficients at 530 nm, a MOUDI sampler for chemical and mass size distributions and a TEOM mass balance for fine particle loadings (Daero < 2.5 um). In this study we demonstrate the application of a thermodynamic equilibrium model and observed size-resolved composition for the estimation of mean aerosol refractive index and density. This data set allows a variety of tests of "closure" between predicted and observed aerosol optical and gravimetric properties that will be discussed.

MI01/W/10-A2 1740

ATMOSPHERIC AEROSOL OPTICAL AND PHYSICAL PROPERTIES USING MULTIFILTER ROTATING SHADOWBAND RADIOMETER IN SYDNEY, AUSTRALIA

Ghassan TAHA and Gail P. Box, (both at School of Physics. University of New South Wales, Sydney, Australia, 2052, email: gmt@newt.phys.unsw.edu.au, gpb@newt.phys.unsw.edu.au)

The aerosol optical depth of the atmosphere was obtained using ground-based Multifilter Rotating Shadowband Radiometer to monitor the global, diffuse and direct components of solar irradiance measurements. The columnar size distribution of aerosol particles was retrieved using Analytic Eigenfunction Theory. The correlation between the column and surface properties of aerosols, and the effect of humidity on the growth of aerosol particles are important for both aerosol modelling, and radiative forcing. For this purpose, the ambient optical depth was correlated with the scattering coefficient measured by an integrating nephelometer, and with the mass concentration of a PM10 TEOM. Local meteorological parameters were also investigated, in order to explain the aerosol variability, and it's source, as well as giving some indication about its vertical distribution. Some results from this ongoing study in Sydney, including seasonal and diurnal variation of the aerosol will be presented, and discussed here.

PROPERTIES AND DISTRIBUTION OF CARBONACEOUS AEROSOLS.

T. NOVAKOV, T. Kirchstetter, C. Corrigan, Lawrence Berkeley National Laboratory, Berkeley CA 94720, USA

In contrast to sulfate and other inorganic aerosols our knowledge of sources, spatial and temporal concentrations, optical and nucleation properties of chemically complex carbonaceous aerosol component is largely inadequate and fragmentary. In this paper we present the results of our survey of existing measurements pertaining to carbonaceous aerosols performed over the past 20 years in various regions of the globe. Specifically, we examine the geographical and temporal distributions of reported mass concentrations of black (BC) and organic carbon (OC), the relative contributions of these and inorganic species to aerosol mass, supplemented by information on chemical and physical properties of these species. A simple compilation, however, of results from existing field measurements in not sufficient because the reported concentrations may be influenced by method and sampling dependent artifacts which, if unaccounted for, may either over- or underestimate the actual concentrations. Consequently, evaluation of uncertainties is important because these may be large enough to render some of the reported concentrations unacceptable for achieving either mass or radiative closure. In this work we are using the results of our laboratory and filed measurements to estimate the likely uncertainties in the reported data. The results to be presented should be useful in identifying global regions where useful data exists and regions where there is a severe lack of data.

MI01/P/03-A3 0930

AN OBSERVATIONAL ASSESSMENT OF COOLING TREND IN SOUTH-EASTERN U.S.: ROLE OF SULFATE VERSUS CARBONACEOUS AEROSOLS

V.K. Saxena (Cloud-Aerosol Interactions Lab (CAIL), North Carolina State University, Raleigh, NC 27695-8208, USA; email: saxenageos.ncsu.edu)

We have analysed the regional patterns of climate change in the south-eastern U.S. during the period 1949-94. The results indicate that a cooling trend, albeit very mild, is discernible during these 46 years. One of the explanations for such a trend may be found in the direct and indirect radiative forcing of both natural (such as Mount Pinatubo volcanic emissions) and anthropogenic aerosols (such as those transported from the Ohio River Valley) affecting the region. Using the data from Mount Mitchell, North Carolina (2,038 m masl, at 35°44' 05" N and 82°17' 15" W) for sulfates and soot, we have arrived at the following findings:
1. The sulfate concentrations were greater during 1993-97 when compared to those during 1986-89.
2. Cloud albedo retrieved from satellite data and calculated from surface observations does not indicate a monotonic increase with higher sulfate concentrations.
3. Based on the wintertime sulfate concentrations, the local direct forcing calculated for marine, continental and polluted urban air masses is -0.30, -0.44 and -0.70 W m-2 respectively. Similar calculations based on the soot concentrations yielded +O. I W m-2 approximately for all the three air masses.
4. The direct and cloud-mediated radiative forcing effects due to sulfate aerosols are assessed to be -4.8 and -4.0 W m-2. These values far exceed the current model predictions.

MI01/W/17-A3 0950

EFFECT OF ABSORBING AEROSOLS ON INDIRECT AEROSOL FORCING

Catherine C. CHUANG (Lawrence Livermore National Laboratory, Livermore, CA 94550, USA, email: chuang1@llnl.gov) Joyce E. Penner (University of Michigan, 12455 Hayward St., Ann Arbor, MI 48105, email: penner@umich.edu) Keith E. Grant (Lawrence Livermore National Laboratory, Livermore, CA 94550, USA, email: keg@llnl.gov)

To properly evaluate the effects of aerosols on clouds and thereafter to estimate the magnitude of the indirect aerosol forcing, one must include the effect of absorbing aerosols on radiative properties of clouds. We have modeled this effect through modification of the refractive index for a droplet/soot mixture using the effective medium approximation together with the Maxwell Garnett mixing rule. Given the refractive index for the droplet with embedded soot particles, we approximated the single scattering albedo of a drop using geometric optics. In practice, these approximations fails to be true for typical soot inclusions in water drops (volume fraction of soot within drop ~ 10-7) in the wavelength region > 2 micrometer. Fortunately, in this region absorption by water dominates that by soot, so that a smooth fit between the albedo predicted above and that from pure water provides a sufficiently accurate approximation.
These approximations have been incorporated into our global climate model for inclusion in the evaluation of the indirect forcing by absorbing aerosols. Results from this improved radiation code have shown lower indirect cloud forcing by carbonaceous aerosols than simulations without considering effect of absorbing aerosols on the single scattering albedo of clouds.

MI01/W/16-A3 1010

GCM TESTS OF A NEW PARAMETERIZATION FOR CCN CONCENTRATIONS

JÓN EGILL KRISTJÁNSSON, Alf Kirkevåg, Øyvind Seland and Trond Iversen Department of Geophysics, University of Oslo, P.O.Box 1022, 0315 Oslo, Norway

Recently Kirkevåg and Iversen developed a new parameterization scheme describing aerosol size distributions, subject to diffusion, coagulation and in-cloud oxidation, as functions of relative humidity. The scheme treats anthropogenic sulfuric and black carbon aerosols, in addition to a "background" consisting of various hygroscopic and hydrophobic particles. The parameterization scheme was designed for use in global models and consists of look-up tables of aerosol radiative properties in subsaturated air. Supersaturated conditions are also considered in which case the scheme provides concentrations of cloud condensation nuclei.
We here present the first results from the implementation of this parameterization into a version of the global climate model NCAR CCM3, which carries prognostic cloud water. The release of precipitation in warm clouds is a function of the cloud droplet number concentration, which has separate prescribed values over land and over ocean. This represents our "control run" in the experiments that follow. We then replace the prescribed CCN by the output of the above parameterization scheme. The distribution of sulfuric and black carbon aerosols globally and in the vertical is obtained by running a life-cycle scheme recently developed by Seland and Iversen within the CCM3. The spatial distribution of background aerosols is based on literature estimates.
A number of sensitivity runs have been conducted with the model, as guidance for future model development. In these experiments we have e.g., looked at the sensitivity to the criteria for cloud formation. The simplest approach is to prescribe a "supersaturation threshold", which then determines the CCN concentration in a grid box, but alternative approaches are also considered.
We also investigate the sensitivity to assumptions on some aspects of the aerosols, such as spatial distribution, size distribution, and hygroscopicity. In some cases single-column model results are used as supplement to results from the full GCM simulations.

MI01/L/04-3 Invited 1055

INSIGHTS INTO AEROSOL DISTRIBUTIONS AND RADIATIVE FORCING FROM ACLIMATE MODEL WITH ON-LINE SIZE-DISTRIBUTED AEROSOLS (NARCM)

L.A. BARRIE, J.P. Blanchet, P. Chylek, R. Hoff, G.Lesins, S.L. Gong, M.Lazare, R. Leaitch, H. Leighton, H. Lin, U. Lohmann, N. McFarlane, N.O'Neill and A. Royer, K. von Salzen and L. Spacek

A government/university effort in Canada is underway to put size-distributed aerosols into Canadian climate models (global and regional). It is intended that eventually a Canadian size-distributed aerosol modelling capability is developed by: (1) incorporating size-distributed aerosols processes in the models (2) simulating the spatial-temporal distributions of major aerosol types and checking with observations, (3) linking aerosols actively with clouds and atmospheric radiation, and (4) assessing the role of aerosols in climate processes. Currently, two natural aerosol types (sea salt and biogenic sulphur) as well as two anthropogenic aerosols(sulphate and black carbon) are modelled using a 12 size bin sectional model, off-line chemistry, an explicit cloud scheme, relative humidity dependent aerosol size and wet/dry aerosol removal processes. To date, steps (1) and (2) have been the focus of our effort. Next, we will begin to investigate the interplay between natural and anthropogenic aerosols in influencing the concentration and size distribution of atmospheric aerosols and hence their impact on direct and indirect radiative forcing. Highlights of the first two and a half years of this study are presented. In particular, the role of sea salt in influencing sulphate distributions will be discussed.

MI01/E/13-A3 1125

STUDY ON THE CHARACTERISTICS OF AEROSOL OPTICAL DEPTH AND NUMERICAL SIMULATION OF AEROSOL RADIATIVE FORCING AND CLIMATE RESPONSE OVER CHINA

LUO YUNFENG and Lu Daren (both at Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, 100029, Email: lyf@linux2.iap.ac.cn) Zhou Xiuji and Li Weiliang (both at Chinese Acad. Met. Sci., Beijing, 100081)

Since pre-industrial times, the concentrations of tropospheric aerosols have been increasing obviously. Nowadays, with more attention to environment change and climate prediction, it is an urgent and important work to obtain aerosol's distribution, simulate its radiativ e forcing magnitude and finally study its climate response regionally and globally.
In this paper, by using the diurnal solar radiation and sunshine duration data of 47 solar observation stations in China from 1961-1990, as well as the TOMS version-7 ozone data, we retrieve the values of annual and monthly mean 0.75(m aerosol optical depth. Based on the results, we analyze the geographical distribution and temporal variation of aerosol optical depth in China. Then, we include aerosol radiative effect into the China Regional Climate Model (CRCM), and nest the CRCM into the NCAR CCM1 Genel

MI01/P/02-A3 1145

STUDY OF OPTICAL AND PHYSICAL PROPERTIES OF HAZE AEROSOLS IN WINTER AT PUNE, INDIA

P.C.S. DEVARA, P. E, Raj, R.S. Maheskumar and K.K. Dani (Indian Institute of Tropical Meteorology, Pune 411 008, India, email: devara@tropmet.ernet.in)

Atmospheric aerosols at Pune, a semiarid station in India, exhibit unique features during winter months due to frequent low-level inversions and dust haze formations. Apart from the passage of airmass (rich in nuclei of continental origin) over the station, rapid fall in daily temperature, light surface winds, low relative humidity and incursion of aerosol particles due to combustion processes during these months make the study of aerosols more interesting and important. In order to investigate these distinct properties of aerosols, ground-based sunphotometer observations of direct solar radiation were carried out at the Indian Institute of Tropical

M

Meteorology (IITM), Pune (18°32'N, 73°51'E, 559 m AMSL), India on several cloud-free days during October 1998 - January 1999. These measurements obtained in different spectral bands were utilised to deduce columnar aerosol optical depth, size distribution and perceptible water vapour content. The aerosol optical depth was found to be large (more than double) on hazy days as compared to clear stable days. Size spectra of aerosols on hazy days show characteristic bimodal distribution with mode radii between about 0. I and 1.0 µm. Further increase in optical depths and drastic change in the size spectrum of aerosols were noticed during the occasions of smoke particles' emission from combustion processes in proximity to the experimental site and high water vapour content in the atmosphere. These aerosols during winter season at Pune reduce the solar radiation reaching the ground on cloud-free days and cause poor visibility. In this paper, we discuss the data retrieval procedures and explain the results in the light of transport of continental aerosol dust and trapping of surface-generated aerosols due to close-to-ground inversion during winter months at the observing station.

MI01/E/11-A3 1205

THE EVOLUTION OF AEROSOL PARTICLES IN A CLOUD-CAPPED MARINE BOUNDARY LAYER

SIMON R. OSBORNE, Douglas W. Johnson, Robert Wood (all at Meteorological Research Flight, Y46 Building, DERA Farnborough, Hampshire, GU14 0LX, UK, Email: sosborne@meto.gov.uk, dwjohnson@meto.gov.uk, robwood@meto.gov.uk)

Large uncertanties exist in the magnitude of the indirect forcing of aerosols on climate and so further measurements are required to elucidate the processes responsible for changes in the radiative properties of clouds. Parametrisations can then be developed for use in general circulation models.
Results presented show observations made upon the Meteorological Research Flight's C-130 aircraft during the second Aerosol Characterisation Experiment over the North Atlantic during June-July 1997. Measurements were made of the aerosol and cloud microphysics, the dynamic and thermodynamic characteristics, and trace gas chemistry within the marine boundary layer (BL) and lower free troposphere (FT) of a tagged column of air as it advected away from Portugal towards Tenerife. The aircraft followed the column of air over 3 back-to-back flights that covered a 29 h period of evolution.
Analysis shows that cloud processing of the aerosol was responsible for some of the modal changes in the aerosol size spectrum; an increase in the aerosol sulphate fraction and decrease in SO2 substantiate this reasoning. However, the changes were complicated by entrainment of both polluted and clean aerosol from the FT, changes in the subsidence rate in the FT, and changes in the BL and cloud depths. The changes in the cloud microphysics were due to a combination of aerosol modification and BL dynamics.

MI01/P/01-A3 1225

GREENHOUSE WARMING VERSUS AEROSOL COOLING IN THE CONTEXT OF GLOBAL CLIMATE CHANGE

K.Ya. KONDRATYEV (Russian Academy of Sciences, Research Centre for Ecological Safety, 18 Korpusnaya St., 197110 St.Petersburg, Russia, email: nansen@online.ru)

I believe the time has come to reassess the situation in global climate studies from the viewpoint of priorities. Since it is doubtless true that global greenhouse warming may be compensated by aerosol cooling to a considerable extent, it is important to analyse the reliability of relevant estimates because the assumption of purely scattering aerosols is far from reality /1/. The results of complex CAENEX and GAAREX field programmes conducted in Russia have been considered in this context to demonstrate the significance of aerosol absorption. Also in this context, the case of Arctic haze deserves special attention. Another important aspect is the necessity to take into account the indirect aerosol impact on climate via changes in cloud optical properties. Since global climate modelling is still at an early stage of its development, the decisive role belongs to climate observations. The optimisation of the Global Climate Observing System (GCOS) with regard to combined use of conventional and satellite observations to solve climate dynamics problems in the context of global change is a must of current climate studies. Various aspects of this optimisation have been considered.

THE INVESTIGATION OF SPREADING OF AN AEROSOL CLOUDS IN ATMOSPHERE AND THEIR INFLUENCE ON THE CLIMATE

BIBILASHVILI, Tamar, Tbilisi State University, Email: sciteco@access.sanet.ge

In order to work out the models of aerosol spreading in the atmosphere and in the clouds the authors carried out the examinations of the formation and development of the artificial aerosol clouds formed by means of the explosion in the atmosphere. Experiments were carried out on the height of 3-6 km. The tension of the electric field, temperature humidity of the atmosphere have been registered by means of laboratory plane when flying through the artificial cloud. Geometrical sizes of the artificial cloud changed from 300-600m. Theoretical bases of modelling the spreading of aerosol clouds in the atmosphere have been worked out paralleled with it. Carried out numerical experiments and their comparison with the natural field experiments give the satisfactory result.

MI01/E/09-A1 Poster 0900-02

EFFECT OF CLOUD CONDENSATION NUCLEI ON THE OPTICAL PROPERTIES OF A LAYER CLOUD

Naomi KUBA, Kenichi Maruyama (both at Frontier Research System for Global Change, SEAVANS North BLDG. 7F 1-2-1 Shibaura Minato-ku Tokyo 105-6791, Japan, email: N.Kuba: kuba@frontier.esto.or.jp, K.Maruyama: maruyama@frontier.esto.jp), Hironobu Iwabuchi, Tadahiro Hayasaka (both at Center for Atmospheric and Oceanic Studies, Tohoku University, email: H.Iwabuchi: buchi@caos-a.geophys.tohoku.ac.jp, T.Hayasaka: hayasaka@mail.cc.tohoku.ac.jp), and Takao Takeda (Institute for Hydrospheric-Atmospheric Sciences, Nagoya University, email: takeda@ihas.nagoya-u.ac.jp)

The influence of aerosol particles on the atmospheric radiative budget; especially the effect of cloud condensation nuclei (CCN) on the radiative properties of clouds, is one of the key issues to deeply understand and predict global climate change. The purpose of this paper is to quantitatively study the effect of CCN on the optical properties of a low-level layer cloud by numerically simulating. The vertical profile of the size distribution of cloud droplets, which form on the CCN and grow through condensation and coagulation processes is numerically simulated as accurately as possible. Our numerical model is an one-dimensional micro-physical model, in which the activation of CCN and the condensational growth of cloud droplets in the layer near cloud base are computed in a Lagrangian framework to estimate the solution effect of CCN accurately and to avoid the artificial broadening of droplet size distribution. A special computational method is used for computing droplet size distribution in the middle and upper parts of a cloud, where the coagulational growth and sedimentation of droplets have a large influence on the change in droplet size distribution, to avoid the numerical diffusion of droplet size distribution. On the basis of the simulated vertical profile of the droplet size distribution, optical thickness, reflectivity, absorptivity and transmissivity of the cloud for short-wave radiation are computed by solving strictly radiative transfer equation, using a discrete ordinate method without any parameterization. It is widely understood that a cloud, which contains small cloud droplets in larger number concentration, has a tendency to show deeper optical thickness and larger reflectivity. In this paper, special attention is given to the sensitivity of cloud optical properties to the size distribution and constituents of the CCN and the velocity of an ascending air-current especially the number concentration of the activated CCN.

SIMULATING THE TRANSPORTATION OF SMOKE FROM A FOREST FIRE IN EASTERN, CANADA

H. Lin, W.R. Leaitch, C.M. Banic, S.L. Gong, and L. Spacek (1). P., King, B. Stocks (2)
Atmospheric Environment Service, 4905 Dufferin Street, Downsview, Ont. M3H 5T4, Canada,
(1) Earth Sciences department, UQAM, Montreal, Que. H3C 3P8, Canada
(2) Canadian Forest Service,1219 Queen Street East, Sault Ste. Marie, Ont. P6A 5M7, Canada

Smoke originated from forest fires in Quebec, Canada (near 50N and 74W) was transported to the Canadian Maritime Provinces and Maine area on Aug. 22, 1995. Observations of the smoke plume were made at 44N and 66W, about 1000 km downwind of the source, in during the Radiation, Aerosol and Cloud Experiment (RACE 95). The measured aerosol properties include number concentration, size distribution, CCN concentration and major iron chemical composition was measured. The transport of the forest fire plume is studied using a Regional Climate Model coupled with a newly developed Canadian Aerosol Module (CAM). CAM is a size-segregated multi-component aerosol model simulating aerosol processes. It includes nucleation, condensation, coagulation, dry deposition and interaction with clouds as well as wet removal. The simulation has successfully been able to re-produce the observed transport pattern and vertical distribution of the smoke aerosol particles released from the location of the Quebec fires. We will present details of the simulation and comparison with the observations.

MODEL EVALUATION OF PARTICULATE CARBON IN MARINE AEROSOLS

Yulia LYUBOVTSEVA (Geophysical Center of RAS, 3, Molodezhnaya str, 117044 Moscow, Russia, email: lyubov@wdcb.rssi.ru)

Dimethylsulfide (DMS) is commonly recognized to be the major contributor to particulate nonseasalt sulfur. The conversion of DMS to sulfuric acid via the reaction with hydroxil radical producing SO2 and methylsulfonic acid (MSA). The subsequent transformation of sulfur dioxide is believed to produce additional sulfur containing cloud condensation nuclei. This path is well studied in contrast to the carbon path that was so far ignored as a producer of new aerosol particles. Meanwhile, some experiments indicate to the existence of the particulate carbon in the products of DMS destruction. This presentation reports on the evaluation of possible parameters of carbon containing aerosols that presumably form in the course of not yet well understood chemical and photochemical transformations of the oxidation products of DMS. The model used for the evaluation assumes that DMS is emitted by the ocean surface, then diffuses (turbulent diffusion is implied) in the atmosphere. The production of carbon containing precursors is supposed to be proportional to the rate of the DMS+OH process. Low volatile gaseous products are then assumed to nucleate (nonbarrier nucleation is considered) and to condense onto the surfaces of sea salt particles. An interplay of these two processes defines the concentration of newly born carbon containing aerosols. The latter is shown to be able to reach 10000 particles per cubic centimeter.

ORGANIC COMPOUNDS AND NONSEASALT SULFATE IN MARINE AEROSOL

Yulia LYUBOVTSEVA (Geophysical Center of RAS, 3, Molodezhnaya, 117044 Moscow, Russia, email: lyubov@wdcb.rssi.ru)

Main sources, size distributions of organic components (including MSA, its salts) and nonseasalt SO4 are discussed on the basis of fractional analysis of IR absorption spectra of aerosol samples collected over different region of the Pacific and Atlantic oceans. Basic attention is given to the analysis of samples collected over remote regiond with high biological productivity where the oxydants of DMS emitted from sea water define considerably the chemical composition of submicron aerosols overoceans. Maximal presence of the organics is observed in aerosols collected over remote oceanic areas with high concentration of primary organics and phytoplancton whose activity is directly linked to vertical streams exerting intense water mixing. The fractional analysis of the IR spectra evidences in favour of heterogeneous condensation of DMS oxidants onto sea-salt particles. The presence of bands of other organic compounds (intence bands of CH2, CH3 groups etc) pushes to the assumption on possible contribution to the particulate organics from two other sources: 1. organic hydrosol-aerosol transition and 2. Particles originated from slicks highly enriched with surface active hydrophobic organics like fatty acids, high alcoholes etc. As a rule, in the particles collected over remote regions of the Pacific ocean low concentration of (NH4)2SO4 are observed in contrast to highly polluted areas of the Atlantic ocean where the main component of the nonseasalt SO4 is (NH4)2SO4.

ESTIMATING THE ANTHROPOGENICALLY INDUCED CHANGE IN GLOBAL AEROSOL NUMBER DISTRIBUTIONS.

Julian Wilson and Frank Raes, Environment Institute, European Commission

We have developed a simplified model of sulfate aerosol dynamics (Wilson et al, 1999) and coupled this to a model of the global black carbon aerosol cycle in an offline global transport model. The coupled model is able to describe the evolution of the size distributions of carbonaceous aerosols, pure sulfate aerosols and mixtures of the two. The model simulations for present day conditions show that the black carbon and mixed black carbon-sulfate aerosols predominate the estimated accumulation mode concentrations in the sourece regions while in remote regions the accumulation mode is pimarily sulfate aerosol formed by gas to particle conversion and growth.
We will present both our present day and pre-industrial estimates of global aerosol number distributions, and investigate the sensitivity of these results.

STUDY OF INTERCORRELATION BETWEEN THE CHEMICAL AND THE OPTICAL PROPERTIES OF THE AEROSOLS

Veronique SOUFFLET, Karine Deboudt, Pascal Flament and Richard Santer (Laboratoire Interdisciplinaire en Siences de l'Environnement, Universite du Littoral Cote d'Opale, 30 Avenue Foch, BP 59, F-62930 WIMEREUX, e-mail: Veronique.Soufflet@loalit.univ-littoral.fr)

Simultaneous in-situ measurements of physico-chemical and optical properties of the aerosols were made during February and March 1998 in the North Littoral of France. The chemical characteristics were determined by the concentration and the size distribution of four major components: Organic carbon, Sulfate, Chloride and Nitrate, which are representative of 6 consecutive hours during the day. Parallel optical measurements of solar radiation extinction were performed at four wavelengths: 440, 670, 870 and 1020 nm, in order to follow the diurnal variation of the total aerosol optical thickness. Both maritime and urban aerosols were detected depending on the air mass backtrajectories. The intercorrelation between the two complementary types of information is studied. In particular, the relative contribution of each component in the optical signal is determined.

RADIATIVE FORCING BY ANTHROPOGENIC SULFATE, NITRATE AND AMMONIUM AEROSOLS

Joyce E. PENNER, (University of Michigan, 12455 Hayward St., Ann Arbor, MI 48105, e-mail: penner@umich.edu) Yan Feng (University of Michigan, 12455 Hayward St., Ann Arbor, MI 48105, e-mail: fengy@engin.umich.edu)

Climate forcing by anthropogenic aerosols has, in the past, been estimated in isolation of the volatile anthropogenic aerosol components nitrate and ammonium. For example, aerosol forcing by anthropogenic sulfate is typically estimated as the difference in reflected solar radiation at the top of the atmosphere with and without anthropogenic sulfate, assuming that all other aerosol components (except water) remain fixed. Alternatively, a fixed amount of ammonium has often been assumed to be associated with anthropogenic sulfate. Here, we investigate the possible changes in aerosol size distribution and forcing that result from the presence of the volatile aerosol components associated with ammonia and nitric acid in equilibrium with a specified distribution of sulfate. Accounting for the equilibrium distribution of volatile aerosols in general total forcing over that calculated from anthropogenic sulfate alone. This paper examines the forcing by anthropogenic sulfate, nitrate and ammonium and the effect of relative humidity on total forcing. We show the range of possible impacts from the major industrial and biomass burning areas associated with anthropogenic emissions.

REGIONAL AEROSOL AND LONG RANGE TRANSPORT OVER THE PACIFIC OCEAN

Clarke, A.D., Moore, K.G. and KAPUSTIN, V. N., School of Ocean and Earth Science and Technology, University of Hawaii, Honolulu, HI 96822

We have measured various aerosol types undergoing long range transport to the North and South Pacific during several recent experiments. These include dust events in the North Pacific and biomass burning in the South Pacific. Dust events from Asia were found to be several kilometers deep and reach down to the inversion near the Japan but after long range transport they tended to occur in thinner layers or "rivers" aloft and often mixed with submicrometer pollution aerosol. Ship measurements from Alaska to Samoa showed that the marine boundary layer (MBL) aerosol could also be significantly perturbed by pollution several thousand kilometers downwind of Asia. Here the MBL aerosol light scattering, light absorption and concentration all decreased as we approached the equator where a prompt transition to clean air was evident.
A climatological study in Hawaii (20N, 155W) is also underway with continuous optical depth measurements made at the surface and at Mauna Loa Observatory (MLO @ 3,400m). This has revealed that dust events observed at MLO show a much smaller perturbation to optical depth than detected at the surface. Some local vertical profiles indicate that much of the transported aerosol lies below 3,500m but above the trade wind inversion (about 1,600m) where it can be steadily entrained into the boundary layer. Other studies in the South Pacific reveal a layered combustion aerosol with a soot core and volatile coatings carried westward between 2-5km from South America. These had a low single scatter albedo of about 0.7-0.8 but lay above a clean Marine boundary layer with single scatter albedo near 1.0. The data suggest that regional aerosol characteristics above the MBL may be needed to interpret their radiative impact.

LONG TERM VARIATION OF THE CHEMICAL COMPOSITION OF FINE AEROSOL PARTICLES IN HUNGARY

Laszlo Bozo, Hungarian Meteorological Service, H-1675 Budapest, P.O.Box 39. HUNGARY e-mail: bozo@met.hu

Aerosol particles have been sampled in the central part of Hungary (K-puszta) under regional background conditions since the late 70's. Samples are analysed for sulfate, nitrate, ammonium and metals. In 1996, two additional stations joined the programme (Nyirjes, NE of Hungary and Farkasfa SW of Hungary). Trace gas precursors (sulfur dioxide, nitrogendioxide, nitric acid etc.) are also monitored at the stations.
Long term and seasonal variation of aerosol concentrations are presented in the paper. Regarding sulfate particles, the variation of atmospheric sulfur budget (sulfur dioxide and sulfate) over Hungary, and the country's role in the European sulfur budget is also evaluated for the period of 1980-1998.

CHEMICAL ANALYSIS OF AEROSOL IN SEOUL DURING THE SPRING OF 1998

Ha-Man Cho, Jae-Chon Choi, Young-Sin Chun, Ji-Young Kim and Ki-Joon Park(Meteorological Research Institute, Seoul, Korea, E-mail : hmcho@iris.metri.re.kr)

Intensive observation of aerosol has been conducted in Seoul during the spring(March to May) of 1998 in order to understand the chemical properties of aerosol in Seoul with putting special emphasis on the effect of Yellow sand. The measurement items were mass concentration of TSP/PM10 with the ion and heavy metal components and aerosol number density. The sampling of TSP/PM10 and the other observations have been carried out basically with the interval of about twice a week, however when the Yellow Sand occurred the observations were made every day. The chemical analysis of ion components was made by Ion Chromatograph and that of heavy metals was made by Inductively Coupled Plasma..
The mean TSP mass concentration during the spring of 1998 was 98.9?g/m3 with the maximum 264.8?g/m3 and the minimum 23.9?g/m3. The major ion components in Seoul during spring were NO3-, SO42- and NH4+ with the mean concentrations 9.7?g/m3, 8.3?g/m3 and 4.2?g/m3, respectively. The ion concentration ratios of Yellow sand cases to the non-Yellow were 2.00, 1.61, 1.43 for Ca2+, Mg2+, SO4-, respectively, while were near 1.00 for F-, Cl-, Na+, NH4+, showing that the high ratio of the ions particularly Ca2+, Mg2+ were closely related with the Yellow Sand. The major heavy metals in TSP in Seoul during spring were revealed as Al, Ca and Fe with the mean concentrations 3.2?g/m3, 2.3?g/m3 and 2.1?g/m3, respectively. In contrast with this, concentrations of some important pollutant heavy metals such as Pb, Cd, were 69.9ng/m3 and 2.3ng/m3. The heavy metal concentration ratios of Yellow Sand cases to the non-Yellow were generally larger for Al, Ca and Fe with the ratio 3.30, 2.51, 2.65, showing that these high ratios of heavy metals were also have close correlation with the Yellow sand.

ATMOSPHERIC CORRECTION ALGORITHM FOR CHINA COASTAL AREA

WENYING SU and Beiying Wu Lab for Middle Atmosphere and Global Atmospheric Observation Institute of Atmospheric Physics Beijing, 100029, China

Atmospheric correction is the key step to obtain the primary productivity of the ocean from the ocean color satellite since the atmosphere's contribution to the total radiance is about 70-80%. We devote our effort to establish an atmospheric correction model for the coastal area of China. The atmospheric radiative transfer model DISORT is used in combination with the aerosol model. First a Look Up Table (LUT) is calculated for case I water for various conditions. A clear and turbid water detection algorithm is developed to distinguish clear pixel from unclear pixel. Based on the LUT and the satellite observed total radiance the water-leaving radiance of clear pixel can be determined and the atmospheric correction factor. Then extrapolate this method to unclear pixel by using the atmospheric correction factor of adjacent clear pixel. Much of our concern are for the turbid water and try to correct our clear water algorithm for turbid water. The water-leaving radiances (or reflectances) of the coastal area of China are analyzed. Then the obtained results are compared with the outputs of the SeaWiFS Data Analysis System and the reasons for the difference are analyzed.

THE EFFECTS OF THE SILVER IODIDE AEROSOLS INJECTION INTO A CUMULONIMBUS CLOUDS

Mladjen CURIC and Dragana Vujovic (both at Institute of Meteorology, University of Belgrade, Belgrade, Yugoslavia, email: curic@rudjer.ff.bg.ac.yu) Biljana Music (Agricultural Faculty, Belgrade, Yugoslavia)

Hail suppression by seeding from the ground has been run in a large area of Yugoslavia since 1967. The primary purpose of the hail seeding is to reduce damage due to the hail.But, if we know seeding technology the increase in rainfall is logical to be occurred. In the area important amount of silver iodide is released in the atmosphere. The further behavior of this particles is analyzed by using numerical model of convective cloud. It is shown that silver iodide aerosols significantly influence the precipitation amount. Depending of the amount of aerosols the mean mountly precipitation may be increased by the 25%.

ANALYSIS OF THE EVOLUTION OF THE ASH CLOUD FROM THE DECEMBER 26, 1997 (BOXING DAY) DOME COLLAPSE OF SOUFRIERE HILLS VOLCANO, MONTSERRAT USING GOES-8 IMAGERY

Ms. Gari C. MAYBERRY, Michigan Technological University, Department of Geological Sciences, email: gcmayber@mtu.edu Dr. Bill I. Roseand Dr Gregg Bluth, Michigan Technological University, Department of Geological Sciences

There have been many serious incidents of aircraft encountering volcanic clouds in the past. By studying volcanic clouds we can monitor their paths, as well as learn more about their evolution, in an effort to mitigate the hazard they pose to aircraft.
The December 26, 1997 dome collapse of Soufriere Hills volcano, Montserrat resulted in a pyroclastic flow that descended the White River Valley ~4km and traveled across the
sea an unknown distance. The slope failure and subsequent dome collapse occurred around 0700Z and lasted approximately 15 minutes and an associated volcanic ash cloud rose to an altitude of 47,000 ft. (14.3 km). The volcanic cloud was observed by the geostationary (GOES-8) satellite every 30 minutes, which resulted in a comprehensive record of its evolution. Seventeen images of the volcanic cloud, between 0715Z and 2345Z, were analyzed. The brightness temperature difference (BTD) between bands 4(10.3-11.3 microns) and 5 (11.5-12.5 microns) of GOES-8 was used to distinguish the ash cloud from meteorological clouds. Ash clouds have a negative BTD while meteorological clouds have a positive BTD (Prata, GRL 16: 1293-1296, 1989). BTD data are used to map the volcanic cloud and retrieve basic data about the area of the cloud, mass of the fine ash particles (<10 microns radius), and the optical depth (Wen and Rose, JGR 99:5421-5431, 1994).
The volcanic cloud moved rapidly 20-28 km/hr to the south east until around 1145Z when it became more transparent and began to dissipate. The largest band 4 optical depth (~3) occurred at 0745Z, shortly after the eruption began, and rapidly decreased to about .3 less than 2 hours after the onset of the eruption. From about 0845Z to 1045Z the ash signal of the volcanic cloud was obscured by "masking", which was caused by a cloud of liquid water droplets with a positive BTD. The cloud with the positive BTD may have overlain or …

TROPOSPHERIC OZONE

MI02/E/08-A4 0930

SURFACE OZONE IN THE INDIAN REGION

Shyam LAL, Manish Naja (Physical Research Laboratory Navrangpura, Ahmedabad 380 009, India)

Tropospheric ozone plays an important role in the radiative forcing due to its increasing abundance. However, the increase rates varies largly from place to place and at some of the locations mainly in Canada, it even shows declining trend. We have made measurements of surface ozone in different environments in India and also in the Indian ocean. Diurnal buildup of ozone is seen at sites where higher levels of NOx and other precursor gases are observed. Observations in the Indian ocean show sharp decrease in ozone mixing ratios from the coastal region to the opean ocean. However,events of higher ozone levels are also seen in the opean ocean due to transport of the polluted continental air.
These results with emphasis on the measurements in the Indian ocean will be presented.

MI02/E/04-A4 0950

VARIATIONS OF ATMOSPHERIC OZONE IN GEORGIA

Jumber Kharchilava, Avtandil AMIRANASHVILI (both at the Institute of Geophysics of Georgian Academy of Sciences, 1, M. Aleksidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com)

Measurements of atmospheric ozone (total ozone - TOZ, vertical distribution of ozone VDO, surface ozone concentration - SOC) began in Georgia in 1957 and are carried out also at present. It has been established, that TOZ, VDO, SOC variations depend on atmospheric processes, atmospheric pollution, local orography. A decreasing of TOZ during years has been revealed. It amounts to -0.3% per year in Abastumani and -0.2% per year in Tbilisi. Also an increase of SOC was detected fro Tbilisi and rural locations, which is particularly high in the winter and amounts to 0.2% per year. Considering the fact, that the process of modern climate warming in Georgia manifests itself mainly in the considerable increase of the winter temperature, one may conclude, that the mentioned decrease of TOZ and increase of SOC contribute to a certain extent to this process.

MI02/E/01-A4 1010

VERTICAL OZONE TRANSPORTS MEASURED AT A HIGH ALPINE SITE

Michael STAUDINGER (Zentralanstalt f. Meteorologie und Geodynamik, Freisaalweg 16, A-5020 Salzburg, Austria, email: staudinger@zamg.ac.at)

Most ozone in the troposphere is photochemically produced. Still, a significant part is imported through stratospheric intrusions in particular synoptic patterns like tropopause foldings, cut-off lows or thunderstorms. These situation show a strong vertical gradient of the ozone concentration within the troposphere. Therefore high elevated mountain stations are perfect sites to monitor the daily variation of the ozone concentrations. Most of these episodes are very short term events, as the responsible synoptic patterns develop and cross the alps sometimes within less than a day. At the Sonnblick Observatory in the Austrian Alps (3105 m.a.s.l) under clear sky conditions measurements in ten minute intervals of vertical thickness of the ozone column are taken with a Brewer spectrometer. The comparison of the dataset of the last 4 years with water vapour satellite imagery and vertical cross sections of radiosonde soundings over Europe show the corresponding vertical motions in the different parts of the troposphere in the investigated periods. Some of these events cover only small areas, partly larger fields of downward motions are involved.

MI02/E/10-A4 1100

THE EFFECT OF CONVECTIVE TRANSPORT ON THE RADIATIVE FORCING FROM TROPOSPHERIC OZONE

William COLLINS (email: wjcollins@meto.gov.uk); David Stevenson, Colin Johnson, Richard Derwent (Hadley Centre for Climate Prediction and Research, The Met. Office, Bracknell, RG12 2SZ, UK)

We have used a Lagrangian global tropospheric chemistry transport model with a Lagrangian convective transport scheme to investigate the effect of convection on tropospheric ozone. The strongest radiative impact of ozone is in the upper troposphere. We show that convective processes can efficiently transport surface emissions to the upper troposphere where, due to the cleaner environment, they are more effective at producing ozone. Our model also shows that the upper tropospheric oxidizing capacity is significantly enhanced by photolysis of carbonyl and hydroperoxide compounds that are transported from the surface up to this altitude by convection. Convection can also decrease upper tropospheric ozone by lifting up surface air with low ozone mixing ratios, this vertical redistribution of ozone has the effect of reducing its radiative forcing. We have used our model to investigate the importance of each of the effects mentioned and have calculated a value for the total change in ozone radiative forcing brought about by convection.

MI02/E/02-A4 1120

IMPACT OF CONVECTION AND LIGHTNING NOX ON OZONE IN IN THE UPPER TROPOSPHERE AND ASSOCIATED RADIATIVE FORCING OF CLIMATE.

Didier HAUGLUSTAINE (Service d'Aeronomie du CNRS, Universite de Paris 6, Paris, France, email: dh@aero.jussieu.fr); Guy Brasseur, Louisa Emmons (National Center for Atmospheric Research, Boulder, CO, email: brasseur@acd.ucar.edu)

Deep convection transports rapidly chemical species from the boundary layer to the middle and upper troposphere and, occasionally, to the lower stratosphere. Once aloft, the ozone precursors can be advected by synoptic scale transport and contribute to ozone photochemical production on the global scale. Convective transport can also control the rapid photochemical balance of radicals and NOx in the upper troposphere by bringing fresh NO (from lightning, soil emissions, and combustion processes), and peroxides into this region. In addition to that, NOx production from lightning discharges can contribute substantially to the nitrogen budget in the mid- and upper-troposphere and therefore promote ozone formation. Climate changes have therefore the potential to affect the distribution of ozone in the upper troposphere through perturbations of convective and lightning activities.
In this paper, we apply a global chemical transport model called MOZART to study the changes in ozone and its precursors associated with lightning activity and deep convection. In particular, we illustrate the essential role of lightning NOx in the formation of upper tropospheric ozone plumes in the tropics. The role of convection in the formation of ozone in the remote troposphere is also discussed. The radiative forcings associated with ozone changes and changes in methane photochemical lifetime are also calculated. The possibility of a significant positive climate feedback mechanism between convection and lightning activity and tropospheric ozone formation and associated radiative forcing of climate is discussed.

AIRCRAFT NOX EMISSION, OZONE CHANGES AND THE TROPOPAUSE HEIGHT

Beiying WU (Guohui Li Lab for Middle Atmosphere and Global Atmospheric Observation, Institute of Atmospheric Physics, Beijing, 100029, China)

Using the NCAR/ACD 2D chemical transport model and NCAR/NCEP re-analyzed data, this paper studies the effects of the aircraft emission on local ozone. Two model runs were carried out: a) with aircraft NOx emission; b) without aircraft NOx emission. The results show that the aircraft emitted NOx is about 20-50% of the NOx at levels over mid-latitude from 8-15 km. The responding relative change in ozone mixing ratio is 0.4-0.6% (0.5-0.8ppb in mixing ratio) in January and 1-4% (1-3 ppb) in July. It shows those lower NOx emission height results in fewer changes in O3, but higher NOx emission height leads to larger changes in ozone. It also should be pointed out that lifting the emission height by 3 km in winter produces negative ozone change above 13 km. The tropopause height varies with season. The amplitude of the variation changes with latitude. At the equator, the 12 year average amplitude is about 0.5km while it increases to 3 km at 35N. The phase is reversed in the tropics and in the mid-high latitude. Therefore, effect of the aircraft emission of NOx on ozone could have opposite signs depending on the relative position of the emission source with the tropopause. Thanks are due to Dr. Guy Brasseur for the Socrates Model and many interesting discussions and Dr. Xuexi Tie for helpful suggestions.

DYNAMICAL-CHEMICAL INTERACTIONS IN A 2D-CIRCULATION MODEL

Axel GABRIEL, Gerhard Schmitz (Institut fuer Atmosphaerenphysik der Universitaet Rostock e.V., Schlossstr.6, D-18225 Kuehlungsborn, Germany, email: gabriel@iap-kborn.de)

In this work we present the results of numerical experiments which are carried out with a dynamical-chemical 2D-circulation model to examine the climate effect of natural and anthropogenic induced atmospheric perturbations in an interactively coupled mode. The 2D-model was developed based on the 3D-GCM ECHAM3 and a complex photochemistry model. The model includes parameterizations of radiation, water cycle, clouds and boundary layer. One important feature of the 2D-model is a parameterization of the transient tropospheric eddy heat and momentum fluxes which describes the interactions between the zonally averaged dynamics and the eddy fluxes in a self consistent way. Stratospheric mixing processes are prescribed according to climatological data. The results give a realistic picture of the meridional mass circulation and the meridional distribution of trace gases. A cascade of model runs were carried out with and without natural and anthropogenic induced O3-perturbations and with different modes in the O3-induced radiative forcing, i.e. with the radiation being calculated with prescribed-undisturbed, with fixed-disturbed and with interactively-calculated ozone distributions. The results reveal the contributions of the 'direct' effects induced by the perturbations via the radiative forcing and the 'indirect' effects via additional changes in the heat fluxes, the meridional mass circulation and the transport processes. E.g, present and future NOx aircraft emissions lead to O3-perturbations of several percent in the upper troposphere which induce 'directly' temperature changes of several 0.1K as revealed by the fixed-disturbed mode and 'indirectly' additional changes in the temperature of about 1K and in the O3 mixing ratio of more than 10% as revealed by the interactively-calculated mode. The results of further sensitivity studies help to examine the feedback mechanisms of the dynamical-chemical interactions in connection with the radiation, the water cycle and the meridional mass circulation.

MI02/W/09-A4 1220

GLOBAL SIMULATIONS OF TROPOSPHERIC CHEMISTRY-CLIMATE INTERACTIONS USING THE GISS GCM

J. Lee GRENFELL, D. T. Shindell, D. Rind, D. Koch (NASA Goddard Institute for Space Studies & Columbia University, New York, NY USA); C. Price (Tel Aviv University, Tel Aviv, Israel); M. Prather, O. J. Wild, L. (University of California, Irvine, CA USA); Mickley, D. Jacob (Harvard University, Cambridge, MA, USA)

Results are presented from multi-year integrations of the Goddard Institute for Space Studies (GISS) GCM with tropospheric chemistry. The resolution is 4x5 degrees in the horizontal and spans nine levels up to 10mb in the vertical. The chemistry scheme incorporates 9 dynamical tracers and 24 chemical species. The 'family' partitioning approach is adopted for NOx, HOx and Ox. N2O5 hydrolysis on sulphate aerosol is included. The 'fastj' photolysis scheme is incorporated. CO sources include anthropogenic and biomass burning input. NOx sources include aircraft, soil, fossil fuel, biomass burning, lightning and stratospheric input. The latter is also parameterized for ozone. Dry and wet depositions are coupled with the GCM's convection and circulation. Results focus upon the model's simulation of global tropospheric ozone and related chemical processes. Chemistry-climate interactions are presented from simulations with pre-industrial, present-day and doubled CO2 conditions.

MEASUREMENTS OF SHORT CHAIN ALKYL NITRATES IN AMBIENT AIR FROM MID AND HIGH LATITUDES AND FROM POLAR FIRN IN TWO HEMISPHERES

H.P. McINTYRE, W.T. Sturges, S. Bauguitte, S.A. Penkett (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, UK, email: h.mcintyre@uea.ac.uk); E. Atlas, V. Stroud

(National Center for Atmospheric Research, Boulder, Colorado 80370, USA, email: atlas@acd.ucar.edu); J. Chapellaz (Laboratoire de Glaciologie et Geophysique de l'Environnement, CNRS, 54 rue Moliere, Domaine Universitaire, BP96, 38402 Saint Martin d'Heres Cedex, FRANCE, email: jerome@glaciog.ujf-grenoble.fr); R. Mulvaney, A. Jones (British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET, UK, email: rmu@pcmail.nerc-bas.ac.uk)

The alkyl nitrates (RONO2) are a relatively stable component of odd nitrogen (NOy) formed in secondary reactions of hydrocarbons in the presence of NOx and are capable of transporting NOx long distances. They are therefore potentially significant in determining background ozone levels in the remote troposphere. Measurements of the C1 and C2 alkyl nitrates at Mace Head, Ireland provide information on their contribution to the total NOy budget of the well processed air reaching this site. Evidence for a high natural background was seen since similar levels were observed in oceanic and polluted airmasses.
Measurements of methyl nitrate and ethyl nitrate have also been made from ambient air from two sites in the Antarctic in order to assess their contribution to nitrogen chemistry in polar regions at different distances from the open ocean. Evidence for an oceanic source was again observed, as well as a diurnal cycle, which may relate to uptake in the snowpack. An historical trend of the tropospheric levels of the alkyl nitrates has also been made from air collected from increasing depths through the firn in the Arctic (Devon Island, Canada) and Antarctic (Dronning Maud Land, 1997 and Dome C, 1998). The historical record of methyl nitrate and ethyl nitrate in the firn appears to have been confused by local (marine) or in-situ production of the molecules. C4-C5- nitrates, however, appeared to follow a historical trend of increasing concentration since the late 1950s.

MI02/W/12-A4 1430

TROPOSPHERIC ABUNDANCE AND GROWTH RATES OF RADIATIVELY-ACTIVE HALOCARBON TRACE GASES AND ESTIMATES OF GLOBAL EMISSIONS

David E. ORAM, William T. Sturges, Stuart A. Penkett (School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, UK, email: d.e.oram@uea.ac.uk); Paul J. Fraser (CSIRO/CRC for Southern Hemisphere Meteorology, Victoria, Australia)

As a result of the Montreal Protocol, the tropospheric growth rates of several ozone-depleting compounds such as CFCs have slowed considerably in recent years or even stopped. In contrast, the mixing ratios of CFC-replacements, such as HCFCs and HFCs, are increasing at rapid rates. Furthermore, a number long-lived perfluorinated compounds (PFCs and SF6) have been identified in the background atmosphere, who seconcentrations have risen steadily over recent years. Concern arises as many of these trace gases are efficient absorbers of infrared in the 800-1200 cm-1 region and are among the most potent greenhouse gases known, with GWPs typically 3 or 4 orders of magnitude higher than that of CO2. Measurements of a wide-range of halocarbons are eing made at UEA by GC-MS, and data will be presented showing the changing atmospheric abundance of these compounds over the past 40-50 years, based on the analysis of the Cape Grim air archive, a unique series of air samples collected in Tasmania (41°S) since 1978, and from a preliminary analysis of firn air, dating back to the 1950s. The measurements will be compared with predicted concentrations derived using a 2-D global model, based on known industrial emission estimates. Where emissions are not known, the model will be used to derive an independent emission scenario based upon the measurements. Knowing the current atmospheric abundance and emission rates, the relative contributions to net radiative forcing will be discussed.

VARIATIONS OF METHANE AND CARBON MONOXIDE TOTAL COLUMN AMOUNTS IN THE ATMOSPHERE FROM GROUND-BASED SPECTROSPCOPIC MEASUREMENTS NEAR ST PETERSBURG

M.V. MAKAROVA (St Petersburg State Univ., Russia); A.V. Poberovsky, Yu.M. Timofeev

Ground-based spectroscopic measurements of methane and carbon monoxide total column amounts in the atmosphere are performed by Solar IR Spectrometer near St. Petersburg. Time series of methane (1991-1998) and carbon monoxide (1995-1998) total column amounts measurements were analysed and the seasonal cycle of CH4 and CO was revealed. The seasonal cycle of methane and carbon monoxide has maximum in February-March and minimum in July-September.

MI02/W/08-A4 1510

A SLOWDOWN OF CO TOTAL COLUMN ANTHROPOGENIC INCREASE SINCE EARLY 1980S: IS IT A RESULT OF OH BUILD UP?

Leonid YURGANOV (Department of Physics, University of Toronto, Toronto M5S 1A7, Canada, on leave from the Arctic and Antarctic Research Institute, St.-Petersburg, Russia, email: leonid@atmosp.physics.utoronto.ca); Evgeny Grechko, Anatoly Dzhola (both at Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow 109017, Russia,
email: egrechko@atm.phys.msu.su)

Many of climate-active trace gases are removed from the troposphere in a reaction with tropospheric hydroxyl (OH). Meanwhile, present and future trends in hydroxyl concentration are not understood at all. The main sink for OH is its reaction with carbon monoxide (CO). Measurements of total column amounts of CO in Russia have been carried out since early 1970s. CO amount has been increasing with a rate of 1.5 % per year until 1983. After that considerable fluctuations were observed, but no trend was determined until now. Variations of CO sources and sinks should be studied to explain this slowdown. To determine an importance of changes in the CO sink a correlation between CO and total ozone was analyzed. A positive slope of 0.53 ppb CO in the troposphere per 1 Dobson Unit (DU) of total column amount of ozone was found for deseasonalized data (correlation coefficient 0.64). It is known that ozone total column currently declines in the northern mid latitudes with a rate of -1.3 DU per year. As a result, CO anthropogenic increase should be offset by -0.7 ppb per year. A hydroxyl build up after early 1980s due to more intense photochemical reactions initiated by increased UV was speculated to explain the CO behaviour. If it is the case, scenarios of long-term variations of trace gases, removed by OH, should be reevaluated in view of total ozone trends.

MI02/W/07-A4 1600

MODELLING THE VARIATION OF DELTA 13C IN ATMOSPHERIC METHANE: PHASE ELLIPSES AND THE KINETIC ISOTOPE EFFECT

W. ALLAN, M. R. Manning, A. J. Gomez, D. C. Lowe (National Institute of Water and Atmospheric Research, PO Box 14-901 Kilbirnie, Wellington, New Zealand, email: w.allan@niwa.cri.nz)

Methane is a climatically active gas. Its atmospheric oxidation rate and its consequent lifetime are therefore important factors in the link between atmospheric chemistry and climate.
Using a plausible scenario for global methane source strengths and their isotopic ratios (delta 13C), we run the Max-Planck-Institute for Meteorology's TM2 3-D offline transport model with 1987 ECMWF wind fields to obtain a global set of time series for methane mixing ratio and delta 13C. Isotopic fractionation by OH oxidation of methane is incorporated into the model by including a kinetic isotope effect (KIE) of 5.4 permil. Plots of change in delta 13C versus change in mixing ratio (phase diagrams) are useful for interpreting results. These show that in the extra-tropical southern hemisphere methane oxidation is dominated by the local atmospheric OH sink. Particularly near Antarctica, the diagrams take the form of "phase ellipses". The major axes of these ellipses have tilts that are consistent with the input KIE of 5.4 permil.
Measurements at Baring Head, New Zealand, and Scott Base, Antarctica, show phase ellipses similar to those predicted by the model. However, the tilts of the ellipse major axes imply a KIE of about 13 per mil. The reason for this is not obvious, but the result implies that our understanding of the atmospheric oxidation process is incomplete. We speculate on possible explanations of this anomalous KIE effect.

REACTIVE TRACE GASES AND RADIATIVE FORCING

D. STEVENSON (UK Met. Office, Room 153, London Rd, Bracknell, Berks, RG12 2SZ, UK, email: dstevenson@meto.gov.uk)

New calculations of the global distribution of tropospheric ozone, and its evolution over the period 1860-2050, simulated by the UKMO tropospheric chemistry-transport model, will be presented. The results include the effects of:(1) changing meteorology, as generated by a transient experiment using the fully coupled ocean- atmosphere Hadley Centre climate model; (2 changes in the magnitude and spatial distribution of anthropogenic emissions; and (3) observed stratospheric ozone depletion over the period 1979-1997, and its projected future recovery in the 21st century. The ozone fields for several snapshot years are used to calculate radiative forcings since pre-industrial times. Further sensitivity calculations reveal the contributions of changes in anthropogenic emissions of individual trace gases (NOx, CH4, CO, VOCs) to the ozone field, and hence the ozone radiative forcing. These experiments also show the roles played by these gases in changing oxidant fields (e.g. OH), allowing the impact on CH4 and aerosol distributions to be estimated, raising the possibility of calculating Global Warming Potentials (GWPs) for reactive trace gases.

MI02/L/20-A4 1640

CLIMATE FORCINGS FROM CHEMCAL PERTURBATIONS: ARE THEY DOMINATED BY THE PRIMARY NATURAL MODE OF CH4?

Michael PRATHER, Oliver Wild (both at Earth System Science Dept, UC Irvine, CA 92697-3100 USA, email: mprather@uci.edu, oliver@halo.ps.uci.edu)

Chemical perturbations to the atmosphere that are driven by short-lived gases such as NO and CO are often believed to be short-lived since the gases themselves are highly reactive. Both numerical integrations of 3-D models and the mathematical ecomposition of the chemistry-transport equations admit solutions of the form of eigenvectors for which the emission of NO or CO may excite the long-lived methane-like mode that decays with an e-fold of about 12 years. We look at how the integrated climate impact -- driven in this case by perturbations to the greenhouse gases ozone and methane -- is represented by this single mode rather than the larger, short-lived transient response of ozone.

MI02/E/06-A5 0910

ANALYSIS OF 6 YEAR OF SOUTHERN MID-LATITUDE MILLIMETER WAVE OZONE OBSERVATIONS: IMPROVED METHODOLOGY AND VALIDATION

J.J. TSOU (GATS Inc., 11864 Canon Blvd., Newport News, VA 23606,USA, email: jj@gats-inc.com); B.C. Connor (NIWA, PB 50061, Omakau 9182, New Zealand, email:connor@kea.lauder.cri.nz); A. Parrish (619 IGRC, Univ. of Mass., Amherst, MA 01003, USA,
email: parrish@fcrao1.phast.umass.edu)

A ground-based millimetre wave radiometer has been in daily operation at Lauder, New Zealand (45S, 169.7E) since November 1992 to monitor the middle atmospheric ozone continuously as a part of the international Network for the Detection of Stratospheric Change (NDSC). Due to the special observing conditions at this southern mid-latitude site, 3 refinements to the data processing and retrieval software were proposed: (1) corrections to the radiative transfer model to account for the local tropospheric climate; (2) corrections to observing elevation angles due to the settling of the foundation of the site; (3) usage of radiometric temperatures of calibration loads, instead of the physical temperatures, in the data calibrations and retrievals. The derivation of each of suggested improvements is discussed, and the effects on the overall retrieved ozone profiles were found to be less than 5%. The data from 1992 to 1998 were reprocessed, and the resulting ozone profiles were compared to other coincident ground-based or satellite overpass measurements. The comparison results will be presented here, and the quality of this data set will be evaluated.

MI02/W/04-A5 0930

ON THE STATISTICAS OF THE SOUTHERN OZONE HOLE

Virginia SILBERGLEIT (Dep. de Fisica. Facultad de Ingenieria, Universidad de Buenos Aires, Av. Paseo Colon 850, 1063 Buenos Aires, Argentina, email: vsilber@tron.fi.uba.ar)

The thinning of the stratosphere ozone layer in the Antarctic region is studied by considering ground-based observations at Halley Bay Station.
Gumbel's first distribution extreme values to evaluate the maximum depletion in the ozone layer are used. The present study shows the expected annual minimum values for the ozone layer density in the Southern Hemisphere.

MI02/W/05-A5 0950

MEASUREMENTS OF STRATOSPHERIC OZONE AND CHLORINE MONOXIDE OVER NY-AALESUND, SPITSBERGEN, IN 1998 AND 1999

U. KLEIN, B. Franke, K.F. Künzi, J. Langer, K. Lindner, I. Wohltmann (Institute for Environmental Physics University of Bremen, FB1 P.O. Box 330440, D-28334 Bremen, Germany, email: Ulf.Klein@Uni-Bremen.de)

Observations of stratospheric ozone and chlorine monoxide (ClO) are regularly being performed at the Arctic station of the Network for the detection of stratospheric change (NDSC), using a ground based millimetre wave radiometer. While ozone has been permanently monitored since 1994 at an observation rate of about 20 profiles per day, the strong and variable absorption of tropospheric water vapour and the necessity of day and night time observations are restricting ClO measurements. The location of the observation site, Ny-Ålesund (78.9 N, 11.9 E), enabled us to take data inside, outside and in the edge region of the polar vortex in 1998. We observed enhanced levels of stratospheric ClO from in the end of February 1998 of up to 1.0 ppbv in the vicinity of 20 km of altitude. A subsequent chemical ozone loss of approximately 15 ppb/day was observed in the same altitude range.

MI02/W/06-A5 1010

A VERSATILE MM-WAVE RADIOMETER IN KIRUNA, SWEDEN

Uwe RAFFALSKI, Åke Steen (both at Institute of Space Physics, Box 812, S-98128 Kiruna, Sweden, email: Uwe.Raffalski@irf.se); Gerd Hochschild (Institute of Meteorology and Climate Research, Research Center Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, email: hochschild@imk.fzk.de)

The Swedish Institute of Space Physics in Kiruna (67.52 N, 20.26 W) is located inside or at the edge of the vortex throughout most of the winter period. The winter temperature and humidity provide extremely good conditions for the observation of the Polar stratosphere with both optical methods as well as mm-wave techniques. The institute started a mm-wave project in order to observe ozone at 203 GHz and chlorine monoxide at 204 GHz. The newly built instrument deploys a conventional Schottky receiver (cooled down to appr. 30 K) together with a broadband acousto-optical spectrometer with a total bandwidth of 1.0 GHz and an effective resolution of about 1.2 MHz. Besides monitoring the mentioned stratospheric trace gases in the altitude range of 18-65 km this radiometer will provide with ground truth data for satellite missions like the Swedish ODIN satellite (to be launched in September 1999), the American SAGE III satellite (to be launched in March 1999), or the European ENVISAT satellite planned for the year 2000. The radiometer is designed in a way that it can be pointed into any azimuth and elevation angle. This can be used to observe for instance ozone variation in the vicinity of lee waves due to the Norwegian mountain ridge and lee wave induced PSCs.

MI02/W/15-A5 1100

DEVELOPMENT OF A STRATOSPHERIC NUDGING CTM

H. AKIYOSHI, S. Sugata, H. Nakane (National Institute for Environmental Studies, Tsukuba, Ibaraki 305-0053, JAPAN, email: hakiyosi@nies.go.jp); Takigawa, T. Nagashima, M. Takahashi (Center for Climate System Research, University of Tokyo, Tokyo 153-8904, JAPAN, email: takigawa@ccsr.u-tokyo.ac.jp)

A stratospheric nudging CTM has been developed to study global ozone depletion and variations of atmospheric chemical constituents. Zonal and meridional wind and temperature of ECMWF data are inputted to the model every 12 hours, and nudged to model winds and temperature with the e-folding time of 1 day to avoid artificial oscillations of winds and temperature produced in the model. Photolysis rates of chemical constituents and vertical winds are calculated in the model. The model includes gas phase chemical reactions of Ox, HOx, NOx, hydrocarbons, ClOx, and BrOx, and heterogeneous reactions on PSCs. The maximum height of the model is about 70km. The monthly mean wind and temperature of the CIRA data were used above 10 hPa levels where ECMWF data were not available. The results of a one-year simulation by the T10 version is shown.

MI02/E/12-A5 1120

THREE-DIMENSIONAL CHEMICAL MODEL SIMULATIONS OF THE OZONE LAYER: 1979-2055

John AUSTIN, Neal Butchart, Jeffrey Knight (Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SZ, UK)

A comprehensive description of stratospheric chemistry is included in a state-of-the-art climate model, which has been extended to the middle mesosphere. The ozone concentration from the chemistry package is used in the model radiation scheme, thereby coupling the dynamical and chemical processes. Initial dynamical conditions are taken from a transient climate experiment. Simulations commence on 1 March on each of the years 1979, 1994-2014 (at 5 year intervals), and 2024-2054 (at 10 year intervals) and consist of a 4 month spin-up period, followed by a 1-year integration. The concentrations of the greenhouse gases (GHGs) are taken from the Intergovernmental Panel on Climate Change IS92A projection and halogen amounts evolve according to future expectations. The results for 1979/80 and 1994/95 are generally in good agreement with observations, indicating in the latter case a deep Antarctic ozone hole and some Arctic ozone loss. For the 1979 simulation only a very shallow ozone hole was simulated, in agreement with observations, although the low ozone persisted for longer than observed. As the GHGs increase, Arctic ozone continues to decrease, reaching a minimum in about the year 2010, about 10 years after the peak chlorine loading. In contrast, the Antarctic ozone hole is largest about 5 years earlier. In 2014, the Antarctic ozone hole reduces in size and depth but thereafter increases again, suggesting that in contrast to 2-D model projections the ozone hole will still be present in the second half of the next century due to the importance of chemistry-climate coupling processes.

MI02/L/01-A5 1140

THE LONG-RANGE TRANSPORT OF AEROSOLS AND TRACE GASES OVER SOUTH AFRICA

M.T. FREIMAN, S.J. Piketh, P.D. Tyson (Climatology Research Group, University of the Witwatersrand, Private Bag 3, WITS 2050, Johannesburg, South Africa); M.P. Mittermaier (South African Weather Bureau, Bethlehem, South Africa)

South Africa has one of the largest industrialised economies in the Southern Hemisphere and is the only industrialised regional power on the African continent. A large proportion of the industrial infrastructure, much of which is coal based, is concentrated in the Mpumalanga Highveld region. Air masses originating on the Highveld are transported southeastward and eastward out of an initially anticyclonic circulation, exiting the subcontinent into the southwestern Indian Ocean at approximately 30˚S. Prior to the final exiting of air masses off the subcontinent, regional- to subcontinental-scale recirculation of the air occurs. Alternatively, the air exits directly and recirculates off the African continent, returning inland after some time over the ocean.
The dispersion of pollutant emissions is a function of two components of motion, namely vertical mixing and horizontal movement. Pollutants may be transported thousands of kilometers under suitable conditions. Elevated absolutely stable layers occur throughout the troposphere over South Africa - at 850, 700, 500 and 350 hPa. These layers trap pollutants below their bases, inhibiting vertical dispersion and limiting transport to the horizontal. Consequently, only the depths of the atmosphere between these layers permit the ventilation of pollutants over a region. Such situations create obvious implications for local as well as regional transport of aerosols and trace gases.
The objective of the Aerosols, Recirculation and Rainfall Experiment (Dec-97, May/Jun- 98 and Jan-99) was to examine the seasonal transport and recirculation of aerosol particles and cloud condensation nuclei over the eastern half of South Africa and investigate their possible influence on precipitation development over the region. Results indicate that, depending on the stability structure of the atmosphere and the prevailing circulation patterns, pollutants originating over the Highveld affect all the remote environments of South Africa.

MI02/W/03-A5 1200

THE COUPLED CHEMISTRY-CLIMATE MODEL ECHAM4/CHEM: COMPARISON OF MODEL RESULTS WITH OBSERVATIONS

Ralf HEIN, Martin Dameris, Volker Grewe, Ines Koehler, Michael Ponater, Christina Schnadt

The atmospheric general circulation model ECHAM4 has been coupled with the stratospheric and tropospheric chemistry module CHEM. Dynamical and chemical features resulting from an interactively coupled simulation (where concentrations of ozone, water vapour, methane, nitrous oxide, and CFCs calculated by the chemical model influence the radiative part of the GCM) are presented and compared with observational data. In particular, model calculated total ozone is shown to be in much better agreement with satellite-based observations than earlier model versions. Another outstanding result of the current model version is its capability to reproduce stratospheric warming in the Northern hemisphere.

MI02/W/17-A5 1220

FUTURE DEVELOPMENT OF THE STRATOSPHERIC OZONE LAYER

Christina SCHNADT, Martin Dameris (DLR Institut fuer Physik der Atmosphaere, Germany, email: christina.schnadt@dlr.de)

The coupled atmospheric general circulation and chemistry model ECHAM/CHEM is used to assess the future development of the stratospheric ozone layer. Several time-slice experiments have been conducted to compare possible future climate conditions with the present state of climate. In these simulations, abundance of greenhouse gases are assumed to increase according to the IS92a(IPCC) scenario, the atmospheric concentration of chlorofluorocarbons is specified following the restrictions of the Montreal Protocol (1987)/Copenhagen Amendment (1992). Special emphasis has been laid on the diagnosis of the dynamical and chemical features of the polar regions of both hemispheres in the respective winter and spring periods. First results indicate that the recovery of the ozone layer is delayed due to climate-chemistry interactions.

MI02/E/03-A5 1240

A GENERAL CIRCULATION MODEL STUDY OF OZONE DECREASE AND ITS GLOBAL IMPACT

Tatsuya NAGASHIMA, Masaaki Takahashi, Masayuki Takigawa (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro-Ku, Tokyo, Japan, email: tnagashi@ccsr.u-tokyo.ac.jp); Hideharu Akiyoshi (National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki, Japan, email: hakiyosi@nies.go.jp)

A fully coupled dynamical-chemical-radiative general circulation model has been used to study the evolution of ozone distribution and its global impact. Ozone distribution is calculated by continuity equation which takes account of advection, gaseous chemical reactions, photodissociation and heterogeneous reactions on the surface of PSC(Polar Stratospheric Cloud). The surface area of PSC is calculated from model-computed water vapor pressure, nitric acid vapor pressure and temperature. In this model, the radiative cooling and heating rates are calculated using the model-computed ozone distribution, which is the most significant feature of this model. A single year simulation shows the reasonable seasonal evolution of ozone distribution. The Antarctic springtime ozone decrease is also represented. It starts in late August and persists until early November with a minimum value of 250 Dobson units. The ozone decreases mainly occur in the lower stratosphere by chemical reactions of ClOx. Consequently the lower stratospheric temperature poleward of 60S decreases about 7K compared with the results of no-PSC calculation in late October. These features of ozone decrease are qualitatively similar to those of observed. The results of multi-year simulation using this model will also be shown.

AEROSOLS

MI02/W/11-A5 1410

SULPHUR AS A POSSIBLE SOURCE FOR POLAR MESOPHERIC CLOUDS

Michael J. MILLS, Owen B. Toon, Gary E. Thomas (Lasp, University Of Colorado, Campus Box 392, Boulder, CO 80309-0392, USA); Susan Solomon (Noaa Aeronomy Lab, 325 Broadway, Boulder, CO 80303, USA)

A 2D microphysical model indicates that sulphuric acid derived from OCS, SO2, and volcanic sources reaches the mesopause, where it nucleates aerosol particles, which correspond well to observed polar mesospheric clouds. PMCs form in thin layers near 82 km altitude, and are thought to be composed of ice particles which nucleate on meteoritic dust. This study proposes sulphate aerosol as an alternative site for ice nucleation.
Stratospheric sulphate aerosol evaporates at the high temperatures present in the upper stratosphere, producing sulphuric acid and water vapor. At the very cold temperatures present at the summer mesopause, these gas-phase components nucleate to form new sulfate aerosol. Using observed temperatures from HRDI measurements, the model predicts the formation of aerosol in excess of 0.5 ppbm and 104/cm3 during non-volcanic periods. These calculations increase dramatically following significant volcanic input. The maximum in aerosol

mass and concentration occurs between 75 and 85 km and poleward of 60˚ latitude, providing excellent correspondence to observed PMCs.
The model incorporates sulphur chemistry and microphysics into the Garcia-Solomon dynamical/chemical model, which covers altitudes from 2 to 112 km with 2 km resolution. Microphysical processes include classical binary homogeneous nucleation, coagulation, condensation, evaporation, sedimentation, and atmospheric transport.

MI02/L/18-A5 1430

TRANSPORT OF AEROSOL PLUMES IN RIBBON LIKE STRUCTURES OVER SOUTHERN AFRICA

S.J. PIKETH, M.T. Freiman, P.D. Tyson (Climatology Research Group, University of the Witwatersrand, Private Bag 3, WITS 2050, Johannesburg, South Africa); H.J. Annegarn (Group, Department of Geology, University of the Witwatersrand, Private Bag 3, WITS 2050, Johannesburg , South Africa); G. Helas (Max Planck Institute for Chemistry, Department of Biogeochemistry, Mainz, Germany)

Aerosol measurements have been taken during the Southern African Fire-Atmosphere Atmospheric Research Initiative (SAFARI-92), the Southern African Atmospheric Research Initiative (SA'ARI-94) and the Aerosol, Recirculation and Rainfall Experiment (ARREX-97/98), over southern Africa using a passive cavity spectrometer probe (model PCASP 100X; Particle measuring system Inc. (PMS) Boulder, Colorado). SAFARI-92 was conducted between September and October 1992 to investigate the role that biomass burning plays in contributing to the total atmospheric chemistry over southern Africa and the south central Atlantic ocean region. SAFARI-94 was a follow up experiment to SAFARI-92, to investigate the nature of the tropospheric chemistry in the absence of biomass burning and was undertaken in May 1994. The aim of ARREX (December 1997, May 1998 and January 1999) was to evaluate the recirculation of material over the subcontinent in both summer and winter and to characterise the nature of fine particulate matter acting as cloud condensation nuclei (CCN).
From the combined data sets, it has been possible to identify plumes of elevated aerosol concentrations over the entire southern African subcontinent. These layers occur in distinctive layers in the atmosphere at altitudes that correspond to the presence of absolutely stable layers. The spatial variability of the aerosol layers is determined by the large scale transport over the region. It is hypothesised that emissions from the Mpumalanga Highveld of South Africa feed a polluted layer of the atmosphere for a given period of time. The plume is eventually detached from the source of new pollutants and transported in a structured, highly stable manner over the subcontinent, in ribbon like structures. The ribbons of pollution persist in the atmosphere for days at a time and are transported for several thousand kilometres. There is considerable evidence that shows industrial pollutants impacting at remote sites in South Africa.

MI02/W/01-A5 1450

ULTRA-FINE PARTICLE PRODUCTION IN RURAL AND MARINE AIR MASSES

Hugh COE, Paul I. Williams, Keith, Martin W. Gallagher, Karl M. Beswick, Tom W. Choularton (All at Physics Department, University of Manchester Institute of Science and Technology, P.O. Box 88, Manchester M60 1QD, UK, email: hugh.coe@umist.ac.uk); Gordon McFiggans (at School of Environmental Sciences, University of East Anglia, Norwich NR4 7TJ, UK, email: g.mcfiggans@uea.ac.uk)

In past studies, the nucleation of new ultra fine particles has been observed in a wide variety of environments, but binary nucleation of sulphuric acid and water alone cannot explain the measurements. Breakdown products of biogenic hydrocarbons and photolabile iodine species have been postulated as precursors in coastal locations. Here we present results taken at a coastal location in the UK that in southerly and westerly wind directions samples air advected over agricultural farm land, whilst in northerly winds the site is exposed to polar maritime air, free from the influence of local sources from the inter-tidal zone.
There is some evidence of <5 nm particles existing in marine conditions, however, these particles do not appear to grow into the fine mode. Unlike other coastal observations, no dramatic increases in <5 nm diameter particles were observed and indicating that these phenomena are restricted to areas where substantial algal populations exist in the inter-tidal zone. In southerly and westerly winds substantial new particle production was observed, though not all of the time. These periods of production are compared with a parameterisation for sulphuric acid availability that accounts for both the oxidation of sulphur dioxide and loss to pre-existing surfaces. This correlation provides strong evidence for sulphuric acid driven nucleation, though other variables are clearly also important. The roles of humidity and temperature fluctuations in promoting the nucleation of particles were studied and there is also evidence for an unidentified night-time production mechanism.

MI02/W/13-A5 1510

CONTRAST IN THE ULTRA - FINE MODAL BEHAVIOUR BETWEEN AN URBAN AND A COASTAL SITE

Paul I. WILLIAMS, H. Coe, M. W. Gallagher, K. N. Bower, K. Beswick, T. W. Choularton (Physics Dept., UMIST, P. O. Box 88, Manchester, M60 1QD, Email Paul.I.Williams@umist.ac.uk); Gordon McFiggans (School of Envirnomental Sciences, University of East Anglia, Norwich, NR7 4JT, UK)

Many studies in recent years have concentrated on characterising and understanding the aerosol related processes of the rural and marine environments, and the impact they have on local and regional scales. However, more interest is being generated in probing the urban environment and associated urban plumes. As the investigations continue, it is clear from an aerosol point of view that most of the scientifically interesting behaviour occurs at the small end of the size distribution. This includes the high levels of ultra fine particle production (3 nm - 10 nm) and the secondary modification of accumulation mode aerosol (100 nm - 500 nm) by organics generated from motor vehicles. These facts are often swamped when only looking at PM10 levels as a indicator for urban pollution.
The preliminary results from two extensive field campaigns are presented here to contrast the modal behaviour from an urban and a coastal site. The urban measurements were taken from the city of Manchester in the North West of England and the coastal site is located in the South East of England at Weybourne, Norwich. Within the city there is always a concentration and hence production of ultra fine aerosol, whereas the coastal site concentration depends heavily on wind direction. The Urban measurements suggest that there are two mechanisms for production, one correlated with sulfur dioxide and sunlight and the other with motor vehicle exhausts. At the coastal site the number concentration of these nanometer particulates correlate well with predicated sulphuric acid production, although another damping process would appear to be acting.

MI02/P/01-A5 1600

PRINCIPAL COMPONENT ANALYSIS OF NOX, S02 AND SPM AT URBAN CITIES IN INDIA

H.N. SRIVASTAVA (India Meteorological Department New Delhi- 1 10003, India, email: snb@imd.ernet.in)

Three megacities in India namely Bombay, Calcutta and Delhi and 7 major urban cities namely Ahmedabad, Hyderabad, Jaipur, Kanpur, Kochi, Madras and Nagpur are being monitored for suspended particulate matter (SPM), S02 and NO, since 1978 through National Environmental Engineering Research Institute, Nagpur. In addition, ten Background Air pollution monitoring stations (BAPMON) are in operation in India since 1973-1974 by India Meteorological Department. Principal component analysis has shown that the first principal component explains more than 50% variance at all the stations. The relative loadings of S02, NOX and SPM have been discussed in detail.
Data from Indian BAPMON stations were also analysed using the Principal Component Analysis by examining broadly the temporal and spatial distribution characteristics of the ions, from mineral and gaseous sources observed in rainwater samples. It was found that sulphates and nitrates are more homogeneously distributed and may, therefore, have gaseous precursors from the natural emissions. The anthropogenic impact Of S02 and NOX, results in relation to the urban climate have been discussed in detail using Principal Component Analysis.

MI02/E/07-A5 1620

THE NUMERICAL STUDIES OF AEROSOLS SPREADING IN THE NEAR-BOUNDARY LAYER IN THE BAIKAL REGION

Vladimir Makukhin, Vladimir POTEMKIM (both at Limnological Institute, Irkutsk, 664033 Russia, email: klimat@lin.irk.ru)

Experimental studies of the chemical composition of aerosols in snow cover around industrial sources in the Southern Baikal were carried out. Aerial distribution of mass concentration of main ions in aerosols for 1994-98 different seasons was investigated. It was established that calcium, sodium, and ammonium sulfates, having the total concentration 1.5-3 mkg/cubic meter, were the predominant salts of aerosol soluble fraction. The main sources of air pollution for the coastline and aquatorium of the Southern Baikal are Baikalsk city and Slyudyanka city. The influence of anthropogenic source in Baikalsk city is traced by the sodium ion accumulation in snow cover. At present, this component may serve as a tracer to value scattering of the wastes of Baikalsk pulp and paper plant. For the first time, sampling of aerosols at the high-mountain station Mondy (the Eastern Sayan, elevation 2000 m above sea-level) and their chemical analysis were realised. Mondy may be considered as a station for monitoring of characteristics of the continental background aerosols. Mathematical modelling of transportation and turbulent diffusion of sulphur and nitrogen compounds, which takes into account chemical reactions, was fulfilled. A series of numerical experiments based on the data obtained during expeditional observations in Lake Baikal region was carried out to verify the mathematical models of atmospheric admixtures transportation. Correlation factors between computed and measured concentrations are equal 0.76 for sulphates and 0.84 for nitrates. Relative errors do not exceed 40% for sulphates and 50% for nitrates; mean square deviations of these errors are equal 25%. The highest deviations of computed concentrations from measured ones are connected with the influence of remote sources.

MI02/W/20-A5 1640

THE DUAL APPROACH OF OBSERVATIONS AND NUMERICAL MODELLING

Dr. David LARY (Tel Aviv Univ., Israel)

Issues such as ozone depletion, acid rain, and photochemical smog are all of considerable environmental importance. These issues are studied using the dual approach of observations and numerical modelling. In making balanced assessments of these issues it is vital to make the best use of all the information available to us, both theoretical and observational. This is a non-trivial task. The technique of 'data assimilation' is a powerful tool, which allows us to address this issue. It is revolutionising the way we can study atmospheric chemistry. Data assimilation allows us to simultaneously make good use of however many observations are available to us, our theoretical understanding, and any apriori information we have, within a mathematical framework. It even allows us to infer information about chemical constituents which are not observed. As we move into the new millennium it is a technique which is set to grow rapidly in importance.

PRELIMINARY RESULTS OF OBSERVATIONS OF ELECTRIC FIELD IN CONJUNCTION WITH OTHER METEOROLOGICAL VARIABLES AT THE SURFACE, UNDER A VARIETY OF METEOROLOGICAL CONDITIONS

Aaron R. Bansemer and William H. BEASLEY, School of Meteorology, University of Oklahoma, Norman, OK 73019 and Leon G. Byerley, Lightning Protection Technology, 2744 E. 5th St. Tucson, AZ 85716 U.S.A.

We have obtained a continuous series of observations of the vertical component of electric field at ground level at a remote site of the Oklahoma Mesonet. Thus, in conjunction with the electric-field data, we have comparable series of data on air temperature, wind speed and direction, relative humidity, pressure, rainfall rate, and solar radiation at the same site. The bservations of electric field were obtained with a new, low-cost, low-power, low-maintenance electric-field mill especially designed for deployment at Oklahoma Mesonet stations. When deployed in significant numbers, these instruments will provide electric-field data at the surface in order to monitor the growth of thunderstorm charge overhead. During the first two

months of operation of a single field mill, we have observed the variations in electric field at the surface that occur during thunderstorms, during ice storms, and from day to day in fair weather. We have recorded frequent occurrences of the "sunrise effect" on mornings with appreciable solar insolation. The intensity of the effect appears to diminish with moderate or strong winds, suggesting that gentle surface fluxes, in the absence of signifcant winds, may contribute to the process. Other observations include diurnal varitaions in electric-field intensity, electric-field changes associated with the onset of measurable precipitation, and electric-field changes associated with changes in wind direction.

MI03/E/04-A3 1020

SURFACE OBSERVATIONS OF POINT DISCHARGE CURRENT IN "RAIN" VERSUS "NO-RAIN" SITUATIONS

S.S. KANDALGAONKAR, M.I.R. Tinmaker and G.K.Manohar Indian Institute of Tropical Meteorology N.C.L. Post Office, Dr. Homi Bhabha Road, Pashan, PUNE 411 008, INDIA e-mail : sskandal@tropmet.ernet.in

It is a well established fact that the point discharge current (PDC) through the sharp tips of raised earthed conductors and the topographic features of the earth's surface is established under the influence of high electric fields of the overhead thunderstorms. In thunderstorm activity, the reports of occurrence of precipitation associated with PDC are quite common. Measurements have shown that these precipitation elements are usually electrically charged bodies and normally deposit positive charge to the earth's surface (Williams and Heckman, 1993). A pertinent question that surrounds this situation is the interaction (scavenging and attachment) between the PDC ions and precipitation elements near the ground surface and its likely effect on pdc. It appears that little information on this intuitively appealing problem is available in the literature (price, 1993). In this study we describe the observed behaviour of pdc in "rain" and "no-rain" situations of many thunderstorms at pune (18o32'n, 73o51'e ; 559 m asl). Our sign convention of pdc is that the pdc signal received through the discharge needle is termed as positive when the surface potential gradient is positive and vice-a-versa. e present our results through one table giving average pdc for every half-a-kilo width of electric field in the range -7.0 to +6.5 k vm-1 during "rain" and "no-rain" situations. We also present scatter diagrams of one-minute interval values of pdc vs. electric field drawn over the "two" situations. Our results strongly suggest that PDC of both polarities in "rain" is reduced than that in "no-rain". The reduction for negative current was more obvious.

MI03/E/03-A3 1040

SOME CHARACTERISTICS OF THUNDERSTORM ACTIVITY IN REGION KAKHETI OF GEORGIA

Avtandil Amiranashvili, VAZHA AMIRANASHVILI, Tengiz Gzirishvili (all at the Institute of Geophysics of Georgian Academy of Sciences, 1, M. Aleksidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com) Zurab Chumburidze (Tbilisi State University, 1, Chavchavadze Ave.,Tbilisi 380028, Georgia)

Investigation results of the thunderstorm activity of convective clouds in Kakheti (Eastern Georgia) are presented. Data of thunderstorm discharge observations by a network of thunderstorm registrators and electrostatic fluxmeters in summer months 1978-1984 were analysed. In particular, in the mentioned region the mean season intensity of the total number of intracloud and terrestrial lightning discharges amounts to 0.0017 disch. per minute per square km. The ratio of intracloud and terrestrial discharges equaled on the average to 2.2; during one thunderstorm day on the average 0.069-0.113 terrestrial discharges were detected per square km; the lightning discharge intensity was with a satisfactory precision proportional to the third power of the maximum radar cloud echo.

MI03/E/05-A3 1120

INITIAL DEVELOPMENT OF PRECIPITATION AND ONSET OF CLOUD ELECTRIFICATION IN THUNDERSTORMS AT PUNE

S.S. KANDALGAONKAR, M.I.R. Tinmaker and G.K. Manohar Indian Institute of Tropical Meteorology, Pune-411008, India N.C.L. Post Office, Dr. Homi Bhabha Road, Pashan, PUNE 411 008, INDIA

The understanding of the real-time sequence between the development of Initial precipitation and onset of cloud electrification in the thunderstorms is very important. Such a study is interesting but intricate, because, unlike the other rain bearing clouds the growth of electrification and precipitation in the thunderstorms is so intense and rapid that these two phenomena appear to be simultaneously occurring. The purpose of this study was to examine the relationship between precipitation development and build-up of cloud electrification in thunderstorms. Using one-minute interval data on electric field and the records of rainfall measured at the ground surface, time sequence between initial registration of precipitation and electric field intensification in the neighbourhood of initial registration of precipitation was examined for a series of 14 thunderstorms of the year 1973 at pune (18˚32'n, 73˚51'e ; 559 m asl). The results of the study are presented in the form of one table and figure. The combined result of this study indicated in-cloud development of precipitation at least 3-7 minutes in advance of electric field intensification. Our result suggests that in most cases the precipitation development in thunderstorms is initiated well before the electric field begins to intensify. Our results appear to be in fair agreement with the results of earlier studies (dye et al., 1986 and 1989).

MI03/W/05-A3 1140

NEW INSIGHT INTO THE PHYSICAL CHARACTERISTICS OF COMPACT INTRACLOUD DISCHARGES

D. A. SMITH, P. E. Argo, K. B. Eack, A. R. Jacobson, R. S. Massey (Space and Atmospheric Science Group, MS D466, Los Alamos National Laboratory, Los Alamos, NM 87544, USA, Email: smithda@lanl.gov); W. Rison, P. R. Krehbiel, R. J. Thomas, K. C. Wiens, M. Brook (Geophysical Research Center, New Mexico Institute of Mining and Technology, Socorro, NM 87801, USA, Email: rison@arctic.nmt.edu)

Compact Intracloud Discharges (CIDs) are isolated electrical discharges that occur within intense regions of thunderstorms. We have recently begun to locate the events and characterize their unique physical properties using a number of research systems including the FORTE satellite, the Los Alamos National Laboratory Electric Field Change Sensing Array, and the New Mexico Tech Lightning Mapping System (LMS). Additionally we are employing data from meteorological radars to characterize CID source regions.
It has become clear that CIDs represent a distinct class of thunderstorm electrical discharge, and we are working to quantify physical characteristics that support this distinction. Among their remarkable characteristics are their efficiency at producing very powerful radio frequency radiation, their large characteristic current moments, and their spatial/temporal character. Our most recent results indicate that RF emissions from CIDs are 20-30 dB stronger than radiation from other intracloud or cloud-to-ground lightning processes in the VHF. Current moments associated with the discharges are at least an order of magnitude greater than moments that occur in conjunction with other processes. Early results on the spatial/temporal character of CIDs indicated that the discharges most often occurred as singular, temporally isolated discharges. However, recent comparisons with the lightning mapping observations indicate that CIDs, when they occur, are followed within a few milliseconds or less by "normal" intracloud lightning flashes. The lightning mapping observations also indicate that VHF radiation from CIDs is not as well localized in space and/or time as the impulsive radiation events of normal lightning. The latter is consistent with the inference that CIDs develop at high speeds over a limited (500-1000 m) extent in the storm.

MI03/E/01-A3 1200

EXPERTISE OF GROUND LIGHTNING IMPACT USING REMANENT MAGNETIZATION

Violaine VERRIER and Pierre Rochette (CEREGE, BP80 13545 Aix en Provence Cdx 4, France; email: verrier@cerege.fr)

Most natural (rocks, soils, sediments, wood) or artificial non metallic materials (concrete, brick, plaster, plastic, glass) contain ferromagnetic microparticles carrying a "natural" remanent magnetization (NRM). This NRM, acquired in the weak geomagnetic field during cooling, deposition or solidification of the material, is much weaker than the isothermal remanent magnetization (IRM) acquired instantaneously by exposition to a strong magnetic field. In the environment, only lightning is able to generate a field strong enough to create a lightning induced IRM (LIRM). The LIRM is stable through time after the lightning impact provided that the material is coherent. This phenomenon is well known (e.g. Graham, 1961) but have never been developed for lightning expertise. We designed an original rock magnetic method to retrieve both the direction and intensity of the lightning peak field Bf from any material present in the impact vicinity (up to a few meters). The lightning fields recorded can vary between 10 and 100 mT. From the direction and the intensity of Bf the Ampere or Biot and Savart laws permit to estimate the lightning current geometry and its intensity. On a schoolyard tree struck by a lightning we were able to locate the impact point within a few centimeters, proove that it was a vertical positive current and estimate its peak value at 122 kA. Applications of this technique are numerous from the hazard assesment to the understanding of local magnetic anomalies from field magnetic survey which can be of lightning origin. A calibration of peak currents provided by lightning detection networks can be expected.

MI03/L/02-A3 1220

ON THE ICE CRYSTAL-GRAUPEL COLLISION CHARGING MECHANISM OF THUNDERSTORM ELECTRIFICATION

Peter BERDEKLIS and Roland List (both at Dept of Physics, University of Toronto, 60 St. George Street, Toronto, Ontario, Canada, M5S 1A7 email :peter@atmosp.physcis.utoronto.ca, list@atmosp.physics.utoronto.ca)

The ice crystal-graupel collision charging mechanism was studied using a newly developed Triple Interaction Facility. The facility is the first to allow independent control of the solid, liquid and vapor phases of a simulated cloud.
As observed in previous studies, the sign and magnitude of the charge transferred during ice particle collisions was found to be a function of the temperature and effective liquid water content of the simulated cloud. However, the charge transfer was even more sensitive to the relative humidity (RH) at which the ice crystals were grown. Varying the RH from ice saturation to water saturation could change the sign of the charge transfer and vary the average magnitude by up to 30 fC per collision. At very high humidities charge transfers of up to -60 fC per collision were observed. Ice crystals grown near water saturation also exhibited a non-linear velocity dependence, with the greatest charge transfers occurring at 5 m s^-1.
Analysis of the data indicates that a competition between two micro-physical charging mechanisms can provide a consistent physical model of the effect of RH. It will be shown that differences in the RH can explain quantitatively the discrepancies between the observations of previous investigators. A new conceptual model of thunderstorm
electrification will also be presented.

A STUDY ABOUT THE OCCURRENCE OF DAYS WITH HIGH ACTIVITY OF CLOUD-TO-GROUND LIGHTNING FLASHES IN THE SOUTHEASTERN BRAZIL IN THE YEARS 1992 TO 1994

H. H. Faria, O. Pinto Jr., R. B. B. Gin and I. R. C. A. Pinto (all at the National Institute for Space research, INPE, CP 515, Sao Jose dos Campos 12201-970, Sao Paulo, Brazil, e-mail: heloisa@dge.inpe.br

The occurrence of days with high activity of cloud-to-ground lightning flashes in the southeast of Brazil in the years 1992 to 1994 was investigated. The high activity days were arbitrarily defined as those with more than 20,000 cloud-to-ground flashes. The meteorological conditions and flash characteristics during these days were determined. The lightning data were obtained through a lightning location system (LPATS), and the flash characteristic studied were the polarity, the peak current intensity and the diurnal distribution. Of the 18 events found, 11 occurred in the transition period between the warn and cold seasons, and were associated with the presence of frontal systems organising the tropical convection, and intensifying the lightning activity. Considering the possible contamination of the positive cloud-to-ground flashes by intracloud flashes, only positive flashes with peak current larger than 15 kA were considered. The percentage of positive and negative lightning flashes varied from event to event, presenting average values of 30% and 70%, respectively. No dependence on the period of the year was found. The average peak current was approximately 30 kA for the positive and 40 kA for negative flashes. No dependence on the period of the year was found as well. The negative flashes located at lower latitudes presented higher average peak current than those located more to south higher latitudes, confirming recent studies for the same region. The same was not found for positive flashes. The diurnal distribution of positive and negative flashes presented the same behaviour, with a maximum activity around 18:00 LT. The average duration of the lightning activity during the events (considering 1000 or more flashes per hour) was 4 hours.

THE INFLUENCE OF POSITION AND NUMBER OF ELECTRICAL DISCHARGES ON INITIATION AND INTENSIFICATION OF PRECIPITATION FOR CONVECTIVE CLOUDS

ZLATKO VUKOVIC, 1286 Gryphon Mews Mississauga, L4W 3E5 ONT, Canada, Email: zlatko@armph3.tor.ec.gc.ca; Mladjen Curic, Institute of Meteorology, University of Belgrade, Belgrade, Yugoslavia, Email: curic@rudjer.ff.bg.ac.yu

A one-dimensional axial-symmetric time dependent model has been used to simulate the influence of electrical discharge (ed) on supercooled droplet spectra. The consequence of the lightning channel slope and the number of ed inside the same cloud volume were investigated through 15 different combinations of the initial cloud conditions at a temperature of -10c. The numerical results for a channel slope of 90 (vertical), 60, 45 and 30 degree and 1, 2 and 3 occurrences of ed showed the expected results. The amount of phase transformation of supercooled drops to frozen drop caused by ed shock waves and collisions between supercooled and frozen drops is more significant as the ed is more intensive (energy and number of ed), as the channel slope is closer to vertical position, initial cloud droplets are larger and electrical drop charges are higher. The results also demonstrate the potential of using the acoustic-electric coalescence model to study the microphysical transformations related to ed in convective clouds.

THUNDERSTORM ELECTRIFICATION - COMPARISON BETWEEN DIFFERENT PARAMETERISATION SCHEMES OF NON-INDUCTIVE CHARGING

RUMJANA MITZEVA(Dept. of Meteorology, Faculty of Physics, University o Sofia, Sofia-1164, Bulgaria, email: rumypm@phys.uni-sofia.bg)Atanas Manchev (Dept. of Meteorology, Faculty of Physics, University of Sofia, Sofia-1164,Bulgaria)Clive Saunders (UMIST,P.O.Box 88, Manchester M60, 1QD,UK, email: CPSAUS@mail1.mcc.ac.uk)

Two different sets of equations for non-inductive charge transfer during rebounding collisions between ice-crystals and a riming target, which may be used in numerical models of the development of thunderstorm electric field, will be presented. The first set of equations is derived using Takahashi 1978 and gives the magnitude and sign of charge transfer as a function of liquid water content and supercooling. The second set of equations is derived on the basis of modified laboratory data from Takahashi 1978 taking into account the results and discussion in Brooks and Saunders 1995 and in Brooks et al. 1997. The comparison between the results from the calculations of charge transfer at various cloud temperatures and rime accretion rates using both sets of proposed equations will be discussed.

HIGH SENSITIVITY FIELD MILL

Guiseppe DI STEFANO, Instituto Nazionale di Geofisica,

A simple physical principle, used for the first time at the 1933 by the Harnewell and Van Voorhis, allows building a sensitive and compact electrometer, suitable to measure the atmospheric electric field. Beginning from a mechanic sensor capable to generate a small current, through the electrodynamics induction principle when it is placed into an electric field, has been developed a complex processing system, which utilizes the modern electronic methodology. The differential input allows using the instrument in an electromagnetically polluted environment; a high quality N-path filter and a lock-in detector allow obtaining a dc signal (with sign) by a passive integration process. The timing of the whole system operate in synchronous with only the signal of a quartz oscillator; this method is very elegant because it means that if we change the speed of motor the conditioning system keep a regular operation with its high performance. A built-in self-calibration system is periodically operated. This helps keeping the quality of measurements, and, when the instrument is used on a stratospheric balloon, allows to neglect the effect of the ions trapped on the non conductive parts of the field mill stator. During the periodic calibration a motored cover drown the sensor and some sample voltage are applied on this shield. The value of the electric field induced by the shield is used to calibrate the instrument. The calibration also provides to recover and to control the effect of the bias current.

PARAMETERIZATION OF THE INTERACTION BETWEEN CUMULUS CONVECTION AND THE SUBCLOUD LAYER.

Pier Siebesma, European Centre for Medium-Range Weather Forecasts, Shinfield Park, Reading, RG29AX, England. Email: siebesma@ecmwf.int. and Roel Neggers (Royal Netherlands Meteorological Institute, P.O. Box 201, De Bilt AE3730, the Netherlands. Email: neggers@knmi.nl

It is well known that the roots of cumulus convection reside in strong convective plumes that originate from the surface layer. Yet, in large scale weather and climate models it is still common practice to parameterize the dry boundary layer and the cloud layer separately. This results in unwanted overlaps between the schemes and double counting of the transport mechanisms. It also has the additional disadvantage that it requires extra boundary conditions for the convective fluxes at cloud base, which is usually referred to as the closure problem. To overcome these problems a mass flux parameterization is proposed and analysed for strong thermals in the convective boundary layer. Lower boundary conditions can be formulated using the surface layer similarity theory. By subsequently solving updraft equations for vertical velocity, temperature and moisture, this parameterization estimates the nonlocal convective transport of heat and moisture by strong thermals in the subcloud cloud layer that transform into cumulus updrafts in the cumulus cloud layer above the level of condensation (LCL). This way the closure problem is simply shifted to the surface layer and the interaction of cumulus convection with the subcloud layer is established in a natural way. The parameterization scheme is tested and developed using Large Eddy Simulation (LES) results and its impact is evaluated using the ECMWF model.

INITIAL RESULTS FROM A DEPLOYABLE 3-DIMENSIONAL LIGHTNING MAPPING SYSTEM

William RISON, Paul Krehbiel, Ronald Thomas, Timothy Hamlin, Jerimiah Harlin (all at Geophysical Research Center, New Mexico Institute of Mining andTechnology, Socorro, NM 87801 USA, email: rison@ee.nmt.edu)

A lightning mapping system based on Kennedy Space Center's real-time LDAR (Lightning Detection and Ranging) system has been developed that locates impulsive sources of RF radiation produced by lightning discharges. The system utilizes GPS timing at a number of widely spaced locations to image lightning discharges in three spatial dimensions and time. The system was successfully deployed in two field programs in 1998 - in central Oklahoma during May and June and in central New Mexico during August and September. The RF sources clearly delineate charge layers. In Oklahoma we observe multiple horizontal charge layers, consistent with balloon measurements reported in the literature. We have observed several cases of "inverted" discharges taking place between a main positive charge and an upper negative charge. We also observe high-altitude (15-20 km) RF sources, which are spatially isolated from discharges in the maincloud (at altitudes below 15 km) and appear to occur in overshootingturrets. In New Mexico we observe a lower positive charge region associated with most negative cloud-to-ground discharges. We have located the RF sources from positive bi-polar (+BP) discharges (or compact intracloud discharges), and have found, in the dozen or so cases we have analyzed, that the +BP discharges are followed within a few milliseconds or less by "normal" intracloud lightning flashes.

SOME NEW RESULTS FROM A SIMPLE MODELLING OF THUNDERSTORM ELECTRIFICATION USING THE INDUCTIVE MECHANISM

Staytcho KOLEV (National Institute of Meteorology and Hydrology, Blvd. Tsarigradsko Shaussee 66, 1784-Sofia, Bulgaria, email: stayko,kolev aometeo.bg)

Recent experimental studies in UMIST, have shown that the inductive process of graupel charging, proposed by Sir John Mason, is likely to be an active process of thunderstorm electrification in the later stages of storm development. In the present study are presented the results from modelling numerically the growth of the electric field for realistic thunderstorm conditions. The prepared parametrisation of the inductive charging process permit a wide range of cloud conditions to be examined. The results may be compared indirectly with the electric field growth in thunderstorm leading to the cloud discharges. Assuming that the pollution changes the number and the size of the cloud particles, we could to determinate the electric field variations in the cloud. It gives the necessary information in estimating the expected lightning activity. Using the typical accepted values of the cloud parameters, e.g. hail pellets of averaged radius R=0.2 cm and density r=0.5 g.cm-3, falling at velocity V=800 cm.s-1 through a cloud of ice crystals of radius r=50μm and concentration nc, =105m-3, with a=1 (the fraction of cloud particles lying in the cylinder swept out by the hydrometeors which actually rebound from it) it has been shown the numerically obtained electric field growth depending on nc and r. As it is expected the aerosols, involved by the polluted environmental, in cloud will modify the concentration of small cloud particles and using reasonable assumptions, it has been calculated the expected rates of growth of electric field in the these cases.

MI03/W/03-A3 Oral and Poster **1620**

OBSERVATIONS OF X RAYS AND ELECTRIC FIELD IN AND ABOVE THUNDERSTORMS

Kenneth B. Eack (Los Alamos National Laboratory, Los Alamos, NM 87544, USA, email: keack@lanl.gov), William H. BEASLEY (School of Meteorology, University of Oklahoma, Norman, OK 73019, USA, email: wbeasley@ou.edu), W. David Rust (National Severe Storms Laboratory, 1313 Halley Circle, Norman, OK 73069, USA, email: drust@nsslgate.nssl.noaa.gov), Thomas C. Marshall and Maribeth Stolzenburg (Physics Department, University of Mississippi, University, MS 38677, USA, email: marshall@beauty1.phy.olemiss.edu)

Confirming the 1925 prediction by C.T.R. Wilson, we have observed the occurrence of bremstrahlung x rays in thunderstorms, with durations on the order of seconds, in regions in which the electric field exceeded approximately two-thirds the breakeven field for elctron runaway. We used balloon-borne x-ray detectors and electric-field meters to observe these quantities simultaneously as a function of height in and above thunderstorms. The x-ray observations are similar to those previously made from aircraft, but to the best of our knowledge, these are the only observations of x-ray intensity with simultaneous observations of electric field inside thunderstorms as a function of altitude. The duration of the x-ray events and the coincidence between reduction in the local electric field and reduction of x-ray intensity (to or nearly to background levels) led us to conclude that the mechanism for production of the observed x rays is driven by the large-scale thunderstorm electric field. The observations are consistent with a runaway electron model (electron multiplication) using estimates of the horizontal electric field and estimates of source distance based on the rate of change with height of the x-ray intensity. The observations are consistent with source distances of 100 m to 300 m from the balloon. Although physically plausible, this is certainly not the only possible explanation. Additional observations are needed not only to characterize the x-ray source better, but also to provide more information on the electric-field strength and vertical profile necessary for the production of the large numbers of energetic electrons thought to be responsible for the x-ray production observed.

RADIO EMISSIONS OF LIGHTNING: GLOBAL MAPS AND TIPP HEIGHT DETERMINATION

R.S. ZUELSDORF (Institute of Geophysics and Planetary Physics, University of California, Los Angeles, 405 Hilgard Ave. Los Angeles, CA 90095, Email: rzuelsdo@igpp.ucla.edu) A. Jacobson (NIS-1, Los Alamos National Laboratory, Los Alamos, NM 87545) R.J. Strangeway, C.T. Russell (IGPP/UCLA)

From November 1997 throughout August 1998, the Los Alamos FORTE satellite was set to continuously detect lighting in two separate 22 MHz bands: one centered at 38 MHz and the other centered at 130 MHz. Triggering occurred when an RF transient exceeded the noise riding threshold by 20 dBm for 5 of the 8 1-MHz sub-bands in the 38 MHz centered sub-band. The resultant data have allowed for the production of world-wide maps indicating the rate of RF lightning detection. Initial maps indicated the detection of lightning generated RF transients over the equatorial oceans as well as over the continents. Heretofore lightning detecting satellites, which have had optical triggers, have indicated the vast majority of lighting occurs over land. Unfortunately these initial maps do not allow for the comparison of rates from one region to another since the background radiation from anthropogenic sources varies. Here we present maps showing the geographic variation of RF lightning detection from Northern Hemisphere winter, spring, and summer. We also provide maps where the threshold of detection is set to levels exceeding the highest level of global background noise, thus allowing for inter-region comparison. Such maps of the strongest lightning sources shows a strictly continental distribution. This suggests the most powerful of sources are continental.We also present maps of Trans-Ionospheric Pulse Pair (TIPP) detection. TIPPs consist of and initial pulse and a ground reflection, and have a relatively hard spectrum, the power in the 130 MHz band having at least 30% of the power in the 38 MHz band. Previous studies have shown TIPPs to be the most powerful of all satellite detected RF transients. Here we show that the global distribution of TIPPs is much more limited than all lightning generated RF emissions. Work with the Blackbeard instrument on board the ALEXIS satellite in conjunction with stations in the National Lightning Detection Network shows that TIPP heights can occur unusually high in the cloud. Here we present results indicating heights as great as 18 km.

MI03/W/04-A3 Oral and Poster **1700**

ELECTRIC-FIELD CHANGES CAUSED BY LIGHTNING, OBSERVED AT ALTITUDE IN AND ABOVE THUNDERSTORMS

William H. BEASLEY (School of Meteorology, University of Oklahoma, Norman, OK 73019, USA, email: wbeasley@ou.edu) Kenneth B. Eack and David M. Suszcynsky (Los Alamos National Laboratory, Los Alamos, NM 87544, USA, email: keack@lanl.gov)

The atmospheric electrical phenomena known as sprites, elves, and jets have received considerable attention over the last five years. Observations of gamma emissions by the orbiting NGRO, our own observation of a burst of x-ray emissions, lasting about one second, at an altitude of 15km MSL, well above any significant accumulations of charge in a thunderstorm, and unaccompanied by any significant steady electric field, and, at about the same time, speculation in the literature that a quasi-static electric-field change caused by lightning might be the cause of discharges in the upper atmosphere above thunderstorms altogether led us to undertake a program to observe changes in electric field at altitude above thunderstorms, using balloon-borne instruments. We also made observations of x rays with sufficient time resolution to try to determine whether changes in electric field caused by lightning might be the cause of short-duration pulses in x-ray emissions such as those we had observed, as well as the cause of discharge phenomena above storms. During the summer and fall of 1998 we obtained a number of data sets of electric-field changes at altitude, some with accompanying x-ray data, but unfortunately nature did not cooperate with our attempts to get these data at the time of occurrence of sprites in the region. We present comparisons between the field changes as seen at altitude and correlated lightning data from the National Lightning Detection Network.

INSIGHTS INTO OBSERVED STORM-TRACK BEHAVIOUR OBTAINED BY FEATURE TRACKINGAPPLIED TO THE ECMWF RE-ANALYSES

Kevin I. HODGES (ESSC, University of Reading, Harry Pitt Building, 3 Earley Gate, Whiteknights, PO Box 238, Reading RG6 6AL, U.K., Email: kih@mail.nerc-essc.ac.uk); Brian Hoskins (Dept. of Meteorology, University of Reading, Whiteknights, PO Box 238, Reading RG6 6AL, U.K., Email: B.J.Hoskins@reading.ac.uk)

When the planetary scales are removed from meteorlogical fields it is possible to track individual features automatically, in a manner similar to that traditionally performed for surface low pressure centres. This procedure has been applied to a large number of fields on several levels from the ECMWF analyses for 1979 onwards. Diagnostics such as track density, feature strength, growth/decay rates and genesis regions have been produced as well as the traditional eulerian diagnostics.
It will be shown that the variables all show the two Northern Hemisphere winter storm-tracks but that they emphasise different aspects. For example 850mb cold and warm features both show a definite N Pacific track but with relatively weak features. The amplitudes are much larger on the upstram side of the N Atlantic storm-track. The cold features tend to originate over N America and the warm features over the subtropical ocean.
The procedure has also been performed on the data stratified by PNA and NAO indices, and interesting differences are apparent, paricularly with respectto growth/decay rates.
If time permits some results of the inter-seasonal variation in the northern hemisphere and southern hemisphere will also be presented.

MI05/W/42-A1 0930

PRIMITIVE EQUATION MODELLING OF MOIST BAROCLINIC WAVES

Dr Marrizio FANTINI (FISBAT-CNR, Email: M.Fantini@fisbat.bo.cnr.it)

A primitive equation model, in which latent heat release is represented by a small value of static stability for ascending air, is used to examine the early stages of nonlinear evolution of moist baroclinic waves. Results reveal an inconsistency of a previous quasi geostrophic study, and highlight the importance of the formulation of perturbation buoyancy, which is responsible for a temporary increase in growth rate. The perturbation buoyancy term can have a large effect on the dynamical fields even at small amplitude when it acts near the threshold of saturation, as it is shown by comparison of four alternative representations.

MI05/E/19-A1 0950

MOIST PROCESSES IN STORM-TRACKS AND LARGE-SCALE TEMPERATURE STRUCTURE

Mike BLACKBURN (Centre for Global Atmospheric Modelling, University of Reading, PO Box 243, Earley Gate, Reading RG6 6BB, UK, email: M.Blackburn@rdg.ac.uk)

Moisture is a major contributor, through both its latent and radiative effects, to the distribution of heating and therefore of temperature in the extratropical troposphere. The latent heating occurs primarily in weather systems in the storm-tracks, whilst moisture transport in the weather systems helps to determine the distribution of moisture and therefore its radiative impact. Moisture thus plays a role in feedbacks between storm-track activity and the large scale structure of the extratropical atmosphere. Idealised experiments are performed to investigate these moist storm-track processes. The experiments build on the "dynamical core" framework, which excludes orography and land-sea contrasts and which includes only fixed or linear diabatic and frictional effects, by adding a simple interactive moisture cycle and associated heating. Results focus on compensation between sensible and latent heat transports and on tropopause height. An aim is to understand systematic differences in large scale temperature structure and storm-track activity seen in climate simulations by GCMs which differ only in their dynamical formulation. The fact that dynamical processes alone appear unable to explain these differences points to the role of moisture in driving them.

MI05/W/05-A1 1010

THE MEAN DISTRIBUTION OF 500 HPA CYCLONE CHARACTERISTICS OVER THE SOUTHERN HEMISPHERE

Murray Keable and Ian SIMMONDS (both at School of Earth Sciences, The University of Melbourne, Parkville, Victoria, 3052, Australia, email: ihs@met.unimelb.edu.au)

The 500 hPa level is understood to be an important 'steering' level for the development of weather systems. It follows that a deeper understanding of the behaviour of cyclonic systems at this mid-tropospheric level will aid in our interpretation of the development and evolution of their counterparts at the surface.
We present here the first comprehensive climatology of 'cyclones' at the 500 hPa over the Southern Hemisphere. This has been obtained by applying a state-of-the-art automatic cyclone tracking scheme to the 500 hPa analyses from the NCEP re-analysis set covering the period 1958-97. Overall, the climatological distribution of systems at 500 hPa bears great similarity to that at the surface and, in particular, both show high densities in the circumpolar trough region. A significant difference, however, is the high number of 500 hPa systems to be found over the Antarctic continent.

MI05/E/26-A1 1100

LOW FREQUENCY VARIABILITY IN A COUPLED ATMOSPHERE-SEA ICE MODEL

G. Garric and I.N. JAMES (both at Dept of Meteorology, University of Reading, Box 243, Reading RG6 6BB, UK. E-mail: I.N.James@rdg.ac.uk)

A simplified global atmospheric circulation model is used to study the interactions between developing baroclinic waves and sea ice. A simple dynamical model of sea ice, in which the ice moves in response to the low level wind, leads to a prognostic equation for the lead fractionof the ice cover. At the same time, increasing lead fraction leads to enhanced heat fluxes into the atmosphere. The system gives rise to the possibility of strong feedback between the developing baroclinic wave and the distribution of sea ice, via an "anti-CISK" mechanism: divergence of the ice cover leads to enhanced low level heating while ice convergence leads to reduced low level heating. Even small changes in the ice fraction can lead to large changes in the low level heating. In turn, the changes of the low level heating modify the wind field and the development of the baroclinic wave.
Our parameterisation has relatively small impacts on the linear growth rates and structure of growing baroclinic waves. However, the effects on the non-linear phases of the lifecycles are more pronounced. In some circumstances, the feedback leads to pronounced large scale, low frequency fluctuations of the ice cover. These fluctuations may have spatial scales of several Rossby radii and periods of 50-100 days.

THE ATMOSPHERIC SIGNATURE OF THE NORTH ATLANTIC OSCILLATION

Marten H. P. AMBAUM, (Dept of Meteorology, University of Reading, UK)

The North Atlantic Oscillation (NAO) is thought to be the major mode of variability in the North Atlantic storm track. It is associated with a dipolar anomaly pattern in the sea level pressure over the Atlantic with opposing centers of action over Iceland and over the Azores. The NAO also has a large impact on the Northern Hemisphere circulation, though the dominant mode of variability for the whole hemisphere has been identified recently as the so-called the Arctic Oscillation (AO). The sea level pressure pattern associated with the AO is more zonally symmetric and has a pronounced center of action over the Pacific. In the presentation, the relationship between the two modes of variability will be put forward. At the same time some comments on the physical interpretation of the two will be made. Evidence is shown that indicates that the NAO, as opposed to the AO, is the dominant physical mode of variability in the Northern Hemisphere midlatitude circulation.

MI05/E/07-A1 1140

THE STRUCTURAL ORGANIZATION OF ERRORS DURING S.H. BLOCKING

MOZHENG Wei and Jorgen S. Frederiksen (CRC for Southern Hemisphere Meteorology CSIRO Atmospheric Research, PMB 1, Aspendale Victoria 3195, Australia email: mozheng.wei@dar.csiro.au)

The structures of randomly generated errors evolving in a barotropic tangent linear model, with time-dependent basic states taken from observations, is examined for cases of block development, in the Southern Hemisphere in 1989. The statistics of 100 evolved errors are studied for six day periods and compared with the growth and structures of fast growing finite-time normal modes(FTNMs). The amplification factors of most random errors are slightly less than those of the fastest growing FTNM for the same time-interval. During their evolution, the standard deviation of the error fields become concentrated in the regions of rapid dynamical development, particularly associated with developing and decaying blocks.
The probability distributions and the mean and standard deviations of pattern correlations between each of the 100 evolved error fields and the five fastest growing FTNMs have been calculated for the same time interval. The mean of the largest pattern correlation, taken over the five fastest growing FTNMs, increases with increasing time interval to a value close to 0.6 or larger after 6 days. FTNM 1 generally, but not always, gives the largest mean pattern correlation with error fields. Mean pattern correlations with fast growing FTNMs increase further when the time interval is increased beyond 6 days. The implications of our results for methods of ensemble prediction is
discussed.

CONNECTION BETWEEN THE ATLANTIC AND PACIFIC STORM TRACK

Ulrike BURKHARDT (Department of Meteorology, University of Reading, 2 Earley Gate, Whiteknights, Reading RG6 6BB, UK, Email: ulrike@met.reading.ac.uk)

The separation between the Atlantic and Pacific storm tracks is pronounced only at the lower levels. In the upper troposphere, there is very little break between the two storm tracks. The suggestion is that upper level disturbances cross North America, but the low level,more baroclinically active parts of the disturbances are blocked, mainly by the Rocky Mountains. The traversion upper level systems provide the seeds for the Atlantic storm track. In this way, there can be a coupling between the Pacific and Atlantic storm track. An analysis of this coupling in observational data and in simulations of a simplified global circulation model will be presented.

LARGE SCALE ASPECTS

MI05/E/09-A1 1400

ON THE EDDY ACCELERATION OF THE MEAN ZONAL FLOW IN THE ATMOSPHERE

Arne M. BRATSETH (Dept. of geophysics, University of Oslo, 0315 Oslo, Norway, email: arne.bratseth@geofysikk.uio.no)

Data sets from a GCM and from the real atmosphere have been analysed in order to study the effect of eddies on the zonal mean zonal flow. For this purpose it is necessary to isolate the Coriolis torque of the mean meridional overturning. In order to avoid Stokes drift effects this is done by means of a transport circulation based on an advection-diffusion operator with transport characteristics as close as possible to the zonally averaged advective transport of the total data set. This trans-port circulation is direct almost everywhere, but very weak outside the tropics. The diffusivities show a complicated structure with minima near the jet maxima.
Zonal accelerations due to other motions than the transport circulation are shown to be correlated to the diffusivities. It will be argued that this is to be expected on the basis of potential vorticity thinking. Weather systems which do not mix the air (for example steady waves) will not change the average PV-distribution, and will have no effect on the mean zonal flow. Strong accelerations of this flow are found when wave growth leads to irreversible wave breaking and mixing. These ideas are supported by an application of the circulation theorem which makes it possible to estimate the effect, and show that it is compatible with the analysed data

MI05/E/04-A1 1420

GREENLAND AND THE AMBIENT SYNOPTIC-SCALE FLOW

Cornelia SCHWIERZ, Rene Fehlmann and Huw C. Davies (all at Institute for Atmospheric Science, ETH Zurich, Honggerberg HPP, CH-8093 Zurich, Switzerland, email: schwierz@atmos.umnw.ethz.ch)

A study is undertaken of the influence of Greenland upon the synoptic-scale flow. The massif has several distinctive features that can exert significant dynamical constraints upon the nature of the orographic modification of the ambient flow: (1) its high plateau (heights > 3000m) and steep lateral slopes connote a major nonlinear perturbation of incident airflow, (2) its delta-shape yields longitudinal scales that range from supra-synoptic in the north to meso-alpha further south (3) and its polar location places it somewhat north of the Atlantic storm track in a region with a low ambient tropopause and it also renders curvature effects significant.
In the present study we adopt two complementary approaches. First case studies of uniform incident flows and of an upper-level trough (PV anomaly) translating toward Greenland are performed using ECMWF analysis fields, and second a set of idealized simulations are undertaken with a modified version of the Europa Model (EM) of the German Weather Service (DWD). Together these approaches provide insight on key dynamical aspects of the synoptic-scale flow over and in the vicinity of Greenland.

MI05/W/28-A1 1440

AN INTERCOMPARISON OF TRACKING STATISTICS FOR ERAAND UNIFIED MODEL CLIMATOLOGY

David ANDERSON. (Dept. of Meteorology, University of Reading, Earley Gate, PO Box 243, Reading, RG66BB) Brian Hoskins. (Dept. of Meteorology, University of Reading, Earley Gate, PO Box 243, Reading, RG66BB)

The success of a GCM can be judged by its ability to reproduce features and behaviour present in the atmosphere itself. The ECMWF ERA data set represents the best available estimate of the state of the atmosphere during the eighteen year period that it covers. The ability of the UK Met. Office Unified Model (UM) to reproduce mid-latitude variability is investigated by comparing data obtained using a tracking program developed by Dr. Kevin Hodges with similar data derived from the ERA data set. The version of the UM used is called HADAM3. It has produced an eighteen year simulation forced by prescribed sea surface temperatures.
Previous studies have focused on the comparison of the mean fields or the variability about this mean from an intrinsically Eulerian perspective. This study takes the more system orientated approach of tracking individual synoptic scale features throughout their lifetime and then compiling statistics to investigate the atmospheric variability. The results are complementary to the standard view of looking at the variability at a point. Also they allow further insight into the nature of this variability as it is possible to look at the contribution to the variance of the cyclonic and anticyclonic systems separately. Tracking results from a variety of diagnostics will be presented, including mean sea level pressure, meridional wind, geopotential and vorticity. The implications of these results will then discussed in terms of the ability of the UMto reproduce features observed in the ERA statistics.

MI05/W/20-A1 1500

A GCM INVESTIGATION INTO THE NATURE OF BAROCLINIC ADJUSTMENT

Leon BARRY, George Craig and John Thuburn (Department of Meteorology, University of Reading, Whiteknights, Reading, RG1 6BB, UK, email: swr97lb@met.rdg.ac.uk)

Spin down experiments have been conducted using an atmospheric general circulation model to determine the nature and timescale of adjustment to a baroclinic neutral state. The spin down was obtained by turning off the radiative cooling of the atmosphere. The neutral state was characterised by narrower baroclinic zones with increased static stability but little reduction in maximum meridional temperature gradients. The adjustment was roughly exponential with a timescale of 15-20 days. A spin up experiment was also performed, where the radiation was turned back on in the adjusted state. The original climate was returned in a timescale of 5-10 days. This timescale is clearly shorter than the adjustment timescale, adding to the evidence that the mean state of the atmosphere cannot be said to be baroclinically adjusted.

MI05/E/12-A1 1550

THE ROLE OF FRONTOGENETIC AND FRONTOLYTIC CIRCULATIONS DURING THE DOWNSTREAM DEVELOPMENT OF BAROCLINIC WAVES

Manfred KURZ, Deutscher Wetterdienst, Frankfurter Strasse 135, D-63067 Offenbach a.M., Germany, e-mail: istehr@dwd.d400.de

The amplification of an unstable baroclinic wave is often followed by the intensification or new formation of waves in the upper current downstream of the first wave. With the aid of a typical example it will be demonstrated that during this process normally frontogenesis takes place ahead of the intensifying ridge or trough through which a solenoidally direct circulation across the frontal zone is released and an upper jet streak develops. The shear vorticity at the flanks of this jet streak is then advected downstream and contributes to the intensification of the next wave. Ahead of the jet streak the particles undergo a frontolytic effect in the wind field leading to a circulation in the opposite direction with an ascent of the colder air and a descent of the warmer air. As a result cold troughs and warm ridges develop, which are eventually cut off during their further development. The approach of such a cold trough towards a baroclinic zone in the lower troposphere can give rise to a coupling of waves and a strong cyclogenesis throughout the whole troposphere. On the other hand also a decoupling of waves with originally upright axes is possible during this kind of intensification process.

MI05/E/15-A1 1610

THE EFFECT OF MERIDIONAL STRAIN ON BAROCLINIC INSTABILITY

S.HARE and I.N.James, (Department of Meteorology, University of Reading, U.K.)

Meridional overturning is found in the atmosphere in association with zonal acceleration at tropospheric jet entrance and exit regions. We suggest that such overturning will have an effect on the lifecycles of baroclinic waves, and, in particular, provides a mechanism for breaking the midlatitude baroclinic zone into relatively isolated storm tracks. The growth rates of normal modes of the linearised primitive equation model are reduced by up to 20% by realistic strengths of meridional overturning, and normal mode structures are also significantly effected.
Meridional circulations have a more dramatic effect on the non-linear stages of the lifecycle. A jet entrance type circulation leads to a reduction in maximum eddy energy of up to 80%, while a jet exit type circulation slightly increases the maximum eddy energy. Both types of circulation cause significant changes in eddy structure, particularly in the decay phases of the lifecycle. The calculations are being extended to allow the basic state to evolve, in order to represent the passage of evolving disturbances along the jet.

MI05/E/06-A1 1630

INTERACTION OF MESOSCALE TROPOPAUSE DEPRESSIONS WITH A WARM-CORE CYCLONE

K.A.BROWNING, A.J.Thorpe, A. Montani, M. Griffiths, P.Panagi, E.M.Dicks, (Dept. of Meteorology, University of Reading, Reading, RG6 6BB, UK. email: k.a.browning@reading.ac.uk); D.Parsons, National Centre for Atmospheric Research, Boulder, Colorado, USA. email: parsons@atd.ucar.edu

This talk focuses on the coupling between the warm core of extropical cyclone Lili and 2 pre-existing mesoscale tropopause depressions (TDs), ie downward intrusions of stratospheric air. The TDs approached the cyclone from widely separated sources after becoming cut off from different upper-level troughs upstream of it. Errors identified in model forecasts of cyclone Lili are attributed to analysis errors in the position of one of the TDs. Two methods are used to locate the analysis errors. Both are capable of being used in real time. The first is the identification via satellite imagery of an error in the Met Office model's water vapor analysis, and its translation into thermal and kinematic information via PV inversion. The second method, using singular vectors calculated from the ECMWF model, involves the identification of sensitive regions where any analysis error would be expected to grow rapidly. Forecast reruns made with the Met Office and ECMWF models after modifying the upper-level PV in the analysis showed some limited improvements.

MI05/E/24-A1 1650

AN EXTRATROPICAL CYCLONE'S PV-TOWER

A. M. ROSSA* (email: ros@sma.ch), H. Wernli (email: henry@atmos.umnw.ethz.ch), and H. C. Davies (email: davies@atmos.umn Institute for Atmospheric Science, ETH Hvnggerberg, CH-8093 Zurich, Switzerland * current affiliation: Swiss Meteorological Institute, Krdhb|hlstrasse 58, CH-8044 Zurich, Switzerland

Mature extra-tropical cyclones are often associated with a troposphere-spanning column of anomalous Evidence of the modulating as opposed to the dominating influence of diabatic processes upon the cyclone's structure and strength is derived from consideratio n of: the tower's durable and ephemeral potential vorticity, the PV production along the warm front and sets of model simulations of the event that selectively suppress diabatic PV production.

MI05/W/41-A1 1710

OCCLUDED MID-LATITUDE CYCLONES

J.E.MARTIN (Department of Atmospheric and Oceanic Sciences, University of Wisconsin-Madison, 1225 W. Dayton Street, Madison, Wisconsin, 53706 USA, Email: jon@meteor.wisc.edu)

Occluded mid-latitude cyclones are often characterized by a lower tropospheric thermal ridge that connects the sea-level pressure minimum to the peak of the surface warm sector. In an atmosphere in approximate thermal/gradient wind balance, such a thermal structure is associated with a characteristic tropopause-level potential vorticity (PV) distribution in which an isolated, low latitude high-PV feature is connected to the polar reservoir of PV by a thin filament of PV.
In this paper we employ output from a numerical simulation to investigate the evolution of such a "treble clef" tropopause PV distribution during the development of an observed occluded cyclone. It is found that at the tropopause the occlusion process involves the roll up and

breaking of a PV wave. The vector quantity, Q_pv, defined as the Lagrangian rate of change of the PV gradient on an isentropic surface, is employed to examine the kinematics of this wave breaking. Through appropriate partitioning of Q_pv it is shown that the vorticity at tropopause-level controls the cyclonic roll up of the low latitude portion of the "treble clef" (i.e. the PV wave crest). The total deformation field plays a dual role in the observed evolution. It serves to dilate the filament of high PV that connects the low latitude PV feature to the polar reservoir. Deformation also contributes to the wavebreaking by rotating the northern portion of the PV wave anticyclonically. The analysis sheds new light on the structural development of some occluded cyclones, emphasizing the distinct but complementary roles played by vorticity and deformation in the occlusion process. The results are considered in the light of recent idealized numerical experiments regarding the life cycles of extratropical cyclones.

MESOCYCLOGENESIS IN THE WEDDELL SEA AND THE ROSS SEA REGION OF ANTARTICA

Thomas KLEIN (Meteorologisches Institut der Universitaet Bonn, Email: unf43e@rhrz.uni-bonn.de)

The Weddell Sea and the Ross Sea of Antarctica are favourable regions for mesocyclogenesis. The interaction of the katabatic wind system in these areas and the development of mesocyclonic vortices is investigated by means of numerical simulations. In contrast to the more homogeneous flow over the interiour regions of Greenland and Antarctica, a more complex behaviour of the katabatic winds can be observed in the coastal areas, where the strongest topographical gradients are present. An intensification of the katabatic wind up to gale force can occur in large valleys near the coast, where the topographical structure leads to a channeling of the flow. Additionally, a quasi-permanent baroclinicity is present close to the coast, which can be intensified by the transport of cold air over the open water in association with katabatic surges. Several case studies using the mesoscale model NORLAM were performed in order to investigate the impact of the katabatic wind system on mesocyclogenesis in the Weddell Sea and Ross Sea areas of Antarctica. It is demonstrated that - in connection with suitable synoptical forcings - the katabatic wind system in these regions can trigger mesocyclonic developments by vortex stretching or/and by enhancing the baroclinicity near the surface.

MI05/L/02-A2 0950

OBSERVATION OF A POLAR LOW ON THE ROSS ICE SHELF, ANTARCTICA

Michael Beles and Charles STEARNS (both at Space Science and Engineering Center, Universsity of Wisconsin, 1225 West Dayton Street, Madison, Wisconsin 53706, USA)

Satellite images show the development of the comma shaped cloud system on the Ross Ice Shelf, Antarctica commonly called a polar low. The system passed over two United States Antarctic Program automatic weather stations (AWS) on the Ross Ice Shelf. The time variation of air pressure, air temperature, wind speed and wind direction provided a record for a sector of the polar low as the system passed over the two sites compared to nearby AWS sites whose records showed no evidence of the polar low. This polar low did not develop as a classical comma-type system, as is the case when polar lows develop over the open water. Data from the two AWS suggest that local sensible and latent heat fluxes as well as low level cyclonic voricity contributed to the development of this polar low.

MI05/W/18-A2 1010

CASE STUDY OF A QUASI-STATIONARY SYNOPTIC CYCLONE TO THE WEST OF THE ANTARCTIC PENINSULA AND RELATED MESO-SCALE DEVELOPMENTS

Charlotte HEARNSHAW (The Environment Centre, University of Leeds, Leeds, LS2 9JT.); Doug Parker (The Environment Centre, University of Leeds, Leeds, LS2 9JT.)

A case study of a synoptic cyclone which became quasi-stationary to the west of the Antarctic Peninsula shall be presented. As the fronts from this system crossed the peninsula from North West to South East satellite images showed meso-scale developments to the lee of the mountain barrier.
The dynamics of the processes which lead to these developments will be discussed with the aid of ECMWF operational analyses and data from the Antarctic First Regional Observing Study of the Troposphere (FROST) Special Observing Period 3 (SOP-3), January 1995. This data archive includes scatterometer measurements of surface winds, 1km resolution satellite images, Automatic Weather Station (AWS) data from the east side of the peninsula, data from manned stations on the west and surface pressure charts for the peninsula region prepared by the duty forecaster at Rothera.

MI05/E/25-A2 1100

POTENTIAL VORTICITY AND SINGULAR-VECTOR PERSPECTIVES OF DOWNSTREAM BAROCLINIC DEVELOPMENT DURING THE NORTH PACIFIC EXPERIMENT (NORPEX)

Melvyn SHAPIRO (National Center for Atmospheric Research, Boulder CO, 80303, USA, email: mshapiro@etl.noaa.gov); Heini Wernli (Institute for Atmospheric Science, ETH, Zurich, Switzerland, email henry@atmos.umnw.ethz.ch); and Rolf Langland and Ron Gelaro (Naval Research Laboratory, Monterey CA, 93943, USA, email: langland@nrlmry.navy.mil)

Simmons and Hoskins (1979) and Orlanski and Chang (1993) extended Rossby's (1949) concept of barotropic energy dispersion to idealized and observed downstream (upstream) baroclinic development. Operational analyses, enhanced with adaptive observations from NORPEX, reveal baroclinic wave packets initiated by cyclogenesis east of Japan. Downstream developing baroclinic disturbances from these packets led to destructive weather events over the western North America and rapidly deepening cyclones off the North-American Atlantic seaboard. Mid-Pacific lower-tropospheric upstream developments which phase with transient upper-level waves in the westerlies are identified. Analyses of tropopause potential vorticity (PV), and lower-tropospheric temperature and wind velocity from ECMWF analyses are used to describe the synoptic perspective of downstream (upstream) development for situations during NORPEX. Hovmoeller diagrams for the latitudinal belt 35 to 55 N illustrate the longitude-versus-time evolution of the downstream (upstream) dispersion of tropopause potential vorticity anomalies and surface-based thermal anomalies for expanding baroclinic wave packets. Singular-vector calculations prepared from the NRL/NOGAPS global model identify both west-Pacific developments and their concurrent mid-Pacific downstream developments as observational targets for the reduction of analysis errors that limit 2 to 3 day forecast skill over western North America.

MI05/E/14-A2 1120

UNDERSTANDING SINGULAR VECTOR EVOLUTION FROM A PV PERSEPCTIVE

Michael C. MORGAN and Chih-Chieh Chen (both at Department of Atmospheric and Oceanic Sciences, 1225 W. Dayton Street, University of Wisconsin - Madison, Madison, Wisconsin 53706 USA, email: morgan@meteor.wisc.edu, chen@meteor.wisc.edu)

In this presentation, the basic mechanisms for development of SV's in a hierarchy of rather simple QG models (Eady, Green and Charney models) are discussed. The salient features of the transient development of these singular vectors are then identified and characterized by the SV's evolving PV distribution. Piecewise PV diagnostics are applied to interpret the SV evolution in terms of the evolution of the SV's interior PV and boundary potential temperature (BT) distributions. Decomposition of the SV's into modal structures (normal modes and continuous spectrum (CS) structures) reveals the role these modes play in the development. It will be shown that the modal decomposition of the SV's reveals that the continuous spectrum plays a detrimental (positive) role in the development for sufficiently long (short) waves. The structure of the CS is described and interpreted in terms of its PV and BT characteristics.

MI05/E/27-A2 1140

IDEALIZED MIDLATITUDE CYCLONE DEVELOPMENT: SENSITIVITY TO SURFACE PARAMETERS

Jake BADGER, Brian Hoskins, Paul Valdes (Department of Meteorology,University of Reading, Earley Gate, PO Box 243, Reading, RG6 6BB, UK, E-mail: J.Badger@rdg.ac.uk); and Mike Blackburn (Centre of Global Atmospheric Modelling, Department of Meteorology, University of Reading, Earley Gate, PO Box 243, Reading, RG6 6BB, UK)

Experiments have been performed that explore the sensitivity of initial cyclone development to various profiles of fixed surface temperature, surface moisture and initial interior moisture, using the Reading Intermediate General Circulation Model. These experiments have shown that surface moisture, in conjunction with conditional instability, is crucial in determining system growth rates. How the ocean surface parameters are altered by the passage of weather systems will be shown by driving a mixed layer ocean model non-interactively using the atmosphere boundary layer fluxes. The importance of the feedback between the oceanic mixed layer and the atmospheric cyclone will be investigated by rerunning the life-cycle experiments with a fully coupled oceanic mixed layer. Implications for storm-track behaviour will be discussed.

MI05/L/01-A2 1200

UPSTREAM DEVELOPMENT IN IDEALIZED BAROCLINIC WAVE EXPERIMENTS

Heini WERNLI (Institute for Atmospheric Science, ETH Zurich, Switzerland,
email: henry@atmos.umnw.ethz.ch); Melvyn A. Shapiro (National Center for Atmospheric Research, Boulder CO, 80303, USA, email: mshapiro@etl.noaa.gov); and Juerg Schmidli (Geography Institute, ETH Zurich, Switzerland, email: juerg@atmos.umnw.ethz.ch)

An idealized dry primitive equation model on the f-plane is used to study upstream (and downstream) baroclinic wave development. The simulations are initiated with localized finite amplitude and vertically evanescent perturbations, specified either as upper-level potential vorticity or surface potential temperature anomalies. The nonlinear evolution of these nonmodal perturbations leads to the generation of large-scale upper-level induced primary and downstream surface cyclones, and of distinctively smaller, shallow and more slowly intensifying upstream systems. It is shown that in particular the genesis and evolution of upstream cyclones is highly sensitive to the scale of the initial perturbation. Narrow upper-level troughs (or zonally confined surface temperature anomalies) are favorable for upstream development, whereas no or only weak upstream activity occurs with broad planetary-scale troughs (or zonally extended surface temperature anomalies) as initial perturbations. It is proposed that this sensitivity property of upstream development is qualitatively related to the dispersion characteristics of surface edge waves. Consideration is also given to the vertical coupling of lower tropospheric upstream systems with transient upper-level waves.

MI05/W/47-A2 1400

APPLICATION OF THE SPLITTING DIAGNOSTIC METHOD TO A RAPIDLY DEVELOPING CYCLONE

Qiu-shi CHEN (Byrd Polar Research Center, The Ohio State University, 1090, Carmack Rd., Columbus, OH 43210, USA, Email: qchen@polarmet1.mps.ohio-state.edu)

Sensitivity studies only reveal long-term, integrated effects and stop short of providing interpretations of how the evolution of the phenomenon is controlled by the step-by step interactions and feedbacks. The method of combining diagnostic and sensitivity studies together is a way for removing this shortcoming and for understanding the evolution of a phenomenon simulated in complex models. The traditional definition of the geostrophic wind cannot be used in the region near the equator because the Coriolis parameter is present in the denominator. Using the wind partitioning into the streamfunction and velocity potential, the geopotential field can be separated into a geostrophic part and an ageostrophic part. The horizontal pressure gradient force of the geostrophic geopotential is equal to the Coriolis force of the rotational wind. The ageostrophic part is the difference between the geopotential and its geostrophic part. An ageostrophic temperature is defined from the ageostrophic geopotential based on the hydrostatic equation. The vorticity and divergence equations are transformed into the inner part equations of streamfunction and velocity potential in a limited region (Chen et al. 1997, Mon. Wea. Rev., 143-167). These inner part equations are solved by a semi-implicit time splitting scheme with zero lateral boundary value, and the advection and heating terms are expressed by forcing terms. The solutions of the equations for each of splitting time steps can be separated into two parts. One is the solution of the homogeneous equations with the initial values, and it describes the geostrophic adjustment process from the initial values. The other is the solution of the inhomogeneous equations with the zero initial value, and in this solution, the ageostrophic geopotential and velocity potential are generated from the zero value by the advection-heating process. These two processes are interacted between two adjacent splitting time intervals. These interactions are the basic mechanism for the variations of the synoptic and mesoscale systems. The splitting diagnostic method is to use these interactions in diagnosis.

MI05/E/21-A2 1420

MESOSCALE STRUCTURE OF CYCLONES IN THE NEW ZEALAND AREA

Michael REVELL and Warren Gray (National Institute of Water and Atmospheric research, Wellington, New Zealand, email: m.revell@niwa.cri.nz); James McGregor (Research School of Earth Sciences, Victoria University of Wellington, Wellington, New Zealand, email: Jim.mcgregor@vuw.ac.nz)

Based on earlier classification work by Sinclair and Revell we have selected 4 cases of cyclogenesis (one from each of the major classes with contrasting frontal structures) that produced heavy rainfall, flooding and strong winds over northern New Zealand. The 4 cases consist of (a) an ex-tropical cyclone, (b) a convective storm, (c) a well organised intense front in a northwest-southeast trough, (d) a 'bomb' in the NE Tasman Sea. Calculations of potential vorticity (PV), system relative flow and trajectories derived from high resolution RAMS runs nested in ECMWF data will be used to explain some of the fine scale wind and rain patterns observed in high resolution satellite and radar output. Conceptual models will be presented showing how the the differing synoptic-scale environments for the different classes, e.g the position of the major jet streams and PV anomalies relative to the storm, lead to contrasting frontal development.

MI05/E/18-A2 1450

EXTRA-TROPICAL LIFE-CYCLE STUDIES OF COLD AIR CONVECTION IN HADAM3

L. SHAFFREY (CGAM, Department of Meteorology, University of Reading, Reading, RG6 6BB, U.K., email: L.C.Shaffrey@reading.ac.uk); C. Jones (SMHI, Norrkoping, Sweden, email: Colin.Jones@smhi.se)

In common with many AGCMs (Atmospheric Global Circulation Models),large amounts of convective activity can be seen in the wintertime storm tracks of the UKMO's atmospheric climate model, HadAM3. High resolution life-cycle studies of extra-tropical cyclones observed during FASTEX (Fronts and Atlantic Storm Track Experiment) are integrated and compared with UKMO analyses. This comparison reveals that there is too much convection occurring in the cold air behind the modelled extra-tropical cyclones.
A new non-local boundary layer scheme has been developed at the UKMO which should improve the representation of convective boundary layers in the model. The introduction of the new boundary layer scheme reduces the errors associated with the cold air convection, suggesting that some of these errors are due to a poor interaction between the boundary layer and the convection schemes.

MI05/E/22-A2 1550

A PIECEWISE POTENTIAL VORTICITY DIAGNOSIS OF FRONTOGENESIS

Michael C. MORGAN (Department of Atmospheric and Oceanic Sciences, 1225 W. Dayton Street, University of Wisconsin - Madison, Madison, Wisconsin 53706 USA, email: morgan@meteor.wisc.edu)

The technique of "piecewise" potential vorticity (PV) inversion is used to identify the non-divergent wind fields attributed to upper, middle, and the lower tropospheric PV anomalies in addition to the irrotational wind with the goal of diagnosing the respective wind field's frontogenetic potentialities. Frontogenesis is diagnosed using a piecewise separation of the Q-vector into parts associated with the partitioned wind field. Partitioned geostrophic Q-vectors are used to diagnose the vertical motion attributed to the upper, middle, and lower tropospheric PV anomalies.
Insight gained from this new diagnostic technique is demonstrated by examining surface and upper tropospheric frontogensis associated with a particular case of extratropical marine cyclogenesis resulting from the interaction of an upper tropospheric shortwave trough with a surface thermal wave.

FRONTOGENESIS AND FRONTAL COLLAPSE IN THE ADJUSTMENT OF NON-UNIFORM POTENTIAL TEMPERATURE GRADIENTS AND VERTICAL SHEARS OF HORIZONTAL WIND

cZhe-Min TAN, (Department of Atmospheric Sciences Nanjing University Nanjing 210093 PR China)

In the atmosphere, a frontal-type discontinuity, e.g. see-breeze front and gust front can be formed with a few hours and have gravity current structure that limit the useful of balanced theory of front, e.g. the semi-geostrophic balanced mode. The geostrophic adjustment is one possible mechanism of frontogenesis when the deformation filed is imposed. The frontal discontinuity was developed by the geotrophic adjustment. The frontogenesis and frontal collapse in the adjustment of non-uniform potential temperature gradients and vertical shear of horizontal wind under different initial conditions were discussed in detail. The initial unbalanced state play an important role in the time-scale of adjustment frontogenesis and frontal structure. Moreover, the role of diabatic heating on the frontogenesis by geostrophic adjustment were investigated by an approximate method.

THE EVOLUTION OF A PASSIVE TRACER IN THE VICINITY OF AN ATMOSPHERIC FRONT AND ITS IMPLICATIONS FOR THE DEVELOPMENT OF NON-COINCIDENT FRONTS IN THE THERMAL AND TRACER FIELDS

Douglas J. PARKER (The Environment Centre, University of Leeds, Leeds, LS2 9JT, UK)

Many observations have shown that a synoptic front is not generally an airmass boundary, and that there may be relative airflow through the frontal zone at different heights. Semigeostrophic theory allows for the description of frontal zones which are not airmass features: it will be shown how the evolution of such fronts allows trace properties of the air to be advected through the frontal zone, and thereby form fronts in the tracer field which are not coincident with the thermal front. These ideas will be used to suggest an explanation for the formation of forward-sloping cold fronts, and to describe the likely evolution of pollutants in a frontal environment.

MI05/E/13-A2 1650

THE USE OF OBJECTIVE FRONTAL ANALYSIS TO CHARACTERIZE FRONTS IN THE NEW ZEALAND REGION

Warren GRAY and Michael Revell (National Institute of Water and Atmosphere, PO Box 14 - 901,Wellington New Zealand, Email w.gray@niwa.cri.nz)

A simple objective method for the analysis of fronts in numerical model output, based on that of Hewson (1998), will be presented. This approach uses the Laplacian of the gradient of the temperature field to diagnose the location of fronts, and diagnostics of temperature advection to characterize the front. The role of this simple diagnostic in the synoptic weather systems program will be outlined - and its use in linking mesoscale model output to remotely-sensed observations of the weather associated with fronts. This research will lead to the development of conceptual models that will relate the model fields to the weather being experienced on the surface. A case study of a frontal system which lead to heavy rainfall, flooding, and strong winds will be presented. At various stages this front exhibited both forward and rearward sloping cold frontal systems (analogous to ana and kata fronts). Overlaying satellite imagery with model output and frontal analysis highlighted the cloud patterns associated of with these particular examples. Diagnostics of potential vorticity highlighted an area of inertial instability. Analysis suggests that this area of instability was the consequence of diabatic heating resulting from latent heat release. Examples of radar-observed rainfall and wind fields will also be shown. WHAT ARE THE MOST IMPORTANT ERRORS IN THE INITIAL CONDITIONS FOR NUMERICAL WEATHER FORECASTS ?

C. SNYDER, (NCAR/MMM PO Box 3000 Boulder CO 80307 USA, Email: chriss@ucar.edu); T. Hamill (NCAR) and R. Morss (MIT)

From the perspecitve of numerical weather prediction, errors in initial conditions (or, the analysis) are important to the extent that they influence subsequent forecast errors. Owing to random errors in the observations and in models, this problem is inherently statistical; forecast uncertainty or expected forecast skill is quantified by the forecast covariance matrix. The leading eigenvector of that matrix is the structure that ``explains'' the largest fraction of forecast error variance, and the initial error that gives rise to that eigenvector (i.e., that is mapped onto the leading eigenvector by the forecast model) is the most important analysis error. We employ a simple quasi-geostrophic model and three-dimensional variational data assimilation scheme to produce Monte-Carlo simulations of analysis and forecast error statistics, from which we calculate the leading eigenvectors of the forecast error covariance matrix, and the analysis errors that give rise to them. The resulting initial errors have maximum amplitude aloft, near the tropopause, are deep with decay toward the surface, and have weak or nonexistent tilts in the vertical. These properties stand in contrast to those of the fastest growing errors (in, say, an energy norm), which are concentrated in the mid- to lower troposphere and have fine vertical structure and large vertical tilts. Although the optimal design of observing networks is a subtle question that itself depends on the statistics of short-range forecast errors, the results indicate that observations need not necessarily resolve fine vertical structure in the lower troposphere as has recently been speculated.

MI05/W/14-A3 0920

SINGULAR VECTOR GROWTH FOR FASTEX CYCLONES

Andrea MONTANI (ARPA-SMR, Viale Silvani 6, 40122 Bologna, Italy, Email: m1xukuej@sirio.cineca.it); Alan J. Thorpe (Dept. of Meteorology, Univ. of Reading. Reading RG6 6BB, UK, Email: swsthorp@reading.ac.uk)

Calculations of localised singular vectors (SVs) have been performed using the ECMWF/IFS forecasting model and the dynamical properties responsible for the SVs' growth have been investigated for cases of cyclogenesis during FASTEX. Theoretical results from earlier studies on fast--growing perturbations are examined and their applicability to events of SV growth related to real cases of cyclogenesis is assessed, gaining insight into the mechanisms by which SVs grow. Potential vorticity (PV) diagnostics are used to investigate the dynamical processes responsible for SV growth in terms of total energy and PV and SVs' growth rates are compared to those predicted by normal mode theory. The most dynamically active regions within a SV are looked for, by considering the independent evolution of perturbations initially confined either in the lower or in the upper troposphere. The part of SVs located below 500 hPa is found to play a major role in the interaction processes between the perturbation and the basic state fields and to be responsible for the SVs' development. The relative increase in terms of energy is related to the vertical propagation of the disturbance. In the early stages, SVs' growth rates well exceed those predicted by the Eady model, the non—normal nature of the perturbation being more evident. Then, the growth rates decrease, being closer (but still larger) than those predicted by normal theory. SVs also grow in terms of PV when their velocity components can interact with basic state PV horizontal gradients.
Perturbations initially confined at low levels can propagate vertically more efficiently than those localised above 500 hPa and the interaction with the upper--level basic state fields is much more effective. The extent to which balanced--flow theory, valid in idealised models of non--normal growth, can be applied during the evolution of SVs is also examined. If SVs are calculated with the total energy norm, their initial state is found to be out of balance, because of a lack of amplitude in the vorticity component, being about a factor 4 too small. During the evolution, SVs achieve a more balanced configuration. SVs, calculated with initial norms which are better approximation of the analysis error covariance metric, show no sign of imbalance also at initial time.

THINKING AND SENSITIVITY TO INITIAL CONDITIONS:TO THE PRECURSORS OF A CYCLOGENESIS

Philippe ARBOGAST . Joly. (G. Coriolis Toulouse Cedex France, Email: philippe.arbogasta@mateo.fr)

the last few years, the theoretical study of cyclogenesis experienced a remarkable renewal. The new data required by 's concepts is provided by the observations collected during FASTEX field experiment. The aim of the presentation is to preexisting synoptic scale disturbances responsible for cyclogenesis using a new diagnostic tool: the manipulation initial conditions through quasi-geostrophic potential and its variational inversion. The QG perspective of the inversion, apparently not consistent with a primitive equation , turns out to be efficient in the modification of initial of a primitive equations model. technique is applied to demonstrate quantitatively various occurring between the key dynamical patterns involved the 17th Intensive Observations Period (IOP) of FASTEX. study reveals the unexpected importance of a low level whereas this case looked like a straightforwardof the cyclone by an upper tropospheric disturbance.way this precursor influences, at a distance, the baroclinicwhere the new cyclone will form is studied quantitatively.is shown that this happens where the perturbation introducedthe precursor favours barotropic energy conversion

COMBINED USE OF SENSITIVITY INFORMATION AND OBSERVATIONS TO IMPROVE METEOROLOGICAL FORECAST

Gwenaelle HELLO (Meteo-France/CNRM/GMME, 42 Av Coriolis, 31057 Toulouse cedex, FRANCE. E-mail: Gwenaelle.Hello@meteo.fr)

Progress in the area of the numerical prediction of weather events leads to a strange inconsistency: as the realism of the numerical modelling of very fine scale process such as regional winds, local events (fog, breeze) is increasing, the synoptic forecast of meteorological events of larger scales such as storms or cyclogenesis is still subject to major numerical forecast failures. Most part of it can be attributed to initial conditions errors. These errors are generally of little consequence, except in those situations that support large amplification of small perturbations. This underdetermination of the analysis state of the atmosphere can be due to the lack of observations and/or to the weakness of the assimilation scheme to use them properly.
The sensitivity fields (such as gradient fields, singular vectors) can be use in a pronostic way in order to identify in the initial conditions the geographical areas where analysis errors are likely to grow rapidly leading to a change inside the area of interest. This is used for example to determine the location of targeted observations. In this study, the sensitivity fields are used to perturb the analysis state in order to provide new initial conditions more consistent with the atmospheric flow. This is done using the available observations inside the sensitive area which are used to calibrate the amplitude of the "sensitive" perturbation.
The method and its application to real cases will be presented. The feasibility of the method in regard to operational applications as well as undergoing developments of it will also be discussed.

MI05/W/21-A3 1100

ASSIMILATION OF OBSERVATIONS INSIDE SENSITIVE AREAS

Alex DOERENBECHER Meteo-France/CNRM/GMME, 42 Av Coriolis, 31057 TOULOUSE cedex, FRANCE E-mail: Alex.Doerenbecher@meteo.fr Gwenaelle Hello and Thierry Bergot (same address)

Forecasts of rapid cyclogenesis events leads sometimes to predictability problems in Numerical Weather Prediction even at very short ranges. The study of such topics was one of the scientific objectives of the FASTEX field phase (Joly et al. 99). The concept of adaptive observations was tested in the experimental context of FASTEX. That means to make specific "targeted" observations inside geographical sensitive areas which had been numerically preprocessed (singular vectors and or gradient sensitivity fields). On the first hand, the current assimilation methods are not efficient enough to optimaly take into account these observations, made inside sensitive areas. In cases of very weak predictability, the projection of the analysis error into the unstable subspace is detrimental for the forecast (Bergot et al. 99). On the other hand, adaptive observations is based on the only information available that is the definition of the area to sample. The challenge is then to sample efficiently this sensitive region. In order to achieve optimal sampling, the role and properties of data assimilation scheme employed cannot be neglected anymore. Extra observations, assimilation and the dynamical properties of the current trajectories must be linked together in a consistent global approach. The goal is to determine in advance where and how much extra data are required to maintain a good control of the unstable plane, knowing that a 3D-VAR or a 4D-VAR technique is employed. The theoretical approach needed will be outlined and some of the difficult or open points that it contains will be documented by diagnostic calculation performed on some FASTEX cases.

MI05/W/44-A3 1120

DATA IMPACT EXPERIMENT OF FASTEX ADAPTIVE OBSERVATIONS

T.BERGOT (Meteo-France, CNRM, 42 Av Coriolis, Toulouse, 31057, France,
Email: Thierry.Bergot@meteo.fr); HELLO and Alex Doerenbecher (same address)

Of the main scientific objectives of FASTEX was to provide called adaptive observations, in area of strong sensitivity, order to control the development of forecast errors. The purpose this concept is to concentrate observations in that of the flow from where small analysis errors will amplify. Aircrafts equipped for GPS dropsoundings (NOAA Gulstream IV, herafter GIV, and NCEP Learjet36, hereafter L36)tasked to sample these dynamically crucial areas (12 L36 flights and 8 GIV flights are studied here).main goal of this work is to investigate the efficiency of adaptive observations obtained in real time during FASTEX.model used for these tests is the ARPEGE/IFS model with a of T95C3.5 (3.5 stretching factor) and 27 vertical levels.the first step, the assimilation scheme used is an incremental 3Dvar,a T63 resolution for the increments. Most FASTEX adaptive observations a non-negligible impact on the short-range forecast (the impactdefined as the difference between forecasts with and without observations).mean impact is about 9hPa for 36h forecasts (10.8hPa for the GIV7.8hPa for the L36), with a maximum of 28hPa.improvement of forecast quality is tested by comparing forecastsand without adaptive observations to verifying analyses.mixture of improvement and deterioration is obtained,for the 20 cases studied, the mean improvement is weak and hassame order of magnitude as the analysis errors, but with a large spread.discriminating study of the cases shows that a strong improvement iswhen the guess is found a posteriori to be poor (i.e. whenpredictability is weak).these results prove that the adaptive observation technique, in real time during FASTEX, a large amplifying impact and could strongly influence forecasts. But also suggest that the current assimilation system, as 3Dvar, is not able to build efficient initial field (with no error in the most unstable directions for example).assimilation inaccuracies may hide the impact ofobservations, pointing out the lack of optimality of the assimilation system. results, using advanced assimilation method(4Dvar, control of the error on the unstable subspace), will also presented, and will allow to discuss this point.

MI05/W/45-A3 1140

FASTEX 4 D VAR RE-ANALYSIS

G.DESROZIERS (Meteo-France, CNRM, 42 Av Coriolis, Toulouse, 31057, France,
Email: Gerald.Desroziers@meteo.fr)

An unique observation network has been settled during FASTEX in the Northern Atlantic ocean. This observation set was particularly based on high cadence radiosoundings performed by ships and dropsondes launched by planes. The dropsondings were made, for a part of them, in a far upstream domain, in order to observe precursors of subsequent cyclones. Additional vertical profiles were given by FASTEX ship soundings or by dropsondes in a "near" upstream area, observing cyclones at their developing stage. Finally, cyclones were sampled, at their mature stage, by high resolution dropsondes focussing on fine scale structures. We aim at producing a complete reanalysis of the FASTEX situations. A particular difficulty to handle the FASTEX observations is due to the fact that most of them are not synchronous with synoptic time. This problem is solved with a 4D-Var scheme, which allows the use of such asynoptic data. Such a 4D-Var analysis is under development at Meteo-France. A main feature of the 4D-Var scheme developed at Meteo-France is the use of a stretched geometry for the reference trajectory, which provides a very high local resolution. The application of the 4D-Var scheme to the FASTEX data is found very encouraging, since it appears to handle this dataset consistently. There is also a clear impact of the FASTEX observations, which contain an information that is not given by the operational network. This is particularly true for high resolution dropsondes sampling the cyclones at their mature stage, and providing, through the use of 4D-Var, a description of the mesoscale structures of cyclones.

MI05/W/29-A3 1200

SENSITIVITY OF DEEPENING CYCLONE WITH RESPECT TO THE SST IN THE FASTEX EXPERIMENT: APPLICATION TO THE IOP15

Hervé GIORDANI (Meteo-France, CNRM, 42 Av Coriolis, Toulouse, 31057, France,
Email: Giordani@meteo.fr); Guy Caniaux

Sensitivity of the cyclogenesis with respect to the SST is poorly known and theoceanic component of FASTEX experiment (1997) called CATCH contribute to answer towards this open question. Thanks to the operationnal and experimental data ships, optimal SST re-analyses were performed in the North Atlantic current region where the SST gradients reach $10^oC/50 km$. This paper presents the cyclogenesis development of the IOP15 (13-15 February 1997) because its strongest surface depenning occurs precisely when the cyclone crosses the SST front from the cold to the warm waters. In order to evaluate the impact of the surface differential heating on the frontogenesis and cyclogenesis, three atmospheric simulations were performed with the non hydrostatic model Meso-NH. The reference simulation was performed with the SST re-analysed and the other both are respectively carried out with constant SSTs of 3^oC and 15.6^oC over the domain. It appears that the reference simulation is 12 hPa lower, 10^oC warmer and 5 g/kg moister in comparison with the cold SST simulation, and the low center trajectory is different in comparison with the warm SST simulation. Therefore spatial distribution of the surface turbulent fluxes will be presented and their impact on the atmospheric front intensity (vertical velocity, shear wind, precipitations, cold sector activity,) will be analysed for the three simulations.

DETERMINATION OF THE THERMAL STRUCTURE AROUND THE TROPOPAUSE FROM TOVS OBSERVATIONS FOR 3 FASTEX IOPS

N. FOURRIE (1), C. Claud (1), J. Donnadille(2), A. Joly(3), R. Armante(1) (1) CNRS/LMD/ARA, Ecole Polytechnique, F-91128 PALAISEAU Cedex (2) Laboratoire d'Aérologie, Observatoire Midi-Pyrénées, 14, avenue Edouard Belin, F-31400 Toulouse (3) METEO-FRANCE CNRM/GMME/RECYF, 42 av. G. Coriolis, F-31057 Toulouse Cedex 1

Among the numerous scientific objectives of the FASTEX campaign, an important issue concerns the genesis mechanism and more specifically the existence of preexisting upper level anomalies. Observations from the satellites of the TIROS-N series, equipped with the HIRS-2 (High Resolution Infrared Radiation Sounder) and MSU (Microwave Sounding Unit) radiometers, allow for the determination of the so-called Temperature of the Lower Stratosphere (TLS) as it has been defined in the 3I (Improved Initialization Inversion) approach to the inversion of the Radiative Transfer Equation and which represents the temperature around the tropopause. This parameter is determined at a spatial resolution of 100 X 100 km2 which is a compromise between HIRS 2 and MSU spatial resolution.For 3 FASTEX IOPs (12,17 and 18), TLS fields have been derived and will be discussed. TLS anomalies have been compared to other independent diagnostics : in particular, MSU channel 3 brightness temperatures, and 2PVU surface thermal fields computed with the ARPEGE model (Meteo-France). Such studies show the interest of such a variable for characterizing and following upper level structures (jets, potential vorticity cores).
In addition, recently, a new method for calculationg TLS at HIRS 2 resolution (30 km2) has been developped. We will therefore show the advantages of an increased spatial resolution for the diagnostic of altitude precursors.

SPLITTING WEATHER SYSTEMS: CYCLOGENESIS IN A COMPLEX SETTING SEEN IN FASTEX AND A CLIMATOLOGY OF NORTH-ATLANTIC CYCLONES

Alain JOLY, Franck Ayrault, Christophe Baehr (Météo-France, CNRM/GMME/RECYF, Toulouse, France)

On several occasions during the two months of the FASTEX field experiment, the tendency for one well developed cyclone to split into two or even three new individual systems has been observed. One such case will be shown in some detail, and the other occurrence will be listed. From the point of view of predictability, this situation generates a maximum of uncertainty for the forecaster: which system will grow the most ? Models often make different choices in these circumstances. This behaviour is also the characteristic feature of several "initiation" classes of the climatological study of cyclogenesis performed by one of us by an automatic classification procedure based on the tracking of all the cyclone events found in the ERA re-analysis. These classes show new lows forming in close proximity of older, larger ones. The environment is not a simple, 2D front or baroclinic zone, but a fully featured cyclone. It is possible, from this classification, to provide a sound statistical idea of the frequency and main characteristics of this behaviour. The possible mechanisms that can play a role in this problem will be reviewed finally.

MI05/E/01-A3 1420

LOCAL ENERGETICS APPLIED TO FASTEX-CYCLONES

Fred KUCHARSKI, Alan Thorpe (Department of Meteorology, University of Reading, Reading RG6 6BB, UK)

In this contribution the energetics viewpoint of cyclone development will be investigated. A local energy concept based on the extended exergy is applied to FASTEX-cyclones. The extended exergy has its roots in technical thermodynamics and characterizes the work availability of systems. When extended exergy is applied to the atmosphere it is a locally positive measure of deviations from a globally defined hydrostatic reference state and yields in combination with the kinetic energy a global conservation law for reversible-adiabatic processes. Because all scales of atmospheric motion are included in the deviations from the hydrostatic reference state, the extended exergy as well as the kinetic energy are decomposed into a mean part and a perturbation part. The perturbation part is interpreted here to mean the synoptic-scale disturbances while the mean part is defined as a zonal mean

extended exergy (e.g. over the longitudes covered by the cyclone) not resolving synoptic disturbances.
The importance of the different energy-production mechanisms in generating FASTEX-cyclones will be discussed. This provides a tool for classifying cyclones due to their generation mechanisms. The extent to which pre-existing diabatically-generated static-stability anomalies are important in determining the location and scale selection of some small-scale cyclones will be presented. This mechanism is additional to the classical one of baroclinic production and is proportional to vertical heat fluxes.

MI05/W/07-A3 1440

DIAGNOSTIC STUDY OF AN UPPER-LEVEL FRONTOGENESIS EVENT DURING FASTEX IOP16

DONNADILLE (Laboratoire d'Airogies, OMP, 14 Ave, Toulouse, 31400, France, Email: lamd@aero.obs.mip.fr); D. Lambert, J.-P. Cammas and P. Mascart.(Laboratoire d'Aerologie (UMR CNRS/UPS 5560), 14, Ave. E. Belin, F-31400 Toulouse. Email: donj@aero.obs-mip.fr)

During FASTEX IOP 18 (Fronts and Atlantic Storm-Track EXperiment) an upper level frontogenesis develops as a Coherent Tropopause Disturbance (CTD) brings closer to the cyclonic shear side of the polar jet. This work, based on Arpege/IFS operational analyses, available every six hours, uses a new partitioning of the Q-vector into along- and cross-isohypse components (Jusem and Atlas, 1998). Using a quasigeostrophic omega equation we associate a vertical velocity to diagnose processes that appear to contribute to upper level frontogenesis such as confluence, horizontal shear in presence of thermal advection and curvature. Forcings having a key role on the transverse and direct ageostrophic circulation give way to a very deep tropopause fold. A meso-scale limited area model including a stratospheric passive tracer, transported by turbulence scheme, convection scheme and standard mass conserving and positive transport scheme. The stratospheric passive tracer is used to discuss the deep tropopause folding.

MI05/W/37-A3 1500

REDUCED UPPER-TROPOSPHERIC POTENTIAL VORTICITY IN FASTEX INTENSIVE OBSERVING PERIOD ONE

H.R. POMROY (Dept of Meteorology, Uni of Reading, UK Email: h.r.birkett@reading.ac.uk); A. J. Thorpe

Diabatic processes are recognised as an important secondary mechanism in cyclone genesis and development. Within the potential vorticity (PV) framework this is commonly thought of as adding a large positive PV anomaly at mid-levels. Theories of PV modification by latent heat release also imply a negative PV anomaly (Northern Hemisphere) at upper-levels. This phenomena of Reduced Upper-tropospheriv PV (RUPV) will be looked at in a case study from the field programme FASTEX. The evolution of RUPV and its influence on the parent cyclone has been examined, and observational evidence from the experiment surveyed. The observations show that operational models do not have sufficient amplitude RUPV. The re-run forecasts with and without RUPV anomalies indicate that these anomalies can have significant dynamical effects on cyclone growth but that this depends on their location relative to downstream systems. Evidence from trajectory calculations shows that the evolution of RUPV is dependent on the structure of the air flow through the parent low.

MI05/E/08-A3 1600

ANALYSIS OF THE STRUCTURES WITHIN A DEVELOPING CYCLONE

N M.ROBERTS and M.A.G.Dixon (Joint Centre for Mesoscale Meteorology UK Met Office and Dept of Meteorology) University of Reading, Reading, RG6 6BB, UK.

A wealth of information about the structure and development cyclones in the North Atlantic can now be gained from observations made during FASTEX experiment. Here, we concentrate mostly on the FASTEX case IOP16 of a rapidly deepening frontal wave cyclone. A combination of subjective and objective analysis techniques along with a synthesis of the available observations is used to identify structures within this system on a variety of scales. We examine how the overall system development is related to features such as multiple cloud heads associated with multiple cross-frontal circulations, convective rainbands and the low-level jet and infer some processes that may be responsible. Such a multi-scale observational study is essential if we wish to assess the performance of numerical models in representing these weather systems.

MI05/W/27-A3 1620

DIAGNOSTIC AND IDEALIZED MODELLING STUDIES OF SLANTWISE CONVECTION

R.S.DIXON and K.A.Browning (both at Department of Meteorology, University of Reading, Earley Gate, PO BOX 243, Reading RG6 6BB United Kingdom, Email: rdixon@met.rdg.ac.uk); G.J.Shutts (Meteorological Office, Bracknell)

A method of calculating the Slantwise Convective Availiable Potential Energy (SCAPE) in the UK Meteorological Office's Limited Area Model (LAM) is used to find situations where regions of the atmosphere may be slantwise unstable. By using an idealized model with a resolution fine enough to resolve slantwise convection well and with initial conditions based upon case studies from the LAM exhibiting an apparent existence of SCAPE in the model's atmosphere, we have attempted to assess whether slantwise convection actually occurs in these situations.

MI05/W/25-A3 1640

SLANTWISE INSTABILITY IN THE CLOUD HEADS OF FASTEX CYCLONES

Suzanne GRAY and Alan Thorpe (both at Department of Meteorology, University of Reading, Earley Gate, Reading RG6 6BB, UK, Email: S.L.Gray@rdg.ac.uk)

The issue of slantwise convective or symmetric instability must be considered separately from that of upright convective instability in mesoscale models. Slantwise instability may be released through slantwise ascent in the absence of upright instability. This is believed to occur in the cloud heads associated with some midlatitude cyclones. These distinctive features are often linked the to the explosive deepening of cyclones into intense depressions with strong surface winds. The release of slantwise instability occurs over a greater horizontal extent than that of upright instability and, unlike upright convection, may potentially be explicitly resolved at mesoscale resolutions. The presence and release of slantwise instability in cloud heads associated with cyclones observed during FASTEX (the Fronts and Atlantic Storms Experiment, January and February 1997) has been investigated using data obtained from observations and simulations of the Unified Model at mesoscale resolutions. Values of SCAPE (Slantwise Convective Available Potential Energy) have been calculated for these three-dimensional systems. The interpretation of this quantity in terms of the release of instability will be discussed.

MI05/E/20-A3 1700

MODELLING STUDIES OF MESOSCALE STRUCTURE OF A DEVELOPING CYLONE

H.W.LEAN, P.A.Clark and N.M.Roberts (Joint Centre for Mesoscale Meterology UK Met Office,University of Reading, Reading, RG6 6BB, UK.)

The FASTEX experiment provides a unique observational dataset including several cases of rapidly developing systems. These data provide an excellent oportunity to compare mesoscale model representation of systems with the real atmosphere. We present results of running the UK Met Office Unified Model at 11km resolution for the FASTEX IOP16 case of a rapidly developing secondary cyclone with emphasis on the model representation of mesoscale structures in the system such as multiple cross front circulations. We will discuss how the model results shed light on the role of diabatic processes in generating this structure and the implications of the results for improving numerical weather prediction.

WARM AND COLD FRONTS OBSERVED DURING FASTEX

Roger M. WAKIMOTO and Brian Bosart (Department of Atmospheric Sciences, UCLA, Los Angeles, California, 90095-1565, USA, Email: roger@atmos.ucla.edu)

The finescale structure of warm and cold fronts collected using an airborne Doppler radar flown by the National Center for Atmospheric Research (NCAR) Electra during the Fronts and Atlantic Storm Track Experiment (FASTEX) is shown. Even though there have been numerous observational studies of fronts, few have documented the detailed three-dimensional structure of the cold front in general, and the warm front in particular. Most of the flight tracks for the cold front analyzed during FASTEX were flown in an elongated "box" pattern with the front centered within the box. The classical picture of a narrow cold frontal rainband associated with precipitation core and gap regions will be shown. The wind syntheses suggest that the strongest horizontal shears develop within the cores regions while weaker shear values are found within the gap regions. The updraft pattern provides a clearer picture of the vertical velocity/precipitation core than has been previously documented. The three updrafts are all located in the southeast corner of the core. Accordingly, these updrafts are located to the south of the locations of maximum reflectivity. This suggests that precipitation forms first in the southern section of the cores and is subsequently advected to the northeast before descending to the lowest levels. The flight pattern for the warm front was flown approximately perpendicular to the boundary. The unique aspect of this track was the distance flown by the Electra to the rear of the front (over 200 km) and the concurrent dropsondes deployed by the United Kingdom C-130. This flight pattern resulted in the construction of mean vertical cross sections that revealed the detailed kinematic and thermodynamic structure using the Doppler wind syntheses and the dropsonde data, respectively. In contrast to the cold front, the surface frontal boundary was not characterized by a ribbon of maximum vertical vorticity. Rather, an alternating pattern of anticyclonic and cyclonic vorticity maximum were noted. An assessment of the thermal wind balance of the wind field in the vicinity of the front will be shown.

SIMULATION OF FASTEX IOP11 CLOUD SYSTEM COMPARISONS WITH OBSERVATIONS

Jean-Pierre CHABOUREAU, Jean-Pierre Cammas, Isabelle Mallet*, Patrick Mascart, (Laboratoire d'Aerologie, Universite Paul Sabatier, 14 av. Belin, 31400 Toulouse, France) *CNRM/MesoNH, Meteo-France, 42 av. Coriolis, 31057 Toulouse cedex 1, France)

The interaction between the baroclinic forcing and the diabatic processes in the development of extra-tropical cyclones has been recently hightlighted during the ``FASTEX cyclone'' (Cammas et al 1999, Mallet et al. 1999). The role of such mechanims and their interaction are investigated in a rather typical cyclone, Low 30 observed during IOP 11.Simulations with and without cloud processes have been done using Meso-NH, a non-hydrostatic mesoscale model with a very advanced set of cloud and hydrometeor schemes. Low 30 is also one of the well-documented FASTEX cases for which the survey involved the three instrumented aircrafts of the campaign. The extremely rich description of the simulated cloud system has been compared with in-situ observations and satellite retrievals (cloud classification from TOVS, water parameters from SSM/I). In addition, the brightness temperatures observed by Meteosat (in the so-called infrared and water vapor channels) have been compared with those simulated from Meso-NH. All these comparisons will be presented to validate the structure and the quality of the cloud fields simulated by Meso-NH, therefore to assess the confidence on their role on the development of Low 30.

MULTISCALE BUDGETS OF MOMENTUM, HEAT AND MOISTURE WITHIN SECONDARY CYCLONE SAMPLED DURING FASTEX

Y. LEMAITRE,(CETP/UVSQ, Email: lemaitre@cetp.ipsl.fr); A. Protat and D. Bouniol, CETP/UVSQ.

Airborne Doppler radar and dropsonde data obtained in the multiscale sampling area of the FASTEX experiment are processed in order to get 3D circulations and cloud physics properties of cyclonic/frontal cloud sytems including sub-structures. This work aims at studying the role of frontogenetic forcings, slantwise and upright convection in the observed cloudy and precipitating structure. It aims also at estimating the relative energetic importance of the various scales of motion involved in these cyclogenetic situations. To do so, budget analyses of momentum, heat and moisture are derived from the retrieved multiscale 3D dynamic and thermodynamic fields. These budgets are analysed in the light of prognostic and diagnostic equations. During the oral presentation, results from two extreme cases (frontal wave and explosive cyclogenesis) observed during Intensive Observing Periods 16 and 12 will be presented.

SIMULATIONS OF FASTEX CLOUD SYSTEMS WITH THE ARPEGE MODEL

Philippe LOPEZ (CRNM/GMME/RECYF, METEO-FRANCE, Toulouse, France, Email:lopez@cnrm.meteo.fr)

As part of the FASTEX-CSS Project, a series of 24-hour simulations of various cloud systems observed during the FASTEX campaign (Jan-Feb 1997) in the North Atlantic, have been

carried out with the ARPEGE model, developed at METEO-FRANCE. These simulations have been validated using all kind of available observational data, including multi-channel measurements from satellites (METEOSAT, DMSP, NOAA), as well as airborne radar data collected during FASTEX. The sensitivity to both horizontal and vertical resolutions have been investigated, with a particular focus on their respective impact on the 3-D distribution of the diagnosed cloud fields. In parallel, a "simplified" large-scale condensation scheme with prognostic cloud condensate, designed for horizontal resolutions of typically 100 km, is being developed. This scheme should make it possible to assimilate cloud water in operational forecast models, and might also be profitable in global climate experiments.The tuning and validation of the cloud scheme will be performed utilizing a set of high resolution simulations from three different mesoscale models (HIRLAM, UKMO, and MesoNH).

RAINFALL FORECASTS DURING FASTEX USING HIRLAM

Klara FINKELE and Peter Lynch (both at Met Eireann, Glasnevin Hill, Dublin 9, Ireland, Email: Klara.Finkele@met.ie, Peter.Lynch@met.ie)

FASTEX (Fronts and Atlantic Storm Track Experiment) took place in January and February of 1997. The main purpose of the experiment was to observe in detail the evolution of weather systems crossing the Atlantic using airborne Doppler radar and dropsonde observations as well as an enhanced coverage of conventional and ship observations. Two storms have been selected for simulation with HIRLAM (HIgh Resolution Limited Area Model). HIRLAM is an operational forecast model for short range predictions. It is a hydrostatic model on a hybrid coordinate system with semi-Langrangian advection scheme and a massflux scheme for convection. The selected cases are the intensive observation periods IOP11 and IOP16, which will also be used, for a model intercomparison study. IOP11 shows a deepening cyclone while crossing the Atlantic. IOP16 shows a fast moving and rapidly deepening cyclone. The simulation results are compared with satellite observations, cross sections derived from dropsonde data and surface rainfall observations over Ireland. Results are compared using a high resolution of 0.1 deg and the operational forecast resolution of 0.3 deg. The sensitivity of different convection parameterisation schemes is explored at these resolutions to the evolution of the storm and rainfall forecasts.

MI05/L/03-A4 1140

EFFECTS OF LATENT HEATING ON A FASTEX CYCLONE

P. MASCART (1), I. Mallet (2), J.-P. Cammas (1), P. Bechtold (1), J.-P. Chaboureau (1), J. Donnadille (1), D. Lambert (1) 1: Laboratoire d'Aerologie, CNRS/UPS, Toulouse, France 2: Meteo-France, CNRM/GMME, Toulouse, France

A set of numerical simulations is used to study the first development phase of a FASTEX cyclone (IOP17), a particularly well sampled frontal cyclone system developing on the trailing front of a primary large--scale baroclinic wave. The model is the Meso-NH non-hydrostatic model jointly developed by Meteo-France and Laboratoire d'Aerologie. The selected part of the life cycle of the cyclogenesis involves intense latent heating associated with warm frontogenesis and cloud head formation. Diagnostics tools are applied to the model outputs to show how the upper levels dynamics are modified by diabatic effects and how a positive feedback develops between the outflow jet aloft and the lower frontal circulation. Use is made of the results of a sensibility study that performs a non-latent heating run to propose a conceptual model of this positive interaction. It is suggested that such a positive feedback explains the near constant deepening rate of the cyclone while the baroclinic forcing associated with the upper level precursor decreases in this part of the life-cycle.

SHORT-TERM WEATHER FORECAST OF BAROTROPIC ATMOSPHERE FOR THE CAUCASUS

KHVEDELIDZE, (Tibilisi State University, Email: scitico@access.sanet.ge)

The autos carried out the numerical realization of the task, the short-term weather forecast of the atmospheric pressure of the barotropic atmosphere according to complete equations of hydrodinamics with due regard for the relief of the underlying surface for Caucasus. Inclusion of the relief effect with the preservation of the precise boundary conditions is realized by the measurement [x,y, sigma=p/ps,t] of coordinate system. The initial data are registered according to AT-850 chart while for every subsequent temporal step values of geopotential on the earth's surface are defined by means of the equations concerning 850mb of the surface. The forecasts were calculated for 24 and 48 hours, in the rectangular network field with the size of 26x22 knots while dt=10 minutes and dL=3x100000m As the average meaning of the relative mistake of the forecast was ~ 0.61 and the coincidence of the sings was 0.55 so the given numerical model cloud be considered satisfactory.

THE IMPACT OF EXTRA-TROPICAL CONVECTION ON THE STORM TRACKS OF HADAM3

L. SHAFFREY (CGAM, Department of Meteorology, University of Reading, Reading, RG6 6BB, U.K., email: L.C.Shaffrey@reading.ac.uk); C. Jones (SMHI, Norrkoping, Sweden, email: Colin.Jones@smhi.se)

Storm tracks are regions where extra-tropical cyclones tend to grow and decay. Transient eddy variance measures can be used to determine the strength and location of the storm tracks. When transient eddy variances are used to compare the observed Northern Hemisphere storm tracks with those from a wintertime ensemble of integrations from the UKMO's atmospheric climate model, HadAM3, it becomes apparent that the lower to mid-tropospheric transient heat fluxes in the model are too weak. The weak transient eddy heat fluxes might be related to overactive extra-tropical convection in the wintertime storm tracks of HadAM3, as excessive lower tropospheric heating by convection in the cold air around the back of extra-tropical cyclones will equate to a reduction in the lower tropospheric transient eddy temperature variance.
A new non-local boundary layer scheme has been developed at the UKMO which should improve the representation of convective boundary layers in the model. Introducing the non-local boundary layer scheme into integrations of the HadAM3 reduces the amount of convection in the storm tracks. Associated with the reduction in convection is an increase in the lower to mid-tropospheric transient temperature variance of the model's storm tracks, even though there are no systematic increases in other measures of storm track strength.
The results of these process studies are compared with longer integrations of HadAM3 with and without the non-local boundary layer scheme, to determine the impact of the boundary layer and the convection schemes on the extra-tropical time-mean flow and the representation of the storm tracks in HadAM3.

MI05/W/36-A4 Poster 1400-03

THE INFLUENCE OF SHEAR FRONTOGENESIS ON THE DEVELOPMENT OF SECONDARY WAVE CYCLONES

H. R. POMROY (Dept of Meteorology, Uni of Reading, UK Email: h.r.birkett@reading.ac.uk) J.-P. Chaboureau, A. J. Thorpe

Previous work has shown that some of the secondary wave cyclones that occurred during the FASTEX field experiment developed whilst in a regime of strong vertical shear. This contradicts theoretical work using an Eady model that suggests in such situations the frontal waves have smaller growth rates than the front itself, and therefore cannot develop. This discrepancy motivates the use of a more complex model to simulate wave growth. Results of three-dimensional simulations of secondary wave development using a semi-geostrophic numerical model will be presented. The basic frontal state is two-dimensional and forced by an ambient along-front potential temperature gradient leading to shear frontogensis. The growth of a "warm band" frontal wave instability has been calculated and will be presented.

COLD AIR CYCLOGENESIS

Abigail C. L. DEVESON and Keith. A. Browning (Joint Centre For Mesoscale Meteorology, Department Of Meteorology, University of Reading, PO Box 243, Reading, RG6 6BB, UK, Email: a.c.l.deveson@reading.ac.uk); Tim D. Hewson (Joint Centre For Mesoscale Meteorology, UK Meteorological Office, Dept. Of Meteorology, University of Reading, PO Box 243, Reading, RG6 6BB, UK)

A method of categorising cyclones by the vertical motion associated with them has been developed as part of an attempt to establish an objective classification scheme for mid-latitude cyclones. Upper level troughs can be identified by a dipole of ascent and descent forced from upper levels (above 600mb) with ascent ahead of any tropopause depression and descent behind. A similar dipole can form, forced at lower levels (below 800mb), close to a low centre with a region of ascent located ahead of the low in the direction of its progression and descent behind. On using this vertical motion diagnostic to investigate FASTEX intensive observation periods (IOPs), two cases were found to be dominated by upper level forced vertical motion. Both IOPs involved cyclones forming at high latitudes, close to the ice edge and on the leading edge of a cold air outbreak. Further investigation revealed multiple cloud features associated with each cyclone. These took the form of shallow comma clouds which developed separately as the ascent maximum, associated with the upper level trough, was located overhead. Evidence showed a difference between the propagation speed of the cloud features and the upper level trough. It was noted that the cloud features grew and became organised only when the upper and lower level forced regions of ascent were in phase. The cloud features then become disorganised and convection within them was suppressed as the upper level trough overtook the cloud feature due to the trough's greater propagation speed. Both these cases of cyclogenesis showed large similarities to polar lows in their initial stages, prior to the development of frontal structures. Theories of polar low development have been applied to explain the development of the cloud features.

MI05/W/26-A4 Poster 1400-05

SEA-LEVEL RISE IN THE SOUTHERN COAST OF BRAZIL APRIL 3-5, 1997

Jaci Maria Bilhalva SARAIVA (Fundação Universidade do Rio Grande-FURG, Rio Grande-RS-Brazil, CEP 96.201-900, Email: dgejaci@super.furg.br); Cláudia Jacondino de Campos (Universidade Federal de Pelotas-UFPel, Pelotas-RS-Brazil, CEP 96.010-900, Email: cjcampos@ufpel.tche.br)

Due to the baroclinic waves position, the southern coast of South America is a source of cyclogenesis. The storms formed on the ocean in this region, when associated to an anticyclone on the continent, generate wind fetch of great extension on the ocean. These wind fetch generate strong waves in the coastal areas that in turn may cause a sea-level rise at the coast of Argentina, Uruguay, and south-southeastern of Brazil. Infrared GOES-8 satellite images and CPTEC (Centro de Pesquisas de Tempo e Clima - Brazil) 00 and 12 UTC Global Model fields were used as input to the Regional Atmospheric Modelling System (RAMS), to simulate the event observed between April 3-5, 1997, in the southern South America. That event consisted of a migratory polar anticyclone (1025 hPa) that reached the South American continent (45ºS,70ºW). It generate a strong horizontal pressure gradient, due to deep marine storm (52ºS,43ºW) having a centre of 985 hPa. The proximity of these two action centres generated SW winds of 20 m/s forming a wind fetch of approximately 2000 km. It caused a sea-level rise, along the Rio Grande do Sul state coast, presenting up to 3-m height waves.

THE SIMULATION STUDIES OF THE INTERACTION OF THE MEI-YU FRONT AND SOUTH-EAST MONSOON FLOW

Jing-Shan HONG (1) And Ben J-D Jou (2), (1)Central Weather Bureau,Taipei,Taiwan, (2) Atmospheric Science Department, National Taiwan University

During 5 intensive observing periods (IOPs) in MYEX98 (Mei-Yu heavy rainfall EXperiment in 1998), IOP4 (4 - 5 June 1998) and IOP5 (9 - 10 June 1998) were conducted due to the vital convective activities which lasted over one week in South China Sea. The heavy rainfall event was occurred as these convective systems are approaching to Taiwan. For example, the accumulated precipitation amount is up to 300 mm/day during IOP4. The convective activities are the interactions among southward movement of Mei-Yu front, the mid-level short wave trough, and the southwest flow associated the monsoon surge. The preliminary analysis also shows that Taiwan topography may pay important roles to modulate the interactions between the Mei-Yu front and the southwest flow when they are approaching Taiwan. Thus, for the purpose to improve the forecast of the heavy rainfall event around south Taiwan, it is necessary to further understand the structure and evolution of the Mei-Yu front near Taiwan, the mesoscale structure of the southwest flow and the role of the Taiwan topography on the evolution of the southwest flow. The proposal is a simulation study to investigate the issues mentioned above during MYEX98 IOP4 by using the Penn State/NCAR MM5 nonhydrostatic mesoscale model. The model initial condition will ingest the global upper air and surface observations (in FGGE format) from Central Weather Bureau and proceed with objective analysis which the firstguess is based on the ECMWF global analysis field with 0.5*0.5 degree resolution. The high-resolution simulation (<10 km) will performed around Taiwan in nested grid system bounded in large domain so that can well represent the topographic effect and avoid the potential improper boundary condition from Tibetic plateau.

COMPARING OBSERVED AND MODELLED AIR-SEA FLUXES DURING FASTEX

D. Lambert (1), J. Donnadille (1), J.-P. Cammas (1), G. Caniaux (2) and P. Mascart (1). (1) Laboratoire d'Aérologie (UMR CNRS/UPS 5560), 14, Ave. E. Berlin, F-31400 Toulouse, (2) Météo-France/CNRM/GMGEC, 42, Ave. G. Coriolis F-31057 Toulouse Cedex.

The aim of the FASTEX/CATCH (Fronts and Atlantic Storm-Track EXperiment / Couplage avec l'ATmosphère en Conditions Hivernales) experiment was to study the life cycle of cyclones evolving over the North Atlantic. In remote areas combining large fetch and strong winds, the interaction of the atmospheric boundary layer and its impact on cyclogenesis remain poorly documented. In this paper, FASTEX dropsonde data and CATCH surface flux measurements from some Intensive Observation Periods are used to validate the boundary layer characteristics modelled by the french Meso-NH (Météo-France/CNRS) mesoscale model. Results obtained with a standard scheme are compared with those of a more advanced package more suitable for high-wind conditions. The validated model results are finally combined with upper-air observations to discuss the impact of air-sea exchanges on cyclogenesis.

THE STRUCTURE OF FLOWS IN FASTEX CYCLONES: AN OBSERVATIONAL ANALYSIS

Mark A. G. DIXON, Keith A. Browning, Nigel M. Roberts (JCMM, Department of Meteorology, Reading University, Earley Gate, Berkshire, RG6 6BB, email: sws97mad@met.reading.ac.uk)

The FASTEX experiment provided an excellent opportunity to perform detailed analyses of the flow structure associated with extratropical cyclones. By combining data obtained using dropsondes and airborne Doppler radar, along with satellite imagery, coherent descriptions have been produced of the flows in rapidly evolving systems. Salient features include transverse slantwise circulations which lead to the formation of multiple cloud heads. Quantitive estimates of length-scales associated with the flows are presented, and possible mechanisms which lead to the analysed structure are considered.

MODELLING STUDY OF SECONDARY CYCLOGENESIS DURING THE IOP12 OF FASTEX EXPERIMENT

K. LAGOUVARDOS1, V. Kotroni1, Y. Lemaitre2 and G. Kallos1(1) Laboratory of Meteorology, University of Athens, Panepistimioupolis Bldg. PHYS-V, 15784, Athens, Greece, E-mail: lagouvar@skiron.mg.uoa.gr) (2)Centre d'Etude des Environnements Terrestre et Planetaires (CETP/IPSL/CNRS), Velizy, France

In the frame of this work, the secondary cyclogenesis developed during the Intensive Observational Period (IOP) 12, of the FASTEX experiment, in the area south of Iceland, is studied. This system is analysed, using the mesoscale non-hydrostatic model CSU/RAMS (Colorado State University/Regional Atmospheric Modelling System). The two-way interactive nesting capabilities of RAMS model permit to resolve the different scales of motion taking into account the interaction among them. Model results are validated through comparisons with airborne observations collected in the Mesoscale Sampling Area of this experiment.
Further, sensitivity tests are performed in order to assess the role of mechanisms such as surface fluxes and latent heat release, implicated in the development of this secondary cyclogenesis.

SINGLE DOPPLER RADAR OBSERVATIONS OF MESOSCALE CIRCULATIONS IN TOGA-COARE MESOSCALE CONVECTIVE SYSTEMS

Scott J. CARPENTER (Department of Atmospheric Science Colorado State University Fort Collins, CO 80523-1371); Dr. Colleen A. Leary (Atmospheric Science, Box 42101 Texas Tech University Lubbock, TX 79409-2101)

In order to obtain a better understanding of the vertical heating distribution of the mesoscale convective systems in the western Pacific warm pool region, the life cycle and morphology of these systems must first be better understood. This was one of the eight goals incorporated into the atmospheric component of the Tropical Ocean Global Atmosphere (TOGA) Coupled Ocean-Atmosphere Response Experiment (COARE) which was conducted from November 1992 to February 1993. This study focuses on obtaining a better understanding of the structure of the wind field within a mesoscale convective system using the single-Doppler radar data collected with the MIT Radar on board the R/V John Vickers.
The 24 December 1992 convective event consisted of several mesoscale convective systems advecting past the domain of the MIT Radar. This event occurred during a period just prior to a westerly wind burst phase of the intraseasonal oscillation (ISO). An analysis of the kinematics and convective and stratiform morphology of two of these systems, which occurred between 1000 UTC and 1800 UTC, will be described using results of a version of the Extended Velocity Azimuth Display (EVAD) method. The results will show that these particular mesoscale convective systems exhibited similar characteristics to the convective systems observed at middle latitudes in the central United States. The existence of front-to-rear system relative flow near the surface and aloft, rear-to-front system relative flow at middle levels near the radar bright band, and the general reflectivity structure of the convective, transition, and stratiform regions will be presented as examples of the kinematic and structural similarities. These similarities, if also observed in the multitude of other convective events during COARE, should help lead the modelling community to better parameterize warm pool convection and lead us to more successful simulations of the ocean-atmosphere interactions over time scales of months to years.

LOW TEMPERATURE OCCURRENCE IN THE SOUTHERN BRAZIL DURING THE SUMMER

Cláudia Jacondino DE CAMPOS (Universidade Federal de Pelotas-UFPel, Pelotas-RS-Brazil, CEP 96.010-900, Email: cjcampos@ufpel.tche.br); Jaci Maria Bilhalva Saraiva (Fundação Universidade do Rio Grande-FURG, Rio Grande-RS-Brazil, CEP 96.201-900, Email: dgejaci@super.furg.br)

Temperatures equal or lower than 15ºC, in January and February, have a harmful effect in the reproductive phase of the rice crop, causing decrease in the productivity. The knowledge of synoptic situations associated to low temperatures, might stablish actions that minimize the meteorological effects in this phase. In this work, surface synoptic charts, satellite images, surface data, and the Regional Atmospheric Modelling System (RAMS) were used to study the synoptic situation that caused temperatures lower than 15ºC in Pelotas-RS, from February 13th to 16th, 1991. It was observed that the low temperatures were associated to a polar anticyclone formed in the region during the period studied.

NUMERICAL STUDY OF HEAT AND MOISTURE EXCHANGE IN THE MORNING BOUNDARY LAYER

Gergana GEROVA and Rumjana Mitzeva (both at the Department of Meteorology, Faculty of Physics, University of Sofia, J.Boucher,5, Sofia -1164,Bulgaria, email: rumypm@phys.uni-sofia.bg)

A one dimensional numerical model of the evolution of the morning convective boundary layer (CBL) for strong insolation and light wind will be presented. The basic assumption is that heat and moisture in the CBL are transported mainly by discrete convective elements - thermals. Governing equations for the vertical profile of horizontal- mean virtual potential temperature and specific humidity are derived by partitioning the CBL at each level and at each moment in two domains, one covered with thermals and the other occupied by downdrafts. The problem is closed by assuming that the thermals evolve as individual ones interecting with the environmental air by buoyancy and entrainment mechanisms.
The impact of the magnitude of the radiation heating , moisture and size distribution of thermals at the earth surface on the CBL characteristics will be studied and discussed. The comparison between model simulations and observations will be presented.

SEASONALITY OF WIND AND GENERALIZED MONSOON SYSTEM

LI Jianping Zeng Qingcun (State Key Laboratory of Numerical modelling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG), Institute of Atmospheric Physical, Chinese Academy of Sciences, Being 100080, China)

The rationality that the seasonality of wind presented by Zeng is used to study monsoon is theoretically investigated. It is proved that the seasonality of wind is proportional to the angle of wind shift, and the critical value of significantly seasonal variation for wind is obtained. Here indicates that monsoon regions are located in the regions of significant seasonlity. Then generalized monsoon system is divided by the global wind for 1958-1997 from the NECP/NCAR reanalysis data, and the vertical structure of generalized monsoon system is discussed. These results further verify that the seasonality of wind is a objective and qualitative index for studying monsoon and generalized monsoon system presented by Zeng is a reasonable and useful concept.

WEATHER OSCILLATION WITH PERIOD 14 DAYS

IVANOVA E.V. (Chemistry Department, Moscow State University, Russia); Ivanov V.V. (Institute of Marine Geology & Geophysics, Yuzhno-Sakhalinsk, Russia)

The spetra of air pressure, air temperature and sea level contain the broad bands close to the frequency 1/28 days, 1/14days, 1/7days. If the spectrum are calculated by time interval more than 4 years the each of these broad bands split into the group of lines. The main line is corresponded to the frequency 1/kTm. k = 1/2, 1, 2, 3, 4. The gap between the lines is equal to 1/Ts. Tm = 27.3 days, Te= 365.25 days. The number of lines inside the band close to the 10.The Moon rotation around the Earth evokes the bands. The splitting the narrow line into the group of lines is caused by the annual variations of the conditions at the Earth. Separate line has heterodyne frequency Wkn = 1/kTm +- n /Ts (k= 1/2, 1, 2.., n=0,1, 2..). The magnitudes of the spectral maxima varies from one year to another. The variation of parameters on time has a period 18.6 years. This is the period of variation of the angle between the axis of the Earth rotation and the Moon rotation round the Earth. This angle varies from 18 to 28 degree. The variation is illustrated by data for period from 1950 to 1990.

WEAKLY-FORCED MOIST SLANTWISE CONVECTION: OBSERVATIONS AND SIMULATIONS

John NIELSEN-GAMMON and Scott Overpeck (Texas A&M University, College Station, TX 77843-3150; email: n-g@tamu.edu)

The theory of conditional symmetric instability (CSI) has remained largely untested because most atmospheric cases studied to date have been strongly forced, either by frontogenesis or by synoptic scale vertical motion. We use the PSU/NCAR Mesoscale Model, version 5 (MM5) to simulate a well-observed case of slantwise convection in a weakly forced environment. The slantwise convection event was initiated by widespread convection over the Gulf Stream and adjacent Atlantic Ocean which evolved into bands with multiple layers of sloping ascent and descent. Observations include Doppler radar and rawinsondes launched at 90-minute frequency.
Numerical simulations are being undertaken at very high horizontal and vertical resolution in order to realistically simulate the event. Nudging to quality-controlled rawinsonde data is applied on outer grids to ensure the accuracy of the synoptic-scale pattern. Numerical output will be analyzed to determine the energetics of the instability, the sensitivity to the microphysical parameterizations, and the nature of along-line variability. Comparisons will be made to strongly-forced vertical motion in the presence of conditional symmetric instability and to along-line variability within squall lines. Results will be reported at the meeting.

CONVECTIVE DESTABILISATION BY A TROPOPAUSE FOLD DIAGNOSED USING POTENTIAL VORTICITY INVERSION

Morwenna GRIFFITHS, Alan Thorpe and Keith Browning (Department of Meteorology, University of Reading, Reading, UK, email: m.griffiths@reading.ac.uk, a.j.thorpe@reading.ac.uk, k.a.browning@reading.ac,uk)

There is observational evidence to suggest that at the time tropopause folds in extra-tropical cyclones are descending into the mid troposphere there is frequently a destabilisation of the lower troposphere to moist convection. Here we consider the dynamical reasons for such a linkage using so-called potential vorticity (PV) attribution concepts. In particular a method is

described using PV inversion to find the wind shear attributable to the tropopause fold itself. Then this shear is used to quantify the tendency to generate regions of potential instability, {\em i.e.} where the wet-bulb potential temperature decreases with height. The method is applied to a case of a modest tropopause fold (PV=2PVU down to 600mb) and it is found that the potential vorticity anomaly contained in the tropopause fold can contribute susbtantially to the instantaneous convective destabilisation. Indeed, at some locations, it can overcome a tendency to stabilise by the atmosphere without the fold. A climatology of extra-tropical cyclones, associated tropopause folds and regions of potential instability over the north Atlantic region will be shown and discussed.

MI05/W/15-A5 0940

RESPONSE OF THE AFRICAN EASTERLY JET TO MESOSCALE CONVECTION

BURTON, R.R & Parker, D. J., (The Environmental Centre, University of Leeds, Leeds, UK.)

The wind structure over west Africa in the Northern hemisphere summer months can be characterized by the low level (~600mb) African easterly jet (AEJ) and the high level (~200mb) tropical easterly jet (TEJ). Instabilities in the AEJ are thought to lead to the formation of African easterly waves (AEWs) with wavelengths of the order of 3000km; such waves have been extensively studied. The present investigation aims to broaden the spectrum of known wave behaviour by examining the response of the jets to an idealised squall-line - type forcing. In addition to AEWs, smaller scale waves propagate on the AEJ and TEJ and act to modify the environment of the storm. A hierarchy of numerical models has been implemented, using both idealised atmospheric profiles and radiosonde data taken over West Africa, to give a complete representation of the problem. The sensitivity of the forced waves to the jet structure (position, strength, related wind shear), and the upstream influence of the waves on the squall-line environment, will be presented.

BUSTER AND BERG WIND ON THE KWAZULU-NATAL COAST

M. P. DE VILLIERS (South African Weather Bureau, Private bag X97, Pretoria, South Africa, 0001. email: mpdev@cirrus.sawb.gov.za)

A Buster is a sudden strong south-westerly wind which occurs with the passage of a coastal low (Tyson 1965). The low is essentially a lee low, which owes its existence to the marked coastal escarpment and the migration of an offshore flow anticlockwise around the coast ahead of an approaching cold front and tends to reach its apex under the north-westerly flow from the interior ahead of eastward propagating west wind troughs (Hunter 1987). When the wind turns through north-westerly and remains moderate or stronger for a few hours, prior to the Buster, hot Berg winds (the local name for the Fohn-type wind) are experienced. These occur mainly in the latter part of the winter and the early summer (Tyson 1965).
Such an event on the 12th October 1995, with temperatures over 40 C, is investigated. Aspects considered are:- propagation of the Buster from automatic weather stations along the coast; the UK Met. Office numerical model surface prognosis, which gave medium and short term warning of the development and progression of the low; low level divergence (calculated from the UK Met. office model grib data) in the 850-700 hPa layer where low level divergence was indicated, which is contrary to Dines compensation, but is consistent with the offshore flow at the level of the plateau; a potential temperature and wind vertical time section, which clearly indicated the displaceent of moist subtropical air, under an inversion, by a trowel of warm subsided air, followed by a bulge of invading cooler Buster air and finally cold front air; and lastly a clear S-shaped leader front ahead of the cold front (Taljaard 1991, McInnes 1993).

RED SEA TROUGH: ITS DEVELOPMENT AND ROLE IN THE MEDITERRANEAN WEATHER

Simon KRICHAK (Dept. of Geophysics and Planetary Science, Tel Aviv University 69978 Ramat Aviv, Israel, e-mail: shimon@cyclone.tau.ac.il); Pinhas Alpert (Dept. of Geophysics and Planetary Science, Tel Aviv University, 69978 Ramat Aviv, Israel, e-mail: pinhas@cyclone.tau.ac.il)

Red Sea Trough (RST) cyclones are quite a typical element of the cool season weather conditions in the Eastern Mediterranean. Their development is characterized by meridional northward penetration of a subtropical trough along the Red Sea area. These cyclones are found during all periods of the cool season. During the winter months the axe of the upper tropospheric subtropical jet (STJ) is oriented to the central Europe. During the intermediate months of the cool season the axe of the average STJ ridge is oriented to the western part of north-Africa. During these periods the STJ wind maxima are frequently concentrated over the mountaineous area of Red Sea. Analysis of the factors responsible for this process is performed. A low latitude, low resolution version of the MM4 PSU/NCAR model was used in a part of the simulations. Real data numerical simulations of the process of the RST cyclone development during the Alpex 3-5 March 1982 period with different parameters included are performed. Results of the experiments are analysed by means of the factor separation approach. Contributions of four acting factors, - topography, surface latent and sensible heat fluxes and latent heat release due to cumulus convection and those of the synergistic interactions of the factors are analysed.
A separate set of the simulations of the RST is performed with the FSU Global Model. According to the model simulations the convective processes over the equatorial Africa play a major role in the developments. Also, the intensification of the upper tropospheric westerly winds due to the convection over the equatorial Africa stimulates the northward extension of the Red Sea trough which consequently diminishes the moisture influx for the tropical convection and therefore seems to serve as a negative feedback.

CLASSIFICATION OF THE POLAR MESOSCALE VORTEX DISTURBANCES OVER NORTH - EUROPEAN SEA BASIN

Victor LAGUN, E.I. Lutsenko (both at Arctic and Antarctic Research Institute, 38 Bering str., St.Petersburg, 199397, Russia; e-mail: lagun@aari.nw.ru)

Results of diagnosis of the wide range of different types of the mesoscale cyclonic cloud eddies in the polar atmosphere are presented. On the ground of the visual and infrared NOAA and METEOR sattelite images for period of 1981-1995 the morphometric and genesys classifications of mesoscale disturbances, including polar low events, are made. According to shape and size morphometric parametrs the mesoscale eddies are classified as coma, spiral and stripe ones. Due to genesys of eddies the secondary subsynoptic eddies, developing inside the extratropical cyclones, summer mesoscale eddies, polar lows and mesoscale vortex inside the anticyclonic areas are selected. For each type of eddies the frequency is calculated and the prevalied formation regions are determined. The analysis of ynoptic conditions of mesosale eddies development is presented based on the data from meteorological, aerological, hydrological and ice cover measurements. For the qantitative estimations of mesoscale vortex parameters (boundary layer and free atmosphere energetics, sea -air energy exchange etc.) the multiyear NCAR/NCEP data set was used. The classification presented is compared with other modern known mesoscale and polar low studies results. The examples of analysis of the mesoscale eddies development under the extraordinal weather conditions over the Barentz and Kara Seas are discussed.

FORTE OBSERVATIONS OF GLOBAL THUNDERSTORM CHARACTERISTICS

Paul ARGO, David Smith, Abram Jacobson, and Steven Knox,(Los Alamos National Laboratory, Los Alamos, New Mexico, USA)

The FORTE satellite carries radio-frequency-receivers for the study of lightning. Although we observe emissions characteristic of the usual cloud to ground and intra-cloud lightning strokes, we also often observe very short (a few microseconds) wide band emissions that appear to come from very localized (hundreds of meters) regions within the thunderstorm. In fact, these impulsive emissions seem to predominate in the tropical regions.
Among the many interesting phenomena observed in the FORTE database is one we have termed "recurrent-emission storms." In fact, a majority of the RF events detected by the FORTE satellite are part of these recurrent-emission storms. We believe that the data is best described as emissions coming from a single storm which is radiating to FORTE recurrently during the overhead passage of the satellite (a single ground point is visible for approximately 15 minutes for a directly overhead passage). By using propagation effects on the pulse dispersion and the pulse separations measured for the trans-ionospheric pulse pairs (TIPPs) we can estimate the location of the recurrent emission centers.
As opposed to previous studies of satellite optical observations of lightning (and the optical systems carried on FORTE), we find that many of the cloud systems connected to these recurrent-emission storms appear (at somewhat reduced levels) over oceanic areas. This may be due to the specific discharge processes that could lead to such isolated impulsive events. Measured seasonal variations of the storm locations indicate a strong correlation with the Intertropical Convergence Zone boundaries. Using models of the TIPP separation dependence on source height, we have been able to map the height function of the observed discharges both geographically and seasonally, and will discuss these.

MI05/W/06-A5 1150

SENSITIVITY OF TRAJECTORY FORECASTING IN STRONG LOCAL WINDS TO WIND DATA FREQUENCY

Lazar LAZIC and Ivana Tosic (both at Department of Meteorology,University of Belgrade, P.O.Box 368, 11001 Belgrade, Serbia, Email: lazar@indy1.meteo.yu)

The Eta Model, with vertical coordinate which permits a step-like representation of mountains and quasi-horizontal coordinate surfaces (so-called eta coordinate), has shown to have excellent capabilities for simulation of mountain-induced phenomena. Trajectories are defined as the paths followed by air parcel with time. They are calculated from forecasted wind fields, with both horizontal and vertical wind components, derived from the Eta Model. Trajectories can be calculated forward and backward in time. Forward trajectories are calculated by specifying initial parcel locations and time and then tracing the parcels with increasing time to determine their final positions. Backward trajectories are calculated by specifying final parcel locations and time and than tracing the parcels with decreasing time to ascertain their origins. The realistic 48 h Eta Model based trajectories forecasted forward of the strong local bora and koshava winds in the winter season based on ECMWF (European Centre for Medium-Range Weather Forecasts) operational analyses i.e. real-time data for initial conditions and forecasts for boundary conditions, are presented. The model was run with 0.25° x 0.25° horizontal resolution (28 km x 28 km) and 16 layers in vertical. The maximum wind speed is predicted through tree-dimensional channels in the step eta mountain representations. In this paper sensitivity of forward trajectory forecasting to wind data frequency (every time step - 90 s - control case, 15 min, 30 min, 1 h, 3 h, 6 h and 12 h) are studied. Trajectories with wind data frequency of 15 min, 30 min and 1 h are accurate enough. Mean absolute error and mean relative error of parcel positions along trajectories show large values in case of 3 h, 6 h and 12 h wind data frequency. Trajectories calculated from the observed wind data (12 h data frequency) are not accurate.

MI05/W/11-A5 1210

ON THE SIMULATION OF THE SURFACE METEOROLOGICAL DIURNAL CYCLES BY ARTIFICIAL NEURAL NETWORKS TECHNIQUE

Oleg POKROVSKY (Main Geophysical Observatory,Karbyshev str.7, St.Petersburg, 194021, Russia phone:+7(812)247-64-43, fax:+7(812)247-86-61 e-mail: pokrov@main.mgo.rssi.ru)

The joint statistical distribution of principal meteorological variables (temperature and humidity of air , atmospheric precipitation, pressure, short-wave radiation, cloudiness) are investigated. Ten year length time series of one hour temporal resolution for several meteorological sites of Russian North -West Region are used. The data set of simultaneous observations (for all variables and stations) allows to reveal main features of joint diurnal distributions by means of known "min-max" fuzzy set approach. Known and novel interrelationships between various meteorological variables are reviewed. The revealed relationships between solar downward radiative fluxes and air temperature and humidity diurnal patterns allow to simulate all principal elements of surface energy exchange : longwave outgoing radiative fluxes in the atmosphere, soil heat fluxes, available, turbulent and latent heat fluxes.This approach could be considered as an alternative one to improve the simulation of surface meteorological, radiation and heat balance component diurnal cycles in most climate and weather models. Introduced stationary and transition modes for main meteorological variable diurnal patterns represent the background for simulation of all known weather phenomena. This modes are used also as a neural network's nodes for hidden layers. Implementation of neural networks (back propagation algorithm) allowed us to perform several modelling experiments. Observed and simulated diurnal pattern departures are explored. Intercomparison results, derived by proposed technique and conventional linear regression method , shows substantial modelling accuracy improvement due to nonlinear mapping advantage of artifical neural network . Problem of optimum network configuration (number of nodes in hidden layers) is discussed. Here number of nodes is equal to number of clusters. Another implementing direction is the diurnal cycle meteorological variable reconstruction. Our investigation show the ability of one hour diurnal pattern reconstruction with sufficient accuracy, based on 3-5 instantaneous meteorological observations. Adapted nonlinear mapping of one group variables (and its diurnal distributions) on another one allow to investigate the possibility of this approach application for diagnostical aims.

ABL STRUCTURE AND EVOLUTION OF LOW PRESSURE SYSTEM DURING INDIAN SUMMER MONSOON

C. A. BABU and Leena P, (Department of Atmospheric Sciences Cochin University of Science and Technology, Cochin - 682 016, INDIA)

The features of atmospheric boundary layer (ABL) in the coastal environment are examined during the presence of a monsoon depression in order to understand the influence of ABL structure on the formation of low pressure system during the Indian summer monsoon. The presence of such meso scale low pressure system enhances the activity of synoptic scale monsoon. The variations in fluxes of sensible heat, latent heat, water vapour and momentum that take place in the ABL and the thermodynamic structure of the atmosphere during the period from the formative stage to the dissipation stage over the vicinity of track of the system are studied. It is well known that the cyclones and depressions are regions of immense convection. CAPE and CINE are employed to evaluate the intensity of convective activity in association with the depression. The study is carried out using daily radiosonde and rawin data pertaining to the depression.
The day to day variation of ABL structure, characteristic features of fluxes and thermodynamic parameters during the evolution of the monsoon depression are discussed in detail. In addition, the variation in circulation above ABL due to the change in ABL structure during the presence of the depression is also discussed.

THE IMPACT OF SURFACE BOUNDARY FORCING ON SIMULATION OF THE 1988 SUMMER DROUGHT OVER THE U.S. MIDWEST USING FACTOR SEPARATION TECHNIQUE

Uri STEIN and Michael Fox-Rabinovitz (Department of Meteorology, University of Maryland, College Park, MD, 20742-2425, USA)

The factor separation (FS) technique (Stein and Alpert 1993) has been utilized to evaluate quantitatively the impact of surface boundary forcings on simulation of the 1988 summer drought over the Midwestern part of the U.S. The four surface boundary forcings used are: (1) SST, (2) soil moisture, (3) snow cover, and (4) sea ice. The Goddard Earth Observing System (GEOS) GCM is used to simulate the 1988 U.S. drought. A series of sixteen simulations are performed with climatological and real 1988 surface boundary conditions.
The major single and mutual synergistic factors/impacts are analysed. The results show that SST and soil moisture are the major single pro-drought factors. The couple synergistic effect of SST and soil moisture is the major anti-drought factor. The triple synergistic impact of SST, soil moisture, and snow cover is the strongest pro-drought impact and is, therefore, the main contributor to the generation of the drought. The impact of the snow cover and sea ice anomalies for June 1988 on the drought is significant only when combined with the SST and soil moisture anomalies.

MI07/L/01-A2 1120

ON THE IMPACT OF BIOGENIC EMISSIONS ON OZONE FORMATION IN THE MEDITERRANEAN AREA – A BEMA MODELLING STUDY

P. THUNIS, C.Cuvelier, P.Grossi (all at Joint Research Centre, Environmental Institute, TP 051,1-21020 Ispra, Varese, Italy.)

The aim of this modelling study and to quantify the influence of biogenic volatile organic compound (BVOC) emissions on the formation of trosposheric ozone in the Burriana area (North of Valcencia) on the east coast of Spain. The mesoscale modelling system used consists of the meteorology/transport module TVM and the two chemical reaction mechanisms LCC and RACM. The results of the model simulations are validated and compared with the data collected during the BEMA (Biogenic Emissions in the Mediterranean Area) field and air measurement campaign that took place in June1997. The impact of the biogenic emissions is investigated on peak ozone values by performing simulations with and without biogenic emissions, while keeping anthropogenic emissions constant. The impact on ozone formation is also studied in combination with some antropogenic emmissions abatement strategies, i.e when antropogenic VOC emissions and/or Nox emissions are reduced. A factor separation technique is applied to isolate impact due to biogenic emissions from the overall impact due to biogenic and anthropogenic emissions together. The results indicate that the maximum impact of biogenic emissions on the formation of ozone represents at most 10 ppb O3 while maximum ozone vealues are of the order of 100ppb. At different locations the maximum impact is reached at different times of the day depending on the arrival time of the sea breeze. It is also shown that this impact does not coincide in time with the maximum simulated ozone concentrations that are reached over the day. The Burriana area is characterised by large citrus plantations and amongst the various BVOC's emitted, the carbonyl species turned out to be the most efficient in producing ozone.

MI07/W/05-A2 1140

SYNERGIES BETWEEN SURFACE HYDROLOGY AND ENERGY BALANCE FOR A VARYING CO2 ENVIRONMENT

Devdutta S. NIYOGI, Kiran Alapaty, Sethu Raman, Yongkang Xue (North Carolina State University, Raleigh, NC 27695-7236, USA); (University of Maryland, College Park, MD, USA, email: dev-niyogi@ncsu.edu. Telephone No: +001-919-513-2101 Fax No: +001-919-513-1441)

Soil Vegetation Atmosphere Transfer (SVAT) processes have a significant role in simulating planetary boundary layer interactions, mesoscale circulations, and regional climate. Two dominant components of the SVAT are CO2 and soil moisture. Measurements suggest increasing CO2 would increase vegetation resistance inhibiting transpiration, while soil moisture availability initiates easier transpiration. Understanding the effects CO2 and soil moisture exerts on surface energy will be hence both informative and critical.
Traditional techniques yield only lumped contribution providing a net effect. To explicitly quantify and extract the individual contribution due to each of the two variables: CO2 and soil wetness, and their interactions, a designed experiment approach is adopted.
Variables considered in the design are: soil wetness, CO2, soil texture, and LAI Analysis of the synergies is performed using two different approaches: Fractional Factorial and Alpert's Factor Separation technique.

MI07/W/02-A2 1210

INFLUENCE OF INITIAL AND LATERAL BOUNDARY CONDITIONS ON THE SIMULATION OF A HEAVY PRECIPITATION EVENT IN THE WESTERN MEDITERRANEAN

V. HOMAR, C. Ramis, R. Romero and S. Alonso (all at Meteorology Group, Departament de Física, Universitat de les Illes Balears, 07071 Palma de Mallorca. Spain, email: dfscrn0@ps.uib.es); P. Alpert (Department of Geophysics and Planetary Sciences, Tel-Aviv University, Tel-Aviv, Israel 69978, email: pinhas@cyclone.tau.ac.il)

A sensitivity study of the simulations of a heavy precipitation event in the Western Mediterranean to the initial and lateral boundary conditions, using the Hirlam mesoscale model, is presented. The study assesses the relative roles of these non-dynamical factors and their interaction as function of the simulation running period prior to the end of the event. That is, the simulations start at different times but end at the same time. For each running period a factor separation technique was applied, so four simulations were performed: a control experiment, a highly smoothed initial conditions experiment, a non-updated lateral boundary conditions experiment and a fourth one with highly smoothed initial fields and non-updated lateral boundary conditions. The analysis focuses on the effects of the considered factors on Potential Vorticity features and rainfall field.

MI07L/04-A2 1230

AN AGEOSTROPHIC GEOPOTENTIAL AND A SPLITTING DIAGNOSTIC METHOD

Qiu-shi CHEN, (Byrd Polar Research Center, The Ohio State University, 1090, Carmack Road, Columbus, OH 43210, USA, Email: qchen@polarmet1.mps.ohio-state.edu, Fax: 614-292-4697)

Numerical models provide a power tool for studying atmospheric motions caused by various individual factors. One of the most convenient ways is by performing sensitivity studies, which are conducted through the comparison of different simulations "with" and "without" a factor, respectively. However, these sensitivity studies only reveal long-term, integrated effects aand stop short of providing interpretations of how the evolution of the phenomenon is controlled by the step-by step interactions and feedbacks. The method of combining diagnostic and sensitivity studies together is a way for removing this shortcoming and for understanding the evolution of a phenomenon simulated in complex models.
The traditional definition of the geostrophic wind cannot be used in the region near the equator because the Coriolis parameter is present in the denominator. Using the wind partitioning into the streamfunction and velocity potential, the geopotential field can be separated into a geostrophic part and an ageostrophic part. The horizontal pressure gradient force of the geostophic geopotential is equal to the Coriolis force of the rotational wind. The ageostrophic part is the difference between the geopotential and its geostrophic part. The ageostophic characteristics of the atmospheric motion can be shown much more clearly and explicitly by the ageostrophic geopotential annd velocity potential.
The vorticity and divergence equations of the streamfunction and velocity potential in a limited region (Chen et al. 1997, Mon. Wea. Rev., 143-167). These inner part equations are used instead of the primitive equations and they are solved by a semi-implicit time splitting scheme with zero lateral boundary value. In these equations, the advection and heating terms are expressed by forcing terms. The solutions of the equations for each of splitting step times can be separated into two parts. One is the solution of the homogenous equations with the initial values, and it describes the geostophic adjustment process from the initial values. The other is the solution of the inhomogeneous equations with the zero initial value, and in this solution, the ageostrophic geopotential and velocity potential are generated from the zero value by the advection-heating process.

MI07/E/03-A2 1400

SEA-LEVEL, VEGETATION AND THEIR SYNERGISM IN THE RESPONSE OF THE LLN CLIMATE MODEL TO ORBITAL FORCING OVER THE LAST GLACIAL-INTERGLACIAL CYCLE

BERGER Andre, Dutrieux A., Loutre M.F. (Universite catholique de Louvain, Institut d'Astronomie et de Geophysique G. Lemaitre, 2 Chemin du Cyclotron, B-1348 Louvain-la-Neuve, Belgium, email: berger@astr.ucl.ac.be)

Sensitivity experiments have been made over the last glacial-interglacial climatic cycle using the Louvain-la-Neuve 2-dimension Northern and Southern hemispheres climate model. The continental ice volume was simulated for the last 122 kyr in response to changes of both the insolation and CO2 atmospheric concentration. The sensitivity of such a response to sea level changes and to the taïga-tundra - snow albedo feedback indicates that the 100-kyr cycle cannot be sustained if these processes are not taken into account. The factor separation technique was finally used to quantify the pure contribution of and the synergism between the sea-level-ice volume feedback and the high latitude forest-snow albedo feedback.

MI07/W/03-A2 1420

ROLES OF ATLAS RANGE AND IBERIAN TOPOGRAPHY ON A HEAVY PRECIPITATION CASE IN THE WESTERN MEDITERRANEAN

C. RAMIS, V. Homar, R. Romero and S. Alonso (all at Meteorology Group, Departament de Física, Universitat de les Illes Balears, 07071 Palma de Mallorca. Spain, email: dfscrn0@ps.uib.es)

A convective case producing heavy precipitation in the Western Mediterranean region, characterised by pronounced upper levels forcing and main rainfall over the sea, is studied by means of a factor separation technique. On the day of the event (28 September 1994), more than 140 mm were recorded in coastal lands of eastern Spain, and 180 mm were estimated over the sea. Synoptically, the case combines warm and moist easterly advection at low levels, typically observed in torrential rainfall events of the region, with a less common strong upper

levels dynamical forcing. The influence of the topography on the rainfall field has been investigated through mesoscale numerical simulations with the Hirlam model. A complete simulation indicates that in addition to the lower levels forcing, a two-jets interaction is decisive for the triggering and driving of the convection during the event. A non-topographic simulation reveals that, although a significant part of the precipitation can be attributed to the dynamical forcing, nearly a half is forced by topography. With two additional simulations, the first including only the African topography and the second only the European one, the Atlas and Iberian peninsula individual effects, as well as their synergism, can be isolated. It is shown that the Atlas range induces an across-ridge pressure dipole, redistributing the precipitation over the Western Mediterranean. Iberian topography is responsible for notable local rainfall enhancements over the eastern coastal lands of Spain. The synergism between both topographic systems exhibits only weak effects.

MI07/W/04-A2 1440

BIOSPHERIC INTERACTIONS IN TROPICAL AND MID-LATITUDINAL REGIMES

Devdutta S. NIYOGI, Yongkang Xue*, Sethu Raman (North Carolina State University, Raleigh, NC, USA); *(University of Maryland, College Park, MD, USA)

Land Surface Processes are known to have a pivotal role in the manner in which climate forcing and climatic change can take place globally. In this study, we adopted the simplified version of the Simple Biospheric Model (SSiB) to study this feature in more details. What makes this study unique is that an attempt is made to delinate the synergistic interactions underway in the biospheric components, which provides an insight in the possible causality for the perceived climate change. Using SSiB, our aim is to compare the biospheric response in two different climate regimes: tropics and mid-latitude. The tropical and the mid-latitudinal scenarios are important as they represent a diverse landscape for regional climate simulations, in terms of both the hydrological and boundary layer feedback as well as the synoptic forcing. Using observations from two special field experiments: FIFE (for mid-latitude) and HAPEX-Sahel (for tropics), the SSiB model is integrated. For each of the two cases (FIFE and HAPEX-Sahel), 32 sets of simulations were performed with six varying factors (two-level variation). These factors were initial conditions of: surface albedo, soil wetness, stomomatal (surface) resistance, vegetation cover, vapour pressure deficit, and ground temperature. The output analysed was the SSiB predicted evaporation, sensible heat flux, effective ground temperature, and the components of these output as resolved for bare ground, canopy and interception. Using these two-level interactions, direct synergiesm was extracted using a graphical analysis. This was further extended by performing 48 sets of simulations for the two cases, with three levels of variances in the input data. Through this analysis, explicit non-linear interactions were resolved for the biospheric variables. Results provide large details regarding the control mechanism for each of the surface charactersitic. Overall it was concluded mid-latitudinal climate has larger interactive feedback while the tropical landscape was dominated by more stringent, non-interactive

MI07/E/02-A2 1510

ROLE OF TROPICAL AREA MOIST DYNAMICS IN NOVEMBER 1-5, 1994 WEATHER

Simon KRICHAK (Dept. of Geophysics and Planetary Science, Tel Aviv University 69978 Ramat Aviv, Israel, email: shiman@cyclone.tau.ac.il); Pinhas,Alpert (Dept. of Geophysics and Planetary Science, Tel Aviv University, 69978 Ramat Aviv, Israel, email: pinhas@cyclone.tau.ac.il)

Investigation of the role of moist dynamics in the atmospheric processes during the abnormally intensive stormy period of November 1-5, 1994 over the Mediterranean region is presented. Analysis focuses on the eastern Mediterranean area employing 96-hour model predictions over the Mediterranean region with the Florida State University (FSU) global spectral model. Sensitivity simulations differ only by prescribing the initial moisture fields in the selected regions located in the Arabian Sea, Red Sea, and over large areas in the low latitudes. The role of the moist effects in these regions in the Mediterranean large-scale atmospheric developments is considered as "factors" for the factor separation analysis. Synergistic interaction between the factors is analysed. Both the tropospheric trajectories and the model tests suggest that the heavy rains over the eastern Mediterranean were associated with unusually intensive propagation of air masses from the Arabian Sea region, which took place before and during the first 24 hours of the period. Air masses from the Arabian Sea participated also in the intensive developments in Italy and southern France on November 5, 1994.

MI07/L/03-A2 1600

RADIATIVE DE-STABILISATION OF A STABLE SMOKE AEROSOL LAYER BY CLOUDS

Joachim H. JOSEPH(1), Ilan Koren(1), Lorraine Remer(2) 1)Dept. of Geophysics And Planetary Sciences, TAU, Tel- Aviv 69978, Israel 2)Code 913, NASA Goddard SFC, Greenbelt, MD 20771, USA

The aged heavy smoke aerosol, covering extensive areas in Brazil during the biomass-burning season, may generate scattered clouds at its top. Factor analysis of the radiative fluxes divergence shows that the heating of the smoke layer is then largely due to synergism between the cloud and the aerosol. The clouds radiatively increase the local instability enough to lead to a positive feedback above and in the layer, increasing the depth of the latter as well as making the whole troposphere become thermo-dynamically unstable. The physical mechanism responsible will be described.

MI07/L/02-A2 1620

EFFECT OF SEA-BREZE ON AIR POLLUTION IN THE GREATER ATHENS AREA: ANALYSIS OF DIFFERENT EMMISION SCENARIOS

P.GROSSI (1), P.Thunis (1), A.Martilli (2), A.Clappier (2). (1) (Joint Research Centre, Environment Institute, TP051, 1-21020 Ispra (Varese), Italy, (2) (Swiss Federal Institute of Technology, CH-1015 Lausanne, Switzerland

The MEDCAPHOT-TRACE campaign, that took place in the Greater Athens Area from 20 August to 20 September 1994, has confirmed the role of sea-breeze circulation in photo-smog episodes already suggested by a number of experiments and numerical studies.
This work focuses on the study of the 14 September photo-smog event, associated with sea-breezes is investigated by isolated the effect of nighttime and daytime emissions on ozone levels. The same principle is then used to isolate the impact on ozone levels arising from the two main sources of emissions in the GAA: the industrial area around Elefsis and the Athens urban area. Finally the building up ozone from one day to another is investigated.
From this study, it comes out that ozone production in the Athens area is mainly a daily phenomenon. Indeed, the elevated values of photochemical pollutant (up to 130ppb at ground level) reached during summer time late afternoons on mountain slopes to the N and NE of the city are mainly related to the current day emissions. Nevertheless, the re-circulation of old pollutants can have an important impact on ozone levels in Athens downtown, but significantly in the Southern part of the Peninsula and over the sea, especially near Aigina Island.

MI07/E/04-A2 1640

A NUMERICAL INVESTIGATION OF SYNERGISTIC CONTRIBUTIONS TO LEE CYCLOGENESIS

Marina TSIDULKO and Pinhas Alpert (Department of Geophysics and Planetary Sciences), Raymond and Beverly Sackler (Faculty of Earth Sciences, Tel Aviv University, Israel, e-mail: marina@cyclone.tau.ac.il and pinhas@cyclone.tau.ac.il)

A number of simulations were carried out in order to investigate the roles of topography, lateral boundaries and upper-level dynamics during lee cyclogenesis. The PSU/NCAR mesoscale model (MM5) was employed (Grell et al, 1994). The well-studied ALPEX case of 3-6 March 1982 was chosen for experiments. In earlier numerical studies it was most surprisingly found that the lee cyclone was in the same location and almost with the same deepening in the simulations even without topography. It led to the conclusion that this case that earlier seemed to be the most 'classical' case of lee cyclogenesis is actually not caused by topography, and the topography only modifies its development. Two "no-topography" simulations with the same resolution (60-km) but with the different number of gridpoints in horizontal direction (31x46 and 58x73) were performed. It was found that topography/no topography simulations, usually applied by researchers for the mountain role estimation, should be carried out very carefully because of the significance of lateral boundaries and their hidden synergistic effect with the topography, which was shown to be of a considerable effect.
The factor separation method (Stein and Alpert, 1993) was applied to the dynamics of the process. Two factors were chosen for investigation - the upper-level PV advection (PV) and the mountains. The pure and synergistic contributions of the upper-level PV and topography were calculated. Their interactive effect was found to be strong and comparable to the pure PV advection contribution. Only the synergistic contribution produce the dipole structure oriented in agreement with theory and phase but becomes strongly cyclolitic at the second phase of lee cyclogenesis development. Superposition of the pressure change patterns, produced by the two factors along with their interaction, has resulted in a strong deepening in the right location. Hence, the joint cyclogenetic action is proposed as an explanation

MI07/E/01-A2 1700

THE FACTOR SEPARATION METHOD, ADVENTAGES AND PROBLEMS

Pinhas ALPERT (Dept. of Geophysics and Planetary Science, Tel Aviv University 69978 Ramat Aviv, Israel, e-mail: pinhas@cyclone.tau.ac.il)

The factor separation method has been adopted by estimated 15-25 groups since it was introduced for atmospheric modelling in 1993 by Stein and Alpert (JAS, 1993). I will try to summarise the various applications with focus on new insights and findings directly related to the method.
Also, some questions/problems will be addressed. One example is the influence of the particular choice by the modeller of a particular set of factors on the final results. It was shown, for instance, by Alpert et al. (JAS, 1995) that if an important factor is for any reason being omitted, its contribution must show up with another factor that was chosen and the one which is the most synergic with the factor that was omitted. Another problem to be discussed is the effect of the basic or control run choice on the results; I will show such an example from paleoclimate simulations by A. Berger. Can we choose any control case we wish? Or, are we allowed to choose unconventional factors like initial conditions and lateral boundary conditions; how can this be performed?

POLAR CLOUDS AND THE BUDGETS OF HEAT AND MOISTURE AT HIGH LATITUDES - A REVIEW OF RECENT OBSERVATIONAL STUDIES

Thomas P. CHARLOCK (NASA Langley Research Center, Mail Stop 420, Hampton, Virginia 23681, USA, email: t.p.charlock@larc.nasa.gov) and Takashi Yamanouchi (National Institute of Polar Research, B1-9-10 Kaga, Itabashi-ku, Tokyo 173, Japan, E-mail: yamanou@nipr.ac.jp)

This presentation gives a broad review of observational studies of clouds which have been reported by colleagues in the polar meteorology community. Recent advances have been enabled by the provision of large scale data sets, especially ISCCP D, TOVS Pathfinder, and Reanalyses; and through intensive measurements of ARM NSA, FIRE III, Syowa, and the remarkable SHEBA ice drift.
Analyses by NCEP/NCAR provide more accurate estimates for the atmospheric heat flux (largely by transient waves in the lower troposphere and by stationary waves at all levels) to

high latitudes. The new ISCCP D climatology (now spanning 9.7 years) reports more clouds and smaller optical depths than the earlier C version, but much of its seasonal variation has vanished. In the Arctic, ISCCP D clouds have a positive forcing to the surface. A surprisingly good match of the surface LW cloud forcing at SHEBA by ECMWF during the Arctic winter suggests that we may be approaching a satisfactory closure for the LW budget in the polar night. Polar clouds significantly contribute to the cooling of the atmosphere in NH and SH. Observations at Syowa and Amundsen-Scott in the Antarctic, and at FIRE III and SHEBA in the Arctic, do not find the "anomalous" SW absorption by clouds which has been reported by some researchers in lower latitudes. The active remote sensing at SHEBA (i.e., phase discrimination of water/ice by cloud lidar depolarization) is providing clues to puzzles such as the impact of pollution on IFN, the dessication of the Arctic atmosphere, and cloud/sea-ice feedback.

MI08/L/03-A3 Invited 1010

ATMOSPHERIC PARTICLE CHARACTERISTICS AND RADIATIVE PROPERTIES OF CLOUDS: APPLICATION TO POLAR CLOUDS

GAYET J P (Laboratoire de Meteorologie Physique, UPRESA/CNRS 6016 Universite Blaise Pascal, 24 avenue des Landais, 63 177 Aubi Cedex, France, e-mail : gayet@opgc.univ-bpclermont.fr

The communication highlights the role of the characteristics (size distribution, shape,) of condensed atmospheric particles on the radiative properties of cold clouds. Based on recent in situ observations of both ice particle size & shape and corresponding scattering phase function, experimental results show major differences with theoretical scattering phase functions used in cloud models which assume ice spheres or simple geometric shape of ice particles. Subsequent differences on derived optical and radiative parameters can result from radiative transfert models. Interpretation of the results suggests that neither the presence of interstitial particles nor the presence of black carbone condensation/ice nuclei inside the condensed particles significantly affect the scattering phase function. On the contrary, the shape and/or the surface roughness of the ice crystals can explain the reported differences. Furthermore, examples of observations realized in mixed stratiform clouds show thin layers of supercooled water droplets which occur preferentially near the cloud top whereas the scattering properties are dominated by ice particles in the lower cloud parts. These results highlight new potential insights, particularly for polar clouds which remain poorly documented, on both modelling of climate processes and methodologies of cloud remote sensing from satellite measurements.

MI08/E/13-A3 1100

CLOUDS OVER SEA ICE AND OPEN WATER IN THE SOUTHERN OCEAN: SOLAR TRANSMITTANCE AND CLOUD OPTICAL THICKNESS OBTAINED FROM SHIPBOARD RADIOMETERS

Melanie FITZPATRICK (Geophysics Program, University of Washington, Seattle, WA, 98195-1650, USA, email: fitz@atmos.washington.edu) Stephen G. Warren (Department of Atmospheric Sciences, University of Washington, Seattle, WA 98195-1640, USA, email: sgw@atmos.washington.edu)

Atmospheric transmittance and surface shortwave cloud radiative forcing are determined for a springtime voyage of RSV Aurora Australis between Tasmania and East Antarctica, 47-69°S. Broadband solar irradiance was measured by two pyranometers on opposite sides of the ship. Visible irradiance is inferred from measurements by a quantum sensor. Surface albedo is obtained from hourly visual observations of fractional areas of ice types taken throughout the two-month voyage from September to November 1996, together with measured albedos of each type.
We define raw cloud transmittance (trc) as the ratio of the downward irradiance under cloud to that under clear sky at the same solar zenith angle. Clear sky is much more common over the sea ice. In the sea-ice zone trc under cloud is greater principally because of multiple reflections over the higher surface albedo. Transmittance through even the thinnest clouds was usually 20% less than that of clear sky, probably due to the threshold nature of the aerosol-to-cloud-droplet transition. The shortwave cloud radiative forcing at the surface is smaller over sea ice due to both the higher surface albedo and the less-frequent occurrence of clouds.
Cloud optical depth is calculated from a simple parameterization relating clear-sky and cloudy-sky downward fluxes to surface albedo, solar zenith angle, and cloud droplet number density derived by Wiscombe in 1973 for Arctic stratus clouds. Clouds over sea-ice and open water exhibit a similar range of optical depths. The values found are smaller to those found by Leontyeva and Stamnes over Barrow in the Arctic (0-100) and larger than those found by Mahesh, Walden and Warren over the South Pole (0-6).
Sensitivity of the parametrisation to cloud droplet number density is determined. Comparison with spectral measurements made at the same time on the same voyage enables evaluation of the model. In future work the analyses will be repeated for other voyages in different seasons and prior years for which the same instrumentation is available, to obtain representative seasonal values of cloud optical thickness and
transmittance in the Southern Ocean and Antarctic sea-ice zone.

MI08/E/07-A3 1115

IN-SITU MEASUREMENTS OF CLOUDS IN THE COASTAL AREA OF ANTARCTICA

Tom LACHLAN-COPE and Russ Ladkin (British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET. email: t.lachlan-cope@bas.ac.uk)

The British Antarctic Survey has developed a kite-borne cloud particle replicator and this has been used during the 1998/99 field season to take in-situ measurements of cloud particle size, phase and shape at a site at 75(S and 76(W in the coastal region of Antarctica. As well as the cloud measurements broadband radiometers were used to measure the surface radiation balance.
This paper reports the first results from this project and compares the results with measurements taken in previous field campaigns and with similar mid-latitude measurements. The difference between Antarctic clouds and mid-latitude clouds is emphasised as well as the difficulty in taking in-situ cloud measurements in Antarctica.

MI08/W/19-A3 1130

IS THE DETAILED PATTERN OF SNOW ACCUMULATION OVER ANTARCTICA PREDICTED BY GLOBAL MODELS?

Tom LACHLAN-COPE, Russell Ladkin and Steven Leonard (British Antarctic Survey, High Cross, Madingley Road, Cambridge CB3 0ET. email: t.lachlan-cope@bas.ac.uk)

During the 1998/99 summer a series of 10m firn cores were taken in a traverse inland from the coast in the Bryan Coast area of Antarctica. The annual accumulation was determined from these cores using the Electrical Conductivity Method (ECM) in the field using a new portable ECM instrument developed for this project. The results give a detailed picture of how the accumulation varies with height during 1997and 1998. The results are compared with the annual precipitation, over the same period, given by the UK Met Office operational forecast model, the ECMWF operational model and a Lagrangian version of the UK Met. Office single column model.
A detailed comparison of the accumulation will show any gross errors in the parameterisation of clouds and precipitation processes in numerical models. Some thought is given to possible differences between the precipitation predicted and the accumulation measured, in particular the effect of blowing snow will be considered.

MI08/W/12-A3 1145

SUMMERTIME ARCTIC STRATUS CLOUDS: MICROPHYSICS AND MORPHOLOGY AS OBTAINED FROM IN-SITU MEASUREMENTS DURING REFLEX III

ANDREAS REUTER (GKSS Research Centre, Institute for Atmospheric Physics, Max-Planck-Str., D-21502 Geesthacht, Germany, email: andreas.reuter@gkss.de)

During the field experiment REFLEX III (Radiation and Eddy FLux EXperiment), 17 flights through Arctic Stratus Clouds (ASC) over the pack ice in Fram Strait had been performed between June and August 1995. This field project is a cooperation between the Alfred-Wegener-Institute for Polar and Marine Research, AWI (Bremerhaven, Germany) and GKSS. Four PMS probes had been operated to cover the entire particle size range between 0.1 and 800 µm. The obtained large dataset was utilised to derive more characteristic features of ASC regarding layering, morphology, microphysical properties and liquid vs. mixed-phase nature.
One of the most striking results of REFLEX III is that classical single-layered ASC was only encountered in 30% of the cases while 35% of the cloud decks had been double-layered and the remaining 35% multi-layered ASC. For the single-layered ASC, average microphysical properties are in good agreement with literature. However, coherent cellular structures had been observed in some of these cases, illustrating inhomogeneity.
Double-layered ASC was present on days when boundary layer temperatures had been relatively high. In these cases, the 0°C-isotherm was located at an average of 800 m (in comparison to 50 m for single-layer ASC).
Multi-layered ASC was always associated with frontal systems. These clouds showed a complex morphology and up to four separate cloud layers. Two third of them also contained ice particles. In all mixed-phase clouds, ice-enhancement could be observed with local ice particle concentrations up to 86 per litre for cloud top temperatures around -10°C.
Precipitation development, either drizzle or snow, occurred in 15 of the 17 cloud systems.

A NUMERICAL MODEL OF THE CLOUD-TOPPED PLANETARY BOUNDARY-LAYER: INTERACTION BETWEEN AEROSOLS, CLOUDS AND RADIATION

ANDREAS BOTT, Institut fuer Physik der Atmopshaere, Johannes Gutenberg Universitaet Mainz, D-55099 Mainz, Germany

In a numerical sensitivity study with the microphysical stratus model MISTRA the interaction between aerosols, clouds and the atmospheric radiation field is investigated. Model runs with different aerosol size distributions are presented. The numerical results show that the microphysical structure of the clouds is strongly affected by the physico-chemical properties of the aerosol particles. In situations with low aerosol number concentrations the clouds consist of few but large droplets. In contrast to this, model studies with high aerosol number concentrations yield many but relatively small cloud droplets.
The different droplet spectra have a direct influence on the radiative forcing of the clouds. In situations with many small droplets the reflectivity of the clouds is distinctly higher than in cases with few but large cloud droplets. The effective cloud droplet radii are larger in the model runs with few large cloud droplets than in the other cases. In all simulations the effective radii show a strong diurnal variation.

MI08/W/15-A3 Invited 1430

SIMULATIONS OF MIXED-PHASE CLOUDS IN THE ARCTIC BOUNDARY LAYER

J.Y. Harrington and P.Q. Olsson., A. SCHWEIGER, (University of Washington/Applied Physics Laboratory, 1013 NE 40th Street, Seattle, Wa. 98105 USA, e-mail: axel@apl.washington.edu
Telephone No: 206-543-1312 Fax No: 206-543-3521)

Simulating clouds in the arctic regions poses challenges unlike those experienced in other geographic regions. Over the arctic pack ice, strong surface inversions and significant wind shears produce a complex turbulent environment. Cold temperatures ensure an active ice phase even during the summer months, which has a significant impact on cloud evolution and the boundary layer thermal and moisture structure. Frequent leads produce strong heat and moisture fluxes which can penetrate well into the overlying atmosphere. Additionally, air flowing off of the pack ice and over the marginal ice zone experiences extremely large heat fluxes which can produce a heavily cloud covered region composed largely of mixed-phase clouds.
Simulations of mixed-phase clouds that exist within the arctic boundary layer will be presented for two diverse situations. The first situation is that of mixed-phase stratus clouds positioned over the arctic ice pack during fall. The second situation is that of mixed-phase clouds produced during off-ice flow over the marginal ice zone. In each case, mixed-phase clouds have a strong impact on the evolution of the turbulent, thermal, and moisture budgets of the arctic boundary layer.

MI08/E/12-A3 1500

INTERACTION BEWEEN ARCTIC SEA ICE AND LOW-LEVEL CLOUDS IN A ONE-DIMENSIONAL MODEL

Shouping WANG, Universities Space Research Association,USA

Arctic sea-ice processes influence global climate by modifying the surface albedo and regulating the thermohaline circulation of the global ocean. Arctic sea ice covers a large area and has an average albedo on the order of 0.7, compared with only 0.06 for the ocean surfaces. Thus, variability of sea ice coverage could considerably affect solar energy input into the Arctic Ocean in the summer season in the absence of clouds. In the mean time, coverage of the Arctic low-level clouds, with an albedo about 0.6, increases significantly from Spring to Summer. These clouds have a significant impact on the surface processes.
Recently, a year long SHEBA-FIRE field experiment was conducted aiming at understanding

the interaction among ocean, sea-ice, clouds and radiation. This study uses a one-dimensional PBL-sea ice coupled model combined with the SHEBA-FIRE data to study the interaction in a relative idealized scenario: given large-scale atmospheric and ocean dynamic forcing, how the clouds and sea ice interact each other in the spring-summer transition season.
The coupled model includes a atmospheric boundary layer model and a ocean-sea-ice model. The PBL is represented by a third-order turbulence closure model with a parameterization of clouds (liquid and ice phase), rain, snow and radiation. The sea-ice model is that of Elbert and Curry (1992) including sea ice, snow, leads, ponds and detailed parameterization of surface albedo. The two models are fully coupled through radiation and surface turbulent fluxes.
We first applied the PBL-only model forced by ECMWF large-scale advective tendencies to May, 1999 to simulate the evolution of PBL during SHEBA period. Compared with the field experiment data, the general feature of the PBL is represented. We then applied the model to the transition of May to June. In the one-month coupled simulation, cloud water path (including liquid and ice) increases with increasing ice and snow temperatures, and decreasing ice and snow thickness. The simulated cloud water path is significantly larger than those in ECMWF analysis. High level clouds have significant impact on the low-level clouds and sea ice, since existence of the clouds will reduce the cloud-top cooling in the boundary layer and thus reduce low-level clouds and turbulent fluxes. The leads seem to have weak influence on the coupled system since the ice-air temperature difference is not large enough. The research is going on, we will report more in the meeting.

MI08/W/05-A3 1515

AN ENHANCEMENTS OF A TWO-STREAM APPROXIMATION

Dietmar FREESE (Alfred Wegener Institute, 27515 Bremerhaven, Germany, email: dfreese@awi-bremerhaven.de)

To study the interaction between radiation, cloud microphysics and dynamic processes, the experiment REFLEX III (Radiation and Eddy Flux Experiment) was conducted in summer 1995 in the European Arctic. Airborne mounted Eppley pyrgeometer and pyranometer as well as FSSP-100 probes are used to measure the short- and longwave irradiance and the particle size spectra of liquid water drops. The measurements consist of 400 vertical profiles as well as over 200 horizontal flight sections in arctic boundary layer clouds. With statistical methods we find a dependence not only between the radiation profiles and the liquid water path but also between radiation and the droplet size. Comparisons between two-stream models and measurement results of irradiance profiles in clouds show, that the best two-stream concept for shortwave radiation consist of the modified delta-Eddington approximation of Meador and Weaver [1980]. The back scattering function is parameterized with an analytic approximation of the Henyey-Greenstein backscatter function. The optimized value for the diffusivity-factor is a function of the liquid water path.

MI08/E/11-A3 1530

TURBULENT STRUCTURE OF SPRING ARCTIC BOUNDARY LAYER CLOUDS OBSERVED IN SHEBA-FIRE EXPERIMENT: A LARGE EDDY SIMULATION AND OBSERVATIONAL STUDY

Shouping WANG, Universities Space Research Association, USA, Qing Wang, Naval Postgraduate School, USA

This study focuses on the turbulent structure of the arctic cloud-topped boundary layer observed in SHEBA-FIRE experiment. The Flight 5 of C-130 presents a well-defined mixed-layer and predominately super-cooled liquid water clouds. With large-scale conditions obtained from the observations and ECMWF analysis, a LES model is used to simulate the turbulent structure. Turbulent fluxes are also obtained from high rate aircraft measurement. The simulated and observation-derived turbulence variables are compared well. Some sensitivity tests are performed to evaluate some external effects. The following results are interesting:1. The presence of 2% leads has little impact on the overall cloud structure, although it indeed increases surface turbulent fluxes. This occurs because the surface temperature is not low enough (-7C) and sea ice-air temperature difference is not sufficiently large. 2. The turbulence is predominately driven by sensible heat flux (> 20 W/m^2) since moisture flux is very small (several w/m^2). Thus the latent heat contribution to the buoyancy flux is small, and thus cloud-top entrainment is primarily driven by radiative cooling, while evaporative cooling effect is significantly less. This is in contrast to the situation of subtropical marine boundary layer clouds where both radiative and evaporative cooling are very important in defining the entrainment.3. Solar absorption by clouds reduces liquid water, although it does not decouple the cloud from the subcloud layer as in the subtropical marine boundary layer. 4. Existence of high clouds significantly increases downward longwave radiative flux so as to decrease the radiative cooling at the cloud top. Thus the turbulence intensity is significantly reduced.

REMOTE SENSING

A STUDY OF CLOUD MICROPHYSICAL PROPERTIES WITH USE OF VISIBLE, IR AND MICROWAVE IMAGERS

Teruyuki NAKAJIMA, Kazuaki Kawamoto, Shuichiro Katagiri, and Shunsuke Kuroda Center for Climate System Research, The University of Tokyo 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904 TEL: +81-3-5453-3959; FAX: +81-3-5453-3964 e-mail: teruyuki@ccsr.u-tokyo.ac.jp

Possibility of retrieving cloud microphysical parameters, such as optical thickness and effective particle radius, will be discussed in this study. It is a big concern for cloud physics and cloud-aerosol interaction studies to depict the global distributions of these parameters. Our recent study found that combined use of wide spectral range radiances from visible to microwave wavelengths is useful for such retrievals. Especially, detection of effective particle radius for different cloud types, such as water and ice clouds, looks possible to be performed with multi-channel analyses. Global features of the water and ice cloud microphysics distributions, thus obtained, will be shown and discussed for understanding the cloud formation mechanism and strength of cloud-aerosol interaction.

MI08/W/14-A3 Invited 1635

SATELLITE CLOUD DETECTION AND CLASSIFICATION IN THE POLAR REGIONS

DAN LUBIN, (Scripps Institution of Oceanography, University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093-0221 USA, e-mail: dlublin@ucsd.edu. Telephone No: 619-534-6369 Fax No: 619-534-7452)

There are several well-known difficulties with polar cloud detection and classification using satellite imagery. These include (a) small shortwave radiance contrasts between high albedo surfaces and cloud tops, (b) small or negligible brightness temperature differences between low cloud tops and snow/ice surfaces, (c) large bi-directional reflectance effects at low sun elevations, and (d) smaller radiances in general over colder and darker scenes that are in the lower part of a given sensor's dynamic range. Several methods have been proposed in recent years to manage these difficulties, and our ability to use satellite data for polar cloud detection and classification is improving. These methods include multispectral threshold techniques, Bayesian classifiers that use a balance between spectral and textural (grey level difference) features, the training of neural networks to recognize texture, and supplementing high resolution visible/mid-IR imagery with passive microwave data to classify the surface type underneath the cloud. This presentation will give an overview of these methods as applied primarily to AVHRR and similar polar-orbiting sensors. With the recent completion of the Surface Heat Budget of the Arctic (SHEBA) field program, new data sets exist that can provide objective validation and refinement of satellite cloud detection techniques.

MI08/L/05-A3 1705

RADIATIVE FORCING OF WINTERTIME POLAR CLOUDS: SENSITIVITY TO CLOUD PROPERTIES

J. M. INTRIERI, C. W. Fairall, and R. E. Moritz NOAA/Environmental Technology Laboratory 325 Broadway, R/E/ET2, Boulder, CO 80303 USA Tel: (303) 497-6594; Fax: (303) 497-5318 Email: jintrieri@etl.noaa.gov

The ETL's depolarization lidar, deployed in the Arctic for the year-long(1997-98) SHEBA experiment, provided unique measurements of the annual cycle of polar cloud occurrence and phase. These data, when combined with radiosonde and radiometer observations, provide more detailed information on cloud radiative forcing than previously possible. Results of radiative forcing with respect to the cloud temperature, cloud height, and cloud phase will be presented and discussed in terms of their relative importance and their respective impacts on the underlying surface.

MI08/W/11-A3 1720

ARCTIC CLOUDS FROM MULTIYEAR SATELLITE AND IN SITU CLIMATOLOGIES

Axel J. Schweiger, J. Key, J. Francis and R. Lindsey. University of Washington/APL, Seattle, WA 98105, USA

Previous comparisons of satellite climatologies of Arctic cloud properties and surface radiative fluxes showed large descrepancies between surface and satellite observations. In this paper we revisit this issue in light of new or reprocessed data sets. Recent progress in satellite retrievals is described, and a comparison of cloud parameters derived from the TOVS Polar Pathfinder Project, the AVHRR Polar Pathfinder Project, and the ISCCP D1 cloud product is presented. Satellite-derived cloud parameters and radiatives fluxes are compared to surface observations from the Russian North Pole drifting stations and field experiments. The results show that significant problems remain in the reprocessed ISCCP-D1 data set with respect retrieved cloud and surface parameters. Comparisons of surface observations with cloud information from the TOVS Path-P data set and the AVHRR Polar Pathfinder data set show promise. The TOVS Path-P data set properly captures the synoptic and annual variability of cloudiness in the central Arctic and appears suitable for a range of applications.

MI08/E/10-A3 1735

RETRIEVAL OF LOW AMOUNTS OF PRECIPITABLE WATER VAPOR USING MILLIMETER-WAVE RADIOMETRIC MEASUREMENTS

Paul RACETTE and Ed Kim NASA/GSFC, Mail Code 975 Microwave Sensors Branch Greenbelt, Maryland 20770 Phone: 301-614-5653 Fax: 301-614-5558 email: per@meneg.gsfc.nasa.gov Al Gasiewski, NOAA Environmental Technology Laboratory 325 Broadway MS R/E/ET1 Boulder, CO 80303 303-497-7275 Ed Westwater, and Yong Han CIRES 325 Broadway MS R/E/ET1 Boulder, CO 80303 303-497-6527 David Jones Numerical Weather Prediction Division Meteorological Office, London Rd, Bracknell, RG12 2SZ, UK Tel: +44 1344 854072, Fax: +44 1344 854412, email: dcjones@meto.gov.uk

The Atmospheric Radiation Measurement Program (ARM) operates a Microwave Radiometers (MWR) which measures downwelling radiation at 23.8 and 31.4 GHz. Measurements from this instrument are used to derive precipitable water vapor (PWV) and cloud liquid water. Retrievals of PWV using microwave radiometric measurements near the 22.231 GHz water vapor absorption line, like those made by the MWR, have been shown to be very accurate over a wide range of PWV values. However, when the amount of PWV falls below 10mm the accuracy of the derived estimates rapidly degrade; such conditions exist during the coldest driest days of the arctic winter. The degradation is attributed to the relatively weak response of the 22.235 GHz spectral line and limitations of the brightness temperature measurement accuracy. Numerical analysis based upon a set of model atmospheres has shown that improved retrieval accuracy under extremely dry conditions can be achieved by combining measurements near the 22.231 GHz line with those made near the much stronger 183.31 GHz water vapor line. An experiment is planned for 21 days during March 1999 at the North Slope of Alaska Cloud and Radiation Test (NSA/CART) site to investigate the utility and limitations of millimeter-wave radiometry during extremely dry conditions. Existing instrumentation at the NSA/CART site will be complemented by 24 additional radiometric measurement channels ranging from 20.6 GHz up to 340 GHz. These measurements will provide unique data under extremely dry conditions, as well as on millimeter wavelength spectra from liquid and ice clouds. A summary of the numerical analysis, an overview of the experiment, and preliminary results from the measurements will be presented.

MI08/L/04-A3 1750

ICE CLOUD SINGLE SCATTERING ASYMMETRY FACTOR FROM GLOBAL AVERAGED TRMM/VIRS BIDIRECTIONAL REFLECTANCE PATTERNS

YONG-X. Hu Mail Stop 420, NASA LARC, Hampton, VA 23187, USA

The average single scattering asymmetry factor of non-spherical ice particles is significantly smaller than that of liquid water cloud droplets. The asymmetry factors differ for particles with different shapes, size parameters and aspect ratios. A simple method is developed here to compute the asymmetry factor from globally averaged bi-directional reflectance distribution functions (BRDFs) from TRMM/VIRS data. The cloud phase is determined from the combined visible, near-IR and IR window channels. Weighted mean radiance fields, with a strong weighting toward thin clouds, are investigated to uncover the cloud single scattering properties. Theoretical BRDFs are computed from different ice cloud phase functions with DISORT and are compared with the averaged VIRS BRDFs. The results show that the BRDF is very sensitive to the phase function, especially the asymmetry factor. The method is also applied to infer water cloud single scattering asymmetry factor and turns out to be reasonable. The ice cloud asymmetry factors derived in this study from the narrowband visible radiances, are applied to compute broadband radiances that are very close to the TRMM/CERES observations

SURFACE PROPERTIES AND CLIMATOLOGY OF POLAR REGIONS

MI08/E/09-A4 Invited 0830

SURFACE RADIATIVE PROPERTIES OF POLAR REGIONS

STEPHEN G. WARREN (Department of Atmospheric Sciences, University of Washington, Seattle, WA 98195-1640, USA, email: sgw@atmos.washington.edu)

The spectral albedo of snow is sensitive to grain size and zenith angle in the near-infrared but not in the visible and UV. Radiative transfer modelling has proven successful in explaining the most accurate observations. The visible light penetrates deeply into the snow but eventually re-emerges upward from the surface. Essentially all of the absorbed radiation is in the near-IR, and this radiation is absorbed in the top few millimeters. The visible albedo is sensitive to small amounts of absorptive impurities. There is often sufficient soot in Arctic and midlatitude snow, but not in Antarctic snow, to reduce the spectrally-averaged albedo by 1-2%.
The albedo of growing snow-free sea ice depends on ice thickness and bubble content; for melting sea ice it depends on melt-pond coverage. Just a few millimeters of snow can dramatically raise the albedo of sea ice, especially in the near-infrared. The broadband solar albedo in the sea-ice zone varies from 0.07 for open water to 0.85 for snow-covered thick ice. The thermal infrared emissivity of snow and sea ice is very high, about 99%, but lower at large emission angles.
Snow is the most isotropic reflector of all natural surfaces on Earth, but still exhibits substantial anisotropy, which can be altered by natural forms of surface roughness. The BRDF is least variable in the near-nadir direction, and on central Greenland and the Antarctic Plateau the snow surface can be used as a calibration target for satellites. For near-nadir viewing, clouds also have little effect on reflected radiances over snow at visible and UV wavelengths, but they do cause an increase in near-infrared reflectance.

MI08/W/06-A4 Invited 0900

POLAR CLOUDS: NOW YOU SEE THEM, NOW YOU DON'T

FRANCIS,Jennifer (Institute of Marine and Coastal Sciences, Rutgers, 71 Dudley Road, New Brunswick NJ 08901-8521 USA. E-mail: francis@imcs.rutgers.edu Telephone No: 732 708 1217 Fax No: 732 872 3088)

Over many regions of the Earth, detecting and measuring clouds with satellite sensors is a challenge, but no where is it more difficult than in polar regions. Contributing to this problem are persistent surface-based temperature inversions, cold temperatures that approach sensor limits, months of continuous darkness, weak cloud-surface contrast, frequent non-black clouds, and diaphanous clear-air precipitation (diamond dust). In this presentation I will discuss existing and new techniques for detecting clouds and measuring some of their bulk properties under these difficult conditions.

MI08/E/04-A4 0930

PRELIMINARY RESULTS OF OBSERVATION OF LONGWAVE RADIATION AT DOME FUJI STATION, ANTARCTICA

Naohiko HIRASAWA and Takashi Yamanouchi(both at National Institute of Polar Research, 1-9-10 Kaga, Itabashi-ku, Tokyo 173-8515, Japan, email: hira@nipr.ac.jp)

The observation of upward and downward longwave radiation was performed almost throughout a year in 1997 at Dome Fuji Station (77.3S and 39.7E), Antarctica. The station is located on the ridgeline of the continental ice sheet. This program was supported by the 38th Japanese Antarctic Research Expedition (JARE-38). Our presentation will focus on the relationship between downward longwave radiation (Ld) and cloud amount based on surface observation in wintertime.
"Diamond dust" fell almost every day at Dome Fuji Station in wintertime. However cloud amount was generally small. For example, monthly mean cloud amount was 1.3 (21 days; This is the number of days of cloud amount<1.5 in daily mean) in May and 3.0 (17 days) in July, respectively. Generally, clouds were not so thick as moon and stars lights do not directly penetrate. While the marked increases in the thick cloud amount were rare, those cases usually occurred under the influence of strong disturbances associated with blocking in the middle and high latitudes.
In our preliminary results, Lu (upward longwave radiation) is larger than Ld by about 15W/m2 at the case of clear sky. On the othe hand, Ld is larger than Lu at the thick cloud cases and Ld is comparable with Lu at the cases of cloud amount from 2 to 10-. "10-" means overcast with thin. Interestingly, Ld is comparable with Lu at some cases of no cloud. This situation might be induced by spreading of extremely thin cloud or by warm air intrusion.

MI08/E/02-A4 0945

CLOUD LONGWAVE RADIATIVE FORCING IN ANTARCTICA

J.C. KING and S.R. Leonard (both at British Antarctic Survey, Cambridge CB3 0ET, UK, email: j.c.king@bas.ac.uk)

We study the influence of clouds on downwelling longwave radiation at the snow surface (Ld) over Antarctica during the winter (June-August) season using in-situ radiation measurements, cloud observations and data from the UK Meteorological Office global NWP model. At the South Pole, observations show that the mean Ld is about 81 W/m^2 under clear skies, rising to 130W/m^2 under fully overcast conditions. However, overcast conditions occur relatively infrequently here and the net cloud longwave radiative forcing is only about 10 W/m^2. The NWP model gives a mean Ld of only 70 W/m^2 under clear skies and exhibits much weaker cloud radiative forcing than that observed. At Neumayer (a coastal station), observations indicate somewhat stronger cloud radiative forcing, and the NWP model and observations are in fair agreement. The parametrisations used for cloud physical and optical properties in the NWP model thus appear to work reasonably well in the relatively warm conditions that prevail around the coasts of Antarctica, but exhibit serious deficiencies when applied to the colder, drier environment of the Antarctic Plateau. Errors in the calculation of Ld contribute to a 2.5 degC cold bias in 3-day forecasts of South Pole surface temperature.

RADIATION CLIMATOLOGY OF THE GREENLAND ICE SHEET: SEASONAL AND INTERANNULA VARIATIONS

Konrad STEFFEN (University of Colorado, Cooperative Institute for Research in Environmental Sciences, Boulder CO 80309-0216, USA, email: koni@seaice.colorado.edu)

The Greenland Climate Network (GC-Net) was established in spring 1994 with the emphasis to monitor climatological and glaciological parameters at various locations on the ice sheet over a time period of up to ten years. The objectives of the monitoring network are to assess daily, annual and interannual variability in accumulation rate, surface climatology and surface energy balance at selected locations on the ice sheet. Each instrument tower measures 32 parameters including temperature, humidity and wind profile at two levels, net radiation and shortwave radiation balance. The radiation is sampled at 15 s intervals and averaged over 60 minutes. All the other parameters are sampled every 10 minutes and averaged over 60 minutes. A total of 15 stations have been installed on the ice sheet by fall 1998. The data are continuously downloaded via the satellite link (ARGOS and GOES satellites). This project is part of the Program for Arctic Regional Climate Assessment (PARCA), more information can be found at http://cires.colorado.edu/parca.html
The seasonal and interannual variations of net radiation will be discussed. The net radiation balance for the dry snow area of the ice sheet is negative throughout the year with smallest values in spring and fall. Cloud parameterization based on longwave sky radiation is in good agreement with surface observation for low and middle level clouds. The cloud radiative signal is decreasing from 60 W m-2 in summer to 25 W m-2 in winter. Short-term surface temperature forcing in winter is mainly due to the turbulent mixing of heat from the top of the boundary layer, whereas radiative cloud forcing plays a secondary role.

MI08/E/01-A4 1015

CLOUD CLIMATOLOGY AT THE INTERIOR OF ANTARCTICA

Takashi YAMANOUCHI and Naohiko Hirasawa (both at National Institute of Polar Research, 1-9-10 Kaga, Itabashi-ku, Tokyo 173-8515, Japan, email: yamanou@pmg.nipr.ac.jp)

Polar cloud climatology is an urgent issue to be solved for the study of global climate. Cloud radiative forcing is very special in the Antarctic. However, detection of clouds in the polar regions from satellite visible or infrared data involves many difficulties on account of the high albedo and low temperature of the snow and ice covered ground surface. Distribution of clouds over East Antarctica was derived using AVHRR split window channel data of NOAA satellite for thirteen months from January 1987 to January 1988. Brightness temperature differences of 11 and 12 mm for the indices of thin clouds, and the correlation of the brightness temperature difference and the brightness temperature itself was used for the cloud analyses. Annual mean cloud fraction ranged from 5 (tenth) to less than 1 according to the region, and seasonal variation of the area mean varied between 4 and 1.
Wintering observations were carried out at inland station Dome Fuji (77_$B!#_(J19' S, 39_$B!#_(J 42' E, 3810 m a. s. l.) for three years, 1995 - 1997. From manual observation, monthly mean cloud amount ranged from 1.3 in May to 6.6 in December in 1997, normally smaller cloud amount in winter months. Though not in the same year, these results support the former AVHRR cloud climatology, qualitatively. Now, using a new data of ground surface measurements including radiative fluxes, cloud observation from AVHRR could be assessed. Clear sky precipitation (diamond dust), which we had occasionally, was a critical issue for the satellite detection.

FORMATION AND ADVECTION OF CLOUDS

MI08/W/04-A4 Invited 1050

ANTARCTIC ICE CLOUDS AND SIMULATED GLOBAL CLIMATE

David H. BROMWICH and Keith M. Hines (both at Byrd Polar Research Center, The Ohio State University, Columbus, OH 43210, USA, e-mail: bromwich@polarmet1.mps.ohio-state.edu) Dan Lubin (Scripps Institution of Oceanography,University of California, San Diego, La Jolla, CA 92093, USA, email: dlubin@ucsd.edu)

A sensitivity study with the NCAR CCM2 evaluates the local and global impact caused by changing the optical properties of clouds over the Antarctic continent. Runs are performed in which radiation interacts with 10 micrometer radius ice clouds rather than with the standard CCM2 water clouds. Experiments are carried out for perpetual January (summer) conditions with the diurnal cycle considered. Changes of the cloud radiative properties to those of ice clouds over Antarctica has significant impacts on regional climate during January including temperature increases throughout the Antarctic troposphere by 1-2 degrees. As a result of Antarctic warming the drainage flows at the surface and the meridional mass circulation are weakened. Similarly, the circumpolar trough weakens and moves northward. The simulated impacts of the Antarctic cloud radiative alteration are not confined to the Southern Hemisphere as the meridional mean mass flux, zonal wind and latent heat release exhibit statistically significant changes in the tropics and even extratropics of the Northern Hemisphere.

MI08/L/01-A4 Invited 1120

CYCLONES AND CLOUD BANDS OVER THE EAST ANTARCTIC PLATEAU - INDICATIONSFROM THE FROST ANALYSIS SET

MICHAEL POOK Antarctic CRC University of Tasmania GPO Box 252-80 Hobart Tasmania 7001 Email: M.J.Pook@utas.edu.au

The detection and tracking of cloud bands and associated cyclonic systems remains a difficult task over Antarctica and particularly, over the elevated plateau of East Antarctica. The problem becomes more acute during winter when the visible channels of AVHRR imagery lose effectiveness. Yet these cloud systems are responsible for a significant proportion of the precipitation falling over Antarctica. The First Regional Observing Study of the Antarctic Troposphere (FROST) which was conducted during the winter and spring of 1994 and in January of 1995 provided an opportunity to assemble comprehensive data sets for the region. The data obtained from this intensive collection effort were analysed at several centres around the world, including Hobart in Australia (Turner et al. 1996). The Hobart synoptic analysis program completed a set of MSLP, 1000-500 hPa thickness and 500 hPa contour fields for the region south of 50° S. Additionally, satellite imagery from the Defense Meteorological Satellite Program (DMSP) and AVHRR data were studied for evidence of the inland migration of cyclonic vortices. The imagery provides evidence of several vortices that moved southwards over East Antarctica during the latter part of July 1994 and appeared to decay over the high plateau. Other vortices were detected in the summer observing period, as well. Data from the network of automatic weather stations (AWS) over East Antarctica were combined with satellite imagery to infer the movement inland of these synoptic-scale and meso-scale systems. This investigation has identified broad-scale and synoptic-scale influences that contributed to the inland penetration of cyclones during the FROST Program. In particular,

atmospheric blocking in the South Pacific Ocean was found to exert a major influence on storm tracks in the Southern Ocean and the migration of lows across the Antarctic coast.

MI08/W/18-A4 1150

ROLL CHARACTERISTICS AND MICROPHYSICS OF CLOUD STREETS IN ARCTIC COLD AIR OUTBREAKS DURING ARTIST

Andreas REUTER, Frank Albers, Uwe Maixner and Erhard Raschke (all GKSS Research Centre, Institute for Atmospheric Physics, Max-Planck-Str., D-21502 Geesthacht, Germany, email: andreas.reuter@gkss.de)

The objective of the EU-funded joint German-Italian-Finnish research project ARTIST (Arctic Radiation and Turbulence Interaction STudy) is the investigation of the Arctic wintertime boundary layer in the marginal ice zone of the Fram Strait. Among other things, airborne measurements of microphysics, turbulence and radiation of cloud streets in Arctic cold air outbreaks had been accomplished during the field phase of this project (March and April 1998). For microphysical measurements, several PMS probes and a Nevzorov TWC/LWC probe had been operated by GKSS.
The purpose of this contribution is twofold: First, it focuses on roll characteristics of the encountered cloud streets in Arctic cold air outbreaks. In this context, horizontal wavelengths of the circulation as well as aspect ratios are presented. It shows that in some of the cases the aspect ratio of the rolls stays constant while the wavelengths of the rolls are increasing further downstream in the outbreak. Here, the circulation is mainly limited by the boundary layer height. In some of the outbreaks, multiscale rolls with up to three consistent wavelengths had been observed.
The second focus of this work is the investigation of the microphysical properties of the cloud streets. Conditional sampling schemes have been applied to elaborate the variation of microphysical parameters across the cloud streets at certain distances from the ice edge. It reveals that the strongly increased liquid water content in the centre of the streets is primarily caused by a higher particle concentration since the particle diameter is only slightly increased. In addition, glaciation processes inside these convective clouds are investigated. For this purpose, particle habit detection schemes are applied to the OAP data to separate ice particles from water droplets, resulting in individual liquid- and ice particle size spectra. They illustrate the different particle growth processes inside mixed-phase convective systems. Generally, the upper third of the cloud was predominantly liquid, even at ambient temperatures around -20°C. These findings are corroborated by the Nevzorov probe data since this instrument allows the direct calculation of a separate liquid- and ice water content. Near cloud base, about 75% of the cloud water was frozen with a pronounced production of snow.

MI08/W/01-A4 1205

SIMULATIONS OF AEROSOL ENTRAINMENT IN THE ARTIC BOUNDARY LAYER

W. R. COTTON, H. Jiang, and G. Feingold (Colorado State University, Dept. of Atmospheric Science, Foothill Campus, Fort Collins, CO 80523, USA Email: cotton@atmos.colostate.edu)

Using RAMS developed at Colorado State University, we have performed large eddy simulations(LES) of the 18 May 1998 FIRE/SHEBA case. Because our previous simulations of Arctic stratus have revealed considerable sensitivity to the concentrations of cloud condensation nuclei(CCN) and ice-forming nuclei(IFN), we use this case to investigate the possible importance of entrainment of CCN from the overlaying stable air on cloud microstructure and macrostructure.
The warm-cloud bin-resolving microphysics version of RAMS described by Feingold et al., (1998) is set up as an LES model with cyclic lateral boundaries, a rigid lid with a Rayleigh friction layer, and specified specified surface temperature of 266.0 K and surface roughness of 0.05 m. Simulations are done on a domain of 45 X 45 X 55 grid points with a 50 m grid spacing in the horizontal and 25 m grid spacing in the vertical. A time step of 2 sec is used in all integration.
The thermodynamic and CCN sounding data are taken from FIRE/SHEBA research Flight #5 (May 18, 1998) during the spring IOP. The CCN sounding is based on Hudson's CCN spectrometer data reported on his web page for a 0.2% supersaturation. The profile exhibits concentrations ranging from 40/cc below cloud base to a peak above the cloud in the base of the inversion of 250/cc, lowering to 160/cc at 700m.
After 2 hours of simulation we find that the cloud droplet concentration varies with height through the cloud layer with cloud base values being 50-60/cc and values near cloud top being as high as 200/cc. Sensitivity simulations with vertically-uniform values of CCN are being performed to examine the importance of entrainment of CCN to the radiative, microphysical, and dynamical structure of Arctic stratus.

MI08/L/02-A4 1220

SIMULATION OF ARCTIC WEATHER WITH A SINGLE-COLUMN MODEL

Douglas G. C , Cara-Lyn Lappen, and David A. Randall (Colorado State University, Fort Collins, Colorado)

Among the various climate regimes of Earth the Arc\-tic presents particular challenges. Complex feedback mechanisms of the ocean-ice-atmosphere system, in conjunction with the paucity of observational data, pose modelling difficulties not encountered elsewhere on the planet (Randall et al.,1998) In this study, we explore some of these issues by simulation of the Arctic environ\-ment with the Colorado State University (CSU) Single- Column Model (SCM), which is then compared with observational data gathered at the Surface Heat Budget of the Arctic (SHEBA) field project. Within the context of SHEBA, observational data were provided by both the Atmospheric Radiation Measurement (ARM) program, and the First ISCCP (International Satellite Cloud Climatology Program Regional Experiment (FIRE). The CSU SCM has been used to simulate the observed sequence of weather events for the month of May at the SHEBA site. The results show periods of both agreement and disagreement with temperature and moisture sounding analyses provided by ECMWF, as well as the in-situ moisture and radiation measurements provided by SHEBA. Additionally, though not presented here, the SCM produced more precipitation than indi\-cated by the ECMWF analyses. The most likely causes for the discrepancies in the SCM\rquote s performance are errors arising from the parameterizations of cloud char\-acteristics and formation processes, and atmospheric radiative transfer inherited from the parent GCM. For example, deficiencies in the parameterizations of the radiation flux or cloud microphysical and optical proper\-ties, or cloud formation processes, or even the surface albedo could combine cumulatively to adversely affect the shortwave radiation received at the surface, which in turn will affect the evaluation of prognostic variables. Problems with the albedo prescription would almost certainly explain the large discrepancies between the observed and SCM-produced net surface shortwave fluxes leading to the warm bias noted at the surface. Though it would be difficult to detect the effects of changing a particular parameterization in a GCM given the complex interactions among its constituents, the SCM provides a means by which an individual parameteriza\-tion made be studied in isolation. The preliminary results presented here are thus a first step in the challenge of using the SCM to individually identify, examine, and ultimately fine-tune the weaknesses of the myriad parameterizations found in GCMs.

MI08/E/06-A4 1235

APPLICATION OF A FLEXIBLE, LONGWAVE RADIATIVE TRANSFER TOOL (FLRT) TO THE POLAR REGIONS

Jennifer DELAMERE and Knut Stamnes (both at Geophysical Institute, University of Alaska Fairbanks, Fairbanks, AK 99775 U.S.A., email: jen@land.gi.alaska.edu). Eli J. MIawer and Shepard A. Clough (both at Atmospheric and Environmental Research, Inc., Cambridge,MA U.S.A.)

We apply a flexible, longwave radiative transfer tool (FLRT) to the study of the radiation and cloud environment in the polar regions. FLRT is used to create a correlated-k, multiple-scattering model across user-specified, spectral bandwidths. The method, which computes the gaseous optical depths required by the model, is based upon the rapid radiative transfer model RRTM (Mlawer et al., 1997), including the technique to handle absorption by multiple gases within a band. The combined contribution of gaseous absorption with absorption and scattering by cloud and/or aerosol particles are ported into the DISORT multiple-scattering algorithm. Using the newly-created radiative transfer model, we will present a study of the contribution of the mid-infrared spectral region to the near-surface cooling and longwave radiation budget at high latitudes. In particular, we will explore the influence of water vapor and clouds on the "Arctic Window", a spectral window (16 to 25 microns) that is infrequently observed in mid-latitudes.

Thursday 22 July PM

Presiding Chair: K. Stamnes (Univ. of Alaska, Fairbanks, USA), G.W. Paltridge (Univ of Tasmania, Australia)

RESULTS FROM SHEBA, FIRE-3, BASE

MI08/L/11-A4 Invited 1400

OVERVIEW OF THE SHEBA AND FIRE-ACE CLOUD RESEARCH PROGRAMS

T. Uttal, R/E/ET6 Environmental Technology Laboratory 325 Broadway, Boulder, CO 80303, USA tel 01-303-497-6409 email: tuttal@etl.noaa.gov

The NSF Surface Heat Budget of the Arctic (SHEBA) and the NASA FIRE Arctic Cloud Experiment (ACE) were conducted North of Alaska over the permanent ice pack of the Beaufort and Chuckchi Seas. SHEBA was a year long program which started in September of 1997 and ran continously until September of 1998. This integrated ocean-ice-atmosphere research program had a state of the art array of instruments for remotely measuring cloud properties including radar, lidar, spectral and broad-band radiometers, and all sky imagers, as well as in-situ sensors flown on tethered balloons. The FIRE-ACE program provided satellite observations of clouds throughout the year, and in the Spring and Summer of 1998, conducted an extensive campaign during which aircraft instrumented within-situ and remote cloud microphysics and radiation sensors made more than 30 flights over the SHEBA ice station. These combined remote sensing and in-situ measurements are already providing a detailed look at previously unknown properties of Arctic clouds. Placed in context of the year long measurements and the equally detailed measurements of ice and ocean characteristics, it is expected that the SHEBA and FIRE-ACE results will significantly improve model parameterizations of Arctic clouds, validation of satellite methods for detecting Arctic cloud properties, and equally importantly, provide a solid observational data base for one full annual cycle of Arctic cloudiness.

MI08/L/08-A4 Invited 1430

ON THE CANADIAN RESEARCH CONDUCTED IN ASSOCIATION WITH THE BEAUFORT AND ARCTIC STORMS EXPERIMENT (BASE)

Ronald E. STEWART, David R. Hudak and Kit K. Szeto Atmospheric Environment Service 4905 Dufferin Street, Downsview, Ontario Canada M3H 5T4 E-mail: Ron.Stewart@ec.gc.ca

A number of high latitude storms were observed} during t he Beaufort and Arctic Storms Experiment (BASE)}, which was conducted from Sept 1 to Oct 15, 1994. Ensuing analysis studies have revealed a great deal about the nature of these cloud systems, and the results are now being applied towards climate model improvements}. The objective of the Canadian effort within BASE was to better understand the nature of the cloud systems occurring over the southern Beaufort Sea and northern Mackenzie River basin during the autumn. A variety of situations were examined, including cyclonic storms, mesoscale vortices, and boundary layer alteration over varying surfaces. During the BASE period, more Arctic-origin storms occurred than is normal, but fewer were of a Pacific origin. These systems were observed by using a number of special measurements, including enhanced satellite data retrievals, additional soundings and surface observations, and special aircraft and Doppler radar observations. A nalyses have included a study of the structure and evolution of a mesoscale vortex over the Beaufort Sea comparison of the broad classes of Pacific storm types studies of the Doppler radar information obtained at Inuvik and Tuktoyaktuk variational analysis of the dominant precipitation formation mechanisms and their associated mesoscale features; and a critical assessment of the International Satellite Cloud Climatology Project (ISCCP) products for Beaufort region cloud systems. High resolution cloud model simulations have also been carried out, and sublimational processes were found to be critical in replicating the observed fine-scale cloud and dynamic structures. In fact, ice phase processes such as sublimation are critical for determining the water budget of the systems, and small changes in initial water vapour content can translate into large effects on the water budgets as a consequence of these processes. These simulation results are now being used to assess the capabilities of climate models to account for such high latitude cloud systems.

MI08/W/03-A4 1500

IMPROVED IN SITU OBSERVATIONS OF MIXED PHASE CLOUDS DURING FIRE.ACE AND IMPLICATIONS ON RADIATIVE TRANSFER

R. Paul LAWSON and Tara L. Jensen, SPEC Incorporated, 5401 Western Ave., Suite B, Boulder, CO 80301, USA, email: plawson@specinc.com

Research conducted over the years for the First ISCCP Regional Experiment (FIRE) has led to major improvements in our understanding of the role of clouds in the global climate system. In the spring of 1998, FIRE conducted Phase III of the program in conjunction with the Surface Heat Budget of the Arctic Ocean (SHEBA). The goal of the FIRE Arctic Cloud Experiment (FIRE.ACE) was to study a variety of arctic cloud systems under spring and summer conditions.
A new instrument, the cloud particle imager (CPI), was deployed on the National Center for Atmospheric Research (NCAR) C-130 during FIRE.ACE in both May and July of 1998. The CPI records high-resolution (2.3 um) digital images of cloud particles "on the fly" as they pass through the instrument sample volume. The CPI makes it possible to study the detailed structure of ice crystals and discriminate them from water drops in clouds.

In this paper, we present an overview of data collected in various cloud types during the FIRE.ACE experiment., including all-water and mixed phase stratus, mixed-phase alto stratus and glaciated cirrus clouds. Particles Images, size distributions, liquid and ice water contents are presented. The results show that there is no discernable correlation between ice particle concentration and temperature. Clouds that were composed of nearly all water drops sometimes existed at temperatures as cold as -24 C, and relatively high concentrations of ice were sometimes observed at -4 C. Also, the clouds were sometimes very inhomogeneous on a spatial domain, transitioning from drizzle drops to rimed ice particles within a few kilometers. Implications on radiation and single column modelling will be discussed.

MI08/W/09-A4 1515

THE INFLUENCE OF THE MICROSTRUCTURE OF ARCTIC STRATUS CLOUDS ON SMALL SCALE FLUCTUATIONS IN SOLAR RADIATIVE FLUXES

Darrel BAUMGARDNER (Centro de Ciencias de la Atmosfera, Universidad Nacional Autonoma de Mexico, Ciudad Universitaria, 04510 Mexico DF, Mexico, email: darrel@servidor.unam.mx), Darnell Powers (Truman State College, Jefferson, Missouri)

Measurements of Arctic stratus clouds during the Surface Heat Budget of the Arctic Ocean (SHEBA) experiment in the spring and summer of 1998 show significant fluctuations in liquid water content, droplet number concentration and effective radius at length scales less than 100 m. These cloud microphysical parameters were measured with optical particle counters mounted on the NCAR C-130 research aircraft and the sample rates (the FSSP-100 at 10 Hz and PVM-100 at 250 Hz) provide information at length scales of 10 m and 0.4 m, respectively. These measurements were used in a one-dimensional, two stream radiative transfer model to evaluate how short wave radiative fluxes are effected by small scale variations in cloud properties. The results of this study show that 1) the variability in cloud microphysical properties and subsequent radiative fluxes increases as measurements are made at shorter spatial scales 2) there is greater sensitivity to changes in length scale as you go from thinner to thicker clouds and 3) the measured variability in down-welling short wave radiation, made with the airborne radiometers, is in good agreement with the 1D radiative transfer model. These results indicate that satellite measurements and global climate models may be missing smaller scale radiative effects that are climatically important.

MI08/W/13-A4 1530

OBSERVATIONS OF INTEGRATED WATER VAPOR AND CLOUD LIQUID WATER AT THE SHEBA ICE STATION WITH A DUAL-CHANNEL MICROWAVE RADIOMETER

James Liljegren (DOE Ames Laboratory, Ames, Iowa, USA, Email: liljegren@ameslab.gov)

In the Arctic water vapor and clouds influence the surface radiation balance to a greater extent than at lower latitudes. Because the integrated water vapor is often less than 5 mm, substantial radiative cooling occurs in the 20 micron infrared region whereas this region is normally opaque at lower latitudes having greater water vapor amounts. Thin, variable liquid water clouds also substantially affect the surface radiation balance. Integrated water vapor and cloud liquid water were measured continuously over a 12-month period at the SHEBA (Surface Heat Budget of the Arctic) ice station with a microwave water radiometer (MWR).
The MWR was among the suite of instruments deployed by the Atmospheric Radiation Measurement (ARM) Program of the U. S. Department of Energy. The radiometer was operated in a continuous elevation angle-scanning mode in order to permit calibration updates whenever the sky was clear. In addition, continuously scanning the sky between +/- 45 degrees about zenith at 5-degree intervals Permitted the time-varying spatial structure of water vapor and cloud liquid water to be observed. Comparison of the liquid water path derived from the microwave radiometer brightness temperatures with liquid water paths from the Gerber PVM probe aboard the NCAR C-130 generally exhibited good agreement.
Measurements of integrated water vapor exhibited good agreement with integrated water vapor derived from radiosondes: a slight bias of 0.2 mm was observed. Comparison of the measured radiometric brightness temperatures with model calculations based on the radiosondes was carried out in order to examine the model performance in the limit of low water vapor where the microwave signal is dominated by molecular oxygen.

MI08/W/08-A4 1545

SOLAR AND INFRARED RADIOMETRIC FLUXES IN THE ARCTIC ENVIRONMENT AS MEASURED FROM THE NCAR C-130 AIRCRAFT DURING FIRE-ACE

S.K. POPE, A. Bucholtz, B.C. Bush and F.P.J. Valero (Scripps Institution of Oceanogfaphy, University of California, San Diego 9500 Gilman Dr., 0242 La Jolla, CA 92093-0242 USA.
E-mail: pope@arlo.ucsd.edu Telephone No: 619-534-9619 Fax No: 619-822-0517)

Airborne measurements of radiative fluxes in the Arctic environment during spring and summer conditions were recently carried out as part of FIRE-Arctic Cloud Experiment in conjunction with the SHEBA (Surface Heat Budget of the Arctic Ocean) field mission. Flux data were collected with a suite of radiometers with hemispherical fields-of-view mounted in zenith and nadir looking ports of the NCAR C-130 aircraft. Broadband fluxes were measured in the total solar bandpass, 0.224 to 3.91 microns, and in the infrared bandpass, 4.125 to 48.25 microns. Narrower bandpass measurements were made with a pair of instruments that have seven channels spanning the 400 nm to 700 nm wavelength range. Of this pair the uplooking one has a shadow arm which allows the measurement of the total, direct, and diffuse components. Flights were based out of Fairbanks, Alaska with multiple patterns flown in the vicinity of the SHEBA ship locked in the ice in the Arctic Ocean. Cloud conditions ranged from clear skies to broken to overcast stratus or cirrus clouds. Surface conditions varied from thick snow/ice with distinct leads in the spring to thin, fractured snow/ice in the summer. Results from these varied measurements will be discussed, including surface albedos, the flux signature due to leads, cloud reflectances, cloud transmittances, and cloud absorptances. Observations will be compared to model calculations.

MI08/W/16-A4 1600

SURFACE ENERGY BUDGETS AND CLOUD FORCING ON THE ARCTIC ICE CAP: ONE YEAR OF DATA FROM THE SHEBA EXPERIMENT

J. M. INTRIERI (Environmental Technology Laboratory, NOAA, Boulder, CO 80303, USA, email: jintrieril@etl.noaa.gov); C. W. FAIRALL (Environmental Technology Laboratory, NOAA, Boulder, CO 80303, USA, email: cfairall@etl.noaa.gov); T. Uttal (Environmental Technology Laboratory, NOAA, Boulder, CO 80303, USA, email: tuttall@etl.noaa.gov) P. O. G. Persson (Cooperative Institute for Research in Environmental Sciences, NOAA/ETL, Boulder, CO 80303, USA, email: opersson@etl.noaa.gov)

From November 1997 to October 1998 the Surface Heat Budget of the Arctic (SHEBA) engaged in a variety of atmospheric, ice, and oceanic measurements on the Arctic icecap as part of ice station SHEBA. The ice station was launched at 143 W and 75 N and ended at 166 W and 80 N. The measurements included eddy-correlation measurements of sensible and latent heat flux, upward and downward solar and IR fluxes, and snow/ice temperatures. Profiles of cloud information were obtained with an 8-mm-wavelength Doppler cloud radar and a 0.523 micron wavelength depolarization and backscatter lidar (dabul). We believe this is the first set of eddy-correlation heat flux, radiative fluxes, and comprehensive cloud data obtained over an entire annual cycle on the ice cap.
In this paper we will present simple statistics on the annual cycle of the components of the surface heat budget and cloud properties (fraction, thickness, ice vs water, etc). We will also provide a preliminary analysis of the annual cycle of cloud forcing of the surface heat budget.

MI08/L/09-A4 1615

ONE ANNUAL CYCLE OF CLOUD PROPERTIES DETECTED WITH LIDAR AND RADAR OVER THE SHEBA ICE CAMP

T. UTTAL, J. Intrieri, and B. Olson Environmental Technology Laboratory, NOAA, 325 Broadway, Boulder, CO 80303 USA email: jintrieri@etl.noaa.gov, tuttal@etl.noaa.gov, bolson@etl.noaa.gov

The NOAA/Environmental Technology Laboratory was funded by the National Science Foundation to operate a 35 GHZ Doppler cloud radar and a dual-polarization lidar at the SHEBA ice camp to observe cloud properties. These two instruments in combination with surface radiometers provide a powerful mechanism for observing cloud properties, including cloud fraction, cloud thickness, number of layers, cloud phase, particle sizes, particle concentrations and optical depths. Some of the preliminary analysis on the variation of these cloud properties over one annual cycle will be presented. Using information from an identical radar operated by the Department of Energy in Barrow, Alaska, some comparisons will be made of these cloud statistics between the Coastal Arctic (Barrow) and the Arctic icepack (SHEBA icestation) sites.

UV RADIATION

MI08/L/10-A4 Invited 1650

UV RADIATION IN THE ARCTIC

ELIZABETH C. WEATHERHEAD, University of Colorado at Boulder, email: betsy@srrb.noaa.gov

UV radiation has always been a significant environmental parameter in the Arctic. Recent changes in Arctic ozone levels have increased the natural UV levels significantly. Changes in ozone, including trends and brief episodes of extremely low ozone are most severe in the spring when biological systems are particularly susceptible to damage. However, assessing UV levels in the Arctic can be extremely difficult. Most primary production in the Arctic occurs under water, making standard measurements and satellite estimates only coarse indicators of biologically relevant levels. Terrestrial UV levels are dominated by low sun angles and high surface albedo, also making standard measurements and satellite estimates difficult to interpret. A number of important projects are currently underway to measure, model and estimate biologically relevant UV levels throughout the Arctic. Current understanding of Arctic ozone chemistry indicates that the Arctic will continue to experience elevated UV levels for at least the next few decades and may not recover to pre-1970 levels. Climate change is likely to slow Arctic recovery considerably. The impact of such a slow recovery in the Arctic is highly uncertain due to the sparsity of studies assessing UV effects in the Arctic. Current ozone and UV measurements will be reviewed and expectations for future will be summarized.

MI08/L/07-A4 Invited 1720

CLOUDS AS MODIFIERS OF UV SPECTRA AT THE GROUND

Dr. Gunther SECKMEYER, Fraunhofer Institute for environmental atmospheric research (IFU), Kreuzeckbahnstr. 19, D-82467 Garmisch-Partenkirchen, e-mail: seck@ifu.fhg.de

Clouds are known to be a major factor influencing UV irradiance at the ground. Usually clouds are attenuating the global irradiance, but there are also cases where the UV irradiance is enhanced due to reflection of radiation by clouds. It has been found that the attenuation of UV irradiance by clouds is not spectrally flat but is a function of wavelength. The radiation conditions under broken clouds can be even more complex. Broken clouds lead to wavelength dependent variations of UV irradiance mainly caused by Rayleigh scattering. An increasing temporal variability with increasing wavelength can be observed under broken cloud conditions. This will be demonstrated as case studies by a combination of measurements and models for cloudless skies.

MI08/E/08-A4 1750

A COMPARISON BETWEEN SATELLITE ESTIMATES AND OBSERVED ULTRAVIOLET (UV) IN THE ALASKAN ARCTIC

Renee TATUSKO, Barry Bodhaine, Ellsworth Dutton (NOAA/Climate Monitoring and Diagnostics Laboratory, 325 Broadway, R/E/CG1, Boulder, Colorado, U.S.A., 80303, email: rtatusko@cmdl.noaa.gov) Elizabeth Weatherhead (University of Colorado at Boulder, Cooperative Institute for Research in Environmental Sciences, Campus Box 449, Boulder, Colorado, U.S.A., 80309, email: betsy@srrb.noaa.gov) Knut Stamnes (University of Alaska at Fairbanks, Geophysical Institute, P.O. Box 757320, Fairbanks, Alaska, U.S.A. 99775-7320, email: knut@gi.alaska.edu) Jay Herman (NASA/Goddard Space Flight Center, Code 916, Greenbelt, Maryland, U.S.A. 20771, email: herman@tparty.gsfc.nasa.gov)

Decreases in ozone over the Arctic region have occurred over the last two decades, with record low levels recorded during the 1997 spring. Ozone depletion and increased UV radiation pose serious threats to the Arctic ecosystems and peoples. In 1997 and 1998, in response to a need for improved ground-based ultraviolet (UV) measurements in the Alaskan Arctic, NOAA's Climate Monitoring and Diagnostics Laboratory (CMDL) deployed narrowband spectral UV radiometers at Barrow, St. Paul, and Nome, which measure global solar UV irradiance in five UV-visible channels. These multichannel instruments show promise for long-term monitoring of UV-B, UV-A, and visible radiation levels as well as changes in the ozone level, cloud cover, and aerosols. Their ease in maintenance and lower cost, compared to a high-resolution spectroradiometer, make these instruments useful for deployment in the harsh Arctic environment. Estimates of UV exposure from satellite data are difficult to make in the Arctic region because of the complexity of atmospheric and environmental conditions. The main cause of difficulty arises from lack of knowledge of surface reflectivity in the presence of snow. A comparison between NASA's UV estimates based on satellite observations and ground-based measurements at the three sites in Alaska will be conducted. The results of this comparison as a function of temporal averaging, variable surface albedo, and cloudiness will be examined.

MI08/W/10-A4 1805

DAILY AND MONTHLY UV DOSES AT A HIGH LATITUDE SITE AND THE EFFECT OF CLOUDS AND SURFACE ALBEDO

Arve KYLLING (Norwegian Institute of Air Research, P.O. Box 100, 2007 Kjeller, Norway, e-mail: arve.kylling@nilu.no), Arne Dahlback (Department of Physics, University of Oslo, P.O. Box 1048, 0316 Oslo, Norway, e-mail: arne.dahlback@fys.uio.no) and Bernhard Mayer (National Center For Atmospheric Research (NCAR), P.O. Box 3000, Boulder, Co 80307, email: bmayer@ucar.edu)

At high latitudes the snowcover may significantly increase the surface UV radiation both for clear and cloudy situations. During 1997 in Tromsø, Norway, the direct and global irradiances were measured between 300 and 600 nm with a spectroradiometer. In addition a multichannel, moderate bandwidth filter instrument measured the ozone column, the cloud optical depth and the erythemally weighted irradiance. An inversion technique was developed to derive an effective regional spectral surface albedo from the measured direct and global irradiance spectra. At 320 nm the albedo varied between 0.57 (snowcover) and 0.08 (snowfree conditions). The derived albedo is used together with model simulations of the filter instrument irradiance to study the effect of a snow covered ground on daily and monthly UV doses both for clear and cloudy sky situations. The clouds are found to reduce the monthly doses by 20-40% compared to cloud free conditions. The snow increases the monthly UV doses by more than 20% compared to snowfree conditions.

REMOTE SENSING OF MINERAL DUST FROM SEAWIFS SPECTRAL MEASUREMENTS

C. Moulin(1)(3), H.R. Gordon(1), V.F. Banzon(2), R.H. Evans(2) (1) Florida Department of Physics, University of Miami, Coral Gables, Florida, e-mail: moulin@fasolt.physics.miami.edu. (2) Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, Florida (3) Laboratoire des Sciences du Climat et de l'Environnement, CEA-CNRS, Gif-Sur-Yvette, France

Mineral dusts are a major component of the tropospheric aerosol in wide oceanic regions such as the tropical North Atlantic and the Mediterranean. Scientific interest for mineral dusts ranges from the assessment of their impact on the radiative budget of the Earth to the removal of their contribution to the signal measured by ocean color sensors. In both cases, large uncertainties remain because of the dust physical and optical properties. Indeed, mineral dusts are large and absorbing (mainly in the blue) particles with poorly known refractive index and size distribution, and their vertical distribution is highly variable. Here, we used spectral measurements of the sea-viewing wide-field-of-view sensor (SEAWIFS) to retrieve relevant information on mineral dust properties.
For several Atlantic and Mediterranean dust events, we extracted the reflectances at all available wavelengths (from 412 to 865 nm). Using radiative transfer computations, we tested the relevance of the spectral behavior of various mineral dust models. We show that for realistic refractive indices, only size distributions with two or three lognormal modes are able to reproduce the spectral variations of observed reflectances, i.e., almost constant between 670 and 865 nm, and decreasing from 555 to 412 nm. For these suitable models, we tested the impact of the vertical distribution of dust in the atmospheric column. We show that the standard assumption (an aerosol layer below a molecular layer) may lead to significant errors at shorter wavelengths (400-500 nm) when applied to a dust layer of few kilometers in height.
An important conclusion of the first part of this work is that the standard aerosol retrieval algorithm (based only on 765 and 865 nm bands) is not able to properly differentiate mineral dust from a sea-salt aerosol since the specific behavior of dust occurs at shorter wavelengths. This is particularly important for ocean color which requires a good accuracy in the blue. We then propose an improved mineral dust retrieval algorithm which uses all available bands and a relevant set of mineral dust models, including information on the altitude of the dust layer. Limitations of the method are shown in terms of in-water optical properties (e.g., case 2 waters). We applied this algorithm to SEAWIFS images and we discuss here the results for both retrieved optical depth and marine reflectances by comparison with SEAWIFS standard products.

MI09/L/02-A5 Invited 0855

ESTIMATE OF THE AEROSOL PROPERTIES OVER THE OCEAN WITH POLDER

Herman, M. (Laboratoire d'Optique Atmosphérique, Université de Lille 1. 59655 Villeneuve d'Ascq Cedex. France. e-mail: herman@loa.univ-lille1.fr); Deuzé J.L., G. Perry, A.Marchand, P. Goloub, and D.Tanré. (Laboratoire d'Optique Atmosphérique, Université de Lille 1. 59655 Villeneuve d'Ascq Cedex. France.)

The wide field of view imaging spectroradiometer POLDER (POLarisation and Directionality of the Earth's Reflectance) developed by CNES (Centre National d'Etudes Spatiales) and operated aboard the Japanese heliosynchronous platform ADEOS (ADvanced Earth Observation Satellite) from October 30th 1996 till June 30th 1997, provided the first global systematic measurements of the spectral, directional and polarized characteristics of the solar radiation reflected by the Earth/atmosphere system. These original observational capabilities offer an opportunity to enhance the characterization of the aerosols. The inversion algorithms from which the aerosol parameters are derived, respectively over the ocean and over lands, are examined and examples of the outputs are presented. Special emphasis is given to the interest of directional and polarized measurements over the ocean.

MI09/E/06-A5 0920

LONG-TERM MONITORING OF GLOBAL AEROSOL CHARACTERISTICS USING NOAA/AVHRR

Akiko HIGURASHI (National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki 305-0053, Japan, e-mail: hakiko@nies.go.jp); Teruyuki Nakajima and Takayuki Usui (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan, e-mail: teruyuki@ccsr.u-tokyo.ac.jp)

Aerosols are recognized to cause significant direct and indirect forcing on Earth's %fs climate. The evaluation of this effects, however, remains still highly uncertain for lack of our knowledge of aerosol characteristics on global and long-term scale.
We have developed the aerosol retrieval algorithm, which estimates aerosol optical thickness and !OgstrSN exponent using two channel radiance data of NOAA/AVHRR and have validated the results with ground-based observations. Retrieving !OgstrSN exponent addition to aerosol optical thickness has been shown to be very effective, as compared with past aerosol retrieval algorithm which obtains only aerosol optical thickness from one channel radiance assuming aerosol model, because it makes possible to distinguish the impact of human activities from that of natural aerosols represented by desert dust, and to estimate the number density of aerosol particles, which is very important to investigate the aerosol indirect effect.
We will report the global distribution of these parameters applying the algorithm to multi-year data sets of NOAA/AVHRR radiances. Preliminary analysis suggests increasing contribution of human emission of aerosols, especially off the east of Asia. Such long term analysis will indicate the natural and anthropogenic variabirities of aerosol properties.

MI09/E/02-A5 0937

DUST FORCING OF CLIMATE INFERRED FROM CORRELATIONS BETWEEN TOMS AEROSOL INDEX AND ATMOSPHERIC MODEL ERRORS

Pinhas ALPERT, I. Carmona(Dept. of Geophysics and Planetary Science, Tel Aviv University 69978 Ramat Aviv, Israel, e-mail: pinhas@cyclone.tau.ac.il) Jay Herman and Yoram Kaufman (NASA/GSFC, Greenbelt, MD20771)

Recently, Alpert et al (1998, Nature), suggested an indirect measure of the tropospheric temperature response to dust aerosols by using model updates, - roughly speaking model errors-of the NASA Goddard Earth Observing System (GEOS-1) data assimilation system. They have shown that these updates, which provide information about missing physical processes not included in the predictive model, have monthly mean patterns which bear a striking similarity to patterns of dust over the Atlantic.
This similarity in the number of dusty days was used to estimate the atmospheric response to dust. Here, the study is extended for all the major sub-tropical deserts over Africa and Asia using the Total Ozone Mapping Spectrometer (TOMS) aerosol index (AI) for dust recently derived by Herman et al (1997). It is shown that the TOMS dust is highly correlated with the model errors with a maximum at the altitude of about 580 hPa and for the month of June with average correlation coefficient of 0.69 reaching up to 0.8 for specific months. In contrast to the previous study where only dust over ocean was employed, here much higher dust concentrations are detected and the linear heating for weak dust becomes quickly saturated for AI above 1.5 then drops for very high AI exceeding about 3 in consistence with the theoretical predictions.

MI09/W/04-A5 0954

LARGE SCALE ANALYSES OF CONVECTIVE CLOUD MICROSTRUCTURE FROM AVHRR DATA

Daniel ROSENFELD (Atmospheric Science, The Hebrew University, Jerusalem, Israel. email: daniel@vms.huji.ac.il) Ron Drori (Atmospheric Science, The Hebrew University, Jerusalem, Israel. email: ron@cloud.es.huji.ac.il)

A method to infer from AVHRR data the precipitation properties of convective clouds has been developed recently by Rosenfeld and Lensky (BAMS, 11/1998). That method was developed for case studies. A new layer to this method had been added that enables us to implement it automatically over large areas. Various parameters, as defined by Rosenfeld and Lensky (1998) can be selected, in addition to newly defined parameters. One important parameter is the warmest temperature at which the effective radius of convective clouds exceeds the precipitation threshold of 15-micron (T15). An effective radius of 14 micron had been shown as a threshold for precipitating clouds (Rosenfeld and Gutman 1994). Reanalysis of the case over the Philippines had shown a rapid decrease of T15 for clouds moving from sea inland, becoming more microphysically continental. A much slower increase of T15 is observed on the downwind side of the islands, showing that the air can get polluted with CCN aerosols over land much faster than it becomes clean again over sea.Furthermore, a bulls-eye of drastically decreased T15 is evident over and downwind of Manila.This is a typical situation. Similar trends are generally observed in most AVHRR images taken at random.

COLUMN CLOSURE EXPERIMENTS OF AEROSOLS

MI09/W/14-A5 Invited 1030

SATELLITE REMOTE SENSING OF AEROSOL PROPERTIES IN COLUMN CLOSURE EXPERIMENTS

P. A. DURKEE, K. E. Nielsen (both at 1Naval Postgraduate School, Monterey, CA USA, Email: durkee@nps.navy.mil), P. B. Russell (NASA Ames Research Center, Moffett Field, CA USA), B. Schmid (Bay Area Environmental Research Institute, San Francisco, CA USA), J. M. Livingston (SRI International, Menlo Park, CA USA), D. Collins, R. C. Flagan, J. H. Seinfeld (all three at California Institute of Technology, Pasadena, CA USA), K. J. Noone, E. Öström (both at Stockholm University, Stockholm, Sweden), S. Gassó, D. Hegg (both at University of Washington, Seattle, WA USA), L. M. Russell (Princeton University, Princeton, NJ USA), T. S. Bates, and P. K. Quinn (both at NOAA PMEL, Seattle, WA USA)

Recent field programs designed to study aerosol properties have produced interesting contrasts across diverse regions of the globe. ACE-1 (Aerosol Characterization Experiment) observed conditions in the relatively unperturbed southern ocean near Tasmania in November-December 1995. The Tropospheric Aerosol Radiative Forcing Observational Experiment (TARFOX) observed aerosol transported of the North American coast over the Atlantic Ocean in July 1996. Most recently, ACE-2 measured the properties of aerosol from Europe and Northwestern Africa over the eastern North Atlantic Ocean in June-July 1997. The differences between these three regions are well observed by satellite remote sensing. The Advanced Very High Resolution Radiometer (AVHRR) aboard NOAA polar orbiting satellites measure radiance in five wavelength bands - two of which are sensitive to scattering by aerosol (Channel 1 - 0.63 µm and Channel 2 - 0.86 µm center wavelengths). Aerosol optical depth calculated for these first two channels of AVHRR and the radiance ratio of these channels can be used to parameterize size distribution properties. Retrieval of aerosol properties requires assumptions about the characteristics of aerosol number distributions, the absorption properties and vertical distribution of aerosol, surface reflectance, and others. This presentation will describe the array of airborne, surface, and shipboard data collected during field experiments that can be used to validate the satellite-based retrieval of aerosol

properties. Analysis of aerosol size distribution, aerosol optical depth, scattering and absorption characteristics will be used to test the assumptions in satellite retrieval algorithms.

DERIVING AEROSOL RADIATIVE PROPERTIES FROM REMOTE SENSING SPECTRAL MEASUREMENTS

John PORTER (Soest, University of Hawaii, 96822, Email: jporter@soest.hawaii.edu)

Satellites offer the possibility to derive aerosol properties over the whole earth. Unfortunately deriving these aerosol properties is not straight forward and typically requires an aerosol model. Here we use an existing aerosol model to develop algorithms to derive aerosol optical properties from multi-angle spectral measurements. The algorithms are applied to upwelling radiaces collected from low flying aircraft during ACE1 and INDOEX. Comparisons are made with other measurements in order to test for closure.

USE OF THE KERNEL COVARIANCE MATRIX TO PREDICT BEYOND THE MEASUREMENT RANGE

Gail BOX (School of Physics, University of New South Wales,Sydney NSW 2052 Australia, email: gpb@newt.phys.unsw.edu.au)

The radiometers which are used to measure optical thicknesses usually make measurements in the range 0.38-1.05 microns. These measurements can be used to determine aerosol size distribution by inverting the integral equation connecting the optical thickness with the size distribution. However, it is known that more accurate inversions can be obtained if measurements over a wider wavelength range are available. Since the kernels of the integral equation are not independent of one another, there is the possibility of using the measurements made to predict measurement values beyond the instrument range.
We have applied a method based on the eigenvalues and eigenvectors of the kernel covariance matrix to predict measurements at wavelengths other than the measured ones, including beyond the range. The results look promising. Some of these results, including the effects of measurement errors, will be presented.

SPECTRAL CHARACTERISTICS OF ASIAN DUST AEROSOL AROUND THE KOREAN PENINSULA AND JAPAN OBSERVED BY SEA WIDE FIELD-OF-VIEW SENSOR (SEAWIFS) IN 1998 SPRING

Hajime FUKUSHIMA (School of High-Technology, Tokai University, Numazu, 410-0395 Japan, Email: hajime@fksh.fc.u-tokai.ac.jp) and Byung-Ju Sohn (Dept. of Earth Sciences, Seoul National University, Seoul, 151-742, Korea, Email: sohnbj@plaza.snu.ac.kr)

The study analyzes aerosol optical thickness and Angstrom exponent for different airmass oberved by SeaWiFS, a satellite ocean color scanner, in the end of March to mid-April, 1998, when a couple of Asian dust (KOSA) event was observed by ground stations in Korea and Japan. The optical thickness and Angstrom exponent are derived from the near-infrared (666, 765, and 865 nm) band data, using SeaDAS, a NASA/GSFC-made SeaWiFS data processing software that assumes an appropriate pair of aerosol models chosen for every pixel out of 12 candidate aerosol model set. It is shown that Asian dust aerosol is well characterized by its relatively high optical thickness (0.6 or more at 865 nm) and low Angstrom exponent (about 0.3), in contrast to the clear-sky condition which typicaly shows low optical thickness (less than 0.1) and high Angstrom exponent. The size distribution obtained from a ground-level sky-radiance observation under KOSA-loaded airmass conducted in Anmyong-do, Korea, shows the dominance of larger particles (1-3 micro m in radius), explaining the low Angstrom exponent. Aerosol optical thickness at shorter wavelength region (443 and 555 nm bands) is also estimated for sampled area of 5 different scenes, assuming nominal or minimum water-reflectances. The results show that the Angstrom's law does not well approximate the spectral dependency of the Asian dust aerosol optical thickness, probably due to the absorption in shorter wavelength region. The study also discusses the applicability of the Asian dust aerosol model parameters proposed by the authors.

LONG-TERM MONITORING OF URBAN AND MARITIME AEROSOL FEATURES WITH MULTI-WAVELENGTH SUNPHOTOMETERS

Jinli LIU, Fang Li, Daren Lu (all at Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029, CHINA, e-mail: jliu@linux2.iap.ac.cn, ludr@sun.ihep.ac.cn)

It is well recognized that the radiative forcing of atmospheric aerosols is a significant uncertainty to climate change prediction. Owing to the complicity of aerosol features and inevitable spatial and temporal variation, remote sensing of aerosol features by both space-borne and ground-based instruments is essential for understanding the function of aerosols in climate radiative forcing. Long-term monitoring of aerosol features at two ground stations are being made with multi-wavelength sun-photometers. The stations are one in Shanghai typical for urban area, and the other in a small island in East China Sea far from continent, typical for maritime atmosphere. The instrument is a ten-wavelength sun-photometer ranging from 400-1000nm. Observations are made for direct solar observation and zenith observation. From these observation, spectral optical depth can be derived at first. With some assumptions and combined with data of zenith observation, the knowledge of aerosol size distribution and single scattering albedo could be obtained. In this paper, results of observation at two sites will be presented and emphasized the difference of urban and maritime aerosols.

SIMULATION AND OPTIMAL PARAMETRIZATION OF AEROSOL OPTICAL PROPERTIES

Alexandr V. Vasilyev, Yuriy M. TIMOFEYEV (both at Research Institute of Physics, St.Petersburg State University, Ulyanovskaya 1, St.Petersburg-Petrodvorets, 198904 Russia, e-mail: tim@troll.phys.spbu.ru)

Statistical approach to modelling the atmospheric aerosol optical characteristics is presented. This approach is based on applying the different recent models of atmospheric aerosol and modelling the aerosol variability by the Monte-Carlo method. Examples of constructing the statistical models of vertical profiles of attenuation coefficients of stratospheric background aerosol are given. These models take into account an aerosol composition (sulfuric acid particles, meteoric dust, two-layer particles with meteoric dust core in sulfuric acid coat) and different correlations (between an aerosol concentration and temperature gradient, between a concentration of sulfuric acid aerosol and SO2 content, etc.).
Different methods of parametrization of vertical and spectral distribution of aerosol attenuation coefficients applied in solving the atmospheric remote sensing problems are examined. Optimal parametrization method basing on the expansion of covariance matrix of aerosol attenuation coefficients in the eigenvectors is proposed. Number of the expansion terms necessary to achieve a preassigned approximation accuracies is determined.
Results of estimating the accuracies of different parametrization methods through numerical experiments are given.

SCIENTIFIC 'NUCLEAR WINTER' PICTURE AND BYRON'S APOCALYPTICAL CLAIRVOYANCE

ANZOR GVELESIANI (Institute of Geophysics, Georgian Academy of Sciences, 1, M. Alexidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com)

The materials of the numerical calculations of the "nuclear winter" model both of American and Soviet scientists represented on the Interantional Meeting (Tbilisi, 27th October, 1983) and other meteorological data and materials related to the global volcanic eruptions consequences manifesting themselves in the form of "year without summer" are analysed. The picture of the "year without summer" in detail described in Byron's famous poem "Darkness" and his journals written in a year after Tambora volcano eruption (April, 1815) almost identically coincides with the "nuclear winter" scenario obtained by the scientists. These results represent an interest in the light of the complex geophysical problems: climate change, volcanic eruptions consequences, climate effects of aerosols, "nuclear winter", etc.

ATMOSPHERIC AEROSOL LOADING 1979 -1999

R.G. GRAINGER and S.M. Wheaton (University of Canterbury, email: r.grainger@phys.canterbury.ac.nz)

This paper presents preliminary results on a project to create an history of aerosol loading in the atmosphere for use in quantifying the effect that aerosols have on the Earth's climate and ozone layer. The need for such a database because the modulation of climate by volcanic eruptions and other episodic events must be accounted for in efforts to detect trends associated with greenhouse gases or other anthropogenic climate forcing. The database is being constructed from measurements by the Advanced Very High Resolution Radiometer (AVHRR), the Stratospheric Aerosol and Gas Experiment (SAGE) I&II, the Cryogenic Limb Array Etalon Spectrometer (CLAES), the Halogen Occultation Experiment (HALOE), the High Resolution Doppler Imager (HRDI), the Improved Stratospheric and Mesospheric Sounder (ISAMS) and the Microwave Limb Sounder (MLS). These instruments offer a unique insight into volcanic clouds as they provide global observations of two of the largest eruptions this century, those of El Chichón and Mt Pinatubo, as well as several smaller eruptions. The database will contain aerosol properties of: composition, effective radius, surface area density, volume density, and multi-wavelength extinction.

NUMERICAL CALCULATION OF THE SPECTRAL AEROSOL OPTICAL DEPTH USING DATA ON INTEGRAL IRRADIANCE OF THE DIRECT SOLAR RADIATION

Vazha AMIRANASHVILI (Geophysics Institute of Georgian Academy of Sciences, 1. M. Aleksidze Str., Tbilisi 380093, Georgia, email: vazha@excite.com)

The determination of the wavelength dependence of the atmospheric aerosol optical depth represents one of important problems of atmospheric optics. A method for the numerical calculation of the spectral distribution of the aerosol optical depth is described in the work. This method is based on the solution of the non-linear integral equation of the radiation transfer, in which spectral aerosol optical depth is considered an unknown function. This equation belongs to s.c. ill posed problems and was solved in two stages. At the first stage the non-linear integral equation was reduced to a sequence of linear integral equations, while at the second stage the latter equations were solved using known methods of regularisation. A uniform convergence of the sequence of solutions of the linear equations to a solution of the non-linear equation is proved. Test calculations showed a good agreement with actual observational data on spectral aerosol optical depth.

RELATIONSHIP BETWEEN OBSERVATIONAL INFORMATION AND EACH PARAMETER OF AEROSOL PROPERTIES

Sonoyo MUKAI, Itaru Sano and Yasuhiko OKADA (Fac. of Sci. & Tech., Kinki University, Higashi-Osaka,Osaka 577-8502, JAPAN. E-mail: mukai@im.kindai.ac.jp)

This paper treats with inverse problems to estimate aerosol characteristics from the space borne data. The second generation of ocean color sensors,e.g. ADEOS/OCTS and POLDER, provide us with multi-spectral and Multi-directional measurements. Furthermore POLDER is the first sensor on board the satellite aimed to measure polarization by the Earth surface-atmosphere system, and performed multi-angle viewing of one target. Simply speaking, four kinds of observational information such as directional and spectral measurements of radiance and those of polarization are available to retrieve aerosol properties.
Aerosol models are described by the size, composition, concentration and shape. Our retrieval algorithm comes from an idea that aerosol properties over the ocean can be estimated in terms of multiple scattering behavior in the atmosphere-ocean system in the near infrared wavelengths. Here we focus on what kind of observational information is the key factor for retrieval of each parameter of aerosol characteristics. As a result effective aerosol retrieval is performed. Then the obtained aerosol models are applied for atmospheric correction of the ocean color data in the visible wavelengths.

MI09/W/07-A5 Poster **1145-10**

LIDAR AND SATELLITE STUDIES OF UPPER TROPOSPHERIC AEROSOL

G.S. KENT and G.M. Hansen (both at Science and Technology Corporation, Hampton, Virginia 23666, USA, email: g.s.kent @larc.nasa.gov) and C.R. Trepte (Atmospheric Sciences Division, NASA Langley Research Center, Hampton, Virginia, USA)

The SAGE II satellite experiment has been used for several years to study the seasonal and global characteristics of upper tropospheric aerosols (for altitudes above 6 km). SAGE II data have been extensively validated for the stratosphere. Validation of similar measurements for the upper troposphere are made difficult by the presence of cloud, and few data intercomparisons have been made. Moreover, SAGE II data are inverted under the assumption of horizontal homogeneity, a condition that normally does not hold for the troposphere. We report recent measurements of upper tropospheric aerosols made using a ground based scanning lidar system. The objective of these measurements was to examine the possibility of obtaining (1) values for the aerosol extinction for direct comparison with the SAGE II measurements, and (2) information about the horizontal and vertical aerosol structure, in order to assess the implications for the SAGE II data inversion and validation. Preliminary data analysis indicates that accurate determination of the aerosol optical depth (~0.01) in the upper troposphere may be limited by the signal-to-noise ratio and the linearity of the lidar system. Analysis of the changes in backscattered signal intensity with direction and time show that measurement of the horizontal and vertical structure size is possible. An experimental case study showed aerosol layering with vertical and horizontal structure sizes of the order of 1 and 10 km respectively.

A PRECISION FILTER RADIOMETER FOR AEROSOL OPTICAL DEPTH DETERMINATION

CH. WEHRLI and C. Fröhlich (both at Physikalisch-Meteorologisches Observatorium Davos, Dorfstrasse 33, 7260 Davos Dorf, Switzerland)

We describe a newly developed Precision Filter Radiometer (PFR) for determination of aerosol optical depth at 4 wavelengths of 862, 500, 412 and 368nm. These instruments are used in a world wide-wide network being built up under the GAW program of WMO. They are radiometrically calibrated by source- and detector based methods in order to tie their sensitivities to traceable standards. Their stability is verified by periodic recalibrations. Exoatmospheric signal calibration values, needed to derive optical depth from irradiance measurements, are determined by Langley extrapolation from a high altitude station and, for one instrument, by a stratospheric balloon flight. First results on the internal consistency of calibrations and the accuracy of optical depths determination will be reported.

DIRECT RETRIEVAL OF AEROSOL RADIATIVE FORCING IN THE SOLAR SPECTRAL REGION: EFFECT OF DIFFERENT PHASE FUNCTIONS

TH. HEINEMANN and J. FISCHER Freie Universitaet Berlin Institut fuer Weltraumwissenschaften Fabeckstrasse 69 14195 Berlin Germany

Aerosol radiative forcing is a key parameter for climate modelling. A global estimation of aerosol radiative effects from satellite sensor data will surely reduce the uncertainties in climate models. The largest direct climatic effect of aerosol is the backscattering of solar radiation to space. Common aerosol remote sensing methods using the backscattered radiation over known surface to estimate aerosol parameters like the optical depth and the aerosol size distribution. Since there is no method to get information about absorption by aerosol particles from nadir viewing sensors, the accuracy of aerosol optical depth retrieval is drastically reduced when absorbing aerosol are present . The change of upward radiative flux at top of atmosphere integrated over the solar spectrum can be derived from retrieved optical aerosol parameters with means of a radiative transfer model. On the other hand the change of upward flux can be derived directly from the measured radiance. The later method is much less sensitive to aerosol absorption. A method for the direct retrieval of upward radiative flux over open ocean water from measurements in the red and near infrared spectral region has been developed using the radiative transfer model MOMO. The retrieval scheme has been successfully applied to MOS-B data. The remaining problem is the unknown phase function. In this paper the effects of phase function change on the direct retrieval of upward flux are discussed. Radiative transfer simulations for 10 different aerosol types and aerosol optical depths between 0.0 and 0.5 were performed for 560 combinations of sun and viewing geometries which represent the whole range that can be observed from a polar orbiting satellite.

STATISTICAL ANALYSIS OF PHASE MATRICES OF ATMOSPHERIC AEROSOLS

Alex A. KOKHANOVSKY (Institute of Physics, 70 Skarina Avenue, Minsk 220072, Belarus e-mail: a.kokhanovsky@ieee.org)

Microphysical and chemical properties of the background atmospheric aerosol vary with space and time. However, changes in optical properties (e.g., phase matrices) at some observation geometries can be not so prominent. The task of this presentation is to study the variablity of the elements of the phase matrix of atmospheric aerosols as functions of the scattering angle. The statistical ensemble of phase matrices was obtained with the Mie theory for effective radii of aerosol particles in the range 0.1-1.5 micrometers. The data obtained were used as an input for the correlation analysis of the statistical ensemble. Average values, coefficients of variance and skewness were calculated. It was found that phase matrices of the atmospheric aerosols only weakly depend on their microstructure at the scattering angle around 150 degrees, which can be used in satellite retrieval algorithms.

POTENTIAL IMPACT OF DESERT-DUST CLOUD INTERACTIONS ON PRECIPITATION FORMING PROCESSES

Rohen LAHAV (Atmospheric Sciencs, The Hebrew University of Jerusalem, Israel Daniel ROSENFELD (Atmospheric Sciencs, The Hebrew University of Jerusalem, Israel.
e-mail:daniel@vms.huji.ac.il)

Microphysical measurements in convective clouds developing in a heavy dust storm over the eastern Mediterranean were made by remote sensing from satellite and in situ by cloud physics aircraft. Clouds forming in the desert dust had smaller droplets The satellite inferred effective radius of cloud particles was much reduced in clouds developing in the dust, as compared to nearby clouds developing in visibly dust free air. The dust reduced the effective radius to below the precipitation threshold of 15 micron.
Aircraft measurements were made in clouds forming in heavy dust. The dust reached the flight level of 3 km, from which the ground was completely obscuring by the dust. Vigorous convective elements, with base at 8C, reached temperature of -20C with more than 3 g/m**3 supercooled liquid water contents, with some dendrite crystals and graupel. No evidence for warm rain processes was evident.
These aircraft measurements corroborate the satellite inferences, and suggest that desert dust might be detrimental to precipitation forming processes. That raises the concern of a feedback mechanism for desertification: Dust causes clouds to precipitate less. The drier conditions lead to even more dust, closing the feedback loop.

OBSERVATIONS OF THE GLOBAL DISTRIBUTION...

Franklin MILLS (Division of Geological & Planetary Science, MS 170-25, California Institute of Technology, Pasadena, CA 91125, e-mail: FPM@mercu1.gps.caltech.edu)

Observations of the global distribution and composition of aerosol and cloud particles are needed to understand the radiative forcing effects of aerosols and their influence on global climatic change. Satellite measurements of aerosol distributions most commonly have been derived from visual and near-infrared measurements, such as those by the Stratospheric Aerosol and Gas Experiment (SAGE) and the Advanced Very High Resolution Radiometer (AVHRR). As shown by previous studies, the 750 - 3000 cm range also has potential for providing information on aerosol distributions and composition. Solar occultation spectra recorded by the Atmospheric Trace Molecule Spectroscopy (ATMOS) Fourier Transform Infrared (FTIR) spectrometer for this wavelength range have been examined to quantify the distribution of sulfate aerosols during the 1992, 1993, and 1994 ATLAS missions.
The ATMOS FTIR collected 4600 spectra during more than 300 occultations with excellent signal-to-noise at spectral resolution of 0.01 cm and vertical resolution of 2 - 4 km. These spectra were first processed to determine the vertical profiles of trace molecules for each occultation. Subsequently, the broad absorption features present in the 800 to 1400 cm spectra were examined to retrieve vertical profiles of sulfate aerosols in the lower stratosphere and upper troposphere. The aerosol distributions derived from our initial analyses are consistent with those published based on data from other instruments, such as the Cryogenic Limb Array Etalon Spectrometer (CLAES) on the Upper Atmosphere Research Satellite (UARS). The possible presence of water ice absorption features has been indentified in some spectra, and further analysis of spectra collected at shorter wavelengths is in process to quantify the water ice distributions. Corrections for collision-induced absorption by O_2 and N_2 are also being implemented to increase the wavelength range that may be examined in search of aerosol absorption features.

A SATELLITE STUDY OF THE LATITUDINAL VARIATION IN THE SMOKE INDIRECT EFFECT OVER TROPICAL SOUTH AMERICA

J.Ramaprasad, L.Remer and Y.Kaufman, Code 913, Laboratory for, Atmospheres, NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA

Analysis of several Advanced Very High resolution Radiometer (AVHRR) images over the Amazon Basin and Cerrado show that the effect of smoke on cloud drop sizes and cloud reflectances varies with latitude. The effect is strongest in the North and much weaker as we move South. Kaufman and Fraser (1997) suggested that this variation in the signal may be linked to variations in the precipitable water vapor in the atmosphere. We analyze model derived precipitable water vapor fields along with satellite signals of smoke optical thicknesses and cloud properties to examine the interactions between these variables. We find higher levels of precipitable water vapor as well as more uniform fields toward the north that could support the hypothesis. We also find that smoke optical thicknesses are negatively correlated with the water vapor levels. Interaction effects of smoke and precipitable water vapor on the magnitude of the indirect effect are to be examined.

OPTICAL CHARACTERISTICS OF AEROSOLS DERIVED WITH TWO STATE OF THE ART SKY RADIOMETERS

G. Pandithurai (Department of Meteorology, University of Maryland, College Park, MD, 20742, USA, email: pandi@atmos.umd.edu); Rachel T. PINKER (Departmet of Meteorology, University of Maryland, College Park, MD, 20742, USA, email: pinker@atmos.umd.edu); Brent Holben (Laboratory for Atmospheres, NASAGoddard Space Flight Center, Code 913, Greenbelt, MD, 20771, USA, email: brent@spamer.gsfc.nasa.gov); Tamio Takamura (Atmospheric Radiation Section, Sensor/Atmospheric Radiation Division, Center forEnvironmental remote sensing (CEReS), ChibaUniversity,Chiba 263, Japan, email: takamura@rsirc.cr.chiba-u.ac.jp) Shi'ichi Kaneta (Atmospheric Radiation Section, Sensor/Atmospheric Radiation Division, Center for Environmental remote sensing (CEReS), Chiba University,Chiba 263, Japan, email: kaneta@rsirc.cr.chiba-u.ac.jp)

Progress has been made in developing instruments with capabilities to provide most of the needed information on optical properties of aerosols. This led to the establishment of coherent programs to characterize aerosol properties at numerous stations over the globe, of climatic importance (e.g., the AERONET program). The instrument selected for this effort is the automatic sun tracking photometer produced by CIMEL ELECTRONIQUE. In parallel, an observing network is being established in Asia, in support of remote sensing research related to observations to be made in the framework of the Japanese Global Imager (GLI) instrument on the Advanced Earth Observing Satellite (ADEOS) II mission, as sponsored by the National Space Development Agency of Japan (NASDA). The sun tracking photometer selected for this effort is the sky radiometer model POM-01L, produced by PREDE Inc. Results will be presented from an effort to intercompare the performance of these two radiometers at one midlatitude location. Use has been made of the SKYRAD.PACK code, as developed by T. Nakajima, to infer the various aerosol optical properties.

NORTH ATLANTIC AEROSOL RADIATIVE IMPACTS BASED ON SATELLITE MEASUREMENTS AND AEROSOL INTENSIVE PROPERTIES FROM TARFOX AND ACE 2

Robert W. BERGSTROM (Bay Area Environmental Research Institute, San Francisco, CA 94122 USA, email: bergstro@sky.arc.nasa.gov,); Philip B. Russell (NASA Ames Research Center, Moffett Field, CA 94035-1000 USA, email: prussell@mail.arc.nasa.gov)

We estimate the impact of North Atlantic aerosols on the net shortwave flux at the tropopause by combining maps of satellite-derived aerosol optical depth (AOD) with model aerosol properties. We exclude African dust, primarily by restricting latitudes to 25-60 N. Aerosol properties were determined via column closure analyses in two recent experiments, TARFOX and ACE 2, as described by Russell et al. (this conference). The analyses use in situ measurements of aerosol composition and air- and ship-borne sunphotometer measurements

of AOD spectra. The resulting aerosol model yields computed flux sensitivities (dFlux/dAOD) that agree with measurements by airborne flux radiometers in TARFOX. It has a midvisible single-scattering albedo of 0.9, which is in the range obtained from in situ measurements of aerosol scattering and absorption in both TARFOX and ACE 2. Combining seasonal maps of AVHRR-derived midvisible AOD with the aerosol model yields maps of 24-hour average net radiative flux changes at the tropopause. For cloud-free conditions, results range from –9 W/m2 near the eastern US coastline in the summer to –1 W/m2 in the mid-Atlantic during winter; the regional annual average is –3.5 W/m2. Using a non-absorbing aerosol model increases these values by about 30%. We estimate the effect of clouds using ISCCP cloud-fraction maps. Because ISCCP midlatitude North Atlantic cloud fractions are relatively large, they greatly reduce the computed aerosol-induced flux changes. For example, the regional annual average decreases from –3.5 W/m2 to –0.8 W/m2. We compare results to previous model calculations for a variety of aerosol types.

VALIDATING ATMOSPHERIC CORRECTIONS TO SATELLITE OBSERVATIONS OF OCEAN COLOUR WITH MULTI-FILTER SOLAR PHOTOMETRY

J. DAVIES, B. Osborne, N. Santich and M. LYNCH (Remote Sensing and Satellite Research Group,School of Physical Sciences, Curtin University of Technology, GPO Box U1987, Perth, WA 6845, AUSTRALIA, email: jim@ra.clc.curtin.edu.au)

In October 1998 a Yankee Environmental Systems Multi-Filter Rotating Shadowband Radiometer (MFRSR-7) was installed at an offshore field station on Rottnest Island, some 18 km west of Fremantle in the Indian Ocean. The instrument was acquired primarily to provide validation data for atmospheric corrections applied to ocean colour data collected by the SeaWiFS satellite sensor. Under westerly flows, photometer measurements provide aerosol data on the maritime airmass through which SeaWiFS is viewing adjacent coastal waters. In this paper aerosol properties estimated from SeaWiFS channel radiances are validated against aerosol data products from the Rottnest Island MFRSR-7 solar photometer.

LONG-TERM MONITORING OF GLOBAL AEROSOL CHARACTERISTICS USING NOAA/AVHRR

Akiko HIGURASHI (National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki 305-0053, Japan, e-mail: hakiko@nies.go.jp); Teruyuki Nakajima and Takayuki Usui (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan, e-mail: teruyuki@ccsr.u-tokyo.ac.jp)

Aerosols are recognized to cause significant direct and indirect forcing on Earth's %fs climate. The evaluation of this effects, however, remains still highly uncertain for lack of our knowledge of aerosol characteristics on global and long-term scale.
We have developed the aerosol retrieval algorithm, which estimates aerosol optical thickness and !OgstrSN exponent using two channel radiance data of NOAA/AVHRR and have validated the results with ground-based observations. Retrieving !OgstrSN exponent addition to aerosol optical thickness has been shown to be very effective, as compared with past aerosol retrieval algorithm which obtains only aerosol optical thickness from one channel radiance assuming aerosol model, because it makes possible to distinguish the impact of human activities from that of natural aerosols represented by desert dust, and to estimate the number density of aerosol particles, which is very important to investigate the aerosol indirect effect.
We will report the global distribution of these parameters applying the algorithm to multi-year data sets of NOAA/AVHRR radiances. Preliminary analysis suggests increasing contribution of human emission of aerosols, especially off the east of Asia. Such long term analysis will indicate the natural and anthropogenic variabirities of aerosol properties.

SATELLITE REMOTE SENSING OF AEROSOL PROPERTIES IN COLUMN CLOSURE EXPERIMENTS

P. A. DURKEE, K. E. Nielsen (both at 1Naval Postgraduate School, Monterey, CA USA, Email: durkee@nps.navy.mil), P. B. Russell (NASA Ames Research Center, Moffett Field, CA USA), B. Schmid (Bay Area Environmental Research Institute, San Francisco, CA USA), J. M. Livingston (SRI International, Menlo Park, CA USA), D. Collins, R. C. Flagan, J. H. Seinfeld (all three at California Institute of Technology, Pasadena, CA USA), K. J. Noone, E. Öström (both at Stockholm University, Stockholm, Sweden), S. Gassó, D. Hegg (both at University of Washington, Seattle, WA USA), L. M. Russell (Princeton University, Princeton, NJ USA), T. S. Bates, and P. K. Quinn (both at NOAA PMEL, Seattle, WA USA)

Recent field programs designed to study aerosol properties have produced interesting contrasts across diverse regions of the globe. ACE-1 (Aerosol Characterization Experiment) observed conditions in the relatively unperturbed southern ocean near Tasmania in November-December 1995. The Tropospheric Aerosol Radiative Forcing Observational Experiment (TARFOX) observed aerosol transported of the North American coast over the Atlantic Ocean in July 1996. Most recently, ACE-2 measured the properties of aerosol from Europe and Northwestern Africa over the eastern North Atlantic Ocean in June-July 1997. The differences between these three regions are well observed by satellite remote sensing. The Advanced Very High Resolution Radiometer (AVHRR) aboard NOAA polar orbiting satellites measure radiance in five wavelength bands - two of which are sensitive to scattering by aerosol (Channel 1 - 0.63 µm and Channel 2 - 0.86 µm center wavelengths). Aerosol optical depth calculated for these first two channels of AVHRR and the radiance ratio of these channels can be used to parameterize size distribution properties. Retrieval of aerosol properties requires assumptions about the characteristics of aerosol number distributions, the absorption properties and vertical distribution of aerosol, surface reflectance, and others. This presentation will describe the array of airborne, surface, and shipboard data collected during field experiments that can be used to validate the satellite-based retrieval of aerosol properties. Analysis of aerosol size distribution, aerosol optical depth, scattering and absorption characteristics will be used to test the assumptions in satellite retrieval algorithms.

AEROSOL SIZE DISTRIBUTIONS, PROPERTIES AND VERTICAL PROFILES OVER THE PACIFIC: TOWARDS AN AEROSOL CLIMATOLOGY

CLARKE, A.D. and Kapustin, V. N., (Department of Oceanography, 1000 Pope Rd. Honolulu, HI 96822, USA, e-mail: tclarke@soest.hawaii.edu)

During the past decade we have participated in numerous ship and aircraft experiments throughout the Pacific. Measurements were made of size-distributions, physicochemistry, aerosol light scattering and absorption coefficients and other aerosol characteristics. Size distributions were obtained from 10 to 5,000nm dry particle diameter by using differential mobility analyzers and optical particle counters. This often included thermal analysis up to 300C that revealed volatile (eg. sulfates) and refractory (eg. dust, soot, sea-salt components) in real time. Variations in the smaller sizes reveal processes related to the formation and processing of aerosol while the larger sizes reveal features that dominate aerosol radiative effects and optical depth. Vertical profiles and horizontal legs in the marine boundary layer and the free troposphere were obtained for diverse regions. These included regions of clean air as well as regions influenced by "layers" or "rivers" of continental aerosol at various altitudes above the MBL. Sources included dust, biomass burning, continental pollution as well as natural emissions including volcanic sulfates and sea-salt. Current work in progress is designed to link some of these features and their optical influence to meteorological and climatological regimes over the Pacific.

COLUMN CLOSURE EXPERIMENTS OF AEROSOLS (CONT.)

MI09/W/15-A5 Invited **1500**

NORTH ATLANTIC AEROSOL PROPERTIES FOR RADIATIVE IMPACT ASSESSMENTS, DERIVED FROM COLUMN CLOSURE ANALYSES IN TARFOX AND ACE 2

Philip B. RUSSELL (NASA Ames Research Center, Moffett Field, CA 94035-1000 USA, email: prussell@mail.arc.nasa.gov); Robert W. Bergstrom and Beat Schmid (Bay Area Environmental Research Institute, San Francisco, CA 94122 USA, email: bergstro@sky.arc.nasa.gov, bschmid@mail.arc.nasa.gov); John M. Livingston (SRI International, Menlo Park, CA 94025 USA)

Aerosol effects on atmospheric radiative fluxes provide a forcing function that can change the climate in potentially significant ways. This aerosol radiative forcing is a major source of uncertainty in understanding the climate change of the past century and predicting future climate. To help reduce this uncertainty, the 1996 Tropospheric Aerosol Radiative Forcing Observational Experiment (TARFOX) and the 1997 Aerosol Characterization Experiment (ACE-2) measured the properties and radiative effects of aerosols over the Atlantic Ocean. Both experiments used remote and in situ measurements from aircraft and the surface, coordinated with overpasses by a variety of satellite radiometers. TARFOX focused on the urban-industrial haze plume flowing from the United States over the western Atlantic, whereas ACE-2 studied aerosols over the eastern Atlantic from both Europe and Africa. These aerosols often have a marked impact on satellite-measured radiances. However, accurate derivation of flux changes, or radiative forcing, from the satellite-measured radiances or retrieved aerosol optical depths (AODs) remains a difficult challenge. Here we summarize key initial results from TARFOX and ACE-2, with a focus on closure analyses that yield aerosol microphysical models for use in improved assessments of flux changes. We show how one such model gives computed radiative flux sensitivities (dF/dAOD) that agree with values measured in TARFOX and preliminary values computed for the polluted marine boundary layer in ACE-2. A companion paper (Bergstrom and Russell, this conference) uses the model to compute aerosol-induced flux changes over the North Atlantic from AVHRR-derived AOD fields.

AEROSOL RADIATIVE CLOSURE EXPERIMENTS FROM TARFOX: A COMPARISON OF THE MEASURED RADIATIVE PROPERTIES AND RADIATIVE FORCING WITH THOSE USED IN GLOBAL CLIMATE MODELS.

James M. HAYWOOD and Peter N. Francis (Meteorological Research Flight, UK Met Office, DERA, Farnborough, Hants, GU14 0LX, UK. Email: jmhaywood@meto.gov.uk, pnfrancis@meto.gov.uk)

A primary aim of the Tropospheric Aerosol Radiative Forcing Observational Experiment (TARFOX) is to obtain closure in terms of the modelled and measured radiances and irradiances. This study presents results from such a closure experiment and compares them with those using size distributions and optical parameters from global modelling studies which estimate the direct radiative forcing of anthropogenic aerosol species.
Two methods for determining the size distribution of the aerosols are used. The first method uses that measured directly by the passive cavity aerosol spectrometer probe (PCASP-100X), and the second is derived from observations of the spectral radiances measured using the Scanning Airborne Filter RadiomEter (SAFIRE). The results suggest that radiative closure can be obtained to within the experimental accuracy provided the aerosol size distribution is well determined. The PCASP-100X may significantly undersize aerosol particles as a consequence of the partially absorbing nature of the aerosols, and possibly due to partial drying of the aerosol within the instrument. A comparison of the measured radiative properties with those used in global calculations of the radiative forcing due to sulphate, organic and black carbon aerosols is also performed.

MEASURED AND CALCULATED CLEAR-SKY RADIATION PROFILES USING DETAILED AIRCRAFT AND LIDAR AEROSOL DATA

Manfred WENDISCH, Andreas Keil, Ulla Wandinger, Dietrich Althausen, Heike Wex and Doerthe Mueller (all at Institute for Tropospheric Research, Permoserstr. 15, 04318 Leipzig, Germany, email: wendisch@tropos.de)

Results of a columnar closure type field experiment (LACE'98: Lindenberg Aerosol Characterization Experiment) are discussed. The campaign was performed south of Berlin in August 1998. The measurements mainly aimed at a comprehensive characterization of microphysical and chemical aerosol properties and an improved understanding of related radiative effects. Beside ground-based measurements, several aircraft and lidar systems were involved.
The aircraft measurements were combined with multiwavelength lidar observations in order to derive precise profile information as input for the radiative transfer calculations. The in-situ aircraft aerosol measurements include size distribution, concentration in different size ranges (>3nm, >10nm, >100nm particle diameter) volume scattering (three wavelength nephelometer) and absorption (photometer) coefficients as well as impactor samples. These data were used for an in-situ volume closure between the scattering and absorption coefficients calculated from the aerosol size distribution via Mie theory and those directly measured by nephelometer and photometer. The lidar measures backscatter coefficients at six wavelengths between 355 and 1064 nm as well as extinction coefficients at 355 and 532 nm. From these measurements, effective particle radius, volume, surface area, and number concentrations are derived. The lidar data are compared with those calculated from the aircraft size distribution measurements.
With the vertical profiles of aerosol microphysical properties as input radiative transfer calculations were performed. The results of the calculations are compared with airborne broadband solar and ultraviolet irradiance measurements and spectral (500-900 nm, 2.4 nm resolution) irradiance data measured simultaneously at the ground.

AEROSOL OPTICAL PROPERTIES AND DIRECT SHORTWAVE RADIATIVE FORCING: DEPENDENCE ON SIZE AND COMPOSITION

Stephen E. SCHWARTZ (Environmental Chemistry Division, Brookhaven National Laboratory, Upton NY 11973 USA, e-mail: ses@bnl.gov); John A. Ogren (NOAA Climate Monitoring and Diagnostics Laboratory, Boulder CO 80303 USA, email: jogren@cmdl.noaa.gov); Michael H. Bergin (Civil and Envirnomental Engineering and Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta Georgia 30332 USA)

Direct shortwave radiative forcing of climate by an aerosol is the difference between top-of-atmosphere radiative flux in the presence of the aerosol and in its absence. The aerosol perturbation in radiative flux depends on the aerosol properties column extinction, the fraction of extinction that is scattered (single scattering albedo), and the angular distribution of light scattering, as well as the geophysical variables solar zenith angle, surface reflectance, and atmospheric transmittance above the aerosol. Aerosol optical properties depend on the size distribution of the aerosol (and shape, if non spherical) and real and imaginary components of index of refraction, which depend on composition. These properties are dependent on the source of the aerosol and its subsequent evolution in the atmosphere as modified by removal processes. Aerosol properties are thus not a constant but are variable, though they tend to be dominated by the most long-lived particles in the radius range 0.1 to 1 _m, which happens to be the most efficient size range for light scattering. For hygroscopic aerosols (which include dominant ionic species sulfates and nitrates) size increases strongly with increasing relative humidity greatly enhancing light scattering and radiative forcing. Unfortunately, for a variety of historical and instrumental reasons, aerosol properties are commonly measured and reported at low relative humidity, leading to underestimate of light scattering and radiative forcing unless properly accounted for. This talk reports measurements of aerosol properties pertinent to shortwave forcing and their implications on estimates of this forcing.

MI09/E/08-A5 Invited 1645

RETRIEVAL OF CLIMATE-RELEVANT AEROSOL PARAMETERS FROM TOP-OF-ATMOSPHERE (TOA) RADIANCE BY CLOSURES WITH GROUND-BASED SUN- AND SKY RADIANCE MEASUREMENTS

Wolfgang von HOYNINGEN-HUENE, Torsten Schmidt, John P. Burrows (IUP University of Bremen FB1, BO-Box 330440, D-28334 Bremen, email: hoyning@gome5.physik.uni-bremen.de) Ana-Maria Silva (Dept. of Physics, Universwity of Evora, P-7000 Evora, email: asilva@evunix.uevora.pt) Bringfried Pflug (DLR, Institute for Space Sensor Technique Berlin, Bringfried.Pflug@dlr.de) Teruyuki Nakajima (CCSR University of Tokyo, email: teruyuki@ccsr.u-tokyo.ac.jp)

The determination of realistic spectral features of the aerosol optical thickness from satellite data is one task to be solved for a determination of global aerosol data sets for different aerosol types and the observation of its variabilty in time and space. Comparisons between TOA radiances obtained a) by multi-channel satellite radiometers and b) by calculations from ground-based sun- and skyradiance measurements can be used for a validation of the aerosol parameters to be applied for the solution of the radiative transfer. Further they allow a determination of specific relationships between TOA-radiance and aerosol optical thickness for multi-channel sensors as OCTS/ADEOS or MOS-B/IRS-P3. This multi-channel approach reduces the errors in the determination of the the Angstoem turbidity parameters compared with the commonly used 2 channel approaches. Examples from ACE-2 CLEARCOLUMN (clean marine conditions) and the forst fire events in South East Asia in October 1997 demonstrate the applicability of such an approach.

MI09/W/16-A5 1710

IMPACT OF CENTRAL AMERICAN FIRES ON THE RADIATIVE BUDGET OVER THE ARM CART SITE

Xiang Li, Sundar Christopher, Joyce Chou and Ronald M. Welch (University of Alabama in Huntsville, Department of atmospheric science, Global Hydrology and Climate Center, Huntsville, AL 35899 USA, e-mail: xli@atmos.uah.edu)

Each year large amounts of biomass burning aerosols are released into the atmosphere, which influence the radiative energy budget of the earth-atmosphere system on both regional and global scales. During April and May 1998, large numbers of fires occurred over Central America, and the resultant smoke aerosols were observed to advect over North America.
In this study, using both satellite and ground-based measurements, the radiative impact of biomass burning aerosols at both the top-of-the-atmosphere (TOA) and at the surface are investigated over the U.S. Southern Great Plains (SGP) Cloud and Radiation Testbed (CART) site in the Atmospheric Radiative Measurement (ARM) program in Oklahoma. With knowledge of optical thickness of biomass burning aerosols from sunphotometer measurements made at the ground, single scattering albedos of the aerosols are retrieved from NOAA-14 Advanced Very High Resolution Radiometer (AVHRR) visible imagery. Then, with these optical properties of aerosols, shortwave radiative fluxes at both the TOA and surface are calculated using a radiative transfer model. The calculated surface fluxes then are compared with the Baseline Surface Radiation Network (BSRN) ground-based measurements; the calculated TOA fluxes are compared with the Clouds and Earh's Radiant Energy System (CERES) S8 ERBE-like product from the Tropical Rainfall Measuring Mission (TRMM) platform. The radiative forcings of biomass burning aerosols are estimated at both the TOA and at the surface.

ATMOSPHERIC MODELLING AND INTERCOMPARISONS

AMIP Overview

MC01/L/01-A1 0930

AN OVERVIEW AND UPDATE ON THE ATMOSPHERIC MODEL INTERCOMPARISONS PROJECT (AMIP)

Peter GLECKLER (Program for Climate Model Diagnosis and Intercomparison (PCMDI), Lawrence Livermore National Laboratory, PO Box 808, Livermore, California, USA Email: gleckler1@llnl.gov

AMIP is a standard experimental protocol for atmospheric general circulation models (AGCMs). It provides a community-based infrastructure in support of climate model diagnosis, validation, intercomparison, documentation and data access. The infrastructure that has been developed in support of AMIP enables a diverse community of scientists to analyze AGCMs in a systematic fashion, a process which serves to facilitate model improvement. Virtually the entire international climate modelling community has participated in this project since its inception in 1990. In this presentation an overview and status report of AMIP will be given.

MC01/E/30-A1 Invited 0945

EVALUATING THE OVERALL PERFORMANCE OF AMIP MODELS

Karl E. TAYLOR, Charles Doutriaux, and Peter J. Gleckler (all at the Program for Climate Model Diagnosis and Intercomparison, Lawrence Livermore National Laboratory, Livermore, CA 94550, U.S.A., email: ktaylor@pcmdi.llnl.gov)

Results from the Atmospheric Model Intercomparison Project (AMIP) are being archived in a common format and structure that facilitates efficient and comprehensive analysis of results. The procedure used to evaluate a single model's performance can be applied to all other models with little extra effort, resulting in an "economy of scale" which is one of the real benefits of model intercomparisons. Even with the advantages offered by a well organized and accessible data base, the enormous amount of model data produced by intercomparison projects like AMIP has made it difficult for comprehensive summaries of model results to be prepared. Recently, however, the Program for Climate Model Diagnosis and Intercomparison (PCMDI) has developed a capability, which continues to evolve, that can provide individual modelling groups with timely summaries of their model's performance. These summaries comprise both traditional plots showing how closely certain aspects of a simulation match observations and also innovative plots that can provide a more comprehensive statistical overview of model skill. These same diagnostic capabilities can be applied to monitor changes in the performance of models as they evolve. As an example, the performance of the most recent AMIP simulations ((ca. 1998) will be compared to that of earlier simulations (ca. 1992).

AMIP II Simulations

MC01/W/42-A1 1015

THE CGAM CLIMATE MODEL EXPERIMENT FOR AMIP-II A

O'Neill (1), W. A. Lahoz (1), J. Slingo (1), J. Cole (1), C. Jones (2) (1) CGAM, University of Reading, RG6 6BB, UK (2) Rossby Centre, SMHI, Sweden

As a contribution to the AMIP-II experiment, the Centre for Global Atmospheric Modelling (CGAM) has run a 17-year integration of a troposphere-stratosphere version of the UK Meteorological Office's Unified Model. The model has 58 levels in the vertical with a top at 0.08 hPa, and a horizontal resolution of 2.5 deg latitude by 3.75 deg longitude. The model contains the same parametrizations of physical processes (so-called HADAM3 physics) as the AMIP-II runs contributed by the Hadley Centre, with the additional feature that the CGAM version has a well-resolved stratosphere. Seasonally varying sources for trace gases were placed at the equatorial and polar tropopause in order to determine the large-scale circulation and mixing processes in the model. A detailed comparison of fields from this experiment will be made with ERA-15 analyses, focusing on the ability of the model to represent aspects of the seasonal evolution, and intraseasonal and interannual variability. Comparison of results with those obtained by the Hadley Centre will be made to determine the benefits of including a well-resolved stratosphere, particularly in the region of the tropopause. It is shown that the simulated atmospheric structure in the upper troposphere and lower stratosphere is sensitive to the number and location of model levels in the stratosphere.

MC01/E/05-A1 1030

CLIMATE VARIABILITY IN THE HADLEY CENTRE MODEL

Henry BUCKLEY and Vicky Pope (both at Hadley Centre for Climate Prediction and Research, Met Office, London Rd., Bracknell, RG12 2SY, UK. Email: hbuckley@meto.gov.uk)

The aim of this study is to describe and validate the simulation of climate variability in the latest version of the Hadley Centre atmospheric climate model (HadAM3). Our model reproduces the mean climate well, and assessment of model variability provides an important and more stringent test of model performance. In climate variability studies a distinction is made between intrinsic variability (reflecting the internal chaotic behaviour of the system) and the systematic response to variable forcing. Ensemble runs provide a useful means of separating these components and studying them in isolation, and enable an estimate of the significance of

results based on single climate runs to be made. We have run an ensemble of six AMIP II integrations, which differ only in their initial atmospheric state; and a control run using climatological SSTs. We present a statistical analysis of the ensemble data, focusing on the spatial and seasonal dependence of the different components of variability, and validate our results against the ECMWF Reanalysis dataset.

MC01/W/40-A1 1115

AMIP II SIMULATION OF NCC CLIMATE MODEL

Zheng-Qing Ye Min Dong (National Climate Center, Beijing, 100081)

A 17-year integration in which the National Climate Center climate model is forced with observed monthly varying sea surface temperatures since 1979 is compared to reanalysis data and observed data. The results show that the model is able to reproduce the basic observed patterns of the pressure field and the properties of their seasonal pressure variations very well at sea level. The simulation can capture the Aleutian low, Icelandic low, Asian continent high in winter and their seasonal variations. On the other hand, the geopotential heights at 500 hPa and 300 hPa are quite well simulated. In winter, the troughs off the east coasts of Asia and North America, the trough over eastern Europe, the ridge over Russia and west coast of North America are simulated very well. In the wind fields, the simulation of jets and storm tracks is very similar to that of reanalysis data in both winter and summer. The location and amplitude of jets and storm tracks are in good agreement with the observed fields. In this paper, the atmospheric energy buget are also analyzed. Some striking results are given. Finally, the reasons for the differences between the simulation and observed data are also analyzed.

SEASONAL PREDICTABILITY EXPERIMENTS BY JMA AGCM

Shoji KUSUNOKI, Masato Sugi and Akio Kitoh (Climate Research Department, Meteorological Research Institute, Nagamine 1-1, Tsukuba, Ibaraki 305-0052, JAPAN,
Email: skusunok@mri-jma.go.jp) Chiaki Kobayashi and Kiyoharu Takano (Climate and Marine Department, Japan Meteorological Agency, 1-3-4 Ootemachi, Chiyoda-ku, Tokyo 100-0004, JAPAN, Email: chiaki_k@hq.kishou.go.jp)

A T63L30 resolution version of atmospheric general circulation model (AGCM) of the Japan Meteorological Agency (JMA) has been integrated for 4 months forced with the observed sea surface temperature (SST). The integrations were started from observed initial conditions of the European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analyses for all four seasons through the 15-years period of 1979-1993. Each ensemble consists of 9 members initiated from consecutive analyses 1 day apart. The skill of the ensemble simulations was evaluated over the extratropics and the tropics. The interannual variation of the boreal summer precipitation over India and Japan were not well simulated, while that over the Yangze river valley in China exceeded the 95% significant level of correlation with observation.

RESULTS FROM AMIP II: THE COLA GCM SIMULATION

C. Adam Schlosser, L. Marx, V. Krishnamurthy, D. Straus, J. L. Kinter III, and J. Shukla

For the AMIP II experiment, an 18-year simulation of the global circulation was performed with the Center for Ocean-Land-Atmosphere (COLA) general circulation model (GCM) using prescribed sea-surface temperatures (1979-1996). We present a summary of the performance of the COLA GCM at simulating the monthly, seasonal, and annual variability of the global climate. Selected regional analyses of the simulation are also presented, and will focus on the performance of the model at reproducing the observed spatio-temporal patterns of regional climate phenomenon (e.g. the India monsoon). Where applicable, the analysis is presented in the context of model development and attempts to identify sources of optimal performance that result from recent changes in the COLA GCM parameterizations.

OHMURAAMIP II SURFACE AND ATMOSPHERIC RADIATIVE FLUXES: SOME PRELIMINARY RESULTS

Gerald L. POTTER, Justin J. Hnilo, Martin Wild and Atsumu

AMIP provided us with an unprecedented yet incomplete data source for climate model evaluation. In the process of preliminary model intercomparison, we found significant systematic errors in short-wave cloud radiative forcing. Unfortunately, insufficient models data was saved to properly diagnose any detail about the discrepancies between the models and the observational data. AMIP II is providing the scientific community with a much more complete data set critical to investigating the large discrepancies. The original errors in net cloud forcing will be discussed along with analysis of the latest results from AMIP II. In addition, implications of the errors as they relate to the controversial anomalous absorption of short wave radiation in the atmosphere by clouds will also be presented. From preliminary analysis, very little improvement in AMIP II cloud forcing has been detected thus indicating that more accurate calculation of solar absorption in the atmosphere continues to be an elusive goal. Part of the error in cloud forcing may be incomplete understanding of atmospheric absorption by clouds and water vapor. Fortunately, new surface data observations taken from updated versions of the Global Energy Balance Archive (GEBA) set has become available to compare with atmospheric model surface fluxes. This study is an extension of the work by Wild and Ohmura and will compare the atmospheric absorption from AMIP II with the new GEBA data.

EVALUATION OF AMIP SIMULATIONS WITH TOVS/MSU

John BATES, Climate Diagnostics Center, NOAA/ERL - R/E/CD1, 325 Broadway, Boulder, Colorado 80303, USA, email: bates@cdc.noaa.gov Coauthors: Richard Engelen, Graeme Stephens, and Darren Jackson

The longest, global observations of the 3-dimensional temperature and moisture structure of the atmosphere has been provided by the TIROS Operational Vertical Sounder (TOVS) suite of instruments on the NOAA polar-orbiting satellites. Since 1979, the High-resolution Infrared Sounder (HIRS) and Microwave Sounding Unit (MSU) instruments have taken radiance observations of the mean layer temperature and moisture structure of the troposphere and lower stratosphere. Traditionally, these radiance observations are inverted to provide profiles of temperature and moisture. The inversion process, however, is ill-conditioned and conditioning the inversion requires a first-guess solution that creates complex and systematic errors in the retrieved profiles. The TOVS Radiance Pathfinder, in collaboration with this experimental subproject, has taken a different approach to producing climate products from the TOVS data. We are producing climate products from the raw radiance data and then comparing these observations with equivalent radiances computed from the AMIP-II simulations. In this presentation, the TOVS Radiance Pathfinder procedure will be outlined. This will include a discussion of instrument calibration and intercalibration, limb correction, and cloud detection and removal. The procedure for computing radiances from GCM simulations will also be outlined with particular emphasis on how to sample the GCM similar to how the NOAA satellites sample the earth. Initial results of comparisons between AMIP-II results from several modelling groups will be presented. A strategy for a 4-dimensional fingerprinting technique using the TOVS Radiance Pathfinder data and AMIP-II results will also be discussed.

MC01/W/62-A1 1430

NOAA/NASA PATHFINDER LARGE SCALE HIGH RESOLUTION RADIATIVE FLUXES

Rachel T. PINKER (Department of Meteorology, University of Maryland, College Park, MD 20742, USA, email: pinker@atmos.umd.edu) Banglin Zhang (Department of Meteorology, University of Maryland, College Park, MD 20742, USA, email: zhang@atmos.umd.edu) Istvan Laszlo (Department of Meteorology, University of Maryland, College Park, MD 20742, USA,
email: laszlo@atmos.umd.edu)

Under the joint NOAA/NASA PATHFINDER activity, uniform, long term data sets from observations made from numerous satellites, are being prepared into homogeneous time series. Some of these data are processed into reduced resolution, multi-satellite, global coverage information, while others are available independently for each satellite from which the observations have been made (e.g., two from the United States (GOES), one European (METEOSAT), one Japanese (GMS), and several polar orbiting satellites). These observations are sampled at about 30 km, have temporal resolution of three hours, and are known as ISCCP DX data. The ISCCP DX data are of particular interest to scientists working on land-atmosphere interactions and hydrologic modelling due to their relatively high spatial resolution, representation of the diurnal cycle, and long term availability. They can also be considered as precursors to data streams anticipated under the EOS missions, such as the Clouds and the Earth's Radiant Energy System (CERES) and the Moderate Resolution Imaging Spectrometer Activity (MODIS). We will present an update as to the scope of radiative fluxes currently available under our PATHFINDER activity, as well as evaluation of the data, and efforts underway, to merge the information from the independent satellites.

MC01/W/02-A1 1445

EVALUATION OF NCEP GDAS AND AMIP-II REANALYSIS RADIATIVE FLUXES WITH CERES/ERBE MEASUREMENTS

Shi-Keng YANG 1, Yu-Tai Hou2, Ken Campana 3 and A. J. Miller 3. 1,RDC/Climate Prediction Center/NCEP/NOAA 2,GSC/Environmental Prediction Center/NCEP/NOAA 3,National Centers for Environmental Prediction/NOAA

The first 8 months measurements of TOA radiation fluxes from CERES/TRMM operation provides valuable information for evaluating the performance of NCEP Global Data Assimilation System (GDAS), which upgrades its shortwave radiative transfer parameterization during the same period. The upgrade was prompted from studying the earth radiation budget of NCEP/NCAR Reanalysis project, in which it was revealed that the global model excessively reflects solar radiation by 10%. Also the global insolation on the surface are more than 12% overestimated. Inadequacy in surface albedo was also found. A new parameterizations includes a shortwave radiative transfer code based on Chou (1992 and 1995), which contains multi bands in the ultra-violet, visible , and near infrared spectral regions is adopted for the improvement. The absorption and scattering by water vapor, ozone, CO2, O2, and those by clouds and aerosols are included. For preserving computational efficiency, Delta-Eddington approximation and two- stream adding scheme are used. The surface albedo scheme of Briegleb et al. (1986) with 14 surface types are implemented. Four components of the surface albedo in the direct and diffuse radiation in the UV-VIS, and near-IR regions are computed. The seasonal variations of the diffused components are derived from the clear sky ERBE data. The new parameterization was first subjected to a series of sensitivity tests, and later implemented for operational GDAS and NCEP/DOE AMIP-II Reanlaysis. Evaluating of its accuracy, as well as its impacts on the dynamics, shows significant improvements in the radiative fluxes. Biases of the surface albedo over ocean and deserts are significantly eliminated as compared to Staylor‘s estimate using ERBE data (1990). Under-estimation of reflected shortwave at TOA is greatly reduced for most of the latitudes, except at the poles as compared to ERBE. The model forecast moisture is sensitive to the changes of the SW parameterization. Maximums are located near the surface for the control run, and are lifted to about 950mb for the experimental run. Temperature near the tropopause increases about 1.5 0C for the summer hemisphere, yet stays fairly constant near 500mb. In response to the warmer temperatures near the tropopause, the jetstreams are shifted pole-ward accordingly. Radiation fluxes from the operational NCEP GDAS are being inter-compared with CERES observations. The preliminary result from OLR shows that the new model substantially reduced the bias in the tropics. Global time series shows a significant reduction of TOA reflected solar flux by ~ 10 W/M**2, which is a very fine improvement. Details of the model accuracy is to be further evaluated.

MC01/W/22-A1 1500

COMPARISON ANALYSES OF GLOBAL SHORTWAVE RADIATION BUDGETS FROM REANALYSIS AND MULTIPLE SATELLITE PROJECTS

Alexander TRISHCHENKO and Zhanqing Li Canada Center for Remote Sensing

Almost seven years of satellite global radiation budgets are available from ERBE (1985-1990), ScaRaB(1994-95) and CERES(1998) projects. They are compared to the product derived from the framework of NCAR/NCEP REANALYSIS project. The surface radiation budget (SRB) fields are stimated from satellite observations with comprehensive validation against surface measurements from several networks. Agreement and disagreement are analysed for different climatic regimes.

MC01/W/33-A1 1515

IMPACT OF AN IMPROVED LONGWAVE RADIATION MODEL, RRTM, ON THE ENERGY BUDGET AND THERMODYNAMIC PROPERTIES OF THE NCAR COMMUNITY CLIMATE MODEL, CCM3

M

M. J. Iacono, E. J. Mlawer, S. A. Clough Atmospheric and Environmental Research, Inc. Cambridge, Massachusetts, 02139

The effect of introducing a new longwave radiation parameterization, RRTM, on the energy budget and thermodynamic properties of the National Center for Atmospheric Research (NCAR) Community Climate Model, CCM3, will be presented. RRTM is a rapid and accurate k-distribution radiative transfer model that has been developed for the ARM program. Among the important features of RRTM are its connection to radiation measurements through comparison to the extensively validated line-by-line radiative transfer model, LBLRTM, and its use of an improved and validated water vapor continuum model. Comparisons between RRTM and the CCM3 longwave (LW) parameterization have been performed for a multi-year climatological SST simulation and a 15-year AMIP simulation using the full CCM3 climate model. RRTM produces an enhancement of LW absorption that is partly due to its use of the CKD_2.3 water vapor continuum model. This reduces the clear sky global average outgoing longwave radiation (OLR) by 8-10 W/m2 and reduces the total sky OLR by 2-4 W/m2. Downward surface LW fluxes are increased by as much as 8-10 W/m2 at high latitudes. The LW tropospheric cooling rate is most significantly impacted at low and mid-latitudes. Greater cooling is noted in the upper troposphere, while less cooling is produced near the surface. This causes a general increase in temperature lapse rate that is shown to affect the thermodynamic properties of the climate model. In terms of computational cost, RRTM is competitive with the current CCM3 LW model while providing enhanced accuracy. RRTM is currently being tested for adoption as a new LW model for CCM4 and for the ECMWF weather forecast model.

Sensitivity and Computational Studies

MC01/E/28-A1 1600

STORM TRACKS IN THE HADLEY CENTRE CLIMATE MODEL - SENSITIVITY TO RESOLUTION

Vicky POPE, Henry Buckley (Hadley Centre for Climate Prediction and Research, Met Office, London Rd., Bracknell, RG12 2SY, UK. Email: vdpope@meto.gov.uk)

The aim of this study is to diagnose and ultimately improve the representation of storm tracks in the Hadley Centre climate model. Most climate models have coarse resolution and can only represent storms very crudely. A likely way of improving the representation of storms is therefore to increase model resolution. We have a series of atmosphere only integrations of HadAM3 (the latest version of the Hadley Centre climate model) made for the AMIPII project which can be used to assess the model climatology and the impact of increasing resolution: Name latitude longitude no. of no. of resolution resolution levels integrations (deg) (deg) SRES 2.5 3.75 19 6 VRES 2.5 3.75 30 3 MRES 1.25 1.875 30 2 HRES 0.888 1.25 30 2 The standard model reproduces the broad climatology of observed storm tracks reasonably well. Increasing vertical resolution alone degrades agreement with climatology. Increasing horizontal resolution as well improves agreement. We use a range of diagnostics to assess the factors that influence these results; for example the relative importance of changes in the underlying background flow (such as a simple measure of baroclinicity) and more accurate respresentation of individual storms.

MC01/L/04-A1 1615

AN EXAMINATION OF THE SENSITIVITY OF A GCM TO A COUPLED AND UNCOUPLED MODE

Justin J. HNILO, James Boyle, Benjamin D. Santer and Gerald L. Potter (all at Program for Climate Model Diagnosis and Intercomparison, Lawrence Livermore National Lab, Livermore, CA, USA, Email: hnilo@pcmdi.llnl.gov) Allen S. Grossman (Atmospheric Sciences Division, Lawrence Livermore National Lab, Livermore, CA, USA, Email: grossman1@llnl.gov) Forcing Atmospheric General Circulation Models (AGCM) with prescribed Sea Surface Temperatures (SSTs) and sea ice in the hopes that the model will mimic observed atmospheric behavior is the emphasis of the Atmospheric Model Intercomparison Project (AMIP).

Results from participant modelling groups in AMIP I and II show that these prescribed boundary conditions appear to be sufficient in supplying enough information to an AGCM to allow it to reasonably represent recent atmospheric behavior. Some concerns have been raised about the use of prescribing SSTs in a model integration such as, the specified SST's might alter the spatial and or the temporal variability of the simulation compared to a coupled run and presumably reality. This effect is expected to be most prominent in the mid to high latitudes. Our research herein directly addresses this issue by using the SSTs from the Coupled System Model (CSM) run which is a fully coupled Ocean-Atmosphere General Circulation Model (OAGCM) as boundary conditions to force the identical atmospheric component alone. Quantifiable differences between the two runs will be attributable in part to the use of prescribing SSTs (as a representation of the ocean) versus using a fully coupled (OAGCM) run. A simple and yet important question that we can quantify and answer is "Does the ocean component in this model act to diminish or enhance atmospheric variability when compared to a prescribed SST run and observations?". This research will highlight variables and regions of greatest magnitude and variability changes.

ELIMINATION OF COMPUTATIONAL SYSTEMATICAL ERRORS AND IMPROVEMENTS OF WEATHER AND CLIMATE SYSTEM MODELS IN RELATION WITH BAROCLINIC PRIMITIVE EQUATIONS

Qing ZHONG Institute of Atmospheric Physics, Chinese Academy of Sciences

Designing of a total energy conserving semi-implicit scheme for multiple-level baroclinic primitive equation remains unsolved for long. In this work, however, following an energy perfect conserving semi-implicit scheme of an ECMWF type sigma-coordinate primitive equation is recently successfully formulated, some real data experiments are conducted. Winter FGGE data test contrast between model of the new conserving scheme and that of an ECMWF type of global spectral semi-implicit scheme shows that RMS error of averaged forecast Height at 500mb can be improved clearly after the seventh integral day and the reduction can reach 40 percent to 60 percent within the tenth integral day and the thirtieth day. Further contrast test demonstrates that RMS error of monthly mean height in middle and low troposphere at the first, the second and even the third integral month also can be reduced largely and some well-known systematical defects can be improved greatly. More detailed analysis reveals that all these main positive contributions come from improvements of extra-long wave components. This indicates that a remarkable improvement of Model Climate Drift level can be achieved by the actual realizing of a conserving time-difference scheme which thereby eliminating a corresponding computational systematic error source/sink in the currently-used traditional type of weather and climate system models in relation with Baroclinic Primitive Equations.

MC01/W/59-A1 1645

HIGH PERFOMANCE PARALLEL COMPUTATION USING A REMOTE LINK LIBRARY IN A TCP/IP NETWORK FOR MODELLING

Ignatius KUNJUMON (Lecturer, School of Marine Sciences, Cochin University of Science and Technology, Lakeside campus, Cochin 682016, India; Email: atmos@md2.vsnl.net.in)

High performance computation can be achieved in a commonly available TCP/IP network. In this method multiple computers are taking part in the computation simultaneously and reducing the effective computation time. An example of a barotropic model is discussed in this paper in detail. First, the single processor program is converted to a parallel program. Then all time-consuming iterative functions have to be converted to remote library functions and be made available to the entire network, which is taking part in the computation. The main; controlling program running on one computer executes the model with the help of other computers. The effective computation time depends on the efficiency of the parallel algorithm, network communication speeds, and number of computers taking part in the computation. Since the speed of the network is increasing very fast compared to the speed of the CPU and TCP/IP networks are becoming more common, parallel computation in a TCP/IP network has greater application in high performance computation.

VALIDATION OF MEAN BOUNDARY-LAYER STRUCTURE IN ATMOSPHERIC GLOBAL CLIMATE MODELS

J.R. GARRATT, L.D. Rotstayn & P.B. Krummel (all at CSIRO Atmospheric Research, Aspendale, Vic.3195, Australia)

Vertical resolution in atmospheric global climate models (GCMs) has increased significantly in recent years, so that significant vertical detail within the atmospheric boundary layer can now be resolved, allowing field observations to be used for validation of model boundary-layer structure and diurnal behaviour. To illustrate, we focus on diurnal and seasonal variations in the boundary layer simulated in the 18-level CSIRO GCM. Observations from six well-documented field experiments allow for detailed comparisons of boundary-layer structure at five locations - two over (Koorin and Wangara) and three south of (Southern Ocean Cloud (summer and winter) Experiments and Atmospheric Chemistry Experiment) the Australian continent, and one (First ISLSCP Field Experiment) over the USA. Comparisons are made in both day-to-day variability and in the monthly-averaged boundary-layer properties. Overall, the results are very encouraging, with features such as (1) capping inversions, and implied boundary-layer heights, (2) height and thickness of cloud layers, (3) early morning temperature and humidity inversions overland, (4) diurnal variation of screen temperature, friction velocity and boundary-layer height, and the absolute values of boundary-layer temperature and humidity well simulated at most locations. As well as strengths, we are also able to identify weaknesses, including (1) unrealistic temperature profiles in the convective boundary layer due to the use of a simple first-order sub-grid turbulence closure scheme, (2 failure to resolve thin regions near the top of both clear-sky and cloudy boundary layers where vertical gradients are large.

MC01/W/19-A1 1715

EVALUATION OF REVISED AMIP I SOIL MOISTURE SIMULATIONS

Alan ROBOCK, G. Srinivasan, Lifeng Luo Department of Environmental Sciences Rutgers - The State University of New Jersey 14 College Farm Road New Brunswick, NJ 08901-8551 USA Konstantin Y. Vinnikov, University of Maryland

Previously, we determined that AMIP I simulations were quite different from each other, especially in the tropics. Models with 15-cm field capacities did not capture the observed large high latitude values of soil moisture. In addition, none of the models properly simulated winter soil moisture variations in high latitudes, keeping soil moisture constant, while observations show that soil moisture varies in the winter as much as in other seasons. The observed interannual variations of soil moisture were not captured by any of the AMIP models. Several models had large soil moisture trends during the first year or two of the AMIP simulations, with potentially large impacts on global hydrological cycle trends and on other climate elements. This is because the simulations were begun without spinning up the soil moisture to the model climatology. The length of time it took for each to reach equilibrium depended on the particular parameterization. Although observed temporal autocorrelation time scales are about 2 months, some models had much longer time scales than that. In particular, the 3 parameterizations based on the Simple Biosphere model (SiB) had trends in some regions for virtually the entire AMIP simulation period. Here we reexamine the simulations that have since been conducted with revised soil moisture schemes by a number of models, and compare them with those previously conducted with bucket models. We compare the simulations to observations in Russia, China, Mongolia, and Illinois, and determine if "improved" land surface schemes produce improved soil moisture simulations.

MC01/E/33-A1 1730

INCLUDING VEGETATION AND CO2 AS INTERACTIVE ELEMENTS IN GCM SIMULATIONS

Peter COX, Chris Jones, Richard Betts (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SY, UK, email: pmcox@meto.gov.uk) Ian Totterdell (Southampton Oceanography Centre, Empress Dock, Southampton SO14 3AZ, UK, email: I.Totterdell@soc.soton.ac.uk)

The land-atmosphere and ocean-atmosphere fluxes of carbon are known to be a strong function of climate, and the distribution and function of vegetation also varies directly in response to changes in atmospheric CO2. However, GCM simulations of climate change typically neglect feedbacks associated with vegetation and the carbon cycle, since they use prescribed CO2 concentrations and vegetation fixed at current distributions. The Hadley Centre is developing a coupled climate-carbon cycle model by including representations of the land and ocean carbon cycles in its modelling framework. The ocean component, "HadOCC", treats the chemical processes involved with the dissolution and outgasing of CO2, and includes important marine biological processes through a 4-compartment model. The terrestrial component, "TRIFFID", calculates the areal coverage and leaf area index of each of 5 plant functional types based on the carbon balance of each and on competition amongst the types. Details of the submodels will be presented, along with early results from the fully coupled system.

MC01/E/08-A1 1745

COMPARING SNOW SIMULATIONS FROM NCAR CCM3 COUPLED WITH TWO DIFFERENT LAND SURFACE PARAMETERIZATIONS: LSM AND BATS

Zong-Liang YANG and Guo-Yue Niu Institute of Atmospheric Physics, University of Arizona, Tucson, AZ, 85721, USA (phone: 1-520-621-8922, fax: 1-520-621-6833, E-mail: zly@stratus.atmo.arizona.edu)

Three research questions remain to be addressed. First, are the current general circulation model (GCM) snow schemes adequately simulating the snow processes? Second, are the available global data sets and the model output variables adequate to assess the simulations of snow in GCMs? Third, what are the processes responsible for different snow simulations? The snow simulations from the National Center for Atmospheric Research (NCAR) Community Climate Model Version 3 (CCM3) coupled with the Land Surface Model (LSM) and the Biosphere- Atmosphere Transfer Scheme (BATS) are compared with each other and with global data sets from various sources including the National Oceanic and Atmospheric Administration satellite data and the Nimbus-7 Scanning Multichannel Microwave Radiometer data. For both North America and Eurasia, LSM-BATS produces less snow mass than BATS-CCM3 during the snow season (November-April). Some of these differences can be attributed to different simulated precipitation, surface air temperature and ground heat fluxes resulting from the fully-coupled land surface-atmosphere interactions. Therefore, it is unknown how the different model structures in LSM and BATS directly affect the snow simulations. To isolate this direct impact, an intercomparison of both land models is also made in off-line mode (i.e. uncoupled to the CCM3) using the long-term snow cover and meteorological data from a grassland catchment at the Valdai water-balance research site in Russia. This data set has been used in the Project for Intercomparison of Land-surface parameterization Schemes (PILPS) Phase 2(d) in which BATS participates. This paper presents results from the models in their original structure, and also investigates the impacts of using different parameterizations for snow density, albedo and snow cover areal extent. Like the on-line simulations, the off-line runs also reveal that LSM predicts less snow mass than BATS, mainly because of two reasons. First, the iterative surface energy balance in LSM tends to predict higher surface temperature and greater snow melt. Second, more vegetation is allowed to exist outside the snowpack which results in lower surface albedo and more solar energy for melting snow.

HIGH-RESOLUTION SIMULATIONS OF THE GLOBAL CLIMATE - VALIDATION OF MONSOON SYSTEMS OVER SOUTH AMERICA AND SOUTHWEST U.S.

Andrea N. HAHMANN (Institute of Atmospheric Physics, University of Arizona, Tucson, AZ 85711, Email: hahmann@atmo.arizona.edu), Rong Fu and Robert E. Dickinson (both at Institute of Atmospheric Physics, University of Arizona, Tucson, AZ 85711).

Research over the past decade has demonstrated that sub-grid scale spatial heterogeneities in soil moisture, precipitation, and vegetation cover have substantial effects in determining surface evapotranspiration, runoff, and other surface properties coupled to atmospheric climate. Many of these processes occur on spatial scales too fine to be resolved by most current climate models. This paper will present the validation of a fine-mesh global model (CCM3/HRBATS) which explicitly includes spatial heterogeneities. Severe problems in the simulation of the hydrological cycle have been diagnosed with the standard model (CCM3) at T42 resolution for the main monsoonal regions of the Americas. Over South America, simulations at T42 resolution show that north of the equator, the model simulates a double peak where observations indicate a single peak, and south of the equator, the model has too pronounced a dry season. Over the Southwest U.S., while the simulation of wintertime precipitation appears to improve with increased resolution, the southwest summer monsoon of Arizona and Northern Mexico is consistently underrepresented. This presentation describes the validation of the hydrological cycle produced by the standard and fine-mesh models over the Amazon and Southwest U.S. regions.

MC01/W/60-A2 0945

MONSOON AND VEGETATION INTERACTIONS-- A STUDY USING A COUPLED NCEP GCM/SSIB MODEL

Yongkang XUE (Department of Geography, University of Maryland, College Park, MD 20742,USA Tel: 301-405-4050; fax: 301-314-9299, email: yxue@geog.umd.edu); H. H. Juang, M. Kanamitzu, S.Y. Hong (all at Development Division, NCEP, NOAA, Camp Springs, MD); M. Hansen (Department of Geography, University of Maryland); S. Nicholson(Department of Meteorology, Florida State University, Tallahassee, FL)

A coupled NCEP GCM/SSiB (Simplified Simple Biosphere Model) model has been developed to investigate the interactions between land surface processes and climate, in particular the interactions between land and monsoon system. The NCEP global model is a forecasting model that is also used for climate studies. A version with spectral triangular 62 truncation (T62) is used for this study. The corresponding gaussian grid for T62 is 192 by 94, roughly equivalent to 2 degrees in latitude and longitude. There are 28 unequally spaced sigma levels. About 8 levels are below 800 hpa. There are two soil layers in the original NCEP GCM, representing land surface processes. Using the original NCEP GCM and the NCEP GCM/SSiB, we have integrated the models for 4 months from May 1, 1987 to August 1, 1987, which is the boreal monsoon season. The most substantial differences between the NCEP GCM and the NCEP GCM/SSiB are the simulations in the African monsoon, the East Asian monsoon, and the Mexican monsoon. In the original NCEP GCM, the African monsoon is too week, especially in July. The monsoon rainfall does not fully develop until August. With the coupled NCEP GCM/SSIB, the African monsoon rainfall in July is closer to the observations. In East Asia, the monsoon onset in May is too strong in the original NCEP GCM and the rainfall area approaches farther to the north; whereas the NCEP GCM/SSiB correctly simulates the monsoon's onset. In these experiments, the soil moisture and albedo are similar in the two models. Further experiments are also carried out to explore the impact of initial soil moistures and vegetation maps on the monsoon simulations. A newly developed global vegetation map (UMGEOG1) and a new soil moisture data are introduced to the NCEP GCM to specify land condition. This UMGEOG1 is developed at the Department of Geography, University of Maryland, and is based on the NOAA/NASA pathfinder AVHRR 1-km land data set. The classifications are derived using a decision tree classifier with training data derived from a global network of high resolution Landsat data. The land cover data sets are being validated with Landsat data as well as with regional data sets. The soil moisture data is developed at NASA/GSFC by Sud's group. It is a part of the Global Soil Wetness Project. The SSiB has been driven offline by observed and assimilated meteorological data to produce 1987 soil moisture climatology. The impacts of these two data sets have been tested to compare with the original model simulations.

MC01/W/01-A2 1000

EQUATORIAL CONVECTIVELY COUPLED WAVES IN AMIP II INTEGRATIONS WITH THE UK METEOROLOGICAL OFFICE UNIFIED MODEL

Guiying YANG and Julia Slingo (both at Centre for Global Atmospheric Modelling, Department of Meteorology, University of Reading, Earley Gate, Reading, RG6 6BB, UK. Email: J.M.Slingo@reading.ac.uk)

Synoptic activity in the tropics is often associated with waves which can be related to the preferred equatorially-trapped modes of the atmospheric circulation based on shallow water theory (Wheeler and Kiladis 1998). Various modes (inertio-gravity, equatorial Rossby, mixed Rossby-gravity and Kelvin waves) can be detected, in many cases related to the active phase of the Madden-Julian Oscillation. That being the case, it is important that GCMs are able to represent these convectively-coupled equatorial waves. Global brightness temperature data (from the EU Project, 'Cloud archive User Service (CLAUS)') have been used to identify and characterise the equatorial waves based on time/space spectral analysis. The various modes noted above can be identified. The results have been used to evaluate the tropical variability in AMIP II simulations with the latest atmosphere-only version of the UK Meteorological Office model (HadAM3). The modulation of these waves by ENSO has also been studied.

ASSESSING ATMOSPHERIC GENERAL CIRCULATION MODELS USING ANGULAR MOMENTUM DIAGNOSTICS

David A. SALSTEIN and Richard D. Rosen (Atmospheric and Environmental Research, Inc., 840 Memorial Drive, Cambridge, MA 02139,USA, email: salstein@aer.com) Jean O. Dickey and Steven L. Marcus (Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, Pasadena, CA 91109, USA, email: jod@logos.jpl.nasa.gov)

Being subject to physical conservation laws, atmospheric angular momentum (AAM) has proved to be a robust index of global weather and climate fluctuations on a variety of timescales. Earlier, under the leadership of R. Hide, we examined mean, seasonal, and interannual fluctuations of AAM in the group of models that participated in the first Atmospheric Model Intercomparison Project. The annual cycle proved to be captured well by the AMIP-I models, although a tendency to underestimate the AAM peak in northern winter was noted. Interannual fluctuations in AAM were reasonably well simulated, as were the latitudinal anomalies associated with the El Ni–o/Southern Oscillation. The relative amplitudes of the 1982-83 and 1986-87 ENSO peaks in AAM, however, were not so well reproduced. Now the suite of AMIP-II models are becoming available, we can check if some of the shortcomings in the models' angular momentum series have been corrected. Given the extension of both model results and more recent analyses to higher levels, we will assess the AMIP-II model results for quasi-biennial and semiannual AAM signals that originate in the stratosphere. In addition, the longer AMIP-II period includes ENSO variability beyond that covered by AMIP-I, so that a larger number of ENSO-related AAM signals can be examined. Newly available from analysis systems and a number of AMIP-II models will be values of torques acting to exchange angular momentum between the atmosphere and other Earth components. Thus, we plan to assess how well AMIP-II models reproduce behavior in the relevant torques, due to friction and to pressure gradients across mountainous topography.

INTERCOMPARISON ACTIVITIES

MC01/W/10-A2 1030

THE DYNAMICAL CORE INTERCOMPARISON PROJECT

Michael WEHNER, Program for Climate Model Diagnosis and Intercomparison Lawrence Livermore National Laboratory Livermore, CA 94550 USA
email: mwehner@llnl.gov http://www-pcmdi.llnl.gov/dc

Researchers are invited to participate in The Dynamical Core Intercomparison Project. The aim of this intercomparison is to explore numerical methods for solutions of the hydrodynamic equations of motion on the sphere. In particular, the dynamics schemes of atmospheric general circulation models are targeted. The design of the experiment is intended to be minimally restrictive in order to foster a high degree of creativity. All types of numerical discretizations are encouraged. In the Dynamical Core Intercomparison Project, a prescribed forcing function replaces the detailed boundary layer turbulence, radiative and hydrological parameterizations of the typical atmospheric general circulation model. Only the equations for momentum and thermal energy are to be solved. No moisture equations are involved. Two differing forcing functions (Held-Suarez and Boer-Denis) have been published in the literature. It is requested that participating groups submit results for both forcing functions. Subgrid scale turbulent mixing and dissipation are intimately connected to the details of the numerical formulation. Hence, they are considered part of the model and left to the individual modelling groups to define. Furthermore, the simulated planet is smooth with no topography. Initial conditions are not provided. However, simulations should be run for an initial spinup period of a length chosen by the modelling group. Most of the standard output is defined as 90 day averages of zonal means using the results of 120 day segments of the integration. The first or last 30 days of each period should not be included in the averages supplied to the PCMDI in order to provide statistically independent 90-day samples. An additional request is made for a representative set of winds in order to calculate a kinetic energy spectrum. A small set of computational performance data is also requested to assess behavior of the various algorithms on different hardware. Results that have been submitted by the time of this presentation will be shown. A preliminary conclusion is that the middle atmosphere under the Held-Suarez forcing is far more sensitive to numerics and resolution than is the lower atmosphere.

MC01/W/51-A2 1045

AN AQUA-PLANET TEST-BED FOR AGCMS

Richard NEALE and Brian Hoskins (both at Department of Meteorology, University of Reading, PO BOX 243, Earley Gate, Reading RG6 6BB, UK, Email: R.B.Neale@reading.ac.uk)

It is proposed that aqua-planet runs of atmospheric GCMs for a set of specified idealised sea surface temperatures (SSTs) should be used as a standard test of the interaction of the physical parameterizations with each other and with the dynamics. Dynamical core tests have proved very useful in testing numerical formulation of models. Single column experiments are

valuable in developing parameterizations, but at present there is nothing between them and full GCM runs in which conclusions about how the parameterizations perform and interact are difficult to make. As an example, results will be shown from an aqua-planet version of the UKMO Unified Model (version HadAM2B) run with equinoctial solar forcing and idealised SSTs. Zonally symmetric SSTs test whether the model tends to have a single equatorial convective maximum or ITCZs off the equator and for what weak equatorial SST gradients the Hadley Cells disappear. Zonally asymmetric SSTs test the relative longitudinal location and magnitude of the convective maximum, the extent to which westerly tropical zonal flows are generated and to which the extratropical storm-tracks are organised.

MC01/L/05-A2 1100

SNOW MODEL INTERCOMPARISONS

Richard ESSERY (Hadley Centre, UK Meteorological Office), Eric Martin (Centre d'Etudes de la Neige, Météo-France), Hervé Douville (Centre National de Recherches Meteorologiques, Météo-France), Alberto Fernández (Instituto Nacional de Meteorología, Spain) and Eric Brun (Centre National de Recherches Meteorologiques, Météo-France)

Snow can greatly increase the albedo of a surface, reduce its roughness, insulate the underlying ground from the atmosphere and store or release large amounts of water. Models of snowpack processes are thus needed for a wide range of applications, from forecasting floods and avalanches to simulating long-term changes in climate, and many different models have been developed. To investigate the performance of snow models, the IAHS / ICSI working group on Snow and Climate is planning a snow model intercomparison project (SnowMIP), to be launched in 1999. A detailed comparison will be made between a wide range of snow models using data from several sites with different climates and characteristics. The aims of SnowMIP will be discussed, and results will be presented from a pilot study in which four models with a range of complexities were compared using observations made during two contrasting winters at a site in the French Alps. Experience gained in this study will be used to make recommendations for SnowMIP.

OCEAN MODELLING AND INTERCOMPARISONS

MC01/W/52-A2 Invited 1135

MODELLING LARGE-SCALE OCEAN CIRCULATION: LESSONS FROM SENSITIVITY AND INTERCOMPARISON STUDIES

Claus BOENING (Institut fuer Meereskunde, Kiel, Germany)

Understanding the relative impacts of resolution, parameterisations and numerics on the performance of ocean circulation models is still in its infancy. Some insight into the sensitivity to various model factors is provided by an increasing number of simulations for the North Atlantic, including dedicated model intercomparison studies such as in the DYNAMO project. While the simulation of seasonal to interannual (primarily wind-driven) variability is very robust, with little model-to-model differences or effects of parameterization schemes, simulation of the "mean" circulation and its response to low-frequency (decadal) variations in the surface buoyancy fluxes is extremely dependent on the representation of interior, often very small-scale processes: e.g., flows through sills and gaps, entrainment in downslope flows, interaction with topographic irregularities. It is obvious that ocean model development will benefit greatly from co-ordinated programmes of experimentation that systematically assess alternate model approaches; as part of these, ocean model intercomparisons are meaningful, if embedded in an exploration of the sensitivity to the representation of critical physical processes.

MC01/E/24-A2 Invited 1155

A FORWARD-LOOKING RETROSPECTIVE OF OCEANIC CIRCULATION MODELLING

Dale B. Haidvogel (Institute of Marine and Coastal Sciences, Rutgers University, 71 Dudley Road, New Brunswick, NJ 08901-8521; E-mail: dale@ahab.rutgers.edu)

The decade of the 1990's has witnessed significant improvements in the algorithmic variety, physical completeness, and realism of large-scale ocean circulation models. Factors related to these successes include the steady increase in spatial resolution made possible (largely) by enhanced computer performance, improved subgridscale parameterizations for (e.g.) eddy transports, and multiple classes of numerical models offering shared community development, regular user interaction, and ready availability of software and documentation via the World Wide Web. An increasing trend is the adaptation of ocean circulation models for studies of coupled physical/bio-geochemical interactions and the global climate system. Such coupled systems place further demands on the spatial resolution, numerical integrity, and sub-gridscale treatments of ocean models. Generalized coupling strategies, sophisticated parameterization schemes, and further gains in computer performance are all necessary ingredients for future progress in these inter-disciplinary areas. Also, given the relative lack of observational data (in particular, for the bio-geochemical variables), advanced forms of model/data fusion are essential. It is easy to show that continued improvement in computer power alone cannot meet these growing needs. One central issue that emerges instead is the interplay between spatial approximation and numerical resolution. Despite the overall simplicity of spatially structured, static grids, the inherent advantages of regionally enhanced resolution and adaptivity must in future spur the evolution of alternate approaches including finite element and block- structured grids, horizontally adaptive meshes, and various generalized adaptive vertical coordinates. Some initial progress in these areas is discussed.

MC01/E/12-A2 1215

NUMERICAL SIMULATION OF THE NORTH ATLANTIC OCEAN AT 1/10 DEGREE

Richard D. SMITH and Matthew E. Maltrud, Los Alamos National Laboratory B216, Los Alamos, NM 87545 Frank O. Bryan and Matthew W. Hecht National Center for Atmospheric Research P. O. Box 3000, Boulder, CO 80307

We present preliminary analysis of an 0.1 degree simulation of the North Atlantic Ocean using a level-coordinate ocean general circulation model forced with realistic winds covering the period 1985-1996. Results are compared to the North Atlantic sector of a global 0.28 degree simulation with similar surface forcing, and to a variety of satellite and in situ observations. The simulation shows substantial improvements in both the eddy variability and the time-mean circulation compared to previous eddy-permitting simulations with resolutions in the range of 1/2 to 1/6 degrees. The resolution is high enough that the first baroclinic Rossby radius is reasonably well-resolved at all latitudes, and the model appears to be capturing the bulk of the spectrum of mesoscale energy. The eddy kinetic energy constitutes 70% of the total basin-averaged kinetic energy. Model results agree well with observations of the magnitude and geographical distribution of eddy kinetic energy and sea-surface height variability, with the wavenumber-frequency spectrum of surface height anomalies in the Gulf Stream, with estimates of the eddy length scale as a function of latitude, and with measurements of eddy kinetic energy as a function of depth in the eastern basin. The mean circulation also shows significant improvements compared to previous models, although there are notable discrepancies with observations in some areas. The Gulf Stream separates at Cape Hatteras, and its speed and cross-stream structure are in good agreement with current meter data, however, its path is somewhat too far south and its meander envelope too broad to the west of the New England Seamounts. The North Atlantic Current is remarkably well simulated in the model; it exhibits meanders and troughs in its time-mean path that agree with similar structures seen in float data, although the separation of this current in the region of the Northwest Corner is displaced somewhat too far to the northwest. The Azores Current appears in the simulation, perhaps for the first time in a basin-scale model, and its position, total transport, and eddy variability are consistent with observational estimates.

MC01/E/16-A2 1230

INTERCOMPARISON OF FINITE DIFFERENCE AND FINITE ELEMENT MODELS IN THE NORTH ATLANTIC OCEAN

Mohamed ISKANDARANI, Dale B. Haidvogel, Hernan Arango Institute of Marine and Coastal Sciences, Rutgers University, 71 Dudley Road, New Brunswick, NJ 08901-8521

We present an inter-model comparison between a newly developed ocean model based on the spectral element method, SEOM, and a finite-difference-based ocean model, SCRUM. The spectral element method can be briefly described as an h-p type finite element method characterized by rapid convergence rates, geometrically flexible unstructured grids, and dense computations at the element level leading to high scalability on parallel computers. In principle, the spectral element formalism offers attractive opportunites for high-resolution, regional ocean modelling; however, careful evaluation of this new technique in a basin-scale setting has been lacking. The present work is a first "validation" of SEOM simulation capabilities, using SCRUM as a reference. Both SEOM and SCRUM solve the hydrostatic primitive equations, account for the motion of the free surface, and are terrain-following. We summarize differences in the two models, and assess the relative merits of each within the context of the North Atlantic Ocean between 25 S and 75 N, using traditional measures of merit including Gulf Stream separation, water mass formation, and meridional overturning and heat flux. Novel methods of subgridscale mixing are identified as a key ingredient in the successful application of the new spectral element methods.

MC01/W/41-A2 1400

EFFECTS OF LOCALLY ENHANCED VERTICAL DIFFUSIVITY OVER ROUGH BATHYMETRY ON THE WORLD OCEAN CIRCULATION

Hiroyasu HASUMI and Nobuo Suginohara (Center for Climate System Research, University of Tokyo, Tokyo 153-8904, Japan, e-mail: hasumi@ccsr.u-tokyo.ac.jp, nobuo@ccsr.u-tokyo.ac.jp)

Recent observations indicate that vertical diffusivity in the deep ocean is horizontally highly variable: it is much enhanced where the bottom topography is rough or steeply sloping, and it is as small as at the thermocline depths (about 0.1 CGS) elsewhere. Here we investigate effects of locally enhanced vertical diffusivity over rough bottom topography on the world ocean circulation by use of a coarse resolution (3 degree by 3 degree in horizontal) ocean general circulation model. Vertical diffusivity in the model is enhanced in the area where the standard deviation of the bottom depth, calculated from ETOPO5 data set, within a grid divided by the grid-averaged bottom depth is larger than a certain value. For comparison, a case without horizontal variations in vertical diffusivity is also made. Results show that there is significant difference in the three-dimensional structure of the deep circulation between the cases, especially in the Pacific. When the horizontal inhomogeneity in vertical diffusivity is taken into account, upwelling of deep water in the North Pacific is confined to the western half of the basin, where the bottom is rough. Accordingly, horizontal pattern of water transport differs qualitatively.

MC01/L/06-A2 1415

USING NATURAL RADIOCARBON TO ASSESS THE EFFECTS OF NUMERICS ON BIOLOGICAL TRACERS

Jean-Michel Campin (ASTR, Universite Catholique de Louvain, 2 Ch. du cyclotron, 1348 Louvain-la-Neuve, Belgium, email: campin@astr.ucl.ac.be) Anne Mouchet (LPAP, Universite de Liege, 5 av. de Cointe, 4000 Liege, Belgium, email: mouchet@astro.ulg.ac.be)

The biological component of OCCMs often resorts to specific numerical treatment that are not shared by the dynamical component of the model (including active tracers, i.e., temperature and salinity). This choice is often made in order to satisfy particular requirements: off-line integration to save computer resources or positive advection scheme to avoid disastrous negative concentrations. The purpose of this study is to evaluate, in our OGCM, the impact of those numerical implementations used in the off-line carbon model, and thus to strengthen the validation of the second. The analysis concentrates on the simulated natural C14 distribution. C14 combines the advantages of an easy implementation, of a vertical distribution similar to that of several biogeochemical tracers and of a direct interpretation in terms of ventilation time scales. The results of several C14 equilibrium experiments obtained both on-line and off-line are presented. They address the effects of two different advection schemes: a low-dispersive one and the upwind scheme. In addition, two different convective adjustment schemes are tested, by enhanced vertical diffusivity and by vertical exchange of water. The convective adjustment effect is relatively small, whereas the upwind scheme induces significant differences, especially at intermediate depths, that are largely due to the vertical advection term. On the contrary the same modification in the transport scheme hardly has any effect on the salinity field. In order to reduce this effect on C14, a simple modification of the upwind scheme is proposed. Finally, the residual differences between the off-line and on-line models are discussed.

MC01/L/07-A2 1430

ON THE ORIGIN AND PATHWAY OF THE SALINE INFLOW TO THE NORDIC SEAS

L. NEW, S. Barnard (Southampton Oceanography Centre, Southampton SO14 3ZH, UK, email: A.New@soc.soton.ac.uk) P. Herrmann (Institut fur Meereskunde, Dusternbrooker Weg 20, D-24105 Kiel, Germany) and J.-M. Molines (Laboratoire des Ecoulements Geophysiques et Industriel, 38041 Grenoble, France)

Three high-resolution (1/3 degree) ocean circulation models of the North Atlantic, differing in their description of the vertical coordinate, have been intercompared in the DYNAMO project. They are here used to elucidate the origins and pathways of the saline inflows into the Nordic

Seas, which may play a significant role in setting the depth of wintertime convection there, and in driving the Atlantic overturning circulation. In two of the models, Mediterranean Overflow Water (MOW) flows northwards, but only as far as the Porcupine Bank (53 N). In one of the models, the MOW also invades the Rockall Trough. However, none of the models allows the MOW into the Nordic Seas. Instead, they are unanimous in showing that the saline inputs to the Nordic Seas derive instead from near-surface water masses and result partly from branches of the North Atlantic Current (NAC), and partly from a poleward "Shelf Edge Current" (SEC) around the European continental slopes. The highest salinities are set and carried northwards by the SEC itself, which transports Eastern North Atlantic Water from the Bay of Biscay region. The high salinities on density surfaces appropriate to the MOW in the Nordic Seas result from the downward wintertime mixing of these saline inputs. The models also agree reasonably well with available observations. Overall, the intercomparison indicates the importance of the SEC in this process, and reveals the complexity of the current structures, which occur on scales too small to be resolved by typical climate models.

MC01/L/08-A2 1445

SENSITIVITY OF VENTILATION RATES AND RADIOCARBON UPTAKE TO SUBSURFACE MIXING PARAMETERISATION IN OCEAN MODELS

Matthew H. England, Centre for Environmental Modelling and Prediction (CEMAP) School of Mathematics The University of New South Wales Sydney NSW 2052 Australia

The sensitivity of ventilation time-scales and radiocarbon uptake to subgrid-scale mixing parameterisation is studied in a global ocean model. Seven experiments are examined that are identical in every manner apart from their representation of subgrid-scale mixing of tracers. The cases include (1) two runs with traditional Cartesian mixing (HOR), (2) a run with enhanced isopycnal mixing (ISO), and (3) four runs in which the effects of eddies on the mean ocean flow are parameterised following Gent and McWilliams (1990, GM). Horizontal, isopycnal, and isopycnal thickness diffusion coefficients are varied sequentially in the model runs. Of particular interest is the role of the tracer mixing schemes in influencing longer time-scale ventilation processes - centennial and beyond - such as deep water mass renewal and circulation. Simulated ventilation time-scales and 14C vary greatly between the three mixing schemes. The isopycnal mixing run exhibits the most rapid water mass renewal due to strong diffusion effects and excessive surface convective overturn, particularly in the Southern Ocean. In contrast, the GM cases show much more gradual renewal of deep and bottom waters, with limited vertical convection of surface waters and slower abyssal currents. Under GM, a background horizontal diffusion or altered isopycnal diffusion does not significantly change interior ocean ventilation rates. Reducing the GM isopycnal thickness diffusivity, on the other hand, significantly decreases the simulated deep water ventilation time-scales. In comparison with the HOR runs, deep and bottom water ventilation time-scales are reduced by about 30% in ISO, and increased by 30-40% under GM. Comparison is made between model simulated and observed 14C. The GM runs appear to be the least successful in the North Atlantic Ocean, exhibiting very gradual and only shallow water-mass renewal compared to observations. In the Pacific and Indian Oceans, the HOR and ISO runs are ventilated too rapidly due to strong convection and water-mass contribution from the Southern Ocean. In contrast, the GM runs simulate spuriously old and 14C depleted bottom and mid-depth water. Overall, none of the model cases reproduce global ocean ventilation rates over centennial time-scales. Higher horizontal resolution and a spatially-varying GM thickness diffusivity may be required before global models capture long time-scale ocean renewal processes with some degree of fidelity.

MC01/E/26-A2 1500

A MOMENTUM ADVECTION SCHEME FOR OCEAN MODELS WITH BOTTOM RELIEF, CONSERVING TOTAL MOMENTUM AND KINETIC ENERGY

Hiroshi ISHIZAKI and Tatsuo Motoi (both at Meteorological Research Institute, 1-1 Nagamine, Tsukuba 305-0052, Japan, email: hishizak@mri-jma.go.jp)

A finite-difference analogue of the nonlinear momentum advection for Arakawa's B-grid spacing was developed by Takano (1978) and Ohnishi (1978), which contained the concept of diagonally upward/downward mass and momentum fluxes along the bottom slope, and the generalized-Arakawa scheme for the horizontal advection, modified to be fit to arbitrary coastal shape. Here we revaluate the scheme to put it to more practical use, by redefining it in a simple, generalized form and conferming its good performance through a comparison with a traditional scheme. Based on the definition of mass continuity for a momentum cell (U-cell) in terms of that for tracer cells (T-cell), the vertical and horizontal mass and momentum fluxes for U-cells are generalized on the arbitrary bottom relief in simple forms. Total momentum and kinetic energy are conserved in the advection process. A comparison of the present scheme with a traditional one embedded in an eddy-resolving ocean model indicates a less noisy state with a sharper western boundary current, permitting a longer time interval, in the former than in the latter. The present scheme shows better performance in the computational efficiency as well as in the reality of the simulated flow field than the traditional one does.

MC01/L/09-A2 1515

REGIONALIZATION OF CLIMATE MODEL RESULTS FOR THE NORTH SEA

Frank Kauker (AWI, Columbusstr, D-27568 Bremerhaven, Germany,
EMAIL: fkauker@awi-bremerhaven.de)

A regional North Sea version of the Ocean General Circulation Model OPYC is used to investigate the variability of the North Sea and to downscale climate model results for the North Sea. In a hindcast experiment the model is forced with surface data from the the ECMWF reanalysis in the period 1979 to 1993 to investigate the variability on two time-scales; the weekly to seasonal time-scales and the season to decade time-scales. The major modes of variability of the sea level elevation, the sea surface circulation, the sea surface temperature and the sea surface salinity are analyzed with the help of statistical tools as Empirical Orthogonal Functions, Associated Patterns, Canonical Correlation Analysis and Principal Oscillation Patterns. In the downscaling experiment possible changes of the mean state and the variability in the North Sea (and to some degree in the Greenland-Iceland-Norwegian Sea) are estimated in a doupled CO2 climate.

SEA-ICE MODELLING AND INTERCOMPARISONS

MC01/L/10-A2 Invited 1550

SIMIP RESULTS: INTERCOMPARISON OF SEA ICE DYNAMICS MODELS

Markus HARDER, Martin Kreyscher, Gregory M. Flato, Peter Lemke

The World Climate Research Programme (WCRP) has charged the Sea Ice - Ocean Modelling (SIOM) Panel to de-termine an optimized sea ice model for use in coupled climate simulations. The intercomparison is performed in inter-national cooperation in the Sea Ice Model Intercomparison Project (SIMIP) as a part of the WCRP Arctic Climate System Study (ACSYS). Phase I of SIMIP investigated the performance of different sea ice dynamics schemes in a hierarchy of models with increasing complexity of sea ice rheology. All models were run on the same grid for the Arctic Ocean, were forced with the same boundary conditions, and use the same equations/parameterizations (such as thermodynamic ice growth/melt). Only the ice dynamics part differs. The model results are validated against a very large number of observations, such as IABP ice drift buoys, ice velocities and ice extent observed by satellites, ice thickness data measured by ULS on oceanographic moorings or submarines, and other sources. The intercomparison clearly shows that increasing the complexity of ice dynamics and especially sea ice rheology (associated with ice de-formation) significantly increases the performance of the simulation. Among the four models presently tested, the viscous-plastic rheology performed best, especially due to its representation of shear forces. It is planned to include other sea ice dynamics schemes in the intercomparison.

MC01/E/32-A2 1620

SENSITIVITY OF A GLOBAL SEA ICE MODEL TO THE TREATMENT OF ICE THERMODYNAMICS

Thierry FICHEFET (Institut d'Astronomie et de Geophysique G. Lemaitre, Universite Catholique de Louvain, 1348 Louvain-la-Neuve, Belgium, email: fichefet@astr.ucl.ac.be) Miguel Angel Morales Maqueda (Department of Mathematics, Keele University, Keele, Staffordshire ST5 5BG, UK, email: maa21@cc.keele.ac.uk)

The sensitivity of a global thermodynamic-dynamic sea ice model coupled to a one-dimensional upper ocean model to degradations of the model physics is investigated. The study focuses on physical processes pertaining to (1) the vertical growth and decay of sea ice (thermal inertia of snow and ice, heat conduction, and snow cover), and (2) the lateral growth and decay of sea ice (leads and polynyas). A total of six sensitivity experiments have been performed. Each experiment consisted of removing a particular parameterization from the control run computer code. It appears that the thermal inertia of the snow-ice system is negligible in the Antarctic but not in the Arctic, where the total heat content of sea ice is chiefly dictated by internal storage of latent heat in brine pockets, sensible heat storage being of very minor consequence. It is also found that the inclusion of a prognostic snow layer and of a scheme of snow ice formation is important for sea ice modelling in the Southern Hemisphere. Furthermore, our results suggest that the thermodynamic effect of the subgrid-scale snow and ice thickness distributions and the existence of open water areas within the ice cover play a crucial role in determining the seasonal behavior of both ice packs. We can therefore conclude that all these processes should be represented in global climate models.

MC01/E/19-A2 1635

INTERCOMPARISON OF THE MASS BALANCE OVER THE ANTARCTIC AND GREENLAND ICE SHEETS SIMULATED BY GCMS

W. M. CONNOLLEY (British Antarctic Survey, High Cross, Cambridge, CB3 OET, UK; Email: wmc@bas.ac.uk) C. Genthon (LGGE CNRS, 54 Rue Moliere, F-38402 Saint Martin d'Heres Cedex, FRANCE; Email: genthon@glaciog.ujf-grenoble.fr)

Accurate knowledge of the surface mass balance of Antarctica and Greenland is a key component of estimates of the contribution of the ice sheets to sea level rise. Because of the large and inhospitable areas involved, observational estimates are imprecise and it is natural to turn to GCMs which can, in theory, provide a more exact specification. GCMs, if we can believe them to be accurate, are also the best source for predictions of the contributions of the ice sheets to future sea level change. In this contribution we examine the precipitation and evaporation from GCMs of varying sophistication and compare their simulated mass balance to the most up-to-date observations. The best GCMs are found to be accurate (on a continental average) to within the degree of uncertainty in the observations and to perform as well as numerical weather prediction analyses such as ECMWF. However when the detailed pattern is examined there are possibilities for improvement in all GCMs. We examine the change in mass balance in a transient climate change experiment. Overall, the mass balance can be fitted quite well to temperature change. However, the relationship is not the same as for interannual variations in mass balance and temperature change representing internal variability in a control run for present-day conditions, and also there are significant regional variations. This may have implications for existing studies that have parametrized precipitation change by temperature change.

MC01/W/12-A2 1650

ATMOSPHERE-SEA ICE-OCEAN INTERACTIONS IN A REGIONAL CLIMATE SYSTEM MODEL OF THE ANTARCTIC

David A. Bailey and Amanda H. LYNCH (both at PAOS/CIRES, CB 216, University of Colorado, Boulder, CO, 80309-0216, USA, email: bailey@cires.colorado.edu)

High-latitude interactions of local-scale processes in the atmosphere-ice-ocean system have effects on the local, Antarctic, and global climate. Phenomena including polynyas and leads are examples of such interactions which when combined have important impacts on larger scales. These smaller scale features can only be parameterized in global models, but can be explicitly simulated using high resolution, limited area climate system models. As such, the study of these interactions is well-suited to a regional modelling approach and is considered here using the Arctic Regional Climate System Model (ARCSyM). This model has been used for many simulations in the Arctic, and has now been implemented for the Antarctic. This work considers fine-resolution (25km) simulations in the Cosmonaut Sea region, with the eventual goal of elucidating the mechanisms involved in the formation and maintenance of the sensible heat polynya which is a regular occurence in this area. This work will provide insight into the role of such polynyas in the atmospheric and oceanic circulations of the high southern latitudes.

COUPLED OCEAN-ATMOSPHERE MODELLING AND INTERCOMPARISONS

MC01/W/18-A2 1705

THE SEASONAL CYCLE IN COUPLED OCEAN-ATMOSPHERE GENERAL CIRCULATION MODELS

Curt COVEY Lawrence Livermore National Laboratory Livermore, CA 94550, USA

We examine the seasonal cycle of near-surface air temperature in 17 coupled ocean-atmosphere general circulation models. Nine of the models use ad hoc flux adjustments to bring model simulations close to observations of the present-day climate. The seasonal cycle of zonal mean surface temperature is reasonably well-simulated with good intermodel agreement from about 40N-40S. Non-flux-adjusted models perform about as well as the flux-adjusted models for this diagnostic, though a detailed look at land vs. ocean responses shows better agreement with observations for the flux-adjusted models (as expected). Reasonable seasonal cycle simulation by the non-flux-adjusted models is an encouraging indication that GCMs may adequately simulate longer-term climate changes. There appears to be a weak positive relationship between climate sensitivity and seasonal cycle amplitude for the models in this study.

MC01/L/11-A2 Invited 1725

THE NCAR CLIMATE SYSTEM MODEL

Byron A. Boville (National Center for Atmospheric Research, Box 3000, Boulder CO 80307 USA, email: boville@ucar.edu)

The NCAR Climate System Model (CSM) is a physical climate model containing component models for the atmosphere, land surface, ocean, and sea ice. The CSM produces stable solutions for present (or pre-industrial) climate on multi-century time scales, without the need for flux corrections. Although the surface climate was stable, the initial version of the CSM had substantial deep ocean trends. This talk will summarize improvements in the model which have significantly reduced the deep ocean trends and added new capabilities which are used for climate change experiments. These improvement include an interactive sulphate aerosol model in the atmosphere and an asymmetric diffusion tensor in the ocean. Simulations from pre-industrial control simulations, and 20th and 21st century climate change experiments will be discussed.

MC01/W/15-A2 1740

BIOSPHERIC CARBON CYCLE RESPONSE TO GLOBAL WARMING

Pierre FRIEDLINGSTEIN, Patrick Monfray and Philippe Ciais (LSCE, CE-Saclay, 91991, Gif/Yvette, France, email: pierre@lsce.saclay.cea.fr) Herve Letreut, Jean-Louis Dufresne (LMD, CNRS/UPMC, 75252 Paris Cedex 05, France)

The biospheric carbon cycle is directly linked to the climate system. CO2 exchange between the atmosphere and the biosphere is controlled by atmospheric CO2 and surface climate conditions. Elevated atmospheric CO2 favors plant photosynthesis. Climate change, through changes in surface and soil temperature and humidity also affects the biospheric carbon storage. On the other hand, atmospheric CO2 is controlled by anthropogenic emissions but also by land and ocean CO2 fluxes. It is therefore crucial to estimate in the context of future climate what is the carbon cycle response to CO2 increase and climatic change. In the context of the CMIP2 activity, several GCMs estimate the climate response to a 1% increase in the atmospheric CO2 concentration. Here, we use CASA/SLAVE, a global model of the biospheric carbon cycle to estimate the biospheric response to this climate forcing. The model will be forced by atmospheric CO2 and monthly means of surface temperature and precipitation field, available from the CMIP2 runs. The model needs to be initialized to steady state using constant climate, then it is run over the CMIP2 period. A preliminary study has been performed using the CMIP2 outputs from the LMD GCM. The biospheric response to the atmospheric CO2 increase is an important biospheric carbon uptake, but the climate induced response, because of drying of the land surface, is a net release. However, the combined effect is a net biospheric sink.

COUPLED OCEAN-ATMOSPHERE MODELLING AND INTERCOMPARISONS

MC01/E/11-A3 0845

RELATIONSHIP BEETWEEN THE ATLANTIC THERMOHALINE CIRCULATION AND THE DEEP CONVECTION ACTIVITY IN A GLOBAL COUPLED MODEL ?

Yvonnick LE CLAINCHE (1), Pascale Braconnot (1), Olivier Marti (1) and Sylvie Joussaume (1) (1) Laboratoire des Sciences du Climat et de l'Environnement, UMR CEA-CNRS, CE Saclay, Orme des Merisiers, 91191 Gif sur Yvette, France, email: leclain@lsce.saclay.cea.fr

A 200 years simulation has been performed with the global IPSL ocean-atmosphere coupled model (Paris, France) in its low resolution version. No flux correction technique is used at the air-sea interface. The complete thermodynamic sea ice model developed at LODyC (Paris) has been included instead of the old diagnostic approach. It's the only major physical difference with a previous 150 years coupled simulation. We analyze the impact of the sea-ice model on the North Atlantic thermohaline circulation (THC), and relate the larger value produced in the new simulation (about 15 Sv) to the preservation of the deep convection in Greenland and Norwegian seas. Whereas this convection zone had disappeared with the simpler sea-ice representation, the variations of its intensity correlate well with the interdecadal variability of the THC in the last simulation. Furthermore, the mean value of the THC doubles around year 150, and then presents a very larger interannual variability. We'll discuss these important changes, and their links with the resumption of the convective activity in the Labrador sea, and also with the atmospheric forcing.

MC01/W/64-A3 0900

AN EXPLORATION OF THE NAO-RELATED TEMPERATURE VARIATIONS SIMULATED BY 17 GLOBAL COUPLED OCEAN-ATMOSPHERE MODELS

PAVAN, Dr Valentina (CINECA, email: pavan@cineca.it)

This study investigates the North Atlantic surface temperature interannual variability simulated by 17 state-of-the-art global coupled ocean-atmosphere climate models and compares model results with those obtained using Jones (1986) surface temperature data set for the period 1900-1994. The models are those participating in the Coupled Model Intercomparison Project (CMIP). Taking year-to-year differences in winter mean temperatures, interannual variations are separated from longer trends due both to interdecadal variability and to secular model drift. The ability of the models to reproduce the observed interannual variability associated with the North Atlantic Oscillation (NAO) is investigated using first area-average temperatures and then principal component analysis. Most of the models capture the anti-correlation between detrended temperatures over North-West Europe and North-West Atlantic. All the same, few of the models are able to capture the full NAO pattern that has nodes also over southern North America and the Arabian peninsula. For the non-drifting models, the leading principal component of the wintertime temperatures over the Atlantic well fits a red noise model but with a lag-1 correlation close to zero.

SENSITIVITY EXPERIMENTS WITH THE UCL'S COUPLED ATMOSPHERE-OCEAN GENERAL CIRCULATION MODEL

Ch. PONCIN and Th. Fichefet, Institut d'Astronomie et de Geophysique G. Lemaitre, Universite catholique de Louvain, chemin du cyclotron 2, 1348 Louvain-la-Neuve, Belgium,
email: poncin@astr.ucl.ac.be)

The UCL's coupled atmosphere-ocean general circulation model (AOGCM) is a coarse-resolution model, which does not include any flux correction. Its atmospheric component is an improved version of the atmospheric general circulation model (LMD5) built at the "Laboratoire de Meteorologie Dynamique" of the CNRS (Paris). The oceanic model (CLIO) is a free-surface, primitive-equation model developed at the UCL in Belgium. As many other AOGCMs without flux correction, this coupled model drifts away from realistic climatology. In order to improve the model behavior, a better understanding of its sensitivity to parameterizations is needed. Therefore, we have performed sensitivity experiments on atmospheric parameters in forced and coupled modes. The transition zone between cold and warm clouds acts upon the radiative fluxes around 45S and 45N. The precipitation rate of cold clouds regulates the efficiency of the thermal machine associated to the Hadley cell. Three approaches to the cloud overlapping along the vertical have been tested : maximum, random and max/random overlapping. The aim of all these sensitivity experiments is to analyze the model drift away from observed climatology and to choice the best parameters for scenario simulations.

MC01/W/38-A3 0930

LONG-TERM GLOBAL WARMING SCENARIOS COMPUTED WITH THE CLIMBER-2 MODEL

Stefan RAHMSTORF and Andrey Ganopolski Potsdam Institute for Climate Impact Research, PO Box 60 12 03, D-14412 Potsdam, Germany. E-mail: Rahmstorf@PIK-Potsdam.de

We present a new, highly efficient coupled ocean-atmosphere-sea ice model of intermediate complexity, CLIMBER-2. In addition to showing model validation for the present and glacial climates we will discuss long-term global warming scenarios. Our simulations extend to the year 3000, beyond the expected peak of CO2 concentrations. The Atlantic thermohaline ocean circulation declines strongly in all our scenarios over the next 50 years due to a thermal effect, consistent with other climate models. Changes in the hydrological cycle determine whether the circulation recovers or collapses in the long run. Both outcomes are possible within present uncertainty limits. In case of a collapse, a substantial long-lasting cooling over the North Atlantic and a drying of Europe is simulated.

MC01/W/11-A3 0945

MOBIDIC SIMULATED CLIMATE WITHIN PMIP

Loutre M.F., Tulkens P., Crucifix M., Berger (Institut d'astro, email: loutre@astr.ucl.ac.be)

MoBidiC is a zonally averaged climate model. A quasi-geostrophic atmosphere model is coupled to a three-basin (latitude-depth) ocean-sea ice model. The main continental ice sheets are also represented. The atmospheric component of MoBidiC contains an interactive representation of the hydrological cycle based on meridional transport of moisture and zonal redistribution of precipitation. The sea-ice model enables to represent explicitly the climatic effect of ice formation and ablation and their consequences on the ocean circulation. The interconnected ocean basins allow this model to simulate the main thermohaline circulation processes. The six PMIP experiments were performed with MoBidiC. For the present day climate the 1950AD solar forcing and the present-day CO2 atmospheric concentration (345 ppmv) forced the model. The SST and sea-ice were either prescribed or computed by the ocean model. For the 6-kyr experiment only the forcings (CO2 and insolation) were modified compared to the control run. In the 21-kyr experiment the land surface features were adapted in addition to the modification of the forcings. Here we focus on the surface temperatures and precipitation patterns simulated for these experiments. Despite shortcomings in the representation of atmospheric dynamics and in the distribution of ocean salinity, the present-day simulated values are realistic. Moreover the comparison with the results of other models allows to point out the strong features of the model, systematic deviation or weaknesses.

MC01/E/14-A3 Invited 1000

RESULTS FROM THE STOIC CGCM ASSESSMENT PROJECT

Ken Sperber (Program for Climate Model Diagnosis and Intercomparison, LLNL, Livermore, CA, USA), Mike DAVEY and Matt Huddleston (both at The Meteorological Office, London Road, Bracknell, RG12 2SZ, UK, email: mkdavey@meto.gov.uk)

STOIC (Study of Tropical Oceans In CGCMs) is one of several projects set up by CLIVAR-NEG1 (now CLIVAR-WGSIP) to assess climate model behaviour on seasonal to interannual timescales. Monthly sea surface temperature, windstress and upper ocean vertically averaged temperature were collected from (at least) 20 year coupled GCM runs, for the tropics. This information from 24 models has been compared with observations, in terms of annual mean, seasonal cycle, and interannual variability. The models differ substantially in terms of resolution and coupling strategies: nevertheless, some common strengths and defects are apparent.For example, in the equatorial Atlantic, the mean zonal SST gradient in many models is opposite to that observed. Mean zonal winds in the equatorial Pacific tend to be too weak in the central Pacific, but too strong in the west Pacific. Model sea surface temperature anomalies in the Indian Ocean are generally positively correlated with anomalies in the Pacific, as observed.

MC01/L/12-A3 Invited **1020**

ENSIP: THE EL NIÑO SIMULATION INTERCOMPARISON PROJECT

M. Latif, Max-Planck-Institut fuer Meteorologie Bundesstrasse 55, D-20146 Hamburg, Germany and K. Sperber PCMDI, Lawrence Livermore National Laboratory P. O. Box 808, L-264, Livermore, Ca. 94551-9900, U. S. A.

An ensemble of twenty four coupled ocean-atmosphere models worldwide has been intercompared with respect to their performance in the tropical Pacific. The coupled models span a large portion of the parameter space and differ in many respects. The intercomparison includes TOGA-type models consisting of high-resolution tropical ocean models and coarse-resolution global atmosphere models, coarse-resolution global coupled models, and a few global coupled models with high resolution in the equatorial region in their ocean components. The comparison focusses on the tropical Pacific, and the performance of the annual mean state, the annual cycle and the interannual variability is investigated. The primary quantity analysed is sea surface temperature (SST). Additionally, the evolution of interannual heat content variations in the tropical Pacific and the relationship between the interannual SST variations in the equatorial Pacific to fluctuations in the strength of the Indian Summer Monsoon are investigated. The results can be summarised as follows: Almost all models (even those employing flux corrections) have still problems in simulating the SST climatology, although some improvements are found relative to earlier intercomparison studies. Only a few of the coupled models simulate the El Nino/Southern Oscillation (ENSO) in terms of equatorial SST anomalies realistically. In particular, many models overestimate the variability in the western equatorial Pacific. The ev- olution of interannual heat content variations is similar to that observed in almost all models, which indicates that equatorial wave dynamics is also important in coarse-resolution models. Finally, the majority of the models show a strong connection between ENSO and the strength of the Indian Summer Monsoon, which may be important to Monsoon predictions.

LANDSURFACE MODELLING AND INTERCOMPARISONS

MC01/E/31-A3 **1100**

LAND-SURFACE EVALUATION: A MATURE AND SUCCESSFUL "MIP"

Ann HENDERSON-SELLERS (ANSTO, Lucas Heights, Sydney, NSW, Australia
email: ahs@ansto.gov.au)

The first component of any intercomparison must be open to all who wish to participate and demands both high quality observational data and careful experimental design and quality control procedures. The second involves a smaller group of researchers and schemes with the specific goal of enhanced understanding. The two questions being posed by these two complementary activities are: a) does “your” scheme perform well enough to be part of international modelling efforts? and b) it is “understood” why your scheme performs the way it does? PILPS, the Project for Intercomparison of Land-surface Parameterization Schemes, one of the oldest "MIPS", serves the international modelling community in these two different and complementary ways: a) by providing open but quality controlled intercomparison opportunities as international benchmarks against which new and revised LSS can be validated; and b) by providing the tools and (more restricted) intercomparison frameworks by means of which the behaviour of LSS types can be analyzed and more fully understood. So far PILPS has completed seven full intercomparisons so that we estimate the resource commitment to date has been about $7.5 million. The widespread international participation means that every intercomparison involves about one person year from each of 25 groups. Strategies for adding value to future land-surface intercomparisons include: multi-criteria optimization; higher order schemes and use of the CHASM-tool.

MC01/L/13-A3 **1135**

VALIDATION STUDY OF THE CAPS MODEL LAND SURFACE SCHEME USING THE 1987 CABAUW/PILPS DATASET

S. Chang, D. Hahn, C.-H. Yang, and D. Norquist, Phillips Laboratory, Geophysics Directorate, Hanscom AFB, Mass. 01731 USA; M. Ek, NCEP/EMC/Mesoscale Modelling Branch, Suitland, MD 20746 USA

An updated complete and comprehensive description of the land surface parameterization scheme in the Coupled Atmosphere-Plant-Soil (CAPS) model is presented. The CAPS model has been in development at Oregon State University and Phillips Laboratory since 1981. The CAPS model was originally designed for a global atmospheric model, but is has also been used as a stand-alone model for a variety of applications. The land surface scheme in the CAPS model is one of the two dozen schemes that participated in the Project for Intercomparison of Land surface Parameterization Schemes (PILPS). Some unique features of the CAPS scheme are given in detail. A comprehensive dataset of one year (1987), including atmospheric forcing data and validation data from Cabauw, has been provided for PILPS by the Royal Netherlands Meteorological Institute. Using the Cabauw data, a validation study for the CAPS scheme has been carried out. The scheme's self-consistencies in terms of surface energy balance and water budget are discussed. Finally, the results of this validation study with emphasis on the performance of surface momentum and heat fluxes are presented.

MC01/E/10-A3 **1150**

THE VALIDATION OF THE LAND-SURFACE PARAMETERIZATION SCHEME SWAP ON A REGIONAL SCALE

Yeugeniy Gusev and Olga NASONOVA (both at the Institute of Water Problems, Russian Academy of Sciences, Gubkina St.3, 117971 Moscow, Russia, e-mail: sowa@ipcom.ru)

The aim of this study was to evaluate the ability of the land-surface parameterization scheme SWAP to reproduce heat and water fluxes at the land surface at different scales varying from small catchments of areas 102 - 103 km2 to a continental scale river basin (on the order of 106 km2) characterised by different natural conditions. The validation was carried out against streamflow data for the years 1979-1988 for 14 catchments situated within the Arkansas-Red River basin (USA) and for the whole basin. Forcing data and model parameters for 61 one degree grid sells composing the Arkansas-Red River basin, as well as streamflow data for the validation were provided by the organisers of the PILPS (Project for Intercomparison of Land-surface Parameterization Schemes) phase- 2(c) experiment. Runoff simulated by SWAP without any calibration for each grid cell was transformed into streamflow for different catchments and for the basin using the two-dimensional kinematic wave equation and routing model (provided by D. Lohmann, Princeton University, USA). Daily values of the calculated and observed (naturalized) streamflow were compared for 14 catchments and for the basin for 10-year period. For the whole basin the coefficient of correlation for daily values is 0.71, the relative deviation between mean annual calculated and observed streamflow is nearly 3%. For smaller catchments the errors in calculations increase with decrease in a catchment area (to be exact, in the number of grid cells composing a catchment). That is in a good agreement with a theory of random errors. Analysis of the obtained results show that SWAP does not introduce systematic errors into the calculations and random errors mainly depend upon the number of grid sells, and accuracy of hydrometeorological data and land-surface characteristics.

MC01/W/29-A3 Invited **1205**

EVALUATION OF PILPS 2(D) HYDROLOGICAL SIMULATIONS AT VALDAI, RUSSIA

Alan ROBOCK, G. Srinivasan, Lifeng Luo Department of Environmental Sciences Rutgers - The State University of New Jersey 14 College Farm Road New Brunswick, NJ 08901-8551 USA Konstantin Y. Vinnikov, University of Maryland

The PILPS 2(d) experiment at Valdai, Russia offers a unique opportunity to evaluate land surface schemes in a climate with seasonal snow cover and seasonally frozen soil. Here we evaluate the 18-year simulations by the 21 schemes that participated in the experiment, in their ability to correctly partition the melting snow in the spring into runoff and infiltration. Using observed vertical profiles of soil temperature and soil moisture, we evaluate the relationship between infiltration and the frozen layer in the soil, and determine the dependence of this modeled relationship on the correct partitioning of snow meltwater. The large interannual variations allow us to provide new insights into the level of complexity necessary to correctly model this important aspect of land surface hydrology. We find that inaccurate snow simulations produce inaccurate timing of snow melt in some cases. In other cases, runoff is delayed and takes place over a longer time period than observed. Most models do not simulate soil temperature very well, but this does not seem to have a large effect on the accuracy of their runoff or soil moisture simulations. In collaboration with analyses by individual modelers, we identify parameterization decisions that produce both accurate and inaccurate simulations, and produce suggestions for the accurate modelling of cold season hydrology.

ASSESSING SNOW SIMULATIONS OF LAND-SURFACE SCHEMES USED IN ATMOSPHERIC MODELS

A. Schlosser

A suite of 18-year, standalone simulations was performed by 21 land-surface schemes for a grassland catchment at Valdai, Russia (58N, 33E) for the PILPS Phase 2(d) experiment. The simulated water budgets of all the models are presented and compared against hydrologic observations made within the catchment. We focus our analysis on the models' representation and simulation of snow and frozen soil processes. Given the experimental framework, the model scatter of simulated snow is a result of differences in ablation. Scatter in ablation rates is primarily controlled by model disparity of energy available to the snowpack and how energy is distributed within the structure of the model (whether implicit or explicit). Factors such as the treament fractional snow coverage, snow albedo, snow density, and vapor exchange all play a significant role.

MC01/E/04-A3 **1415**

MODELLING SNOW COVER FORMATION AND SOIL FREEZING/THAWING PROCESSES IN THE LAND SURFACE PARAMETERIZATION SCHEME SWAP

Yeugeniy GUSEV and Olga Nasonova (both at the Institute of Water Problems, Russian Academy of Sciences, Gubkina St.3, 117971 Moscow, Russia, e-mail: sowa@ipcom.ru)

The land surface parameterization scheme SWAP (Soil Water-Atmosphere-Plants) includes physically based description of the heat and water transfer processes occurring not only during the warm period of a year, but also during the cold period. The latter represent snow formation processes (snow accumulation including solid and liquid fractions, snow evaporation and snowmelt), soil freezing and thawing, infiltration of liquid water into frozen soil, and surface runoff and drainage from frozen soil. The aim of this study was to validate the ability of SWAP to simulate the mentioned processes. The validation of the model was performed using a set of hydrometeorological data measured at a grassland catchment at the Valdai water balance station (Russia) during 18 years (1966-1983). Most of the data were provided by the organisers of the PILPS (Project for Intercomparison of Land-surface Parameterization Schemes) phase 2(d) experiment. The Valdai data set was chosen for the validation because the Valdai site is characterized by a clear seasonal course of hydrometeorological conditions, deep snow cover and seasonally frozen soil. Besides that, the Valdai water balance station has a unique hydrometeorological, soil and vegetation observations carried out during more than 30 years which are necessary for the model validation. On the base of comparison of the simulated and observed water balance components and different characteristics of snow cover formation we can conclude that the model SWAP parameterizes the cold season processes occurring in mid-latitude grassland quite reasonable.

MC01/W/05-A3 **1430**

SENSITIVITY STUDIES OF MAPS/RUC LAND-SURFACE SCHEME USING PILPS 2(D) DATA

Tatiana G. SMIRNOVA (Cooperative Institute for Research in Environmental Sciences, Boulder, Colorado, USA, email: smirnova@fsl.noaa.gov) John M. Brown, and Stanley G. Benjamin (both NOAA Forecast Systems Laboratory, Boulder, Colorado, USA)

The Mesoscale Analysis and Prediction System (MAPS) is a four-dimensional data assimilation system (implemented operationally at NCEP as the Rapid Update Cycle or RUC) running in real time. The forecast component of MAPS includes a multilevel soil/vegetation/snow scheme for prediction of soil temperatures and volumetric water content, and also snow height and temperature in the cold season. Soil temperature, soil moisture and snow cover, as predicted by the soil/vegetation/snow model, are carried forward from the previous forecast to initialize the next forecast in the MAPS cycle. This continuous cycling allows the effects of abnormally wet or dry soil conditions to positively influence forecasts of the planetary boundary layer through surface fluxes. However, seemingly subtle aspects of the climatology of soil model, and especially the climatology of hydrological cycle components, such as soil moisture, root zone drainage, surface runoff and snow cover, can dramatically affect atmospheric predictions. Further, in the cold season the existence of frozen moisture in soil considerably changes the processes of heat and moisture transfer inside soil, and also affects all components of the hydrological cycle. This motivated us to further improve the soil/vegetation model by searching for ways of incorporating the effects of frozen soil physics into our soil model. In preparation for introducing the frozen-soil physics into the 3-d MAPS/RUC model, we performed extensive testing of this physics enhancement in a 1-d version of the MAPS land-surface model. These tests were performed for the PILPS 2(d)

experiment (Valdai) and also for other Russian stations. We will present results from the Valdai tests showing sensitivity to changes of soil properties with depth and to inclusion of effects of frozen soil.

MC01/E/21-A3 1445

USING CHASM TO EXPLORE SURFACE ENERGY BALANCE COMPLEXITY IN GCM LAND SURFACE MODELS

Dr Carl DESBOROUGH (Macquarie University, email: cdesboro@penman.es.mq.edu.au)

A large number of land surface models (LSMs) have been designed for use in atmospheric general circulation models (GCMs) and GCM modellers therefore have a large number of options when selecting an LSM for their GCM. A framework within which sensitivity to LSM design can be tested is presented and a series of experiments carried out to investigate how general aspects of surface energy balance parameterisation affect land-atmosphere evaporation. Firstly, it is shown that a combination of surface energy balance complexity and aerodynamic parameterisation can be used to explain the gross simulation differences obtained in the Project for Intercomparison of Land-surface Parameterization Schemes (PILPS). Secondly, a simple surface energy balance parameterisation with a constant surface resistance is found to be as appropriate as more complex method for simulating annual, monthly and seasonally-averaged diurnal cycles of evaporation. However, complex aspects of surface energy balance parameterisation (canopy interception, bare ground evaporation and canopy resistance) are shown to contain substantial geographic and daily functionality that is not present in the simpler parameterisation.

MC01/L/15/-A3 1500

LAND SURFACE MODELLING AND CLIMATE VARIABILITY - BACK TO SIMPLICITY

NING ZENG and David Neelin, Dept. of Atmospheric Sciences and Inst. of Geophysics and Planetary Physics Univ. of California, Los Angeles

Land-surface modelling has gone over the last decade and half from the simple bucket model to sophisticated representations of the biosphere and surface energy and water cycle. Yet the models do not necessarily converge on their capability and confidence level in climate simulation. Using a land-surface model of intermediate complexity built on the PILPS experiences, we demonstrate the key aspects of a land-surface model relevant to climate simulation. Example will be shown for the amazon interannual climate and hydrological variability. A method using atmospheric reanalysis data and observed surface runoff to diagnose soil moisture variability will be highlighted as an important way for validating the models.

MC01/E/18-A3 Invited 1535

STATUS REPORT ON PILPS PHASE 3: AMIP DIAGNOSTIC SUBPROJECT 12

Thomas J. PHILLIPS (Program for Climate Model Diagnosis and Intercomparison (PCMDI), Lawrence Livermore National Laboratory, PO Box 808, Livermore, California, USA, Email: phillips14@llnl.gov)

Phase 3 of the Project for Intercomparison of Landsurface Parameterization Schemes (PILPS) entails the diagnosis of diverse landsurface schemes that are designed to operate within atmospheric general circulation models (AGCMs). Because most of the world's AGCM groups have conducted climate simulations according to the standard protocol of the Atmospheric Model Intercomparison Project (AMIP), PILPS Phase 3 has functioned as an AMIP diagnostic subproject. The presentation will review the work of the subproject since 1992, including both the main findings of its first (AMIP I) phase and preliminary results from the recently initiated AMIP II intercomparison.

MC01/E/09-A3 1550

LAND-SURFACE PARAMETERIZATIONS AND CLIMATE SIMULATIONS: PRELIMINARY RESULTS FROM AMIP II DIAGNOSTIC SUBPROJECT 12

HUQIANG ZHANG (Environment Division, Australian Nuclear Science and Technology Organisation, PMB 1, Menai, NSW 2234, Australia) Ann Henderson-Sellers (Environment Division, Australian Nuclear Science and Technology Organisation, PMB 1, Menai, NSW 2234, Australia)

Results from AMIP I diagnostic subproject 12 have shown large inter-model scatter in the surface energy and water partitions. Those large inconsistencies are identified to be partly responsible for the substantial differences in simulated continental climate. However, the analyses of AMIP I results were constrained by the fact that most AMIP I models employed bucket schemes and some models did not conserve energy and moisture. In the current study, we report some preliminary analyses of AMIP II results which became available in early 1999. We will focus on the quantitative assessment of the agreement among the models in simulating the surface energy partition (latent heat and sensible heat) and the surface water partition (evaporation, precipitation, runoff and others). Furthermore, how the differences in those two partitions affect the model simulation of ground temperature, soil moisture and snowpack is investigated. Following the model intercomparison of the aforementioned key surface variables, we then try to link the model performance with the land-surface schemes used in the models themselves. The aim is to understand how much the differences can be explained by the different behaviour of land-surface component in each model. For the models participating in AMIP I and/or PILPS projects, we will compare their performance with that seen in the previous studies. Finally, we will present some on-going activities in the joint AMIP/PILPS project. How to fully explore the AMIP II results to enhance our understanding of the role of land-surface in climate simulations will also be discussed.

MC01/E/36-A3 1605

CHARACTERISING GCM LAND SURFACE SCHEMES TO UNDERSTAND THEIR RESPONSE TO CLIMATE CHANGE

Nicola GEDNEY and Peter Cox (both at Hadley Centre, UK Met Office), Herve Douville (Meteo-France), Jan Polcher (Laboratoire de Meteorologie Dynamique du CNRS, France), Paul Valdes (University of Reading, UK)

The impact of land surface representation on GCM simulations of climate change is analysed using 8 climate change experiments, carried out with 4 GCM's each utilising 2 different land surface schemes (LSS's). In the regions studied (Amazonia, the Sahel and Southern Europe) the simulations differ markedly in terms of their predicted changes in evapotranspiration and soil moisture. This is only partly as a result of differences in the predicted changes in precipitation and available energy. A simple ``bucket model'' characterisation of each LSS, demonstrates that the different hydrological sensitivities are also strongly dependent on properties of the LSS; most notably the runoff which occurs when evaporation is marginally moisture stressed. This parameter varies significantly amongst the LSS's, and strongly influences both the soil moisture in the 1xCO2 control climate, and the sensitivity of evaporation and soil moisture to climate change. It is concluded that uncertainty in the predicted changes in surface hydrology are more dependent on such gross features of the runoff versus soil moisture curve, than on the detailed treatment of evapotranspiration.

MC01/W/46-A3 1620

THE INFLUENCE OF TWO DIFFERENT LAND-SURFACE COUPLING TECHNIQUES IN THE MPI GCM

Jan-Peter SCHULZ (curr. aff.: Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen, Denmark, email: jps@dmi.dk) Lydia Dumenil (Max-Planck-Institut fur Meteorologie, Bundesstrasse 55, D-20146 Hamburg, Germany, email: dumenil@dkrz.de) Jan Polcher (Laboratoire de Meteorologie Dynamique du CNRS, 4 pl. Jussieu, F-75252 Paris, France, email: jan.polcher@lmd.jussieu.fr)

Land surface processes have a significant impact on near surface climate phenomena. The component of an atmospheric general circulation model (GCM), that is responsible for the representation of land surface processes, is the land surface scheme (LSS), which essentially represents the land surface energy and moisture cycles. Various different LSSs have been developed for use in GCMs that utilize very different parameterizations of these physical processes and lead to differences in the simulated climates. In addition, the numerical coupling between land surface and atmosphere can also have a significant impact on the model simulation. The objective of PILPS phase 4 is to intercompare different LSSs which are coupled to the same atmosphere model. The focus is on assessing the impact of the different physical parameterizations on the simulated climate. In the present study, two versions of the ECHAM4 GCM are compared, one with semi-implicit coupling between land surface and atmosphere, the other one with implicit coupling. A global simulation was performed with both models, using the same initialization and climatological sea surface temperatures. The results show that the coupling technique has an important impact on the simulated surface climate and the water and energy cycles. These results are compared to an experiment with a third version of the ECHAM4 GCM, in which the SECHIBA land surface scheme is implemented in an implicit way. This allows one to estimate the relative importance of differences in land surface parameterizations and differences in surface-atmosphere coupling techniques.

MC01/W/13-A3 1635

TESTING AGGREGATION RULES FOR SURFACE PARAMETERS USING REMOTELY SENSED LAND COVER DATA AND THE NCAR COMMUNITY CLIMATE MODEL (CCM3) COUPLED TO BATS

Eleanor J. BURKE, Muhammed Altaf Arain, Zong-Liang Yang, and W. James Shuttleworth (Department of Hydrology and Water Resources, The University of Arizona, Tucson AZ 85721, USA, email: eleanor@hwr.arizona.edu)

The land surface parameters required as input to a GCM grid box (typically a few degrees) are often set to be those of the dominant vegetation type within the grid box. This paper discusses the use and effect of aggregation rules for specifying effective values of these land cover parameters by taking into account the relative proportion of each land cover type within each individual grid box. Global land cover classification data at 1 km resolution were used to define Biosphere Atmosphere Transfer Scheme (BATS) specific aggregate (using aggregation rules) land cover parameters. Comparison of the values of the aggregate parameters and those defined using the dominant vegetation type (default parameters) shows significant differences in some regions, particularly in the semi-desert, and in forested regions, e.g. the Saharan desert and the tropical forest of South America. These two different sets of parameters were used as input data for two 10-year simulations of the NCAR CCM3 model coupled to the BATS land surface scheme. Statistical analyses comparing the results of the two model runs showed that the resulting differences are only significant in specific regions. For example, the sensible heat flux in the Saharan desert calculated for the aggregate run increased due to the marked increase in the minimum stomatal resistance and the decrease in fractional vegetation cover in the aggregate parameters over the default parameters. The modelled global precipitation and surface temperature fields were compared to observations: there is a general improvement in the performance of the aggregate run over the default run in areas where the differences between the aggregate and default run are significant. However, most of the difference between the modelled and observed fields is attributable to other model deficiencies. It can be concluded that the use of aggregation rules to derive land surface parameters results in significant changes in modelled climate and some improvements in the land surface diagnostics at the regional scale, however these are not as wide-spread or dramatic as the changes in vegetation parameters suggest.

MC01/W/53-A3 1650

COMPARATIVE EVALUATION OF SIB2, BATS, AND BATS2 USING AMAZON FIELD DATA

Omer L. SEN, W. James Shuttleworth, and Zong-Liang Yang (All at Department of Hydrology and Water Resources, University of Arizona, Tucson, 85712, AZ, USA, Email: sen@hwr.arizona.edu)

Over the last decade, improved understanding of plant physiological processes has generated a major change in the way stomatal functioning is described in advanced land surface schemes. New versions of two widely-used, advanced land surface schemes, SiB and BATS, exist that reflect this change in understanding, but these two new models make different assumptions regarding the form of the humidity stress factor. The main goal of this study was to evaluate the new version of BATS, here called BATS2, using Amazon field data from the ABRACOS project, with emphasis on comparison against the original version of BATS and on comparison with SiB2. Evaluation of SiB2 using a 3-year time series of ABRACOS data revealed weaknesses not noticed in previous studies. Specifically, the model's description of early morning transpiration is poor with hourly-average forcing data and there is an unrealistic simulation of the yearly cycle in soil moisture status, with a resulting poor simulation of evaporation. Improved long-term simulation by SiB2 requires specification of a deeper rooting depth, this being a general feature required for all three models. In general, the original version of BATS gave good agreement with observations, but it showed excessive sensitivity to vapor pressure deficit in very dry atmospheres, and the value of minimum stomatal resistance specified by default was not optimal. Evaluation of BATS2 revealed that substantial changes are required in the parameters that determine stomatal behavior in the model for simultaneously realistic simulation of the net carbon uptake, nighttime respiration and transpiration. In general, all three models have weaknesses when describing the field data using their default parameters. However, if a few model parameters are modified in a plausible way, all three can give a good time-average simulation of measured exchanges, and there is little evidence of sensitivity to the different forms assumed for the humidity stress function.

MC01/W/54-A3 1705

ENHANCING THE SIMPLIFIED BIOSPHERE MODEL (SSIB) TO ESTIMATE CARBON FLUXES OF TERRESTRIAL ECOSYSTEMS FOR REGIONAL CLIMATE STUDIES

Xiwu Zhan, YONGKANG XUE (both at Department of Geography, University of Maryland, College Park, MD, USA, Tel: 301-405-4050; fax: 301-314-9299, email: yxue@geog.umd.edu), and G. James Collatz(Laboratory for Terrestrial Physics, NASA/GSFC, Greenbelt, MD, USA)

Increase in greenhouse gases, in particular CO2, has great impact on global climate change. It is desirable to accurately assess the CO2 fluxes between the terrestrial ecosystems and the atmosphere in regional climate studies. The current version of the simplified biosphere model (SSIB) does not consider the photosynthetic activities of CO2 assimilation of plants. The work in this paper is an enhancement of the SSIB model for the CO2 flux modelling. The equations and parameters of the photosynthesis-stomatal conductance models developed by Collatz et al. for C3 or C4 plants are adopted for simulating the uptake or release of CO2 by land surface ecosystems. These models have sound physiological basis and fine description to the interactive effects of environmental factors of plant photosynthesis and stomatal movement. However, the equations of these models are solved numerically with iterations, which consumes a great amount of computational time. In some cases, the iteration process may not be convergent and an appropriate solution may be difficult to obtain. In this study, a new procedure is developed to quasi-analytically solve the equations of these models. By using this procedure, appropriate solutions can be directly computed without iterations. When an appropriate solution of these models does not exist under some night time environmental conditions, the simple procedures are applied to simulate the processes because the land surface fluxes in these cases are not significant. The CO2 release from soil surface is modeled with a soil respiration model similar to that of Porter et al's CASA model (the Carnegie, Ames, Stanford Approach). Off-line tests using the enhanced SSIB model are conducted to compare with measured CO2 flux, latent heat and sensible fluxes.

MODELLING EUROPEAN REGIONAL CLIMATE, UNDERSTANDING AND REDUCING ERRORS - THE MERCURE PROJECT

Richard JONES (Hadley Centre for Climate Prediction and Research, UK Met. Office, London Road, Bracknell, RG12 2SZ, UK. Email: rgjones@meto.gov.uk)

MERCURE is a wide-ranging project whose main focus is on the improvement of simulation of European climate but which has implications for modelling regional and global climate generally. The main aim of the project is to improve regional climate models (RCMs) by understanding the source of errors and reducing them by improving the models' representation of physical processes (including increasing resolution). The focus will be on improving the simulation of surface air temperature and precipitation given their fundamental importance in assessing impacts of climate. Four main areas important for modelling regional climate are being focused on and results from these will be presented. 1) Improving the hydrological cycle in regional models via improved formulations of land- surface processes, radiation and precipitation physics. New aspects of the simulations will be validated by comparing with run-off, snow-pack and soil-moisture data. 2) Assessing the ability of regional models to reproduce observed precipitation frequency distributions (including the frequency of heavy events) as well as climatological means. 3) Further characterisation of errors in regional climate simulations nested in general circulation models (GCMs) derived from the GCM driving data. GCM errors which induce large-scale errors in the RCMs will be identified and GCM modellers will be encouraged to reduce them. 4) Providing a statistical-dynamical tool linking RCM and GCM simulations to extend the length of RCM integrations. The method will be able to reproduce the main features of long RCM simulations from large-scale driving data given shorter sets of both for calibration. This will allow the computation of statistical RCM scenarios for a wide range of GCM scenarios.

MC01/W/08-A4 0950

PROJECT TO INTERCOMPARE REGIONAL CLIMATE SIMULATIONS

RAYMOND W. ARRITT, William J. Gutowski, Jr., Eugene S. Takle and Zaitao Pan (all at Department of Agronomy, Iowa State University, Ames, Iowa 50011 USA, email: rwaritt@iastate.edu)

The Project to Intercompare Regional Climate Simulations (PIRCS) provides a common simulation framework for evaluating regional climate models. We describe the motiva-tion and structure for the first PIRCS simula-tion experiment and present initial evaluations of the collective capabilities of participating models. Experiment 1 covers two periods of hydrologic extremes in the central United States: 15 May - 15 July 1988 (drought) and 1 June - 31 July 1993 (flood). For more details see the PIRCS Web site, http://www.pircs.iastate.edu. Initial results indicate that limited-area models forced by large-scale information at their lateral boundaries reproduce bulk temporal and spatial characteristics of observed fields. The 500 hPa height field's time average and temporal variability are generally well simulated by all participating models. Organized synoptic-scale precipitation systems are simulated deterministically, in that precipitation occurs close to the same time and location as observed (though amounts vary from the observations). Episodes of mesoscale and convective precipitation are represented in a more stochastic sense, with less precise agreement in temporal and spatial patterns. Simulated surface energy fluxes near the FIFE region show that inter-model differences in mid-day Bowen ratio tend to be closely associated with precipitation differences. Differences in daily maximum temperatures also are linked to Bowen ratio differences, while daily minimum temperatures show no clear link to Bowen ratio. Although some models have bias all reproduce the synoptic variability of observed daily maximum and minimum temperatures.

MC01/W/47-A4 1005

A MODEL INTERCOMPARISON OVER THE BALTIC DRAINAGE BASIN

Daniela JACOB (1), Xiaohua Yang (2), Werner Wergen (3), Burkhard Rockel (4), Nils Gustafsson (5), Roderick Smith (6) (1) Max-Planck-Institute for Meteorology, Bundesstr. 55, 20146 Hamburg, Germany (2) Danish Meteorological Institute, Lyngbyvej 100, 2100 Copenhagen, Denmark (3) Deutscher Wetterdienst, Frankfurter Str. 135, 63067 Offenbach, Germany (4) Forschungszentrum Geesthacht, Max-Planck-Strasse, 21494 Geesthacht, Germany (5) Swedish Meteorological and Hydrological Institute, Folkborgsvaegen 1, 60176 Norrkoeping, Sweden (6) Hadley Centre for Climate Prediction and Research, Bracknell, Berkshire, RG12 2SY, UK

Within the NEWBALTIC project, an EU-project under BALTEX, mainly concentrating on numerical studies of the energy and water cycle of the Baltic Region, a model intercomparison of regional atmospheric models has been carried out. This study points to differences in numerical modelling of the atmospheric water and energy cycles and it will discover uncertainties in model generated fields. The participating groups agreed on a common grid, identical initial and lateral boundary conditions and a validation strategy. The model intercomparison has been performed for a three months long period (1st August 1995 until 31st October 1995) over the entire Baltic Sea drainage basin. Within this period an intense data collection and analyses took place. Model results and a careful validation against observations will be presented.

MC01/E/34-A4 1020

INTERCOMPARISON OF REGIONAL CLIMATE CHANGE SIMULATIONS FOR EUROPE

Bennert MACHENHAUER, Martin Windelband, and Michael Botzet (all at Max Planck Institute for Meteorology, Bundesstr. 55, D-20146 Hamburg, Germany. emails: machenhauer / windelband / botzet@dkrz.de)

Time-slices of 10-30 years from present-day climate simulations and transient climate change experiments performed with two coupled atmosphere-ocean GCMs were used as boundary conditions for three 50 km resolution Regional Climate Models (RCMs) focusing on Europe. Simulated seasonal mean values of surface air temperature and precipitation in the present-day time-slices were validated against observed climatological data in nine sub-areas covering Europe. The relatively large number of large, statistical significant sub-area mean biases seems to be caused by: 1) systematic errors in the simulated general circulation, in particular in the cyclonic activity over Europe, 2) errors in the parameterization of certain physical processes, 3) errors in the sea surface temperatures determined by the coupled GCMs. In two doubling greenhous gas climate change experiments we find statistically significant mean temperature increases for the whole European region. These are also large compared to the corresponding biases of the present-day climate simulations. However, the changes in sub-areas of the deviation from the European mean temperature as well as the sub-area changes of precipitation are only partly significant and are of the same order of magnitude or smaller than the corresponding biases. In many cases they are also significantly didderent in the two experiments. It is also found that due to interaction between the systematic model errors and effects of the radiative forcing the systematic errors cannot be assumed to cancel out when the changes are computed, i.e. when subtracting a control time-slice from a future scenario time-slice simulation.

MC01/E/23-A4 1035

INTERCOMPARISON OF REGIONAL CLIMATE SIMULATIONS OF THE 1991 EAST ASIAN SUMMER MONSOON: SENSITIVITY TO LATERAL BOUNDARY CONDITIONS

L. R. LEUNG (Pacific Northwest National Laboratory, P.O. Box 999, Richland, WA 99352, USA, email: ruby.leung@pnl.gov) W.-C. Wang, W. Gong (State University of New York at Albany, 100 Fuller Road, Albany, NY 12205, email: wang@climate.cestm.albany.edu) Z.-C. Zhao, and Y. Luo (National Climate Center, China Meteorological Administration, 46 Baishiqiao Road, Beijing 100081, China, email: zhaozc@sun.ihep.ac.cn)

To examine the sensitivity of different regional climate models to lateral boundary conditions (LBC), an intercomparison experiment has been performed where three regional climate models were driven by two sets of LBC from the ECMWF and NCEP/NCAR reanalyses to simulate an extreme flood event. Although the dynamical components of the models are almost identical, the physical parameterizations used to represent clouds, radiative transfer, turbulence transport, and surface processes are very different. Furthermore, some recent modifications have been applied to two of the models which render the simulations rather different from a previous intercomparison experiment reported using earlier versions of the models. The models were used to simulate the heavy precipitation during the 1991 summer which caused severe flooding over the Yangtze River in China. Comparison of the ECMWF and NCEP/NCAR reanalyses of the 1991 extreme flood case shows some large differences in the hydrological budgets represented. For example, the ECMWF reanalysis produced about 10% more net moisture advection into the study domain that centered over China. Consequently all regional climate simulations driven by the ECMWF reanalysis produced more precipitation than those driven by the NCEP/NCAR reanalysis. Analyses of the six regional simulations suggest that minor differences in the large scale LBC could be amplified by differences in the regional models because of the strong interactions among clouds, radiation, and surface processes.

Regional Modelling and Hydrology

MC01/W/44-A4 1110

REGIONAL SIMULATIONS OF CALIFORNIA PRECIPITATION

John ROADS (Scripps Institution of Oceanography, UCSD-0224, La Jolla, CA 92093, Email: jroads@ucsd.edu) Shyh Chen (Scripps Institution of Oceanography, UCSD-0224, La Jolla, CA 92093, Email: schen@ucsd.edu)

A global to regional modelling system, capable of making large-scale climate simulations and forecasts, and then downscaling these forecasts and simulations to regional scales is evaluated for California. Regional climate simulations of wet and dry winters compare well with available observations, especially in comparison to global simulations. While the global model paints a broad swath of precipitation across the western U.S., the regional model, forced by the large-scale background flow produced by the global model, more accurately simulates the increased precipitation over the Sierra Nevada and coastal regions. The regional model is especially advantageous for intense precipitation events at regional spatial scales. Although the regional simulations do not significantly alter the imposed large-scale features, they do significantly enhance the spatial as well as temporal variations of the hydrologic variables. Basically, downscaling by a regional model is a dynamically consistent method, which extends the usefulness of global climate forecasts. Still, current regional simulations are not perfect. Even higher resolution and further improvement in physical parameterizations are still needed.

MC01/W/17-A4 1125

REGIONAL INTERPRETATION OF CLIMATE SCENARIOS FOR NORTHERN EUROPE; COUPLING OF AN ATMOSPHERIC MODEL, A 1.5-D REGIONAL OCEAN MODEL, LAKE MODELS AND HYDROLOGICAL MODELLING

Markku RUMMUKAINEN, Anders Ullerstig, Jouni Räisänen, Björn Bringfelt, Anders Omstedt, Colin Jones, Ulrika Willén, Phil Graham and Ulf Hansson (Rossby Centre, Swedish Meteorological and Hydrological Institute, SE-61076 Norrköping, Sweden. Email: markku.rummukainen@smhi.se)

The climate of northern Europe is affected by numerous small-scale forcing features, or

phenomena that are characterized by large seasonal/spatial contrasts. Air masses arriving from the Oceans in the west and southwest first meet the Scandinavian mountains and thereafter traverse the landscape with numerous lakes as well as the Baltic Sea. The nature of the surface, including snow and ice modifies the surface climate. Variability in the regional topography also affects the strong seasonal transitions in climate via snow cover and in the hydrological budget in general. In order to construct a regional interpretation of the Nordic climate from global model results, it is necessary to improve the description of the small-scale forcing features. In the SWECLIM regional climate modelling programme, this is addressed by coupling a model for the Baltic Sea and lake models into a climate version of a limited area weather forecast model HIRLAM. In addition, formulations from a hydrological model are imported to improve the modelling of soil moisture and point runoff. A description of the coupled model system, as well as results from 10-year downscaling integrations will be discussed, emphasizing the results for snow cover, lake ice cover and the Baltic Sea ice, as well as the hydrological budget. The simulations have been done with time slice data from the control and transient Hadley Centre HadCM2 integrations.

MC01/W/28-A4 1140

WATER AND ENERGY BALANCE OF THE BALTIC DRAINAGE BASIN

Daniela JACOB Max-Planck-Institute for Meteorology, Bundesstr.55 20146 Hamburg, Germany

Within the BALTEX (BALtic sea EXperiment) project the hydrological and energetic budgets of the Baltic Sea drainage basin are under investigation with the aim to understand the water and energy cycles more completely. The budgets are influenced by meteorological phenomena on different time and space scales including the range from single episodes to multi year climate simulations. Extremes,interannual and decadal variabilities are of interest. The atmospheric regional climate model REMO has been used to study the water and energy budgets of the Baltic Sea drainage basin for a period of 21 months. Continous simulations with two different physical parameterization packages and on two different horizontal resolutions have been carried out using analyses fields provided by the German Weather Service as initial and lateral boundary conditions. First results indicate that the annual cycle of the monthly total precipitation have a similar behaviour during the winter months but differences during the summer esp. over land. Furthermore the water balance over the Baltic Sea was positive (more precipitation than evaporation) during the first half of 1992 and during the period January to August 1993, while the signal during the second half of the year 1992 was not clear.

MC01/P/01-A4 1155

NUMERICAL SIMULATIONS ON IMPACTS OF THREE GORGES RESERVOIR ON SUMMER MONSOON RAINFALL OVER EAST ASIA

ZONGCI ZHAO and Yong Luo (National Climate Center, Baishiqiaolu, No.46, Beijing, 100081, P.R. China E-mail: zhaozc@sun.ihep.ac.cn)

Three Gorges reservoir along the Yangtze River Valley of China is going to be reconstructed. The numerical simulations of Three Gorges reservoir have been conducted by using a regional climate model (RegCM2/EA) which was based on the NCAR RegCM2. The model has a domain of about 100-150E and 10-45N with a horizontal resolution of 60km x 60km and a vertical resolution of 23 layers. A sensitive experiment was designed a water body at around the Three Gorges region with 45 grid points and 50m or 100m of water depth to replace the vegetation of the present time. To compare the simulations of Three Gorges' reservoir run with the control run, it is found that the summer rainfall over some regions where are near the Three Gorges reservoir such as Southwest China, Yangtze-Huaihe River Valley and Hetao might be increased clearly. Impacts of the Three Gorges reservoir on Other variables have also been investigated in this research. The numerical experiments with the different areas and depths of this reservoir were also conducted.

MC01/W/38-A4 1210

SOIL WATER PARTITIONING AND ISSUES IN THE COUPLED HYDROSPHERE-ATMOSPHERE RESEARCH MODEL (CHARM)

Lofgren, B. M.

Excessive boundary-layer cloudiness has been a problem within the Coupled Hydrosphere-Atmosphere Research Model (CHARM), a model of the Laurentian Great Lakes' regional climate system that uses the Regional Atmospheric Modelling System (RAMS) as the basis for its atmospheric component. This is in spite of a deficit of humidity in the lower boundary layer, in comparison to observations. Some of this problem stems from continued land surface evapotranspiration following the formation of fog. An altered formulation of evapotranspiration in the presence of fog helps to abate the resulting temperature and precipitation biases. A revised formulation of land surface runoff helps to remedy the problem of dry air in the lower boundary layer, without exacerbating the problem with stratus clouds.

Regional Applications and Scenario Generation

MC01/W/21-A4 1400

THE ROLE OF REGIONAL CLIMATE MODELLING FOR THE IPCC THIRD ASSESSMENT REPORT

Jens H. Christensen (Danish Met. Institute,Lyngbyvej 100, DK-2100 Copenhagen Ø, Denmark)

It is stated by the Intergovernmental Panel on Climate Change (IPCC) that the Third Assessment Report (TAR) - due in 2000/2001 - will be comprehensive and cover the complete range of scientific, technical, economic and social issues associated with the climate system and climate change, will be policy relevant but not policy prescriptive. Compared to the Second Assessment Report (SAR), TAR will emphasize the regional aspects of climate change, place additional emphasis on adaptation, provide a more quantitative treatment of uncertainties and clear exposition of different points of view. It will also describe advances and changes in the understanding since SAR. The major emphasis on regional aspects indicates a substantial change of attitude since the SAR. It reflects the strong development within impact related, economical and social sciences to assess the role of global change on the regional level, where adaptation and mitigation strategies have become relevant to the decision makers. Because of the focus on regional climate in TAR, regional climate modelling will be reviewed in its own chapter in TAR, reflecting the strong scientific investment in this field since the preparation of SAR. Here the role of regional climate modelling as seen from TAR will be reviewed.

MC01/E/35-A4 1415

A TWO-YEARS (1989-90) REGIONAL CLIMATE SIMULATION OVER EUROPE

Clemente Gallardo (email: etnemelc@eucmos.sim.ucm.es), Manuel de CASTRO (email: mcastro@eucmax.sim.ucm.es), Juan A. Prego (email: japrego@eucmos.sim.ucm.es) (all at Department of Geophysics and Meteorology, University Complutense of Madrid, Spain) and Miguel A. Gaertner (Department of Applied Physics, Environmental Sciences Faculty, University of Castilla-La Mancha, Toledo, Spain, email: figeo03@ sis.ucm.es)

A comprehensive atmospheric regional climate model named PROMES, entirely developed at the Department of Geophysics and Meteorology of the Complutense University of Madrid (Spain), has been applied for the period from 1 October 1988 to 28 February 1991, in the framework of the MERCURE European intercomparison project. The model domain covers most of Europe and the Mediterranean basin with a horizontal resolution of 50x50 km2 (cartesian coordinates). In the vertical 26 terrain-following sigma layers from surface up to 100 hPa level were considered. The model run was driven by ECMWF re-analysis (atmosphere and SST values) updated every 6 hours. Initial soil moisture fields were derived from climatological values. The used model version includes a sophisticated land-surface package (SECHIBA), a Fritsch and Chappell-type convective parameterization and a relaxation lateral boundary scheme. The simulated monthly averages of 2-m temperatures and precipitation are compared with CRU climatological data base in several subdomains defined according to the diferent climate regimes existing within the considered region. The seasonal cycle of temperature and precipitation is acceptably reproduced as well as the effects of topography. This shows that PROMES model is feasible to be applied to present and future climate studies.

MC01/E/02-A4 1430

WINTER SEASONAL PREDICTION OF TEMPORAL VARIABILITY OVER NORTH AMERICA - EXPERIMENTS WITH NESTED REGIONAL CLIMATE MODELS

J. L. KINTER, M. J. Fennessy, E. Altshuler, and J. Shukla (Center for Ocean- Land-Atmosphere Studies, 4041 Powder Mill Road, Suite 302, Calverton, MD 20705 USA)

Several recent studies (Shukla, 1998; Fennessy and Shukla, 1999; Shukla et al. 1999; many others) have demonstrated spectacular success in simulating (hindcasting) and predicting the seasonal mean stationary wave pattern over the northern Pacific Ocean and North America in those winters when a large tropical sea surface temperature (SST) anomaly is present, i.e., El Nino or La Nina conditions. The anomalous stationary wave pattern includes the seasonal mean positions of the anomalous ridges and troughs over North America that are associated with departures from normal of the position and intensity of the jet stream and the location of the extratropical cyclones tracks. As a result, the seasonal mean anomalous surface air temperature and precipitation can be forecast in those winters when El Nino or La Nina conditions prevail. Such forecasts are shown in a companion paper (Fennessy et al. 1999) to be more accurate and potentially useful when made using nested regional climate models rather than global atmpospheric general circulation models (AGCMs) only. We have examined the daily variability of temperature and precipitation in several winter cases simulated with the COLA R40 AGCM (C model) and with both an 80-km version of the National Centers for Environmental Prediction, Environmental Modelling Center Eta model (E model) and the MM5 regional model (M model), both for the North American region and both nested in the global COLA AGCM. The geographic distribution of the amplitude and frequency of precipitation events and the associated variations of temperature near the surface are quite well simulated in the E and M models, substantially better than in the C model simulations. Results documenting and quantifying the intraseasonal accuracy of these models will be shown.

MC01/E/03-A4 1445

ARCTIC WINTER SIMULATIONS WITH A REGIONAL CLIMATE MODEL

Annette RINKE, Klaus Dethloff, Antje Weisheimer (all at Alfred Wegener Institute for Polar and Marine Research, Telegrafenberg A43, D-14473 Potsdam, Germany, e-mail: arinke@awi-potsdam.de)Jens H. Christensen (Danish Met. Institute,Lyngbyvej 100, DK-2100 Copenhagen 0, Denmark)

Data analyses show that the circulation of the Arctic atmosphere undergoes large fluctuations about its monthly and annual means. A necessary prerequisite to correctly simulate climatic changes is that models are able to realistically represent this natural variability. The mean Arctic winter climatology and its interannual variation has been examined by regional climate simulations. The employed regional atmospheric climate model is called HIRHAM and includes the physical parameterization package of the GCM ECHAM. The simulations are performed at a horizontal resolution of 50 km and the model is forced at the lateral and lower boundaries by ECMWF analyses. An ensemble of winter simulations (December-February of the six years 1990-1995) has been investigated in which the ensemble is large enough to represent a broad range of climatic conditions. It is shown that the dynamical aspects of the interannual variability can be adequately captured by the model simulations. To gain more insight into the spatial and temporal structures of the model's variability an empirical orthogonal function (EOF) analysis has been applied to determine the most significant structures in the fluctuations of the monthly mean dynamical fields. EOF 1 of the 500 hPa height field describes a regime with well- pronounced polar vortex and corresponds with the "Arctic Oscillation", whereas EOF 2 and 3 show wave structures. A pronounced interannual variability is noticed in the time series of the amplitudes of the EOFs.

MC01/W/14-A4 1155

HIGH RESOLUTION SIMULATION OF ARCTIC CRYOSPHERIC ANOMALIES

A.H. LYNCH, R.I. Cullather, J.A. Maslanik and M.C.Serreze (all at CIRES, CB 216, University of Colorado, Boulder, CO 80309-0216, USA, tel: +1 303 492 5847, fax: +1 303 492 1149, email: manda@cires.colorado.edu)

Recent global climate modelling results highlight the Arctic as a region of particular importance in global climate change. Numerous observational studies have demonstrated the sensitivity of sea ice and snow to changes in regional climate and larger scale modes of atmospheric circulation. The goal of the current work is to identify the mechanisms responsible for recently observed trends and anomalies in the Arctic cryosphere, in an effort to elucidate the most important mechanisms involved, and hence determine the crucial processes missing from GCM simulations of the Arctic climate under conditions of change. A two-fold approach is being used. First, a rigorous testing of simulation skill and model behavior in a regional climate system model of the Arctic has been undertaken using an ensemble approach and highly constrained simulations. Second, analysis of observations and long simulations using a stand-alone sea ice model incorporating elastic-viscous-plastic rheology and multi-category ice thermodynamics have been undertaken to determine the modes of atmospheric variability in which the cryospheric anomalies occur, and whether the anomalies are reporudcible in these modes.

MC01/W/45-A4 1500

REGIONAL CLIMATE MODELLING RESEARCH AT CSIRO

John L. and Jack J. Katzfey CSIRO Atmospheric Research, Melbourne, Australia

For some years CSIRO has had an active programme for modelling climate change using the Division of Atmospheric Research Limited Area Model (DARLAM) nested within the CSIRO spectral GCM. Recently we have extended our range of simulations to include other domains, to perform longer integrations, and to run at finer resolution. The presentation will describe the implementation of the model and its application to climate modelling over Australia, southeast Asia, New Zealand, South Africa and South America for model resolutions of 44 km to 125 km, as well as for the PIRCS experiments over USA. Particularly long nested simulations of 140-year duration for Australia at 125 km and 60 km resolution have been performed; for these the model is nested within the CSIRO GCM for transient increases of greenhouse gases according to the IS92a scenario. CSIRO has developed a new variable-resolution global GCM, which provides different opportunities for regional climate modelling than the one-way nested approach. The formulation of the new global model will be briefly described, and some results of simulations shown for present-day conditions.

MC01/W/23-A4 1515

REGIONAL CLIMATE MODEL SENSITIVITY STUDIES FOR TROPICAL SOUTH AMERICA

Anji SETH (National Center for Atmospheric Research, Boulder, CO, USA, email: seth@ucar.edu)

The prospects for seasonal prediction are good in the tropics, where sea surface temperature influences on regional climate anomalies are direct. Improved understanding of moisture transports, low level jets and other regional circulations which affect seasonal rainfall anomalies require higher resolution of topography, landuse and coastlines than most global models can provide. Results will be presented from seasonal integrations of the NCAR regional climate model (RegCM) over tropical South America. A number of simulations are performed, varying in duration from 1 to 4 months, for the anomalous seasons of 1982/83 and 1986/87. Time evolving atmospheric conditions are taken from NCEP Reanalyses to drive the lateral boundaries of the RegCM domain. Discussion will focus first on the sensitivity of the simulations to the parameterization of convection, and second, on the sensitivity of regional circulations and rainfall on choice of domain.

Land Surface Processes in Regional Climate

MC01/W/30-A4 1615

EVALUATION OF REGIONAL PREDICTION MODELS USING REMOTELY SENSED DATA

Ernesto H. Berbery (Department of Meteorology/CICS, University of Maryland, College Park, MD, 20742 USA, email: berbery@atmos.umd.edu) Rachel T. Pinker (Department of Meteorology, University of Maryland, College Park, MD, 20742 USA, email: pinker@atmos.umd.edu) Kenneth E. Mitchell (Environmental Modelling Center/NCEP/NOAA, Camp Springs, MD, USA, email: wd22km@sgi21.wwb.noaa.gov)

The surface energy budgets from three operational mesoscale models and from the NCEP/NCAR Reanalysis are compared and evaluated against information derived from satellite observations. The three mesoscale models are: 1) the NCEP Eta model, 2) the Mesoscale Analysis and Prediction System (MAPS) model, and 3) the Global Environmental Multiscale (GEM) model. The objective is to evaluate the reliability of the surface energy budgets within the context and requirements of the GEWEX Continental -scale International Project (GCIP), which are aimed at the development and evaluation of coupled hydrologic/atmospheric models at resolutions appropriate to large scale continental basins. In particular, it is aimed to evaluate the land surface and atmospheric parametrizations from regional numerical weather prediction models and their associated Four Dimensional Data Assimilation Systems. Results will be presented on the biases found in all models in respect to "observed" surface radiative fluxes, and on the nature of energy partitioning between sensible and latent heat fluxes, in terms of the Bowen Ratio. Addressed will be plausible causes of the differences and needs for corrections.

MC01/W/35-A4 1630

SURFACE CHARACTERISTICS FOR A REGIONAL CLIMATE MODEL BASED ON NEW HIGH-RESOLUTION DATA SETS

J. H. CHRISTENSEN, O. B. Christensen (both at Danish Meteorological Institute, Lyngbyvej 100, DK-2100 Copenhagen Ø, Denmark, email: jhc@dmi.dk), S. Hagemann, and B. Machenhauer (both at MPI, Bundesstrasse 55, D-20146 Hamburg, Germany, email: hagemann@dkrz.de)

As a part of the MERCURE project, new satellite-based data sets have been used to improve the surface charateristics used by the regional climate model HIRHAM. Based on elevation and land use data sets in 1km resolution from the US Geological Survey, new fields of orography, vegetation ratio, roughness length, albedo, leaf area index and soil moisture capacity have been generated. Previous data sets were of a spatial resolution becoming inadequate for the resolution of present-day regional climate experiments aimed at in the MERCURE project. The algorithms used to construct the new parameter sets and differences to the earlier fields will be described, and the effects on simulations of the present climate will be presented. The latter is based on simulations in integration areas covering Europe with 25 and 50km resolution, respectively. Preliminary results show a better performance in summer in Southern Europe, as an excessive draught problem is diminished. The sensitivity to the particular changed fields will be investigated on the basis of a step-by-step change of these.

MC01/E/27-A4 1645

USE OF AN ATMOSPHERIC RCM TO ESTIMATE THE CLIMATE RESPONSE TO DEFORESTATION OVER WESTERN MEDITERRANEAN

Miguel A. Gaertner (Department of Applied Physics, Environmental Sciences Faculty, University of Castilla-La Mancha, Toledo, Spain, email: figeo03@sis.ucm.es), Juan A. PREGO (email: japrego@eucmos.sim.ucm.es), Clemente Gallardo (email: etnemelc@eucmos.sim.ucm.es) and Manuel de Castro (email: mcastro@eucmax.sim.ucm.es) (all at Department of Geophysics and Meteorology, University Complutense of Madrid, Spain)

A deforestation experiment has been performed over Western Mediterranean with PROMES atmospheric regional climate model, completely developed by the modelling group of the Universidad Complutense. SECHIBA land-surface package has been used to parameterize exchanges between soil-vegetation and atmosphere. Simulations have been done for year 1982, with lateral boundary conditions provided by ECMWF reanalysis. An ensemble technique, with partial reinitialization at the end of each cycle has been used, by allowing soil variables to evolve: the RCM has been run throughout seven iterations over 1982, for each setup of experiment (control and deforestation). This procedure allows to measure the internal variability of RCM and enables us to express conclusions with statistical significance. The deforested area covers basically land zones with Mediterranean climate characteristics. For the present simulations, a 50x50 km uniform mesh has been used, with 25 vertical sigma layers of variable depth (more resolution near the soil). Significant changes in precipitation and evaporation are concentrated in late spring and summer, mainly over regions in the northern half of the domain, with weak Atlantic influence. No significant response is observed in autumn and winter over any region. The results are a good indication of the usefulness of regional climate models in sensitivity studies related to the interaction between mesoscale circulations and land surface processes.

MC01/E/07-A4 1700

MODELLING OF THE SIBERIAN REGIONAL CLIMATE ON THE BASE OF ECSIB MODEL

FOMENKO ALEXANDER (Institute for Computational Mathematics and Mathematical Geophysics of SB RAS, Prospect ac. Lavrentieva, 6, Novosibirsk, 630090, Russia, email: foma@climate.sscc.ru) Krupchatnikoff Vladimir (Institute for Computational Mathematics and Mathematical Geophysics of SB RAS, Prospect ac. Lavrentieva, 6, Novosibirsk, 630090, Russia, email: vkrup@ommfao1.sscc.ru)

The regional model of atmospheric dynamics is presented. The model is a component of global climatic model ECSib, has the increased spatial resolution and is designed for the reproduction of the climatic atmospheric characteristics on spatial scales not described by global model. In model the more detailed account of processes of interaction with the land surface is carried out. The surface and active layers of ground take into account presence of vegetative cover, layer of snow on the surface, processes of heat and moisture transfer in the soil layer, processes of melting of snow on the surface, receipt of moisture into the ground at the expense of large-scale and convective precipitations, interception of precipitations by vegetative cover, effects of moisture filtration. The some results of numerical modelling of Siberia climate are given. This work was supported by the INTAS 96-2074.

MC01/L/18-A4 1715

THE PREDICTION OF THE REGIONAL NCEP ETA MODEL WITH DIFFERENT LAND SURFACE SCHEMES

Yongkang XUE, Y. Ji (both at Department of Geography, University of Maryland, College Park, MD 20742,USA Tel: 301-405-4050; fax: 301-314-9299, email: yxue@geog.umd.edu); E. Roger, T. Black, Z. Janjic and K. Mitchell (all at Development Division, NCEP, NOAA, Camp Springs, MD, USA)

Previous studies show that a coupled Eta/SSiB model is able to realistically simulate different climate scenarios. In these experiments, the model is only integrated for 48 hours. The forecast for June 1988 and July 1993 are averaged, respectively, to obtain the regional climate. However, because the model is initialized every 24 hours in these studies, the prediction for some hydrological variables, such as runoff, is mainly determined by the initial conditions. To understand the regional climate predictability, we have developed the Eta/SiB model for long term prediction studies. Long term numerical integrations are carried out for June and July 1998, June and July 1993, and June 1988 to investigate the time scale of the predictability for the Eta model. Both the 1993 and 1998 spring season have strong ENSO events, The summer of 1988 is extremely dry. The Eta/SSiB has reasonably good simulations for 1998 and 1988. The results from the Eta/SSiB are compared with the current Eta model simulations (with different land surface scheme). The preliminary results show that adequate simulations of large scale circulation, i,e, the low level jet and 200mb wind fields, are the key in successful North American regional climate prediction. The results also show that land surface parameterizations have profound impact on these simulations.

REGIONAL MODELLING AND INTERCOMPARISONS (Cont.)

Implementing Regional Climate Models: Computational Methods and Parameterisations

MC01/W/06-A5 0830

REGIONAL CLIMATE SIMULATION WITH A VARIABLE RESOLUTION STRETCHED GRID GCM: THE 1988 U.S. SUMMER DROUGHT

Michael FOX-RABINOVITZ and Uri Stein(both at Department of Mete- orology/ESSIC,University of Maryland,College Park,MD 20742,USA, Email: foxrab@atmos.umd.edu, uristn@atmos.umd.edu) Lawrence Takacs and Ravi Govindaraju(both at General Sciences Corporation,6100 Chevy Chase Drive,Laurel,MD 20707,USA, Email: ltakacs@dao.gsfc.nasa.gov, ravi@dao.gsfc.nasa.gov) Max Suarez(code 913,NASA/Goddard Space Flight Center,Greenbelt, MD 20771,USA, Email: suarez@maxs.gsfc.nasa.gov)

The variable resolution stretched grid(SG) GCM based on the God- dard Earth Observing System (GEOS) GCM, has been developed and tested in a regional climate simulation mode. The GEOS SG-GCM is used for simulation of the 1988 summer drought over the U.S. Midwest. Within the stretched grid, the region of interest with a uniform ~60 km resolution is a rectangle over the U.S. Outside the region, the grid intervals increase or stretch with a constant stretching factor (as a geometric progression). The results of two-month simulation for the anomalous climate event of the U.S. drought of 1988, are validated against data analysis fields and diagnostics. The event has been chosen by the Project to Inter-compare Regional Climate Simulations(PIRCS). The efficient regional down-scaling as well as the positive im- pact of fine regional resolution, are obtained. More specifical- ly, the precipitation, 500 hPa, and low-level jet patterns and characteristics are well represented in the simulation. The SG-concept appeared to be a promising candidate for regional and subregional climate studies and applications.

MC01/E/15-A5 0845

DYNAMICS, STATISTICS AND PREDICTABILITY OF SIMPLE LIMITED-AREA FORECASTING MODELS

Frederic CHOME (Institut Royal Meteorologique de Belgique, Section de Climatologie Dynamique, Av. Circulaire 3, B-1180 Bruxelles, Belgium, email: fchome@oma.be)

A canonical model describing the instability of plane wave solutions toward inhomogeneous long wave fluctuations emulating mesoscale atmospheric variability is used to analyze different strategies for building high-resolution models providing a more detailed description of a limited area of interest. The cases considered are : a regional fine grid model nested at regular time steps into a globally coarser one which evolves in time independently, and an autonomous continuous model with a variable mesh size. Comparative studies between a reference fine grid ``perfect'' model and the ones provided, successively, by a globally coarse

and the fine scale, limited-area ones are carried out. The statistical properties of the relevant fields are first analyzed, and an optimal size for which the deviations between the ``perfect'' model and the limited-area ones are minimized is identified. Predictability experiments, performed on statistical ensembles of close lying trajectories whose mean distance represents the uncertainty in the initial state of the system, reveals that the continuous variable-mesh model performs better than the nested limited-area one.

MC01/W/49-A5 0900

VERIFICATION AND EVALUATION OF STORM TRACKS IN REGIONAL CLIMATE SIMULATIONS OVER AUSTRALIA

J. Katzfey and J. L. McGregor CSIRO Atmospheric Research, Aspendale, Vic. Australia

Since much of the weather in midlatitudes is associated with the passage of cyclones and anticyclones, an accurate simulation of the climate of a region should not only capture the mean fields correctly, but also the daily variability associated with these weather systems. There are numerous measures which can quantify the location and intensity of weather systems. Two common techniques are either to track lows and highs, or to compute the standard deviation of the geopotential height or winds. In this study of regional climate model (RCM) simulations over Australia, an alternative technique is adopted: the jetstreams are verified using the mean kinetic energy, while the storm tracks are verified against the eddy kinetic energy. RCM simulations nested within ECMWF analyses are evaluated by this method, in addition to RCM simulations nested within the CSIRO GCM for present-day conditions. It is found that the RCM captures the location of the storm track very well, but underpredicts the intensity slightly at upper levels. Changes to the storm tracks under enhanced greenhouse conditions were then examined for simulations having transiently increasing CO2 concentrations. Under these conditions, the upper level storm track intensifies and shifts equatorward. At low levels, the storm track tends to weaken, except in locations where the eddy growth rate increases, resulting in seasonally different changes.

MC01/E/25-A5 0915

COMPARISON OF TWO MOIST CONVECTION SCHEMES IN A REGIONAL CLIMATE MODEL

Daniel LUETHI (Swiss Federal Institute of Technology, LAPETH, Hoenggerberg HPP, CH-8093 Zurich, Switzerland, email: daniel.luethi@atmos.umnw.ethz.ch) Christoph Schaer (Swiss Federal Institute of Technology, GI-ETH, Winterthurerstr. 190, CH- 8057 Zurich, Switzerland)

The representation of mid-latitute summertime precipitation is still one of the most challenging problems in regional climate modelling. This is presumably due to the increased role of moist convection and land surface processes and their interaction during this season. Therefore the parameterisation schemes for these processes contribute essentially to the performance of the model. The present study aims at investigating the influence of the change in the formulation of moist convection to summertime precipitation. The regional climate model used for this investigation is an adapted version of the operational mesoscale weather forecast model EM of the German weather service. The model is run at a resolution of 56 km and the model domain covers the simulation domain defined for the Project to Intercompare Regional Climate Simulations (PIRCS), i.e. essentially the continental US. The two 2-month PIRCS- periods (drought of 1988 and flooding of 1993) are simulated with this model setup using ECMWF-reanalysis data as initial and lateral boundary conditions. The convective schemes used in the model are the operational Tietdke-scheme and the Emanuel-scheme. The simulations with both schemes are able to represent rather well the distribution of precipitation during the dry period and the overall increase of precipitation during the wet period. However, the amplitude of the precipitation maximum is underestimated with the Emanuel-scheme and its location is simulated too far north (Tiedtke-scheme) or northeast (Emanuel- scheme) by about 500 km. Further the sensitivity of the location and amplitude of the precipitation maximae to some tuning parameters of the Emanuel-scheme is investigated. For the interpretation of the results a detailed analysis of the water cycle as represented by the model is undertaken.

MC01/E/17-A5 0930

IMPLEMENTATION OF BOUNDARY CONDITIONS IN NESTED REGIONAL CLIMATE MODELS

Uri Stein and Michael FOX-RABINOVITZ (both at Department of Meteorology/ESSIC, University of Maryland, College Park, MD 20742 USA, Email: uristn@atmos.umd.edu, foxrab@atmos.umd.edu), Raymond W. Arritt (Department of Agronomy, Iowa State University, Ames, Iowa 50011 USA, email: rwarritt@iastate.edu)

Methodology for nesting regional climate models within larger-scale models has been explored using combined global and regional versions of the Goddard Earth Observing System (GEOS) GCM. This procedure allows controlled "twin" and "cousin" experiments to be performed in which the regional model numerics and physics are identical to those in the global model. These experiments have focused on the implementation of the lateral boundary buffer zone where information is transferred from the global model to the regional model. Particular attention is devoted to the effect of discontinuous temporal and spatial resolution. Among the results are that even when the regional model boundaries are updated every six hours the diurnal variation of the average domain-scale surface pressure in the regional model is greatly damped.

MC01/W/34-A5 0945

THE STUDY OF CLIMATE DOWNSCALING WITH INTERACTIVE GENERAL CIRCULATION AND NONHYDROSTATIC REGIONAL MODELS

Georgiy STENCHIKOV and Roni Avissar (both at Department of Environmental Sciences, Rutgers University, 14 College Farm Rd., New Brunswick, NJ 08901, email: gera@envsci.rutgers.edu) To study a climate downscaling we use the Colorado State University Regional Atmospheric Modelling System (RAMS) and the Goddard Institute for Space Studies General Circulation Model (GCM).

We conducted long-term nonhydrostatic calculations with RAMS in a mesoscale domain nested into the GCM grid. The climate and the climate response to CO2 doubling calculated with the RAMS are compared with GCM output. The sensitivity of the calculated regional climate to resolution and size of the nested-grid domain are studied. The parameterized clouds and cloud radiative effects in GCM are compared with the RAMS cloud resolving calculations. The effects on the diurnal cycle of radiative heating, surface air temperature, water vapor mixing ratio, sensible and latent heat fluxes, convective activity, and precipitation are discussed.

MC01/E/38-A5 1000

NESTING STRATEGIES FOR HIGH-RESOLUTION REGIONAL CLIMATE SIMULATIONS: SENSITIVITY EXPERIMENTS FOR THE ALPINE REGION

Jan KLEINN, Christoph Frei, Christoph SchE4r (Institute of Geography, Swiss Federal Institute of Technology (ETH), Winterthurerstr. 190, 8057 Zurich, Switzerland) and Daniel LFCthi (Institute of Atmospheric Science, Swiss Federal Institute of Technology (ETH), ETH Hoenggerberg, 8093 Zurich, Switzerland)

Regional climate models constitute an attractive tool for downscaling the output from General Circulation Models and for conducting sensitivity and process studies. Our study examines the effect of several elements of the nesting strategy upon the results of high-resolution regional climate simulations over the area of the European Alps. Consideration is given to the effect of the boundary updating frequency, the benefit of two-fold nesting versus simple nesting, as well as the resolution of the driving fields. The effects are examined using month-long winter-time simulations driven by observed lateral boundary conditions from the ECMWF reanalysis. The simulated precipitation fields are evaluated against a meso-scale analysis derived from a unique high- resolution rain-gauge data set. The utilized regional climate model is a version of the operational forecast model of the German Weather Service and is used in resolutions of up to 14 km. The experiments reveal a strong sensitivity of the modeled precipitation upon the resolution of the lateral boundary fields, even when the model set-up is otherwise identical. It is demonstrated that the use of double nesting techniques is able to cope with the lack of (spatial and temporal) resolution in the lateral boundary fields. Furthermore, validation against the observational data base serves to demonstrate that increased resolution can substantially improve the mesoscale structure of the resulting precipitation fields.

ATMOSPHERIC TRACER TRANSPORT MODELLING AND INTERCOMPARISON

MC01/L/19-A5 1045

THE ATMOSPHERIC TRACER TRANSPORT MODEL INTERCOMPARISON PROJECT (TRANSCOM)

Denning, S

The Atmospheric Tracer Transport Model Intercomparison Project (TransCom) was begun in 1993 to quantify and diagnose the uncertainty in inversion calculations of the global carbon budget. The specific objectives of the TransCom project are (1) quantify the degree of uncertainty in current carbon budget estimates that results from uncertainty in model transport; (2) identify the specific sources of uncertainties in the models; and (3) identify key areas to focus future transport model development and improvements in the global observing system that will reduce the uncertainty in carbon budget inversion calculations. More than a dozen modelling groups from around the world have participated in TransCom, representing dynamical cores used in most atmospheric chemistry codes as well. Initial experiments focused on the annual mean meridional structure of CO2 arising from industrial combustion and the seasonal cycle produced by terrestrial vegetation. These experiments showed a surprising degree of differences among the models, especially aloft, and highlighted the effect of seasonal interactions between transport and emissions on annual mean gradients. A second experiment, simulated transport of sulfur hexafluoride, allowed "calibration" of the models against data and more detailed diagnosis of transport mechanisms. These results highlighted the importance of subgrid-scale vertical transport for large-scale horizontal spatial structure in the annual mean. A third phase of the study will quantify the sensitivity of the carbon budget to differences in transport among models, inversion methodology, and choice of observational data.

INVERSION METHODOLOGY FOR TRANSCOM 3

Peter RAYNER (CRC for Southern Hemisphere Meteorology Monash University Clayton, Victoria 3168 Australia email: pjr@vortex.shm.monash.edu.au), and Rachel Law (As P. Rayner, email: rml@vortex.shm.monash.edu.au)

This talk presents the underlying inversion methodology for the TransCom3 project. We briefly introduce the technique of synthesis inversion and demonstrate with an example the calculation of best estimates for CO2 sources and their accompanying uncertainties. We show that the methodology is general enough to consider a range of inversion types such as prior constraints vs. unconstrained inversions or many unknowns vs. few. Finally, we show how the uncertainty in source estimates contributed by model-model differences can be compared with that due to uncertain and sparse concentration data.

MC01/W/43-A5 1130

INTER-ANNUAL VARIATIONS OF CO2 NET SURFACE FLUXES AS INFERRED BY INVERSE MODELLING OF ATMOSPHERIC CO2 CONCENTRATIONS

Philippe. BOUSQUET, P. Peylin and P. Ciais (Laboratoire des Sciences du Climat et de l'Environnement, Unité mixte de recherche CNRS- CEA, Orme des merisiers, 91191 Gif sur Yvette cedex. Emails: bousquet@lsce.saclay.cea.fr, peylin@lsce.saclay.cea.fr, ciais@lsce.saclay.cea.fr)

A primary goal of developing the CO2 atmospheric measurement network is to characterise better the sources and sinks of atmospheric CO2. Atmospheric transport models can be used to evaluate atmospheric measurements in terms of surface fluxes using inverse methodology. We present a Bayesian three dimensional inversion of atmospheric CO2 measurements in order to infer monthly sources and sinks of CO2 at a continental scale (continents and ocean basins) for the 1985- 1995 decade. Solving this inverse problem requires 1) a data space representing monthly CO2 measurements, here at 77 sites (surface, ships, planes), 2) a flux space describing a priori fluxes between carbon reservoirs, and 3) a 3-d transport model linking the flux space to the data space. The three components of the inversion are briefly described in this talk. Then we present and discuss the inter-annual net fluxes inferred by our inverse methodology for the 1985-1995 period. Finally, we describe a few tests showing the sensitivity of our standard solution to some parameters of the inversion : atmospheric network, transport model and a priori flux scenario. A special focus is put on the partition of the controversial CO2 sink over the mid and high latitudes of the Northern hemisphere in the early 90's.

MC01/W/07-A5 1145

A TIME DEPENDENT INVERSE CALCULATION OF THE CO2 BUDGET : WHAT CAN WE LEARN FROM THE SHORT TERM VARIABILITY ?

P. Ciais, P. Peylin, P. Bousquet and M. Ramonet.

We will present a time dependent inversion of the atmospheric CO2 budget. The inverse technique is of Bayesian type and uses monthly optimisation of the sources against monthly atmospheric measurements. Usually, inverse calculations are constrained by some estimate of the mean observed CO2 concentration at many sites around the world. Short term variability is considered to be noise, and treated as such (gaussian errors on the data). However, at remote locations, far away from the direct continental and marine sources influence, the atmospheric transport on synoptic time-scales creates CO2 variability whose monthly variance should relate to the sources strengths. We propose to make use of the information contained in the observed short term variability of CO2 in the atmosphere, as an additional constraint on the surface fluxes. Mostly continuous records of atmospheric CO2 can be used safely to serve this purpose. The presentation of our method and some illustration of its results will be given.

MC01/L/21-A5 1200

ATMOSPHERIC CO2 INVERSION INTERCOMPARISON PROJECT (TRANSCOM 3)

Gurney

Most of our understanding of the global carbon budget is derived from atmospheric observations of CO2. Hemispheric or regional fluxes may be calculated from atmospheric concentration measurements by a numerical procedure known as "inversion," which requires that atmospheric transport be accounted for using a chemical tracer model (CTM). Two such inversion calculations were presented at a recent international meeting. Songmiao Fan and colleagues at Princeton University found that most of the terrestrial uptake of atmospheric CO2 is occurring in North America, and that this "sink" approximately balances fossil fuel emissions in the US. Working with the same atmospheric data but using a different CTM and inversion method, Peter Rayner and colleagues at the Australian CSIRO found that the sink is distributed much more widely, with North America accounting for only a small fraction. The Atmospheric Tracer Transport Model Intercomparison Project (TransCom) is a part of the IGBP Global Analysis, Interpretation, and Modelling (GAIM) initiative, whose objectives are (1) to quantify the degree of uncertainty in carbon budget inverse calculations that arises from CTM transport; (2) analyze the mechanisms by which the models differ; and (3) recommend and prioritize improvements to the observing and modelling systems to produce more robust carbon budget inversions in the future. We have previously analyzed the annual mean and seasonal structure of atmospheric CO2 as simulated by leading CTMs (TransCom 1), and calibrated the transport properties of the models against a tracer of known distribution (SF6,TransCom 2). We now propose a third phase of the TransCom activity (TransCom 3), in which participants will perform a full carbon budget inversion using their models. To maximize participation among CTM groups around the world, we have structured the experimental protocol in such a way as to simplify the methods for those groups with limited resources, but allow for more detailed work by those who so choose. This experiment will compare inversion results across more than a dozen CTMs and across multiple inversion methods. The diagnostic output will help us understand why the models differ, how they can be improved, and how the CO2 observing system can be optimized for more robust inversions.

MC01/W/39-A5 1215

BIAS IN INVERSIONS OF ATMOSPHERIC TRANSPORT DUE TO COARSE RESOLUTION OF SOURCES

Thomas Kaminski, Peter Rayner, and Martin Heimann

Models of atmospheric transport can be used to interpret spatio-temporal differences in the observed concentrations of a passive tracer such as CO2 in terms of its sources and sinks. Inversion of the atmospheric transport is the systematic search for both a source(/sink) field that yields an optimal match between modeled and observed concentrations and, equally importantly, the uncertainties in this inferred source field. Since current observational networks are sparse, the inverse problem is underdetermined, i.e. there are many source configurations yielding the same modeled concentration at the observational sites. Hence, additional information about the source configurations is included in inversion studies by a combination of two strategies: - A few fixed source patterns are prescribed, whose unknown magnitudes are to be optimized, and - we require the optimal source field to be close to a prior estimate that reflects our knowledge of sources. The fewer patterns (and hence fewer unknowns) we use, the more the structure of these patterns is imposed on the optimal source field. Conventional approaches to the inverse problem necessitate one transport model run per source pattern, i.e. the number of patterns is limited by the complexity of the transport model. With an adjoint approach, the computational cost is independent of the number of source patterns. Restricting the structure of the optimal source field by prescribing a few fixed patterns not only underestimates the uncertainties in the inferred source field but also causes a bias. The extend of this bias depends on the the location of the stations, the atmospheric transport model, and the number and shape of the patterns. To explore this bias, the solution of the inverse problem has to be known. Hence, we generated ``artificial observations'' by running the atmospheric transport model TM2 for a prescribed CO2 source field on the 8 by 10 degree model grid. Then we defined patterns by forming groups of 16 grid cells and performed an inversion on that coarser grid. Although this inversion was stabilized by inclusion of the (grouped) prescribed source field, the difference between the (grouped) prescribed source field and the optimal source field resulting from the inversion is large: In parts of Asia and South America this difference is about 100% of the prescribed source field itself. This difference is solely a result of the bias due to grouping gridpoints.

MC01/W/50-A5 1230

TRACE GAS TRANSPORT USING THE CONFORMAL-CUBIC MODEL

John L. McGregor and Eva A. Kowalczyk CSIRO Atmospheric Research, Melbourne, Australia

Transport of trace gases has been incorporated into the new CSIRO conformal-cubic model. This is a global grid-point primitive equations model with semi-Lagrangian numerics. The model has provision for stretching the grid to give high resolution over any selected region. The talk will show simulations for transport of CO2 and radon, for both stretched and non-stretched grids. For these simulations the stretched grid has a resolution of about 75 km over Australia. Comparisons will be presented for simulations from the Division of Atmospheric Research Limted Area Model (DARLAM) run at a similar resolution, and for the concentrations of radon and CO2 observed at Cape Grim.

TERRESTRIAL ECOSYSTEM CARBON VEGETATION DYNAMICS: PIK/NPP AND VEMAP2 MODEL INTERCOMPARISONS

Introduction 1400

T. Kittel and K. Hibbard

MC01/E/20-A5 Invited 1405

HISTORICAL AND FUTURE SCENARIO CLIMATE DATASETS FOR THE CONTERMINOUS UNITED STATES AND ALASKA: MODEL INPUT DATA FOR VEMAP PHASE 2 T

G.F. KITTEL, N.A. Rosenbloom, H.H. Fisher, D.S. Schimel (National Center for Atmospheric Research, Boulder, CO 80307, USA; lead author email: kittel@ucar.edu), J.A. Royle (USDI Fish and Wildlife Service, Laurel, MD 20708, USA), C. Daly (Oregon State University, Corvallis, OR 97331, USA), P.E. Thornton (Univ. of Montana, Missoula, MT 59812, USA), and VEMAP2 Participants.

The objective of Vegetation/Ecosystem Modelling and Analysis Project (VEMAP) Phase 2 is to evaluate time-dependent responses of 8 biogeochemical and dynamic global vegetation models to an array of historical and projected transient forcings, including those of climate and atmospheric CO2 (see presentations by Thornton et al. and Bachelet et al.). Crucial to this goal was the development of a common climate database that provided (1) a "level playing field" for intercomparison of models and (2) a faithful representation of the domain's bioclimate permiting the evaluation of model historical- period simulations against observed ecological data. The result is a 0.5-degree latitude/longitude gridded historical climate input dataset for the conterminous U.S. (for 1895-1993) and Alaska (1922-1996) that meets the input requirements for the models. Variables included are monthly and daily

MC01/W/04-A5 Invited 1425

PRELIMINARY RESULTS FROM VEGETATION DYNAMIC MODELS IN VEMAP PHASE 2: VEGETATION DISTRIBUTION AND ASSOCIATED C POOLS FROM 1895 TO 2100

D. BACHELET (Dept of BioResource Engineering, Oregon State University, Corvallis, OR 97330, USA. Email: bachelet@fsl.orst.edu); J.M. Lenihan (Dept. of Botany, Oregon State University, Corvallis, OR 97331, USA). R.P. Neilson (PNW USFS, Corvallis, OR 97331, USA); R. Drapek (Dept. of Forest Science, Oregon State University, Corvallis, OR 97331, USA); and VEMAP2 participants

Predictions of potential vegetation distribution, natural fire frequency, carbon pools and fluxes are presented for DGVMs (Dynamic Global Vegetation Models) involved in the second phase of Vegetation/Ecosystem Modelling and Analysis Project (VEMAP). Results are preliminary since they represent a first attempt to link vegetation dynamics to biogeochemical cycling at a half-degree resolution for the coterminous USA. The models were run with historical (1895-1993) and predicted future climate (1994-2100), as provided by the National Center for Atmospheric Research (Boulder, CO, USA). The models were run with a detrended version of the historical meteorology files, at a constant CO2 concentration, until C fluxes equilibrated (d(NEP)/dt close to 0). Models were then run with historical climate and an increasing CO2 concentration from 295ppm in 1895 to 358ppm in 1993. From 1994, models were run either with a CO2 concentration held constant at 359ppm or increasing to 1026ppm by year 2100. Results are presented with and without masking out cultivated areas in the coterminous USA. Crop growth was not simulated and a fixed fraction of each simulated cell was allocated to agriculture for the entire run. Results only concern the potential natural vegetation fraction of those cells. Results will focus more specifically on one of the DGVM, MC (Corvallis, USA), which was run with and without N limitation. Under the Hadley Climate Center future scenario, MC predicts a large expansion of forests into the Great Plains and into the dry interior west by the end of the 21st century. We will discuss competition between lifeforms as it relates to water and N limitation and affects vegetation dynamics. We will also address the issue of the representation of the CO2 effect in each model and how it affects model response to climate change.

MC01/W/09-A5 Invited 1445

PREDICTED NPP, NEE, AND CARBON STOCKS FOR HISTORIC (1895-1994) AND POTENTIAL FUTURE CLIMATE SCENARIOS OVER THE CONTIGUOUS UNITED STATES: AN INTERCOMPARISON OF TERRESTRIAL BIOGEOCHEMISTRY MODEL RESULTS FROM VEMAP PHASE II.

Peter E. THORNTON, School of Forestry, University of Montana, Missoula, Montana 59812 USA. David S. Schimel, National Center for Atmospheric Research, P.O. Box 3000, Boulder, Colorado 80307-3000 USA, and Natural Resources Ecology Laboratory, Colorado State University, Fort Collins, Colorado 80523 USA. and VEMAP2 Participants.

Predictions of net primary production (NPP), net ecosystem exchange of carbon (NEE), and carbon stocks (vegetation and soil components treated separately) were carried out using three very distinct and well-established models of terrestrial biogeochemical processes (CENTURY, TEM, and BIOME-BGC), all of which used identical inputs for meteorological driving variables and other spatial data layers (described in companion presentation by Kittel). Simulations were performed over both an historical period for which there are observations of the meteorological driving variables (1895-1994), and a period of future climate conditions (1994-2100) derived from the results of a group of general circulation models (details covered by Kittel). All models were run to steady-state using a de-trended version of the historical meteorology files, at a constant CO2 concentration. From this as a starting point, various scenarios were explored, including rising CO2 with no trend in climate, observed trend in climate with constant CO2, and observed climate trend with rising CO2, in an effort to deconvolve the model responses to these co-occurring influences. Similar experiments were carried out over the period of predicted future climate. An additional set of experiments was performed to examine potential regional source-sink strengths under conditions of reforestation following agricultural land-clearance. These experiments involved the simulated removal of woody material at the steady-state and the monitoring of source-sink relationships as a new steady-state was approached. In addition to presenting a summary of the VEMAP Phase II results from these experiments, I will also discuss some implications of the steady-state experimental protocol and the sensitivity of model results to shared input data layers.

MC01/L/22-A5 Invited 1505

RESULTS FROM THE POTSDAM 1995 MODEL INTERCOMPARISON OF TERRESTRIAL NET PRIMARY PRODUCTIVITY (NPP)

Kathy A. HIBBARD, University of New Hampshire;IGBP/GAIM, Durham, NH 03824 USA; W. Cramer, Potsdam Institute for Climate Impact Research (PIK), Potsdam, Germany and "Potsdam '95" participants

M

Seventeen models of terrestrial biogeochemistry were compared with respect to total, regional, annual and seasonal fluxes of net primary productivity (NPP). The models differed widely in complexity and purpose, but could be grouped in three major categories: satellite-based models that use data from the NOAA/AVHRR sensor as their major input stream, models for seasonal fluxes that use a prescribed vegetation structure, and models that simulate vegetation structure and fluxes. Simulated annual NPP ranged from ca. 40-80 Pg C yr-1, however this range decreased considerably when two obvious outliers (which produced extreme results due to calibration problems connected with the comparison, were removed. The broad global pattern of NPP and the relationship of annual NPP to the major climatic variables coincided in many regions of the globe. Systematic biases due to the fundamental modelling strategy could not be found, but the inclusion of nutrient constraints seemed to produce lower values of annual NPP. The regional and global sensitivity of simulated water balance fluxes from diverse modelling strategies were clearly illustrated. Testing modelled sensitivity to the light environment was accomplished by decomposing NPP from those models that did not utilize remote sensing inputs into absorbed photosynthetically active radiation (APAR) and light use efficiency (LUE). A negative relationship between total APAR and LUE was observed when derived variables were compared to those from remotely sensed driven models, suggesting that the models may be unconsciously calibrated to achieve 'commonly accepted values' of NPP, while doing so with widely differing spatial and seasonal patterns. An analysis of the simulated net ecosystem productivity (NEP), using a three-dimensional atmospheric transport model and observed seasonal CO2 observations from the flask sampling network suggested that uncertainties were larger in water limited systems of the southern hemisphere than elsewhere.

MC01/E/22-A5 1525

MODELLING THE EXCHANGES OF CO2 BETWEEN LAND SURFACE AND ATMOSPHERE USING COUPLED VEGETATION - GENERAL CIRCULATION MODEL

Vladimir KRUPCHATNIKOFF (Institute Computational Mathematics and Mathematical Geophysics of SB RAS, Prospect ac. Lavrentieva,6, Novosibirsk, 630090, Russia, email: vkrup@ommfao1.sscc.ru) Galin Vener and Lykossov Vassily (Institute for Numerical Mathematics of RAS, Gubkina Str., 8, Moscow, GSP-1, 117951, Russia, email: galin@inm.ras.ru, email: lykossov@inm.ras.ru)

Land surface processes have a strong impact on atmosphere climate phenomena. They determine surface sensible and latent heat fluxes, radiation budget and biochemical fluxes and therefore influence atmosphere and land parameters. It is therefore important to simulate surface processes in climate model as realistically as possible. Vegetation is important for hydrology of the atmosphere because it determines the rate CO2 during photosynthesis and respiration and because of its effect on the latent heat flux. The most detailed parameterizations of vegetation are often found in the land surface models used with atmospheric models. It may be summarized as follows: effect of leaf area on the absorption of solar radiation at the surface; sensible and latent heat flux; biochemical fluxes; and the soil heat fluxes, which are important due to the effects of soil temperature on biochemical fluxes; soil hydrology. In this report I address the case of interaction between biosphere (vegetation patterns) and atmosphere. Required surface data for each grid cell derived from Olson et. al's (1983), soil colors were taken from Dickinson et.al (1993), sand silt and clay data were derived from Webb et. al's (1993), inland water data were derived from Cogly (1991). This dataset were used to carry out experiment, where the model was running in coupled mode. Five years present-day climate simulation have been performed. The current state of the atmosphere was simulated by Institute for Numerical Mathematics of RAS GCM, which is forced by the climatology of the annual cycle SST. In this report global patterns of photosynthesis, respiration and net fluxes CO2 are presented.

OCEAN CARBON CYCLE MODELLING INTERCOMPARISONS

MC01/W/56-A5 1600

THE OCEAN CARBON-CYCLE MODEL INTERCOMPARISON PROJECT (OCMIP): AN OVERVIEW

JAMES C. ORR (LSCE/CEA Saclay (IPSL), Bat. 709 L'Orme, F-91191 Gif-sur-Yvette, France, email: orr@.cea.fr)

OCMIP is a coordinated model validation and intercomparison effort for global-scale, three-dimensional, ocean carbon-cycle models. Such models describe the transport and redistribution of carbon in the ocean by combining fundamental descriptions of ocean circulation and biogeochemistry. The long-term objectives of OCMIP are to improve the predictive capacity and accelerate development of these models. OCMIP began with four models in 1995 as a project of the Global, Analysis, Interpretation and Modelling Task Force (GAIM) of the International Geosphere-Biosphere Programme (IGBP). Studies within OCMIP have focused on (1) the distribution of oceanic carbon as well as (2) validation of model-predicted circulation (with C-14). The latter is a primary control of the former. For ocean carbon, emphasis has been on comparing and evaluating the state of the preindustrial distribution and how that has and will change as atmospheric CO2 continues to increase. Models roughly agree concerning global uptake of anthropogenic CO2 (on average 1.85 +/- 0.25 Pg C/year during the 1980's). Yet in the Southern Ocean, where uptake is largest, regional uptake differs by nearly a factor of two between models. Comparison of model and data-based estimates of anthropogenic CO2 in the ocean suggests that most of the models overpredict storage in the Southern Ocean. These and other large differences between models have motivated a second phase of this project (OCMIP-2) during 1998-2000. Now being compared are 13 models from Europe, the U.S., Australia, and Japan. The focus remains on CO2, but in addition OCMIP-2 emphasizes new circulation tracers (e.g., CFC-11 and CFC-12), new biogeochemical tracers (e.g., oxygen), a common biogeochemical model, and improved ties to data-synthesis specialists from JGOFS and WOCE.

MC01/W/58-A5 Invited 1620

THE OCEAN'S ROLE IN INTERHEMISPHERIC CARBON TRANSPORT

Olivier AUMONT, James C. Orr, Patrick Monfray (LSCE/CEA Saclay (IPSL), Bat. 709 L'Orme, F-91191 Gif-sur-Yvette, France, email: aumont@lsce.saclay.cea.fr) Jorge L. Sarmiento and Richard Murnane (both at AOS Program, Princeton University, Princeton NJ 08544) Ernst Maier-Reimer (Max Planck Institute fuer Meteorologie, Hamburg, Germany), Wolfgang Ludwig (CFREM, Universite de Perpignan, F-66860 Perpigan, France), and Jean-Luc Probst (EOST, CGS, F-67084 Strasbourg, France)

Both atmospheric and oceanic observations have been used to imply that the preindustrial ocean transported significant carbon (up to 1 Pg C/yr) from the northern to the southern hemisphere. For further insight, we compared results from preindustrial carbon simulations performed with three different ocean models (from Princeton, MPI, and IPSL), who participated in the first phase of the Ocean Carbon-Cycle Model Intercomparison Project (OCMIP). Although regional patterns of the air-sea fluxes of CO2 predicted by the three models differ significantly, predictions of interhemispheric transport are similar. Modeled global interhemispheric transport of carbon during preindustrial time was near zero (<0.1 Pg C/year from north to south). Modeled southward transport in the Atlantic is compensated by northward transport in the Indian and Pacific Oceans. Thus our model estimates of interhemispheric transport of oceanic carbon disagree with larger estimates from previous observational studies. However, we further one mechanism by which to resolve this discrepancy, i.e., the "river effect". Rivers transport atmospheric carbon (from continental erosion and terrestrial photosynthesis) to the ocean, mostly in the in the northern hemisphere. Riverine carbon is subsequently transported within the ocean. We coupled the IPSL ocean carbon-cycle model to riverine carbon fluxes from the Global Erosion Model (GEM). We found that the river effect substantially alters interhemispheric carbon transport. Total southward interhemispheric transport is increased to 0.27--0.43 Pg C/yr, depending on the presumed lifetime of the riverine organic matter.

MC01/L/23-A5 1640

EVALUATION OF MODEL AND MEASUREMENT-BASED ANTHROPOGENIC CARBON TRACER DISTRIBUTIONS

C. L. Sabine, R. M. Key (both at Department of Geosciences, Princeton University, Princeton, New Jersey, 08544, USA, email: sabine@geo.princeton.edu, key@geo.princeton.edu) and J. Orr (Laboratoire des Sciences du Climat et de l'Environnement, CEA Saclay, Bat. 709 - Orme, F-91191 Gif-sur-Yvette Cedex, FRANCE, email: orr@lsce.saclay.cea.fr)

One component of the recently completed U.S. JGOFS field program was a global survey of CO2 in the oceans. Inorganic carbon samples were collected and analyzed on nearly all of the U.S. WOCE one-time survey and NOAA/OACES cruises conducted during the past decade. The quality and quantity of these data will allow the first reliable global estimates of anthropogenic CO2 inventories in the ocean. A parallel U.S. WOCE program, conducted on the same cruises, was the survey of radiocarbon in the world's oceans. One of the many uses of the C-14 data set is an examination of the distribution of bomb-produced C-14 in the oceans. These two anthropogenic carbon tracers have many similarities, however, there are also several significant differences (e.g. atmospheric history and equilibration times). This study will compare the distributions of anthropogenic CO2 and bomb C-14 in the oceans. The observed trends will be compared to 3-D ocean GCM distributions during the second phase of OCMIP. Differences between the observed and model distributions will be evaluated by applying the data-based techniques for estimating the anthropogenic components to model derived properties. These estimates will then be compared to the anthropogenic distributions directly estimated in the model. Special attention will be given to potential sources of error in both the model and data-based estimates.

MC01/W/36-A5 1700

COMPARISON OF SIMULATIONS OF CFC-11 AND CFC-12 DURING OCMIP

J.-Cl. DUTAY (LSCE), J. Bullister (PMEL), J. C. Orr (LSCE), R. G. Najjar (PSU), M. Follows (MIT), R. Matear (CSIRO), S. Doney (NCAR), E. Maier-Reimer (MPI), Y. Yamanaka (IGCR), H. Drange (NERSC), A. Yool (SOC), J.-M. Campin (UCL), M.-F. Weirig (AWI), N. Gruber (Princeton), K. Caldeira (LLNL)

Thirteen groups are involved in the OCMIP2 project (Ocean Carbon Model Intercomparison Project - phase 2). These groups are running a variety of ocean carbon models. Chlorofluorocarbons (CFC's) have been chosen as the first tracers to be examined in detail as part of the project analysis. CFCs have increased rapidly in the atmosphere during the past 50 years. These gases dissolve in surface seawater and are subsequently carried into the interior of the ocean as passive tracers of ocean circulation and mixing processes. CFCs have been used to study a variety of physical processes in the ocean occurring on decadal time scales, including thermocline ventilation and the formation of intermediate and deep waters. In the OCMIP2 study, a common atmospheric CFC input history was used in the models. Results from model simulations of dissolved CFCs are compared to CFC measurements collected during recent major ocean observation programs (eg. AJAX, SAVE, WOCE). These comparisons provide a means of testing and evaluating each model's ability to realistically simulate the uptake and redistribution of gases in the ocean. Our analysis will focus in particular on the Southern Ocean, an important region where large uncertainties presently exist in the magnitude of the anthropogenic CO2 sink.

MC01/W/55-A5 1715

OCEAN CARBON-CYCLE SIMULATIONS OF GLOBAL CHANGE AND INTERANNUAL VARIABILITY: FUTURE EMPHASIS FOR OCMIP

Patrick MONFRAY, Laurent Bopp, Corinne Le Quere, and James C. Orr (all at LSCE/CEA Saclay (IPSL), Unite Mixte CEA-CNRS, CEA Saclay, Bat. 709 L'Orme, F-91191 Gif-sur-Yvette, France, email: monfray@cea.fr)

The first two phases of the Ocean Carbon-Cycle Model Intercomparison Project (OCMIP), during 1995-1997 and 1998-2000, have used ocean carbon-cycle models with fixed ocean circulation, which thus do not consider effects due to climate change and interannual variability. Conversely, the third phase of OCMIP will focus on the effect of climate change on the ocean carbon cycle and marine biomass. The objective will be to study changes in marine biogeochemistry and the air-sea CO2 flux under a warmer, more stratified ocean, where winds, evaporation, and precipitation are different. To validate the coupled carbon-climate ocean models that must be used for such a study, we will rely on simulations of interannual to interdecadal variability with the same models. Interannual variability of ocean carbon and marine biomass is driven by many of the same factors, such as changes in atmospheric fluxes of heat, water, and momentum, as well as changes in the delivery of macro- or micro-nutrients (e.g., N, P, Fe, CO2). Simulations of interannual variability will provide OCMIP with a pertinent, added dimension with which to evaluate ocean carbon-cycle models. Such comparison will lead to more reliable predictions from ocean models that will help shed light on the current controversy surrounding widely different estimates of the interannual variability of the air-sea CO2 flux. With an aim towards model comparison, we will demonstrate what we have learned from making such simulations in one ocean carbon-climate model from IPSL.

MC01/E/01-A5 1730

INFLUENCE ON THE GLOBAL OCEAN CIRCULATION OF A PARAMETERIZATION OF DENSITY-DRIVEN DOWNSLOPING FLOW

Jean-Michel Campin and Hugues Goosse (Institut d'Astronomie et de Geophysique G. Lemaitre, Universite Catholique de Louvain, 2 ch. du cyclotron, 1348 Louvain-la-Neuve, Belgium, email: campin@astr.ucl.ac.be and hgs@astr.ucl.ac.be)

In the world ocean, high density water are found on the continental shelves, mainly near Antarctica, and are responsible for density driven, downsloping currents that influence the deep ocean water masses properties. This process is poorly represented in z-coordinate ocean models, especially in Ocean General Circulation Model (OGCM) with coarse resolution in both horizontal and vertical directions. Here we present a simple parameterization of

downsloping flow, designed for z-coordinate OGCM: at the shelf break, the downsloping current is evaluated from the horizontal density gradient between the two adjacent boxes, using a linear relation, and is assumed to go downward along the slope until it reaches a level of equal density. This parameterization has been implemented in an OGCM and two experiments, without and with this scheme, have been integrated until equilibrium, using annual mean forcing and restoring boundary conditions. The impact of this parameterization on the global ocean is dominated by the improvement of the Antarctic Bottom Water. This tends to reduce the intensity and depth of the North Atlantic Deep Water circulation and increases the density of the deep ocean. As a result of a higher exchange with the open ocean, the properties of continental shelf waters are also improved, with a marked reduction of the Antarctic shelves salinities. An additional simulation using a coupled ocean - sea ice model and a full seasonal forcing based on climatological fluxes, confirms the previous results, especially the improvement of the Antarctic shelves salinities.

MC01/W/24-A5 1745

NUTRIENT, CARBON AND TRACER SIMULATIONS IN THE WORLD OCEAN: MODEL/DATA COMPARISON

Marie-France WEIRIG (Alfred-Wegener-Institut, Columbusstrasse, D-27568 Bremerhaven, Germany, e- mail: mweirig@awi-bremerhaven.de), Reiner Schlitzer (Alfred-Wegener-Institut, Columbusstrasse, D-27568 Bremerhaven, Germany, e- mail: rschlitzer@awi-bremerhaven.de)

We present a large scale ocean circulation model that differs in several aspects from dynamical ocean models. While dynamical models calculate a time-varying ocean velocity field based on momentum equations and external forcing, the AWI- model uses a steady state three dimensional flow field representing the mean ocean circulation. Vertical particle fluxes of organic carbon, calcium carbonate and opal are formulated as functions of depth z (J(z)=a*z^(-b); a and b are time-invariant parameters describing export flux and remineralization depth-scale, respectively.) The steady state circulation field as well as the biogeochemical parameters a and b are obtained by fitting the model to data of temperature, salinity and dissolved nutrients by means of the adjoint method. The resulting optimal model solution together with the standard OCMIP-2 gas exchange equations are implemented in order to simulate the distribution of different tracers in the ocean. Modeled nutrient, carbon and CFC distributions are shown and compared with recently collected data from the WOCE experiment. Deviations to measured concentrations are discussed and systematic model errors are analyzed. In general the calculated CFC concentrations reproduce the available data sets well. Comparing our modeled concentrations with the data of the AJAX1 section and the WOCE A16 section, we actually see the effects of intermediate, deep and bottom water currents, although there is a slight tendency to overestimate these concentrations. First results of carbon dioxide and helium simulations are also presented.

MC06/E/02-A1 0940

LARGE-SCALE DYNAMICS AND THE EQUATORIAL QBO

Peter HAYNES (Centre for Atmospheric Science, DAMTP, Silver Street, Cambridge, CB3 9EW, UK, email: phh@damtp.cam.ac.uk)

The dynamics of large-scale zonally symmetric circulations will be reviewed, focussing on implications for the QBO. The large-scale dynamics themselves have been argued to give a mechanism for determining the latitudinal scale of the QBO, irrespective of any scale set by, e.g. large-scale equatorial wave modes that might provide the necessary momentum fluxes. Simple model experiments have verified that this mechanism sets the latitudinal scale when the wave driving is provided by a homogeneous field of small-scale gravity waves. The relevance of the mechanism to the real QBO, where the wave forcing now appears to be provided by a broad spectrum of waves, including small-scale gravity waves and larger scale equatorial modes, will be discussed.

MC06/W/05-A1 1020

OBSERVATIONS OF THE LINK BETWEEN THE QBO AND EXTRATROPICAL CIRCULATION ANOMALIES

Mark P. BALDWIN (Northwest Research Associates, Bellevue, WA, USA)

Nearly 20 years ago Holton and Tan observed a link between the phase of the QBO and the strength of the northern winter polar vortex. They suggested that the QBO modified the zonal-mean wind in the subtropics, altering the wave guide for upward and equatorward propagating planetary waves. Observations continue to show that the wintertime Northern hemisphere stratospheric polar vortex is modulated by the phase of the equatorial QBO, and that wave propagation is affected in a manner consistent with the changes in the strength of the polar vortex. Modelling studies have confirmed this, and show consistently that QBO has global effects on the stratospheric circulation and distribution of constituents such as ozone. The high-latitude northern stratospheric vortex tends to be stronger during the winter, and sudden warmings are less likely when the QBO is in its west phase at 40 hPa. The effect of the phase of the QBO on the southern hemisphere circulation is similar in magnitude, but the seasonal timing and latitudinal location differ. The southern hemisphere polar vortex is much stronger, and is not easily penetrated by the weaker planetary-scale waves. During midwinter, any effect from the QBO is confined to midlatitudes, near the edge of the polar vortex. It is not until the time of the vortex breakdown (November) that the QBO affects the circulation over the polar cap. The difference between west and east phase composites of zonal-mean wind during November, at the time of the final warming in the southern hemisphere, are comparable to January in the northern hemisphere.

MC06/C/JSM01/W/58-A1 1120

TEMPORAL AND SPATIAL STRUCTURES OF MID-LATITUDE QUASI-BIENNIAL OSCILLATION (QBO) IN THE LOWER STRATOSPHERE OBSERVED WITH OPERATIONAL RAWINSONDES DURING 1990-97

Shin-Ya OGINO (Radio Atmospheric Science Center, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan, email: ogino@kurasc.kyoto-u.ac.jp); Manabu D. Yamanaka (Graduate School of Science and Technology, Kobe University, Nada-ku, Kobe 657-8501, Japan, email: mdy@kobe-u.ac.jp)

Temporal and spatial (meridional and vertical) structures of quasi biennial oscillation (QBO) in the mid-latitude lower-stratosphere are investigated using operational rawinsonde data at about 400 stations over the world for 8 years (1990-97). In order to discuss inter-annual variations, mean seasonal variations and linear trends for the 8 years are subtracted from monthly mean temperature and zonal wind, and the obtained anomalies are smoothed by 12-month running average procedure. Oscillations of temperature and zonal wind anomaly fields in the lower stratosphere with a period of about 2 years accompanied by downward phase propagation with time are detected over the almost every stations located in the mid-latitude region (20-40degN/S), indicating that equatorial QBO-like structures also exist in the mid-latitude region, although in the zonal wind anomaly field vertically standing structures with somewhat longer period are dominated through troposphere and lower stratosphere and consequently the equatorial QBO-like signals are detected relatively weakly. Comparison between meridional gradient of temperature anomaly field and vertical gradient of zonal wind anomaly field shows that thermal wind relation is well satisfied. The phase of the mid-latitude temperature QBO is observed to be almost opposite to that of the equatorial QBO in the period during 1993-97, which is considered to be maintained by the mean meridional circulation. On the other hand, the out-of-phase relation is observed to be broken (the equatorial QBO shows a phase delay of about a half year to the mid-latitude QBO) during about 2 years after Mt. Pinatubo eruption in 1991.

MC06/W/03-A1 1145

SPONTANEOUS QBO-LIKE OSCILLATIONS IN THE GFDL SKYHI MODEL

Kevin HAMILTON (Geophysical Fluid Dynamics Laboratory/NOAA, P.O. Box 308, Princeton, New Jersey 08542, USA, email: kph@princeton.edu)

The tropical stratospheric mean flow in GFDL SKYHI troposphere-stratosphere-mesosphere general circulation model has been found to undergo a long-period oscillation when the model is run at sufficiently fine vertical and horizontal resolution. The boundary in resolution between oscillating behaviour and non-oscillating behaviour is around 250 km grid spacing in the horizontal and 1 km in the vertical. The mean flow oscillation is characterized by downward phase prorpagation, formation of strong shear zones and peak-to-peak amplitudes of ~50 m/s at the equator - all features in good agreement with the observed QBO. However, the period of the oscillation tends to be about half that of the real QBO. A number of experiments will be described which examined the sensitivity of the simulated mean flow oscillation to such factors as subgrid-scale diffusion, sea surface temperature, annual cycle forcing etc.

Monday 19 July PM

Presiding Chairs: K. Sato (Kyoto University, Japan), M.P. Baldwin (Northwest Research Associates, Bellevue, USA)

MC06/W/04-A1 1400

NUMERICAL SIMULATIONS OF THE QBO USING GCM

Masaaki TAKAHASHI, Tatsuya Nagashima (Center for Climate System Research, University of Tokyo, 4-6-1 Komaba, Meguro-Ku, Tokyo 153-8904, Japan, email: masaaki@ccsr.u-tokyo.ac.jp, tnagashi@ccsr.u-tokyo.ac.jp); Masanori Niwano (Grad. Sch. of Environmental Earth Sci., Hokkaido Univ., Sapporo 060-0810, Japan, email: niwano@ees.hokudai.ac.jp), Teppei Uetake, Fumio Hasebe (Department of Environment Sciences, Ibaraki University, Mito, Japan, email: uetake@env.sci.ibaraki.ac.jp, hasebe@mito.ipc.ibaraki.ac.jp)

A simulation of equatorial stratospheric QBO is performed. Reducing horizontal diffusion provides more gravity waves, which are related to noisier precipitation than that in normal general circulation models, to produce the QBO successfully. The period of the simulated QBO in T42 model is 800 days (27 months), which is almost the same as that observed. The amplitude of the zonal-wind oscillation is 20 m/s which is also comparable to the observed value.
Influence of a simulated QBO on the Northern hemisphere winter circulation in the higher latitudes is studied by analyzing output data in a T21 GCM. A comparison between the two phases of the QBO using composite analysis with five easterly and five westerly phase data is made. The zonally-averaged zonal wind composite exhibits a stratospheric dipole structure between high and middle latitudes, which has weaker (stronger) polar night jet during the easterly (westerly) phase of the equatorial QBO.
The ozone QBO is also simulated in a T21 GCM. Modified Chapman reactions of ozone photochemistry are included in the model, allowing the ozone to be fully interactive with the radiative and dynamical fields. The lower stratospheric ozone QBO over the equator is qualitatively similar to that observed, although the simulated amplitude of about 0.3 ppmv is less than that observed. The phase relationship between the equatorial upper and lower stratospheric ozone QBOs is successfully reproduced, although the phase of the modeled ozone QBO slightly precedes the observed phase in the upper stratosphere.

MC06/E/01-A1 1440

SIMULATION OF A QBO-LIKE OSCILLATION WITH THE ECMWF MODEL

Agathe UNTCH (ECMWF, Shinfield Park, Reading, RG2 9AX, UK, email: Agathe.Untch@ecmwf.int)

A realistic looking QBO-like oscillation in the zonal wind of the tropical stratosphere has been simulated in a climate integration with a version of the ECMWF model which resolves the atmosphere up to 0.1 hPa with 50 levels and has a vertical resolution of about 1.5 km in the stratosphere. Results from sensitivity studies of this simulated QBO-like oscillation to horizontal and vertical resolution and to different numerical advection schemes will be shown. Wave diagnostics and Eliassen-Palm diagnostics of wave-mean flow interaction will also be shown in an attempt to interpret the results.

MC06/C/JSM01/E/22-A1 1505

MODELLING THE QBO AND SAO DRIVEN BY GRAVITY WAVES

H. G. MAYR (NASA Goddard Space Flight Center, Greenbelt, MD; J. G. Mengel, Steven Myers and Associates Co., Vienna, VA; K. L. Chan, Hong Kong University of Science and Technology, Hong Kong, China); H. S. Porter (Furman University, Greenville, SC; C. A. Reddy, Formerly at Vikram Sarabhai Space Center, Trivandrum, India)

Our numerical spectral model, which incorporates Hines' Doppler spread parameterization (DSP) for small scale gravity waves (GW), can simulate the salient features of the QBO and SAO near the equator. The model has now been extended to describe phenomenologically the mean zonal circulation below 20 km, in part through tuning of the GW parameterization. To reproduce the upwelling at equatorial latitudes associated with the Brewer Dobson circulation that in part is modulated by the vertical component of the Coriolis force, the eddy diffusivity in the lower stratosphere had to be enhanced; and to compensate for that a larger GW source is required closer to the middle of the range recommended for the DSP. Through global scale momentum redistribution, the above development is conducive to extending the QBO and SAO to higher latitudes. Multi-year interannual oscillations are generated through wave filtering by the annual oscillation in the mean zonal circulation. In a 3D version of the model, GW momentum is absorbed and dissipated by tides and planetary waves. A somewhat larger GW source is then required to generate realistic QBO and SAO amplitudes.

MC06/C/JSM01/E/35-A1 1600

DYNAMICAL EFFECTS OF OZONE FEEDBACK ON THE EQUATORIAL QUASI-BIENNIAL OSCILLATION

Teppei UETAKE (Department of Environmental Sciences, Ibaraki University, Mito, 310-0056, Japan, email: uetake@env.sci.ibaraki.ac.jp); Fumio Hasebe(Department of Environmental Sciences, Ibaraki University, Mito, 310-0056, Japan, email: hasebe@mito.ipc.ibaraki.ac.jp); Masaaki Takahashi (Center for Climate Syatem Recerch, University of Tokyo, Tokyo, 153-9804, Japan, email: masaaki@ccsr.u-tokyo.ac.jp); Tatsuya Nagashima(Center for Climate Syatem Recerch, University of Tokyo, Tokyo, 153-9804, Japan, email: tnagashi@ccsr.u-tokyo.ac.jp)

An Ozone QBO is considered to be driven by the advection due to secondary mean meridional circulation coupled with zonal wind QBO. In this case, ozone and zonal wind QBO are in-phase relationship in the lower stratosphere. However, this is not agreement with observations. In experiment using a mechanistic model, a realistic ozone QBO is reproduced by adding the diabatic heating QBO due to solar absorption of ozone. So it is pointed out the importance of ozone feedback effect. Moreover, because the radiative ozone feedback changes vertical momentum flux through weakening secondary circulation, it affects zonal wind acceleration. In this study, we discuss the driving mechanism of ozone QBO and dynamical effect of ozone feedback, using a CCSR/NIES AGCM which includes photochemical effect of a modified Chapman reaction. In dominant dynamical region, zonal-mean horizontal and vertical ozone fluxes are cancel out in zonally averaged ozone continuity equation over the equator. The ozone QBO is driven by eddy flux divergence. Long and short wave heatings are out-of-phase in the same height region. So we suggest that the ozone feedback effect weakens the secondary circulation and reduces the vertical momentum flux. Similarly, comparing each terms of zonally averaged zonal momentumequation, we conclude that the ozone feedback effect decreases the acceleration due to secondary circulation and produces opposite acceleration.

MC06/C/JSM01/W/43-A1 1625

MODULATION OF STRATOSPHERIC TRACE SPECIE TRANSPORT BY THE QBO: A THREE-DIMENSIONAL MODEL STUDY

Lori BRUHWILER (Climate Monitoring and Diagnostics Laboratory, R/E/CG1 325 Broadway, Boulder, CO 80303, USA, email: lbruhwiler@cmdl.noaa.gov); Kevin Hamiliton (Geophysical Fluid Dynamics Laboratory, Princeton Forrestal Campus, Rt.1, Princeton, NJ 08540, USA, email: kph@gfdl.gov)

The equatorial stratospheric zonal wind and temperature quasi-biennial oscillation (QBO) has been observed for several decades and is well-documented. The response of stratospheric trace species, such as ozone, to the QBO-induced perturbations in stratospheric temperature and circulation have also been topics of intensive study, in particular with respect to tropical and extra-tropical interannual variability. Here, the results of a model simulation of ozone and other stratospheric trace species with a comprehensive general circulation model and a prescribed zonally symmetric QBO momentum source are presented. Use of this QBO parameterization results in a fairly realistic zonal wind and temperature QBO, which in turn result in realistic QBO responses of stratospheric trace constituents. The particular focus of this work will be on how the equatorial QBO modulates transport of trace species into and out of the tropics. In contrast to previous two-dimensional model studies, it is found that transport by eddies varies significantly with QBO phase.

MC06/W/01-A1 1650

QBO-INDUCED VARIATIONS IN ASCENT RATE INFERRED FROM TRACE GAS DATA IN THE TROPICAL LOWER STRATOSPHERE

Masanori NIWANO, Masato Shiotani (Division of Ocean and Atmospheric Sciences, Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060-0810, Japan, email: niwano@ees.hokudai.ac.jp)

Quasi-biennial oscillation (QBO)-induced variations in ascent rate in the lower stratosphere are investigated with use of the Halogen Occultation Experiment (HALOE) data from 1993 to 1998. The ascent rate is inferred from annually varying water vapor plus doubled methane ([H2O]+2[CH4]) profiles in the 20-60 hPa layer within 15 degrees of the equator, where the ascent rate is assumed to be approximately comparable to the vertical advection velocity. The derived QBO components of the ascent rate exhibit maximum amplitudes over the equator. Those are about 0.15 to 0.2 mm/s at 20-50 hPa, which appear to be larger than those of the residual circulation derived radiatively. Above 40 hPa around 10 to 15 degrees in each hemisphere, the ascent rate QBO shows seasonality that enhanced anomalies occur in the winter hemisphere. Phase lags among the QBOs in ascent rate, temperature and ozone are also examined at the equator. It is found that descent anomalies precede positive anomalies of temperature and ozone by about 2-6 months, with its lag decreasing with height below 30 hPa, while some of works using coupled dynamical, radiative and photochemical system models have reported substantial in-phase relationship among the three. The larger lags between subsidence and ozone variations, seen in altitudes with the mixing barriers in the subtropics, may indicate relatively small diffusion in this region.

MC06/W/02-A1 1715

STEPS TOWARDS THE MODELLING OF THE QBO IN THE MIDDLE ATMOSPHERE GENERAL CICULATION MODEL ECHAM4

M.A. GIORGETTA (Max-Planck-Institute for Meteorology, Bundesstr. 55, 20146 Hamburg, Germany, email: giorgetta@dkrz.de)

The simulation of the QBO in a GCM is still a problem in current GCMs. This work aims at the simulation of this phenomenon in the middle atmosphere version of ECHAM4. This model is run with a triangular truncation T30, corresponding to a horizontal resolution of 3.8 degree. The model extends from the surface to 0.01 hPa. The standard version is run with 39 layers and contains the Hines Doppler spread parameterization for a spectrum of gravity waves. The experimental design consists of various sensitivity experiments dealing with vertical resolution, momentum diffusion, deep convection, and gravity wave parameterization. The first three items concern resolved waves and hence the zonal wind forcing by EP-flux divergence. Experiments run with 69 and 88 layers are completed and show the forcing of westerly winds in the QBO domain at 30 hPa where easterlies dominate in the standard 39 layer version. These westerlies alternate with easterlies, but do not expose the observed downward propagation. Experiments with increased source strengths for gravity waves excited within the atmosphere allow to increase the amplitude of westerlies and easterlies, but may also deteriorate the SAO. Other experiments await completion.

RADIATIVE FORCING / CLIMATE RESPONSE STUDIES IN GCMs

MC07/W/01-A2 Invited 0930

RADIATIVE FORCING OF CLIMATE CHANGE

M. RAMASWAMY (Geophysical Fluid Dynamics Laboratory, Princeton, New Jersey, 08542, USA)

The Earth's climate system has been influenced by a number of radiative agents over the past century. These include the forcings induced by anthropogenic changes in the concentrations of various radiatively-active gases and aerosols. While our knowledge of the various agents affecting the radiative balance of the climate system in a secular manner has evolved considerably in recent times, many uncertainties remain for several of the agents. We will review in particular the characteristics of the forcings due to the anthropogenic trace gases and aerosols, including the degree of spatial inhomogeneity of the respective forcings and strategies adopted for estimating them. We will also discuss some recent attempts that have used observations to explore the quantitative features of some of the important forcings. We will also examine the linkages between forcing and modeled climate response for some specific radiative agents.

MC07/W/02-A2 1015

A GCM STUDY OF CLIMATE SENSITIVITY AND CLIMATE FEEDBACKS

B. CHRISTIANSEN (Danish Meteorological Institute, Denmark, email: boc@dmi.dk)

The climate sensitivity factor lambda = d T_s/ d F measures the strength of the climate change d T_s to a prescribed radiative forcing d F. The value of lambda reflects the strengths of the feed-backs in the climate system. Recently, climate model studies have questioned the usefulness of lambda as a predictive tool: in addition to the strength of the forcing both it's latitudinal variation and vertical partitioning influence the climate change. The nature of these complications will be studied by expanding the sensitivity factor in components representing the individual feedbacks. E.g., the change in the lw outgoing flux at the TOA may be expressed as d F^dT_s = F^ T_s + (F^C) (C T_s) + (F^q) (q T_s), where C T_s and q T_s represent the cloud and humidity feedback, respectively. The data for the analysis come from a series of GCM experiments with perturbations in ozone concentration, increased CO_2, and changed solar constant. Our results will be compared with empirical estimates. The approach could also be important for the inter-comparing of models.

MC07/E/01-A2 1035

CLIMATE RESPONSE AND RADIATIVE FORCING FROM ATMOSPHERIC OZONE CHANGES

Michael PONATER, Nicola Stuber, Robert Sausen (DLR-Institute for Atmospheric Physics, Oberpaffenhofen, D-82230 Wessling,Germany, email: michael.ponater@dlr.de)

Based on experience from climate model experiments with either varying greenhouse gas concentrations or varying solar insolation, radiative forcing has been established as a reliable predictor of the associated climate impact. Likewise, the climate sensitivity parameter is usually found to be constant for a given model configuration, indicating a linear increase of surface temperature with increasing radiative forcing.
We have developed a method to calculate the adjusted radiative forcing (and the respective climate sensitivity) within the framework of the 3D climate model ECHAM4/MLO. CO2 increase experiments with this model system confirm the radiative forcing concept outlined above. However, in several experiments with respect to aircraft induced ozone changes a strong dependency of the climate sensitivity from horizontal structure, vertical structure, and amplitude of the ozone perturbation is apparent. The reasons for this failure of the radiative forcing concept is examined further by means of sensitivity experiments implying idealized patterns of atmospheric ozone concentration change.

MC07/W/04-A2 1115

THE RADIATIVE FORCING AND TEMPERATURE RESPONSE DUE TO STRATOSPHERIC WATER VAPOUR AND OZONE CHANGES SINCE 1979

P. M. de F. Forster, K. P. SHINE (Department of Meteorology, University of Reading, Reading, UK, RG6 6BB, email: piers@met.rdg.ac.uk)

There is observational evidence of substantial increases in stratospheric water vapour since 1980, from ballonsonde estimates and, over 1992-1996, from satellite measurements. This paper uses a fixed dynamical heating model and an Intermediate General Circulation model (IGCM) to assess the response of stratospheric temperatures to this water vapour change. It compares the effects of water vapour increases and ozone loss and finds that over the last two decades water vapour changes may have lead to as much cooling, of the lower stratosphere, as ozone loss. Comparisons are also made between the stratospheric temperature response, calculated using the fixed dynamical heating approximation, to the temperature response in the IGCM.

MC07/E/05-A2 1135

SIMULATION OF RADIATIVE FORCING DUE TO POLLUTION OF LYING SNOW

David L Roberts, Luke M. ROBINSON, Richard L H Essery(*) (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SY, UK.) (* also at National Hydrology Research Institute, Environment Canada, 11 Innovation Boulevard, Saskatoon, Saskatchewan, S7N 3H5, Canada.)

It has sometimes been suggested, e.g. by Warren & Wiscombe (1980), that the contamination of lying snow by small concentrations of absorbing particles, especially black carbon particles, may depress the albedo of the snow surface enough to exert a significant warming effect on the climate. The present study is an attempt to assess the significance of this mechanism using the Hadley Centre atmospheric general circulation model. In order to do this, the normal (HadAM3) version of the model has been modified in two main ways. First, the existing snow surface albedo parameterization has been replaced with a more sophisticated scheme. This includes a parameterization of the darkening effect of black carbon particles, as well as a prognostic snow grain size variable which enables the simulation of the ageing of the snow cover. Secondly, the model has been adapted to include the transport and deposition of black carbon particles emitted during fossil fuel combustion and biomass burning. The black carbon deposited in snowfall or by dry deposition (onto an existing snowpack) is used to drive the snow albedo scheme. The resulting radiative forcing is evaluated by calling the radiation scheme twice, once with pure snow and once with polluted snow, and subtracting the radiative fluxes at the top of the atmosphere. The results of preliminary experiments suggest that the magnitude of the effect is not quite large enough to be significant on a global scale, but that it might be important on a regional scale, especially during boreal spring.

MC07/W/12-A2 1155

A GCM STUDY OF RADIATIVE FORCING AND STRATOSPHERIC TEMPERATURE RESPONSE DUE TO PINATUBO AEROSOLS

S. RAMACHANDRAN (AOS Program, Princeton University, Princeton, New Jersey 08542, USA, email: snr@gfdl.gov); V. Ramaswamy, M.D. Schwarzkopf, S.M. Freidenreich (Geophysical Fluid Dynamics Laboratory, Princeton, New Jersey, 08542, USA)

Volcanic aerosols in the stratosphere produce significant transitory solar and infrared radiative perturbations, both at the top-of-the-atmosphere and at the surface. These, in turn, lead to thermodynamical and dynamical changes of the climate system. A spectral, latitude- and month-dependent set of aerosol optical parameters, derived from observations for two years following the Pinatubo eruption (June 1991 - May 1993), are employed in the GFDL SKYHI GCM to determine the associated changes in the radiative balance. Clear- and total-sky forcings, as well as the temporal evolution of the perturbations to the stratospheric heating rates, are analyzed. An ensemble of GCM integrations are performed using predicted clouds and climatologically varying SSTs, one set with and one without the aerosols ("control"), in order to study the evolution of the changes in stratospheric temperatures. These simulations are compared with results from a fixed dynamical heating calculation, and with the observed latitude-height stratospheric temperature changes. The statistical significance of the temperature changes and the relative roles of solar and longwave radiative effects will also be discussed.

MC07/E/04-A2 1215

RADIATIVE FORCING OF CLIMATE BY LAND COVER CHANGE

Richard BETTS (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SY, UK, email: rabetts@meto.gov.uk); Navin Ramankutty, Jonathan A. Foley (both at Climate, People and Environment Program (CPEP), Institute for Environmental Studies, University of Wisconsin, 1225 West Dayton Street, Madison, WI 53706, USA, email: nramanku@students.wisc.edu)

The Kyoto protocol includes afforestation and reforestation as possible means of reducing the radiative forcing of climate change through the uptake of atmospheric CO2. However, vegetation also affects the Earth's radiation budget through its impact on the surface albedo and cloud, so quantification of the net change in carbon fluxes may not provide a true reflection of the impact of forest cover changes on radiative forcing. Since a forest generally has a lower albedo than cultivated land, particularly when snow is lying, decreases in forest cover in mid- and high-latitudes may have provided a negative radiative forcing which partly opposes the positive forcing due to increased atmospheric greenhouse gas concentrations. This negative forcing may be reduced if forest cover in some regions is increased. This paper uses the HadAM3 General Circulation Model and a dataset of historical crop cover change to estimate the relative contributions of vegetation-related albedo and atmospheric CO2 changes to radiative forcing relative to 1860, and discusses the implications of this for the use of afforestation and reforestation in reducing anthropogenic climate change.

RADIATIVE FORCING AND GREENHOUSE GASES

MC07/E/02-A2 1400

GCM STUDIES OF "RADIATIVE FORCING" BY WELL-MIXED GREENHOUSE GASES

William INGRAM, Stephanie Woodward (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berks, RG12 2SY, UK)

We have compared in a GCM the impact of different well-mixed greenhouse gases, explicitly calculating the effects of their associated stratospheric temperature adjustment on their forcings as well as their effects on modelled climate. The qualititative differences between their forcings are as would be expected from the different spectral regions where they absorb. For CO2, stratospheric temperature adjustment seems to be reliably quantifiable as giving about a one-eighth reduction in the size of the forcing. Even allowing for this, we find our model more sensitive to the minor greenhouse gases than CO2 by another 10-15%. We interpret this as due not to remaining inadequacy in our forcing estimates, but to different cloud feedbacks, ultimately attributable again to the different spectral regions where they absorb. Since modelled cloud feedbacks still vary considerably and cannot be considered reliable, this does not provide any good basis for increasing their "greenhouse warming otentials", but such uncertainties should be borne in mind when comparing he greenhouse effects of different gases.

MC07/W/08-A2 1420

THE EFFECT OF UNCERTAINTIES IN RADIATIVE FORCING ON TEMPERATURE TREND PREDICTIONS

F. Forster, K. P. SHINE, Department of Meteorology, University of Reading, Reading, UK, RG6 6BB.

This paper firstly examines the range of uncertainty in our knowledge of the anthropogenic and natural radiative forcings since 1850. Then a Intermediate General Circulation Model (IGCM) is used to examine the likely effect of these forcings on the surface temperature and investigate the robustness of the radiative forcing concept for both idealistic and realistic changes in well-mixed greenhouse gases, ozone, aerosol and solar constant.

MC07/W/15-A2 1440

GREENHOUSE FLUX INCREASES ASSOCIATED WITH INCREASES IN ATMOSPHERIC WATER VAPOUR

W.F.J. EVANS, E. Puckrin (Trent University, Peterborough, Ontario, Canada, K9J7B8)

Water vapour in the atmosphere is responsible for over half of the earth's greenhouse radiation, and therefore is potentially a major contributor to the problem of global warming if water increases. An increase in the amount of water vapour may have significant consequences on global climate change; hence, it is important to investigate the radiative impact of any increase, as well as the physical mechanism which is responsible for inducing changes in this gas. Recently, it has been noted that there may have been an increase by 5% in the water vapour amount in the atmosphere of the northern hemisphere during this century. The warming of the planet's surface by about 0.7oC over the last 100 years can account for only a 2% increase in the atmospheric water vapour amount, based on thermodynamic considerations. There is at present no widely accepted explanation for the cause of the additional 3% amount. However, a possible mechanism may be connected with the increase in tropospheric aerosol over the last 30 years. The combustion of fossil fuels may be responsible for increasing the number of condensation nuclei in the atmosphere on which tiny water droplets form, thereby enhancing the amount of water vapour in the atmosphere. The droplet sizes are typically 10 mm in diameter and they require condensation nuclei with smaller diameters which are commonly observed to exist in exhaust products. As well, over the last year there has been a significant increase in atmospheric water vapour due to the large El Nino which has now dissipated. It is essential to accurately quantify the increase in the greenhouse flux due to the greater abundance of water vapour; hence, we have used an accurate line-by-line radiative transfer code, FASCOD3, to model the radiative greenhouse flux associated with varying amounts of water vapour in the atmosphere. The calculations have been performed for three different scenarios of water vapour content; a 5% increase, a 10% increase, and a 20% increase in the tropospheric water vapour amount over a range of latitudes and seasons. The results show that the corresponding increase in the surface radiative forcing would range from 1.5 to 6.2 W/m2. A value of 1.5 W/m2 represents a flux that is about half as large as the increase in the flux due to all the other greenhouse gases combined since the pre-industrial period. This flux increase may have contributed to the record warm year in 1998.

MC07/W/09-A2 1500

THE ACCURACY OF LONGWAVE RADIATION CALCULATIONS FOR EARTH-ATMOSPHERE APPLICATIONS

Robert G. ELLINGSON (Department of Meteorology, University of Maryland, College Park, MD 20742, email: bobe@atmos.umd.edu)

The WCRP-sponsored Intercomparison of Radiation Codes used in Climate Models (ICRCCM) showed climatically important differences between different model calculations of radiative fluxes and heating rates when using the same atmospheric input - even for clear-sky conditions. Data from ARM have allowed much more stringent tests to be applied to detailed radiation models. The results show that conditions the downwelling clear-sky longwave radiation at the surface can be calculated to about 2 Watts per sq. m using line-by-line models - a reduction of the uncertainty by about a factor of 5. However, such accuracy is not generally supplied by radiation codes used in climate models. This paper summarizes the limitations of such models and summarizes areas needing additional research.

MC07/W/19-A2 Poster 1520-01

UPDATED RADIATIVE FORCING ESTIMATES OF ATMOSPHERIC METHANE

Kamaljit SIHRA (University of Reading, 2 Earley Gate, Whiteknights, P.O. Box 239, Reading RG6 2AU, email: sws98ks@met.rdg.ac.uk); Keith Shine (University of Reading, UK)

Methane in the terrestrial atmosphere is an important greenhouse gas which has been steadily increasing since pre-industrial times. These increases have been shown to contribute 20% towards the radiative forcing from all well mixed greenhouse gases, in addition to causing increases in tropospheric ozone and stratospheric water vapour (IPCC, 1995). A previous investigation of the radiative forcing of methane as a function of concentration, by Myhre et al (1998) using the narrow band model (NBM) of Shine (1991), reveals differences of up to 20%, compared with IPCC (1995) estimates. The NBM is most accurate in the weak and strong limits for a Lorentz lineshape and this may not be appropriate for methane since the absorption for its present atmospheric abundance generally lies between these two limits. This paper tests the validity of the NBM for methane against the Voigt spectral lineshape and line-by-line calculations performed with the Oxford Reference Forward Model (RFM), an evolution of the GENLN2 line-by-line modelling program.

MC07/W/16-A2 1600

A COMPARISON OF GCM MODELS WITH EXPERIMENTAL MEASUREMENTS OF SURFACE RADIATIVE FORCING BY GREENHOUSE GASES

W.F.J. EVANS, E. Puckrin (Environmental Resource Studies, Trent University, Peterborough, Ontario, K9J7B8, Canada)

Climate models predict that the emission of greenhouse gases into the atmosphere has altered the radiative energy balance at the earth's surface by several percent through increasing the greenhouse radiation from the atmosphere. With measurements at high spectral resolution, this increase can be quantitatively attributed to each of several anthropogenic gases. An energy flux imbalance of about 3 W/m2 has been created by anthropogenic emissions of greenhouse gases of which we have measured over 1.0 W/m2. Calibrated radiance spectra of the greenhouse radiation from the atmosphere have been measured at ground level from Peterborough using an FTIR with a resolution of 0.1 wavenumbers. This long wave radiation consists of thermal emission from naturally occurring

M

gases such as CO2, H2O and O3 as well as from many trace gases such as CH4, CFC11, CFC12, CFC22 and HNO3. The forcing radiative fluxes from CFC11, CFC12, CCl4, HNO3, O3, N2O, CH4 and CO2 have been quantitatively measured. The experimental fluxes are simulated well by the FASCOD3 radiation code. The greenhouse radiation fluxes from the various gases have been computed with the radiation code from the NCAR community model for the location and seasons of the measurements. Overall the agreement in most fluxes is good, providing increased confidence in the NCAR CCM. Similar comparisons of our experimental measurements with simulations using the column model from the Canadian GCM will be reported. Differences in the fluxes are over 50 % for CH4 and N2O at mid latitudes in summer.

MC07/W/22-A2 1620

RADIATIVE FORCINGS AND GLOBAL WARMING POTENTIALS OF WELL-MIXED GREENHOUSE GASES, CFCS, AND CFC REPLACEMENT COMPOUNDS

Atul K. JAIN (Department of Atmospheric Sciences, University of Illinois, Urbana, Illinois, USA, email: jain@atmos.uiuc.edu); Bruce P. Briegleb (National Center for Atmospheric Research, Boulder, Colorado, USA); K. Minschwaner (Department of Physics, New Mexico Institute of Mining and Technology, Socorro, New Mexico, USA); Donald J. Wuebbles (Department of Atmospheric Sciences, University of Illinois, Urbana, Illinois, USA); M. D. Hurley (Ford Motor Company, Dearborn, Michigan, USA)

Using narrow-band and broad-band radiative transfer models for the global atmosphere, we evaluate the radiative forcing due to 39 greenhouse gases as a function of latitude and season. The gases examined include CO2, CH4, N2O, plus a number of chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), hydrochlorocarbons, bromocarbons, iodocarbons, and fully fluorinated compounds. Latitudinal and seasonal variations are considered explicitly, using distributions of major greenhouse gases from a combination of atmospheric models and UARS measurements, and cloud statistics from the International Satellite Cloud Climatology Project (ISCCP). The model calculations are performed on a 5 deg. latitude grid from 82.5 deg S to 82.5 deg N. The determined radiative forcings are then used to derive Global Warming Potentials (GWPs) for each of the compounds. These results are compared with prior analyses. In addition, model analyses of the latitudinal and seasonal dependence of radiative forcing since pre-industrial time will be presented.

MC07/W/13-A2 1640

RADIATIVE FORCING, GLOBAL WARMING POTENTIAL AND GLOBAL WARMING COMMITMENT CONCEPTS IN THE CLIMATE FORCING RADIATIVE FACTOR EFFECT ASSESSMENT

Igor KAROL, V.A. Frolkis, A.A. Kiselev (all at Main Geophysical Observatory, 7 Karbyshev Str., St.Petersburg, 194021, Russia, email: karol@main.mgo.rssi.ru)

The Radiative Forcing (RF) and the Global Warming Potential (GWP) are widely used for the assessment of radiative effects of separate active substance content change in the atmosphere. The known advantages and deficiences of these indices and of a concept of Global Warming Commitment (GWC) are discussed with account of the actual evolution of substance during the considered period, and by this it deviates from the GWP, being calculated by the same formula. A comparative analysis of RF and GWC of main Greenhouse Gases (GG) is carried out for their observed evolutions before 1995 and projected ones up to 2050 based on global photochemical models and on the known IPCC-92 scenarios. The GWCs of CH4, N2O and chlorofluorocarbons (CFCs) against CO2 as a standard GG are different from relative RF and much more accurately reflect the real events in the above mentioned periods than the widely used RF of GG relative to RF of CO2, when the character of the GG content evolution during the time period considered is not accounted for.

AEROSOL FORCING AND OBSERVATIONS / MODELLING OF SOLAR RADIATION

MC07/W/05-A3 Invited 0830

SHORTWAVE RADIATIVE FORCING OF CLIMATE CHANGE BY ANTHROPOGENIC AEROSOLS: NARROWING THE UNCERTAINTIES

Stephen E. SCHWARTZ (Environmental Chemistry Division, Brookhaven National Laboratory, Upton NY 11973 USA, email: ses@bnl.gov)

Tropospheric aerosols influence the shortwave reflectivity of the Earth by scattering and, to lesser extent, absorbing radiation (direct effect) and by increasing cloud reflectivity and perhaps lifetime (indirect effect). Increased aerosol loading over the industrial period is thought to exert a negative (cooling) radiative forcing that is comparable in global-average magnitude to the positive (warming) longwave forcing due to increased concentrations of greenhouse gases. However the aerosol forcing is highly uncertain, the greatest source of uncertainty in climate forcing over the industrial period. This uncertainty precludes confident assessment of net forcing over the industrial period and empirical inference of climate sensitivity to greenhouse forcing. Accurate description of the direct forcing requires knowledge of aerosol loading (column mass burden or optical depth) and the forcing per loading. Aerosol loading is highly variable because of nonuniform distribution of sources, short lifetime, sensitivity to relative humidity, and intermittent formation and removal processes as influenced by clouds and precipitation. Aerosol composition, size distribution and other microphysical and optical properties are also highly variable, leading to considerable variability in normalized forcing (forcing per mass burden or forcing per optical depth). Aerosol normalized forcing seems to be rather well modeled, at least for cloudfree sky, provided aerosol optical properties and surface reflectance are specified. The indirect forcing is more uncertain, as it is quite sensitive to perturbation in number concentration of cloud droplets. Because of correlations and feedbacks between aerosols and other climate variables, aerosol forcing must be represented "on-line" in climate models. This requires accurate representation of the source, evolution, and Removal processes governing aerosol mass loading, number, composition, microphysical properties, and geographical distribution, which in turn requires accurate and efficient means of representing aerosol processes in transport models and evaluation of the performance of these models. Future satellite measurements, especially satellite-borne Lidar, should greatly aid in model evaluation, but ground-based and in-situ measurements remain necessary, as do process research studies.

MC07/W/07-A3 0915

FIELD MEASUREMENTS THAT MANIFEST THE FIRST AND SECOND TWOMEY EFFECTS

James G. HUDSON, Seongsoo Yum

The Twomey or Indirect Aerosol Effect comes about through changes in cloud microphysics due to anthropogenic cloud condensation nuclei (CCN). The primary Twomey effect is the increase in cloud droplet concentrations and decrease in cloud droplet sizes, which cause greater cloud albedo. The secondary effect is the inhibition of precipitation due to the smaller sizes of the cloud droplets, which results in greater cloud amounts, durations, and optical thicknesses. Here we present data from two field projects that clearly show that differences in cloud droplet concentrations, sizes, and precipitation are due to differences in CCN concentrations. In both the Small Cumulus icrophysics Study (SCMS) on the East coast of Florida and the Atlantic Stratocumulus Transition Experiment (ASTEX) in the eastern Atlantic there are distinctly different clouds due to differences in CCN concentrations. Clouds formed in continental/anthropogenic air masses with high CCN concentrations are distinctly different from clouds formed in maritime air masses. Throughout these projects there are significant correlations between CCN and cloud droplet concentrations and anticorrelations between CCN and cloud droplet sizes; this is a manifestation of the First Twomey Effect. The anticorrelation between CCN and drizzle suggests the second Twomey effect. The finding of a threshold mean droplet size for the production of drizzle, which is usually exceeded in maritime clouds, which produce abundant drizzle, but seldom exceeded in continental clouds, which produce only small amounts of drizzle, seems to clearly manifest the second Twomey effect. The global significance of these results is bolstered by the consistent continental/maritime differences in CCN and cloud microphysics for the cumulus clouds of SCMS and the stratus clouds of ASTEX.

MC07/W/20-A3 0935

EFFECTS OF RELATIVE HUMIDITY ON THE RADIATIVE FORCING DUE TO SULFATE AEROSOLS. CALCULATIONS WITH A REGIONAL HIGH RESOLUTION MODEL AND A GLOBAL MODEL

Gunnar MYHRE (Department of Geophysics, University of Oslo, Norway, email: gunnar.myhre@geofysikk.uio.no)

The relative humidity has a non-linear effect on the radiative forcing of hygroscopic aerosols. The relativehumidity varies within typical gridcells of global models. To investigate the impact of such variations we have used a chemistry transport model (CTM) with 50km horisontal resolution for a limited area and a global CTM to calculate sulfate distributions and the corresponding radiative forcing. Both CTMs use meteorological input data from numerical weather prediction models for the year 1996. The CTM and the radiative transfer calculations are performed in a consistent way, such that the humidity, clouds, and sulfate distributions are the same in both calculations. Optical properties of sulfate aerosols are the same as those used in a previous global radiative forcing calculation of sulfate. The effect of the relative humidity on the radiative forcing due to sulfate is much higher in the regional model, resolving more of the spatial variation in the humidity, than in the global model and previous global radiative forcing calculation. In addition to the large effect of spatial variation in the relative humidity on the radiative forcing due to sulphate also a large temporal effect is found.

MC07/W/10-A3 0955

MEASURED AEROSOL ABSORPTION PROFILES AND THEIR INFLUENCE ON CLEAR-SKY AEROSOL FORCING

Manfred WENDISCH, Andreas Keil (all at Institute for Tropospheric Research, Permoserstr. 15, 04318 Leipzig, Germany, email: wendisch@tropos.de)

Using a Particle/Soot Absorption Photometer (PSAP), airborne measurements of aerosol volume absorption coefficients were performed over a polluted rural area in Germany. Together with measurements of aerosol size distribution, aerosol composition and meteorological parameters a vertically resolved input for detailed one-dimensional radiative transfer calculations was obtained. A Mie mixing method was introduced in order to include the PSAP measurements in the calculations. Calculations were performed for three air masses with different levels of pollution and absorption which have been observed in December 1997. For the air mass with the highest absorption level and non-snow surface albedo conditions the aerosol forcing at the top of the atmosphere was -11.2 W m-2 without including the measured aerosol absorption in the calculations and decreased to -9.6 W m-2 when the Mie mixing method was applied. Assuming a snow covered ground the aerosol forcing for the same air mass changed from a cooling of -1.3 W m-2 to a heating of +4.8 W m-2. For low levels of pollution (e.g. marine air masses) the inclusion of measured aerosol absorption in radiative transfer calculations had negligible influence. Additionally, vertical profiles of the black carbon volume fraction were obtained from the Mie mixing method. Typically, the black carbon fraction was largest near the ground and decreased rapidly in the free troposphere above temperature inversions. Furthermore, it was shown that unrealistic vertical profiles of black carbon volume fraction can be obtained if the mixing state of the particles is neglected and a size-independent mass absorption of black carbon (e.g. 10 m2 g-1) is assumed.

MC07/W/11-A3 1015

AEROSOL DIRECT RADIATIVE FORCING: A FIVE-YEAR CLIMATOLOGY AT THE ARM SGP CART SITE

Qiang FU, G. Lesins, J. Higgins (All at the Department of Oceanography, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada, Email: qfu@atm.dal.ca)

The aerosol direct radiative forcing at the ARM SGP CART site from the 1994-1998 has been analyzed using a radiation model with the input data collected at the ARM SGP central facility. The downward surface radiation measurements have been employed to validate the radiation model. We have discussed the uncertainties related to the surface albedo, aerosol composition and size distribution, and radiation model and measurements.

MC07/W/14-A3 1055

VALIDATION OF SHORTWAVE SURFACE RADIATION BUDGET RETRIEVALS BASED ON ERBE, SCARAB AND CERES SATELLITE DATA.

Alexander TRISHCHENKO, Zhanqing Li (Canada Center for Remote Sensing, Canada)

The surface radiation budget (SRB), one of the principal component of the earth's climatic system, is still fraught with uncertainties. For example, the estimates of global mean values of SRB vary from 142 Wm-2 (42% of incoming solar flux) to 191Wm-2 (55%). In this study we present the results of validation of algorithm for SRB retrieval developed by Li et al. (1993).

This algorithm is used in the NASA's Cloud and the Earth's Radiant Energy System (CERES) project. We tested this algorithm under variety of clear-sky and cloudy conditions for the satellite data from Earth Radiation Budget Experiment (ERBE), Scanner for Radiation Budget (ScaRaB) and CERES instruments. As ground truth we employed measurements from various radiation networks. They include data from the Atmospheric Radiation Measurement (ARM) in Oklahoma, the World Baseline Radiation Networks (BSRN), the radiation network of the Atmospheric Environment Service (AES) of Canada, etc. Surface albedo necessary to determine surface absorbed flux was derived either from measurements available, or from satellite-based estimation. Special emphasis is given to the SRB budget and effect of cloud radiative forcing in the polar regions over snow/ice covered surfaces.

MC07/W/17-A3 1115

HIGH RESOLUTION MODEL/MEASUREMENT VALIDATIONS OF DIRECT AND DIFFUSE FLUX IN THE SHORTWAVE

P.D. BROWN, S.A. Clough, E.J. Mlawer (Atmospheric & Environmental Research, Inc., USA); T.R. Shippert, Pacific Northwest National Laboratories, USA); F. Murcray (University of Denver, USA); J. Michalsky, L. Harrison, P. Keidron (State University of New York at Albany, USA)

To assess and improve radiative transfer modelling capability in the shortwave, a Quality Measurement Experiment (QME) has been initiated in the solar regime as part of the DoE Atmospheric Radiation Measurement (ARM) Program. The objective of this closure experiment is to study direct and diffuse irradiance in the clear sky, focusing upon three components: (1) measurements of the direct and diffuse irradiance, (2) forward model calculations, including the solar source function, and (3) characterization of the atmospheric state in the radiating column. For this assessment, spectral irradiance measurements in the 2000-28600 cm-1 regime, as measured by the Absolute Solar Transmittance Interferometer (ASTI) and the Rotating Shadowband Spectroradiometer (RSS), are used. The Line By Line Radiative Transfer Model (LBLRTM) is used to obtain layer optical depths, and the Code for High Resolution Accelerated Radiative Transfer with Scattering (CHARTS) is used for radiative transfer calculations in the scattering atmosphere. Results of this study are expected to make a contribution to the understanding of anomalous absorption reported in the shortwave. Of particular interest are issues associated with the line parameter database, water vapor continuum, collision induced continuum, solar source function, aerosol scattering, and surface albedo.

MC07/E/03-A3 1135

INSOLATION REGIME ON AND NEAR THE EARTH'S SURFACE

Tarzadin ULAANBAATAR (Department of Earth Sciences, National University of Mongolia, email: numelect@magicnet.mn)

The current scientific concept concerning theoretical description and calculation of the insolation regime on the earth surface in planetary-scale is faced with some uncertainties in consequence of atmospheric influences. In order to understand and overcome these disadvantages I decided to select the new insolation etalon measuring on the earth surface instead of familier solar constant.
In this work a model which is created by author consists of three simple parameters: date, measuring time in hour, minute and second, and geographical latitude. Calculations based on the selected new etalon indicate that the insolation regime on the Earth's surface is in a good coincidence with the calculations of Detre, L., [1939], Monin, A. S., [1972], and data measured by Geophysical Observatory of National University of Mongolia.
As results, the total insolation in different geographical latitudes or zonal amount of insolation in certain time interval, solar radiation weakening in atmosphere, reconstruction of insolation regime on the Earth's surface in geological past time are described. Furthermore, development of model drives to a new climate theory.

WATER VAPOUR AND RADIATION IN CLIMATE MODELS

Anthony SLINGO (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire RG12 2SY, UK, email: aslingo@meto.gov.uk)

Atmospheric water vapour exhibits a complex distribution in space and time, as a result of the many physical and dynamical processes which act on a water molecule from the moment it enters the atmosphere (mainly by evaporation from the oceans) to the time it leaves as precipitation reaching the surface. Water vapour is the most important greenhouse gas and a necessary ingredient for clouds, which also strongly influence radiative heating. The water vapour distribution thus provides a valuable tool for diagnosing the realism of these processes in climate models. Several new datasets have become available in the last few years from satellite instruments and re-analysis projects, which have been used to diagnose the relationship between the water vapour distribution and radiative heating. Studies of these data have often emphasized the importance of water vapour in the upper troposphere, but the role of water vapour at other levels should not be underestimated. This presentation will review some of the recent results in this field and highlight some of the strengths and weaknesses which have been found in climate model simulations, as well as in the observational data themselves. Some ways in which the weaknesses in both models and observations may be overcome will be discussed.

WATER VAPOR FEEDBACK ESTIMATES FROM GLOBAL CLIMATE MODELS AND CONSISTENCY WITH INDEPENDENT SATELLITE METHODOLOGIES

Franklin ROBERTSON (NASA Marshall Space Flight Center, Global Hydrology and Climate Center, 997 Explorer Blvd., Huntsville, AL 35806, USA, email: pete.robertson@msnfc.nasa.gov)

The fundamental role of water vapour in linking radiation, convection and dynamics has been widely studied and debated as a classical problem in climate dynamics. Water vapour feedback associated with climate change has been a subject of particularly intense debate since it is judged to be the most prominent feedback and the principal mechanism supporting claims of global warming scenarios. The present study uses a combination of space-based observations, radiation modelling, and the global climate models to estimate water vapour feedback associated with recent positive and negative phases of ENSO. ERBE and TOVS-based calculations which earlier suggested positive water vapour feedback based on the 1987/1989 warm /cold SST events are revisited in light of potential effects of undetected oceanic low clouds in biasing the top-of-atmosphere longwave clear-sky estimates somewhat low. Additional calculations of water vapour feedback from an algorithm based on the SSMT2 are used for the period 1993 to the present.
Finally, simulations from the CCM3 and other climate models using observed SSTs are evaluated with the observed data sets to evaluate their ability to simulate longwave clear-sky feedback and its partitioned components of surface temperature and lapse rate feedback and water vapour feedback. The findings are discussed in the context of using short-term climate anomalies to understand feedback processes.

PHYSICAL PROCESSES AND FEEDBACKS OF THE GREENHOUSE EFFECT DUE TO WATER VAPOR: SOME NEW INSIGHTS

Zuohao Cao, Ronald E. Stewart and M. K. Yau (Climate Research Branch, Atmospheric Environment Service Downsview, Ontario, Canada) (Department of Atmospheric and Oceanic Sciences, McGill University, Montreal, Quebec, Canada

This presentation is concerned with the greenhouse effect in the presence of water vapor. In particular, it is aiming at (1) gaining new physical insights by reformulating the expression of the greenhouse effect; (2) examining vertical, latitudinal, and seasonal variations of greenhouse trapping and causes of these variations by performing numerical simulations; and (3) assessing how the greenhouse trapping responds to a warmed atmosphere. It is shown that temperature differences between the surface and atmosphere determine not only the magnitudes but also the sign of the greenhouse effect. Positive (negative) values of this difference contribute to positive (negative) greenhouse trapping.
Numerical simulations using the radiation model MODTRAN with input data from both standard and ECMWF-reanalysis profiles have shown that over different latitudes and seasons the greenhouse trapping exhibits substantial vertical variations up to thetropopause, and these variations are determined by the temperature contrast between the surface and atmosphere. Due to a low-level temperature inversion, there are negative contributions to the greenhouse effect at low levels of the troposphere during the winter over higher latitudes. It is also found that the northward decrease of the greenhouse trapping is attributed to the systematic variations of moisture and temperature. Strong seasonal variations of the greenhouse trapping, controlled by changes of atmospheric moisture contents, are characterized by the largest values in the summer over higher latitudes. Results also indicate that the feedback of greenhouse trapping is positive in a warmed atmosphere, although its magnitude varies with height and with season as a result of perturbations in atmospheric temperature and moisture profiles.

GROUND-BASED WATER VAPOR OBSERVATIONS: NEW TECHNIQUES, ACCURACY ISSUES AND IMPLICATIONS FOR SATELLITE OBSERVING BASED ON RESULTS FROM THE ATMOSPHERIC RADIATION MEASUREMENT (ARM) PROGRAM

H.E. REVERCOMB, D.C. Tobin, R.O. Knuteson, W.F. Feltz (University of Wisconsin-Madison, Space Science and Engineering Center, USA, email: hanks@ssec.wisc.edu); Dave Turner (Pacific Northwest National Laboratory, USA)

Understanding the uncertainties of water vapour observations is an important issue for the whole climate community. This issue is currently being addressed by the Atmospheric Radiation Measurement (ARM) Program of the US Department of Energy, that has established a National observing system for climate research. To support studies of radiative transfer, single-column models, clouds, and aerosols, the ARM Program has implemented new remote sensing technologies for measuring water vapour with frequent temporal sampling. These technologies are combined with more conventional techniques at several sites, the most extensive being at the Southern Great Plains (SGP) Central Facility in Oklahoma. The new profiling capabilities developed by ARM include one active and one passive approach that operate autonomously, day and night: (1) a Raman LIDAR system that samples as fast as once per minute with 39 m vertical resolution and with vertical coverage in the range 3-12 km (depending on averaging times and time of day), and (2) multiple Atmospheric Emitted Radiance Interferometer (AERI) systems that observe high spectral resolution downwelling IR radiance spectra every 8-10 minutes from which temperature and water vapour profiles are retrieved up to 3 km (combination with GOES retrievals gives coverage of the entire troposphere). Several two-channel microwave radiometers and GPS systems are also used to measure the total column water vapour. Questions about the consistency of sonde water vapour observations implied by ARM radiation measurements led to special Water Vapour Intensive Operating Periods (IOPs) conducted in 1996 and 1997 at the SGP Central Facility. The goal was to use the complement of ARM advanced instrumentation to better quantify measurement uncertainties and to find ways of improving the accuracy of water vapour observations (order 2% goal). Using dual sondes on the same balloon, these two IOPs graphically…

NEW WATER VAPOR MEASUREMENTS AND THEIR IMPACT ON THE ATMOSPHERIC RADIATIVE BUDGET

Cathy CLERBAUX (Service d'Aeronomie/CNRS, Paris, France, email: ccl@aero.jussieu.fr); J. Tennyson (Department of Physics & Astronomy, University College London, UK); M. Carleer, R. Colin (Laboratoire de Chimie Physique Moleculaire, Université Libre de Bruxelles, Belgique); A.C. Vandaele (Institut d'Aéronomie Spatiale, Bruxelles, Belgium); A. Jenouvrier, M.F. Merienne (Groupe de spectroscopie Moleculaire Atmospherique, Universite de Reims, France); P. Bernath (Department of Chemistry, University of Waterloo, Canada); T. Clough (Atmospheric & Environmental Research, Cambridge MA, USA)

Accurate measurements of the water vapor absorption spectrum were recently obtained in the near-UV to near-IR region using a multi-reflection absorption cell coupled to Fourier transform interferometer Bruker IFS120M. The analyse of the spectra provides 1/3 more H2O absorption lines than available from the currently used spectroscopic databases. This water absorption dataset was used in a 1D radiative model in order to access its impact on the atmospheric radiative budget.

THE CURRENT SHORTWAVE SPECTROSCOPIC DATA BASE OF WATER VAPOR

Prasad VARANASI (Institute for Terrestrial and Planetary Atmospheres, State University of New York, Stony Brook, NY 11794-5000, USA)

Absorption of solar radiation by atmospheric water vapor is a significant aspect of the climate models. The recent observation that the models underestimate the shortwave absorption considerably has brought the hitherto taken-for-granted extent of our knowledge of the shortwave absorption in water vapor bands under closer scrutiny. Our laboratory has, in collaboration with NASA's Ames Research Center and Science and Engineering Services Inc., performed extensive series of high-resolution measurements during the past year. High-resolution Fourier-transform spectroscopy and photoacoustic spectroscopy using a tuneable laser have been employed to make these measurements. Our recent data will be presented along with comparisons with the available spectroscopic databases.

MC08/W/07–A3 **1210**

AN ESTIMATE OF THE CONTRIBUTION OF UNKNOWN WEAK WATER VAPOUR LINES TO THE OPACITY OF THE ATMOSPHERE

James Clarke, R C M LEARNER, Wenyi Zhong, Joanna D Haigh (all at Department of Physics, Imperial College, London SW7 2BZ, UK, email: r.learner@ic.ac.uk)

Thousands of unknown water vapour weak lines in the visible and near-infrared regions are deduced from extrapolations of experimental results. These extra lines are then included in the HITRAN database and used in line-by-line calculations of atmospheric opacity with standard atmospheric profiles. The effect of including the unknown weak lines will be compared with that of a continuum model.

Wednesday 21 July PM

Presiding Chair: A. Slingo (Meteorological Office, Bracknell, UK)

MC08/W/08–A3 Invited **1400**

OVERVIEW OF WATER PROPERTIES

John BATES (Climate Diagnostics Center)

This overview presentation will begin by examining the current state of knowledge of the spectroscopic properties of water vapor. This will include a summary of what the current state of knowledge is and what observations and enhancements are necessary to improve our knowledge of water vapor radiative transfer. Particular emphasis will be given to recent observational results of the longwave rotational band of water vapor in cold, dry atmospheres. I will then present results of a recent comparison of radiation codes for retrieving upper tropospheric humidity conducted by the GEWEX Water Vapor Project. This will include a comparison of water vapor radiative transfer models including line-by-line models, narrow band models, and single band models. A discussion of the similarities and discrepancies between various models, their dependence on model physics, and implications for their use in climate models will be included.
The second part of this overview will examine how well the radiative properties of water vapor are represented in climate models. I will examine in detail the results from simulations from the NCAR CCM3 and the GFDL climate model. Particular emphasis will be given to the comparison of modelled versus observed water vapor and radiation changes during the extreme ENSO warm and cold events of the last 20 years. In addition, I will examine how well water vapor variability in the tropics is represented in AMIP simulations by comparing modeled versus observed water vapor radiance fields. Finally, I will explore a hypothesis regarding the role of water vapor cycling through deep tropical convection and water vapor-radiation feedbacks in the recent long-term climate stability and in rapid climate change of the past.

MC08/E/08-A3 **1445**

IMPACT OF A VALIDATED RADIATIVE TRANSFER SCHEME, RRTM, ON THE ECMWF MODEL CLIMATE AND 10-DAY FORECASTS

J.-J. MORCRETTE (ECMWF, Shinfield Park, Reading Berkshire RG2 9AX, UK); S.A. Clough, E.J. Mlawer, M.J. Iacono (Atmospheric & Environmental Research, Inc., 840 Memorial Drive, Cambridge MA 02139, USA)

Series of integrations with the ECMWF model including either the Rapid Radiative Transfer Model (Mlawer et al., 1997) or the operational longwave radiation scheme are used to study the response of the model to a better representation of the longwave radiation fluxes and cooling rates, as RRTM corrects a number of clear-sky systematic errors. In seasonal simulations, the impact of RRTM is a warming and drying of the lower troposphere and a cooling of the higher troposphere and stratosphere. Objective scores for 10-day forecasts show a minimum impact on anomaly correlation of geopotential at 1000 and 500 hPa, and a large and usually positive impact on the mean error of temperature at 850 and 200 hPa.

MC08/W/06-A3 **1505**

A NEW FORMULATION FOR THE WATER VAPOR CONTINUUM

Eli J. MLAWER, Shepard A. Clough (Atmospheric and Environmental Research, Inc. Cambridge, MA, USA); David C. Tobin (University of Wisconsin, Madison, WI, USA)

A new formulation of the water vapor continuum, which is based on a conceptual framework that assumes that the continuum includes the effects of collision-induced transitions in addition to contributions from the wings of collisionally broadened allowed transitions, is presented. In previous versions of the CKD formulation, the allowed transitions were the sole source of the water vapor continuum. This new formulation, developed primarily as a result of recent detailed laboratory measurements of Tobin et al. (1996) and field observations obtained as part of the SHEBA under extremely dry conditions, produces a continuum that has higher-frequency features than in the previous formulation for both the self and foreign continua. The effect on model/measurement comparisons of applying the new continuum formulation in model calculations will be shown for the longwave and shortwave spectral regions.

MC08/L/09-A3 Invited **1545**

OUR KNOWLEDGE OF WATER VAPOR ABSORPTION: APPLICATION TO ATMOSPHERIC RADIATIVE TRANSFER WITH IMPLICATIONS FOR CLIMATE

Shepard A. Clough, Eli J. Mlawer, Michael J. Iacono, Patrick D. Brown Atmospheric and Environmental Research, Inc. Cambridge, MA

Water vapor and its distribution in the atmosphere plays a central role in the radiative balance of the earth system. The distribution of water vapor is not only important for the calculation of surface and TOA fluxes, cooling rates and solar deposition, but for the proper treatment of cloud formation, a critical aspect of the earthIs radiative system. In this paper we discuss the current state of our knowledge of water vapor absorption from the microwave to the ultraviolet including the effects of water vapor lines, the self and foreign broadened water vapor continuum (Clough et al., 1992).
The results of extensive atmospheric closure experiments for both the thermal region and the solar region will be presented. These studies have been carried out under the Doe ARM program and involve three critical components: (1) the measurement of atmospheric state; (2) spectral measurements of upwelling and downwelling radiance in the thermal region and direct and diffuse irradiance at the surface in the solar region; and (3) calculations with detailed radiative transfer models for direct spectral comparisons with the measurements. The assessment of errors from these studies and their anticipated effect on calculations for the global scale will be discussed, with particular emphasis on the upper troposphere.
The focus of this paper is on the importance of understanding and monitoring the global system, and GCM calculations for that system, from a spectral perspective and in that context improving our undertstanding of the role of water vapor.
Clough, S.A., M.J. Iacono, J.-L. Moncet (1992): Line-by-Line Calculation of Atmospheric Fluxes and Cooling Rates: Application to Water Vapor. J. Geophys. Res., 97, 15761-15785.

SATELLITE OBSERVATIONS OF CLOUDS AND UPPER TROPOSPHERIC HUMIDITY

W. Paul MENZEL (NOAA/NESDIS, 1225 West Dayton St., Madison, Wisconsin 53706, USA, email: paul.menzel@ssec.wisc.edu); Donald P. Wylie (Space Science and Engineering Center, University of Wisconsin-Madison, 1225 West Dayton St., Madison, Wisconsin 53706, USA, Email: don.wylie@ssec.wisc.edu)

Global upper tropospheric transmissive cirrus cloud cover has been charted for the past ten years (June 1989 - Dec 1998) using NOAA polar orbiting HIRS multispectral infrared data. The HIRS carbon dioxide slicing approach has a higher sensitivity to semi-transparent cirrus clouds than visible and infrared window techniques; the threshold for detection appears to be at visible transmittances greater than 0.1. The global average cloud cover is found to be about 0.75. The effective cloud amount of the all semi-transparent clouds (visible transmittance < 6) ranges from 0.2 to 0.6 with an average value of about 0.5. Time trends of the ten year cloud record show indications of an increase of high clouds in the northern mid-latitudes (0.5% per year) but little change elsewhere. The seasonal cycle of cloud cover in the southern hemisphere becomes very noticeable in 1993. Upper tropospheric humidity (UTH), derived from the global HIRS water vapor sensitive radiances, and global model forward calculations are compared; biases of measured versus calculated water vapor sensitive radiances suggest a dry bias in the models. In addition, water vapor wind field divergences, derived from the geostationary satellites, are compared with the HIRS measured UTH and global cirrus coverage. There are close similarities, especially in the tropics, between areas of increased UTH and upper tropospheric wind divergence and high cloud amount. This suggests opportunities for improved model analysis as the relationship between clouds, ambient relative humidity fields, and large scale dynamics begins to emerge.

MC08/W/03-A3 **1650**

RADIATIVE EFFECT OF MOISTURE IN THE COMPUTATION OF CLEAR SKY OLR

Man LI, C. WU, Siegfried Schubert (Data Assimilation Office, Code 910.3 Laboratory for Atmospheres NASA/Goddard Space Flight Center Greenbelt, Maryland 20771, USA,
email: frmlw@indigowu.gsfc.nasa.gov); Ching I. Lin, Minghang Chen (General Sciences Corporation NASA/Goddard Space Flight Center Greenbelt, Maryland 20771, USA)

This study examines the water vapor effect on the computation of clear sky outgoing longwave radiation (CLR), broad band window radiance win_rad) and narrow band window radiance (nwin_rad, center around 10.8 microns). The radiative calculations employ as input, atmospheric and surface data from ECMWF and NASA assimilated data. Results are compared with CERES-TRMM observations and ISCCP clear sky radiances. We found that most discrepancies in the computed CLR over land are due to differences in the surface skin temperatures in the two assimilated data sets, and most discrepancies over the oceans are due to differences in the moisture. Further analysis shows that the CLR is most sensitive to moisture between 200 and 500 hPa. In general, the sensitivity is largest in the upper levels and reduces with increasing distance from the top. The assimilation of TOVS moisture data in the NASA assimilation system results in a marked improvement in the CLR computation. Detailed discussion of the results will be presented in the conference. The focus will be on studies showing the sensitivity of CLR, win_rad and nwin_rad to the changes of the moisture in different layers of the atmosphere.

GLOBAL WATER VAPOR AND CLIMATE: A GEWEX PERSPECTIVE

Graeme L. STEPHENS (Colorado State University, Dept of Atmospheric Science, Ft Collins, CO 8523-1371, USA)

Water vapor is the key greenhouse gas on Earth linking an assortment of complex and poorly understood processes that, through feedback, can significantly affect the response of the climate system to an imposed forcing. An approach to understanding the role of water vapor in determining such a response requires the integration of observations with models. The goal of the GEWEX Water Vapor Project (GVaP) is to provide a clear vision of the role of water vapor in the climate system. Part of the GVaP strategy is to establish an accurate and validated water vapor climatology on relevant space and time scales. This talk will review the critical issues relating to water vapor and climate and describe the steps GVaP is taking to address these issues.

MC08/L/14-A4 0945

SPECTRAL RADIANCE AND IRRADIANCE, GPS, AND DIAL LIDAR MEASUREMENTS AT SURFACE AND MOUNTAIN TOP SITES IN HAWAII

John Porter, Shiv Sharma, Mike Bevis, Barry Lienert, Steve Businger, Duane Stevens, and Craig Motell (SOEST, University of Hawaii, 96822 USA). Email: jporter@soest.hawaii.edu

In order to measure the radiative effects of water vapor, clouds and aerosol one needs measurements above and below the layer of interest. Dual aircraft experiments have been used successfully to study cloud properties in this way. Here we describe the suite of measurements being set up in Hawaii at a surface site and at Haleakala (height ~3.3 km). The radiation measurements will include broad band and spectral (0.38-3 um) diffuse and direct radiation. The GPS will measure integrated water vapor with ~1 mm accuracy. The radiation and GPS instruments will be at duplicated at both sites. A transportable DIAL lidar will be used to measure the vertical profile of water vapor at the surface site. By making long term differential measurements, the radiative effects of the layer can characterized. Anticipated difficulties in these measurements and our proposed approach will be discussed.

MC08/W/02-A4 1005

MEASUREMENTS OF INTEGRATED WATER VAPOR FROM MICROWAVE RADIOMETER, RADIOSONDES AND GLOBAL POSITIONING SYSTEM: IMPLICATIONS FOR RADIATIVE MODELLING

James LILJEGREN (DOE Ames Laboratory, Ames, Iowa, USA, email: liljegren@ameslab.gov); Barry Lesht (Argonne National Laboratory, Argonne, Illinois, USA, email: bmlesht@anl.gov); Teresa Van Hove and Christian Rocken (both at UCAR/GPS Science and Technology Group, Boulder, Colorado, USA, email: vanhove@ucar.edu, rocken@ucar.edu)

Measurements of integrated column water vapor from a microwave water radiometer (MWR) and a balloon-borne sounding system (BBSS) have been made continuously by the U. S. Department of Energy's Atmospheric Radiation Measurement (ARM) Program near Lamont, Oklahoma, USA since 1992, and at other sites in Oklahoma and Kansas since 1994.
The UCAR/GPS Science and Technology Group has continuously derived integrated column water vapor from global positioning system (GPS) receivers at these locations since 1995. An extensive comparison of integrated water vapor from these sensors for 1996 and 1997 have revealed a bias and increased variability between the MWR and both the BBSS and GPS during the summer months that are consistent from year to year and location to location. We have also observed substantial variations in the BBSS-MWR bias that correlate well with the radiosonde calibration lot number. Vaisala has recently developed a correction for their radiosonde relative humidity measurement.
This correction serves to increase the measured relative humidity. Because this correction depends on the age of the sonde (i.e. the difference between the time the sonde was calibrated and the time it was launched) it accounts for much of the lot-dependent variations we have observed. Because it corrects the relative humidity, the effect on the integrated water vapor is largest in the summer when the largest biases between MWR and BBSS are observed. For 1997 the correction changes the median BBSS-MWR difference during the summer from –1.1 to +0.4 mm of integrated water vapor, accompanied by a substantial reduction in the spread of the distribution of differences. However, during the winter the median difference increases from +0.05 to +0.45 mm due to the correction. Does the radiosonde correction over-correct the relative humidity measurement or …

RELATIVE HUMIDITY VARIABILITY AND THE WATER VAPOUR FEEDBACK

Richard P. ALLAN (Hadley Centre for Climate Prediction and Research, Meteorological Office, London Road, Bracknell, Berkshire RG12 2SY, UK, email: rpallan@meto.gov.uk)

The dependence of clear-sky outgoing longwave radiation (OLRc) on relative humidity (RH) and surface temperature (Ts) variations are examined using a simulation of the clear-sky greenhouse effect based on the European Centre for Medium Range Weather Forecasts Re-Analysis (ERA). There are two distinct regimes: polewards of about 40 degrees OLRc is determined primarily by temperature fluctuations while at lower latitudes humidity variations control the OLRc. The strongest sensitivity of OLRc to RH is experienced in the dry sub-tropical descending regions of low humidity. While OLRc is most sensitive to upper tropospheric RH, humidity variability is greatest at lower altitudes. Away from polar regions, RH fluctuations throughout the troposphere contribute significantly to interannual OLRc anomalies. In a global-mean sense over an interannual time-scale, the water vapour feedback in ERA appears to be similar to the positive feedback exhibited by assuming constant RH (dOLRc/dTs=2.3 Wm-2K-1). This result is dependent on the month chosen (July) and also the quality of ERA humidity. To validate the positive water vapour feedback depicted by climate models it is desirable to measure humidity changes globally throughout the troposphere in conjunction with significantly more than a decade of satellite radiation budget measurements.

MC08/W/04–A4 1130

ASSESSING GCM PERFORMANCE USING A SPECTRAL LONGWAVE RADIATION DIAGNOSTIC PACKAGE

Eli J. MLAWER, Michael J. Iacono, Shepard A. Clough (Atmospheric and Environmental Research, Inc. Cambridge, MA, USA)

An important aspect of GCM evaluations has been the comparison of the spectrally integrated model fluxes with fluxes inferred from satellite-based radiance measurements from ERBE. While evaluations of the overall energy balance of this type are essential, they do not address the necessity that this energy be properly distributed across the longwave spectral region, evidence of the proper treatment in the model of the relevant physical processes. This paper presents the development^ of and initial results from a longwave diagnostic package that has been coupled to a version of the NCAR Community Climate Model CCM3 using the accurate longwave radiation model RRTM. This longwave diagnostic package, employing the same physics and numerical approach as RRTM and run in parallel with RRTM in the GCM, models TOA spectral radiances for comparison with existing datasets. For the initial application, channel 12 of HIRS is used to assess the water vapor fields generated by the GCM. A series of simulations are performed for seasonal periods of interest from a 15-year AMIP simulation and the output spectral radiances are compared to measured values for a range of geographic areas.

MC08/E/04-A4 1150

AIRBORNE MEASUREMENTS OF WATER VAPOUR RADIATIVE TRANSFER USING INTERFEROMETRY AND MICROWAVE RADIOMETRY

Jonathan TAYLOR (UK Meteorological Office, Remote Sensing Branch, Y70 Building, DERA, Farnborough, Hampshire GU14 0LX, UK, Email: jptaylor@meto.gov.uk)

The UK Meteorological Office, Meteorological Research Flight C130, is equipped with a thermal infra-red interferometer called ARIES which has the ability to measure in the zenith and nadir at a range of altitudes between 30 and 9000m over the wavelength range 3 to 16 microns. The in situ measurements of temperature and water vapour measured by the C130 have been used to initialise the GENLN2 line-by-line radiation code. Microwave radiometers flown on board the MRF C130 are used to give further guidance as to the accuracy of the input water vapour profiles. The predicted spectra from these model simulations are compared with the measurements from ARIES. The radiative properties of water vapour in the thermal infrared are important to understand both in terms of optimising the benefit from future space based interferometers for temperature sounding but also in the radiation balance of the atmosphere. In this paper the differences between observed and modelled spectra will be presented and a discussion of the possible causes of the discrepancies presented. This will include an analysis of the contribution of the water vapour continuum looking at data from mid-latitudes and the tropics.

MC08/E/03-A4 1210

RADIATIVE PROPERTIES OF WATER VAPOR

Tarzadin ULAANBAATAR (Department of Earth Sciences, National University of Mongolia, email: numelect@magicnet.mn)

In this paper the understandings of the radiative properties of water vapor and its representation in climate model are described. Based on the thermal regimes (insolation and air temperature) on and near the Earth's surface is constructed a new climate model which is presented so-called World Climate Supercirculation as wishing by the Author.
According to author's studies and climate model the heating and cooling impacts of water vapor on the thermal regimes are existed two main feedback mechanisms (positive and negative) playing central role in World Water Supercycle and World Climate Supercirculation. The both impacts play main role for stabilization of the thermal regime in a certain level, existence of agreeable conditions of life and protection of biosphere from dangerous solar variabilities and external thermal hazards, as well for continuances of World Water Supercycle and World Climate Supercirculation. The radiative properties of water vapor are shown clearly in new climate model.

MC08/E/06-A3 Poster 0900-01

THE NUMERICAL MODEL OF MESOMETEOROLOGICAL HUMIDITY PROCESSES

George GELADZE (Institute of Applied Mathematics, Tbilisi State University, 2, University Str., Tbilisi 380043, Georgia, email: Geladze@viam.hepi.edu.ge)

The two-dimensional non-stationary problem of a mesoscale boundary layer of atmosphere (MBLA) over thermal non-homogeneous underlying surface with regard to humidity processes is stated and solved. In the model humidity processes are taken into account by method, which includes an exclusion of the condensation/evaporation velocity from the equations of heat-transfer, water-vapor and liquid-water mixing ratio. The model was integrated numerically. The simulation of the full cycle (a generation, development and dissipation) of a stratus cloud and radiation fog on athormodynamic background of MBLA is carried out. Time and space distributions of air velocity, temperature, pressure, water-vapor and liquid-water mixing ratio are obtained. The influence of geostrophical wind, relative humidity, temperature of the underlying surface, background temperature and atmospheric stratification is investigated. The moment of the cloud formation, maximum liquid-water mixing ratio level, height,lower and upper bounds of cloud and fog are determined. The latent heat of condensation contribution is estimated in the MBLA thermodynamics. The atmospheric stratification and relative humidity threshold significances are shown, at the beginning of the stream condensation process. The theoretical results are in a good agreement with experimental data.

MC08/E/05-A3 Poster 0900-02

CHANGES IN THE STRATOSPHERIC HUMIDITY DISTRIBUTION CAUSED BY THE INCLUSION OF METHANE OXIDATION IN A 3D CLIMATE MODEL

Ralf Hein, Michael PONATER, Volker Grewe, Martin Dameris, Nicola Stuber (DLR-Institute for Atmospheric Physics, Oberpaffenhofen, D-82230 Wessling, Germany, email: michael.ponater@dlr.de); Benedikt Steil (Max-Planck-Institute for Meteorology, PostBox 3060, D-55020 Mainz, Germany, email: steil@mpch-mainz.mpg.de)

Conventional 3D climate models (without interactive chemistry-climate interaction) do not include the stratospheric water vapour source due to methane oxidation. Hence, their ability to reproduce the observed humidity distribution in the lower stratosphere is inherently limited.
We present a comparison of the stratospheric water vapour distribution simulated by the atmospheric GCM ECHAM4 with and without coupling to a stratospheric chemistry module (CHEM). The inclusion of the chemical water vapour source indeed leads to a substantial enhancement of water vapour mixing ratio in the extratropical lower stratosphere. The humidity distribution produced by the coupled model system ECHAM4/CHEM is in closer agreement to observations. We point out the resulting differences in the stratospheric water vapour balance, radiative fluxes, and temperature. Respective changes of the radiative forcing to the troposphere/surface system are also discussed.

THE KINETIC ENERGY SPECTRUM OF HORIZONTAL MOTIONS IN MIDDLE-ATMOSPHERE GENERAL CIRCULATION MODELS

John N. KOSHYK (Dept. of Physics, University of Toronto, Toronto, Ontario M5S 1A7, Canada, email: koshyk@mam.physics.utoronto.ca)

Data from several middle-atmosphere general circulation models are used to calculate kinetic energy spectra as a function of total horizontal wave number, n. Tropospheric spectra show power-law behavior with slopes slightly shallower than -3 for wave numbers n ~> 10 (horizontal wavelengths ~< 4000 km), and are dominated by the rotational part of the flow. These spectra agree well with those calculated using data obtained from a global assimilation model and with the results of previous observational studies. Stratospheric spectra have larger amplitudes than tropospheric ones at planetary scales and smaller amplitudes at smaller scales. Mesospheric spectra are characterized by enhanced spectral amplitudes at all wave numbers compared to the stratosphere and spectral slopes in the wave number range n ~>10 are generally shallower with values between –1 and -2. Stratospheric and mesospheric spectra include significant contributions from both rotational and divergent parts of the flow for n ~> 20 in all models. These features appear to be independent of model resolution. The divergent part of the flow, presumably associated with naturally resolved inertio-gravity waves in the models, increases more rapidly with height above the lower stratosphere than the rotational part. The divergent part is fairly insensitive to season, whereas the rotational part changes considerably between January and July in the middle atmosphere region. Spectral amplitudes and vertical growth rates of both parts vary widely among models for a given season. The horizontal diffusion schemes used by the models are compared in an attempt to explain some of these differences.

MW01/W/09-A5 Invited **0900**

SENSITIVITY OF MODEL SIMULATION OF THE MIDDLE ATMOSPHERIC CIRCULATION TO VERTICAL AND HORIZONTAL RESOLUTION

Kevin HAMILTON (Geophysical Fluid Dynamics Lab/NOAA, P.O. Box 308, Princeton, New Jersey 08542, USA, Email: kph@princeton.edu)

This paper will begin with a brief review of earlier studies of the effects of model resolution on GCM simulations of the stratosphere and mesosphere. Then results of some recent simulations at very high resolution conducted with the GFDL SKYHI GCM will be discussed. These include one experiment with about 30 km horizontal grid spacing, and another with about 100 km horizontal resolution but roughly 400 m vertical level spacing (in the stratosphere). In general the simulated extratropical circulation is strongly dependent on horizontal resolution, while the tropical stratospheric circulation is much more dependent on vertical level spacing.

MW01/W/05-A5 Invited **0930**

PARAMETERIZATION OF MEAN-FLOW FORCING DUE TO GRAVITY WAVES

Joan ALEXANDER (Colorado Research Associates, 3380 Mitchell Lane, Boulder, CO 80301, USA Email: anlexander@colorado-research.com)

Gravity waves have characteristics that fill a broad spectrum, but have horizontal and vertical wavelengths that make them generally too small to be resolved in current GCMs or in data from the global meteorological observation network. Their global-scale effects are however important and must be parameterized. This parameterization problem has many variables, many unknowns, and too few constraints at present. Attmepts to tun GCMs with existing gravity wave parameterizations typically lead to non-unique solutions and little insight into global wave properties. Some of the current approaches to the problem of parameterizing the effects of gravity waves in GCMs will be described and constraining data, where available, will be summarized. The talk will focus on the method of determining the force on the mean flow from a given source of gravity waves specified in the lower atmosphere.

VERTICALLY PROPAGATING WAVES AND THE MEAN FLOW IN THE EQUATORIAL LOWER STRATOSPHERE OF GRIPS AND OTHER GCMS

Takeshi HORINOUCHI (Department of Atmospheric Sciences, University of Washington, Seattle, WA 98195-1640, USA, Email: horinout@atmos.washington.edu)

Over the past two decades considerable effort has gone into simulating the quasi-biennial oscillation (QBO) in GCMs. Since the QBO affects the entire middle atmosphere, the ability to simulate the QBO is important for any GCM aimed at simulating the middle atmosphere. Recently a couple of GCMs succeeded in reproducing the QBO. Wave statistics of one of them, which was run by the author's group, are compared with those of the middle atmosphere version of the NCAR CCM3. The vertically propagating waves in the CCM carry much smaller momentum flux mainly because of its static cumulus convection. Resolution and cumulus parameterization seem to be the most important factors that affect the wave activities in the equatorial stratosphere. However, our understanding of the waves and wave forcing in GCMs is limited. We are currently collecting a new data set for GRIPS (GCM Reality Intercomparison Project for SPARC) in order to compare the vertically-propagating wave statistics of representative middle atmosphere GCMs. Analyses of dynamical and non-conservative terms will be made to improve our understanding of the causality of the difference between the models and provide a guideline on model settings. The results will be presented in the talk.

MW01/W/01-A5 Invited **1105**

PHYSICALLY-DERIVED DYNAMICAL CORES IN ATMOSPHERIC GENERAL CIRCULATION MODELS

Richard B. ROOD, Shian-Jiann Li (Code 910.3 NASA's Goddard Space Flight Center Greenbelt, MD 20771, USA)

The algorithm chosen to represent the advection in atmospheric models is often used as the primary attribute to classify the model. Meteorological models are generally classified as spectral or grid point, with the term grid point implying discretization using finite differences. These traditional approaches have a number of shortcomings that render them non-physical. That is, they provide approximate solutions to the conservation equations that do not obey the fundamental laws of physics. The most commonly discussed shortcomings are overshoots and undershoots which manifest themselves most overtly in the constituent continuity equation. For this reason many climate models have special algorithms to model water vapor advection.
This talk focuses on the development of an atmospheric general circulation model which uses a consistent physically-based advection algorithm in all aspects of the model formulation. The shallow-water model of Lin and Rood (QJRMS, 1997) is generalized to three dimensions and combined with the physics parameterizations of NCAR's Community Climate Model. The scientific motivation for the development is to increase the integrity of the underlying fluid dynamics so that the physics terms can be more effectively isolated, examined, and improved. The expected benefits of the new model are discussed and results from the initial integrations will be presented.

THE STRATOSPHERE AND CLIMATE MODELLING

W.A. LAHOZ (1), A. O'Neill (1), R. Swinbank (2), S. Pawson (2) and G. Roff (3) ((1) CGAM, University of Reading, RG6 6BB, UK; (2) DAO, NASA-GSFC, Greenbelt, Maryland, USA; (3) BMRC, Melbourne, Australia)

A number of AGCMs participating in both the AMIP-II and GRIPS projects have model levels extending to less than 1 hPa (models from UKMO, NCAR, CNRM and perhaps other institutions). Models such as those at UKMO and NCAR have been developed for use in climate and middle atmosphere studies. These models provide an ideal test-bed for controlled simulations of the stratospheric circulation.
The AMIP-II runs of these models will be compared with climatologies of the stratosphere produced from UKMO analyses, NCEP analyses and the ERA dataset to evaluate the AGCMs' performance in reproducing the mean climate and variability (e.g. stratospheric sudden warmings) of the stratosphere. This study forms the core of the AMIP-II Diagnostic Subproject #16 and addresses the question: "What elements are needed in AGCMs to provide an accurate representation of the stratosphere?"

CLIMATOLOGICAL STRUCTURES OF THE GRIPS MODELS: MEAN STATES AND FORCING

Steven PAWSON (Universities Space Research Association, NASA GSFC, Code 910.3, Greenbelt MD 20771, USA)

The GCM-Reality Intercomparison Project for SPARC (GRIPS) is assessing and monitoring the performance of state-of-the-art general circulation models (GCMs). A wide variety of tasks have been initiated; these are designed to assess the ability of the GCMs to represent the current climatological structure of the troposphere and middle atmosphere, to compare their response to imposed forcing anomalies, and to estimate the certainty with which future climate perturbations can be predicted. This paper is concerned with assessments of the climatological states in the GCM simulations. Comparing the simulations with observational datasets reveals considerable discrepancies in the modelled fields. While it might be anticipated that certain types of biases in the model simulations might be related to the formulation of different aspects of the numerical package (dynamical schemes, cloud schemes, radiation transfer, inclusion of gravity wave drag), there is no clear relationship between these features. This paper attempts to draw a more comprehensive picture of the GCMs' performance than has previously been shown, by comparing the dominant forcing mechanisms in the models with observational estimates, and relating model deficiencies to the differences in the physical mechanisms in the GCMs.

MW01/W/03-A5 Poster **1150-03**

TRACER TRANSPORT WITHIN THE TROPOSPHERE-STRATOSPHERE UNIFIED MODEL

V. WEST and R. S. Harwood (Dept. of Meteorology, University of Edinburgh, JCMB, KB, Mayfield Road, Edinburgh, EH9 3JZ, Scotland. Email: vicky@met.ed.ac.uk)

Studies of atmospheric change, including the climatic effects of ozone depletion require the coupling of chemistry and general circulation models (GCMs). Such work requires that both the chemical and dynamical processes be accurately represented. As part of the UGMAP modelling effort we are currently involved in implementing coupled chemical-dynamical modelling in the Unified Model (UM). As a first step in this process, the ability of the GCM to reproduce known transport mechanisms in the stratosphere and near-tropopause regions is assessed with different configurations of the model.
The UM is run in troposphere-stratosphere mode and includes the simulation of several long-lived tracers such as H_2O, CH4, O3, N2O and CFCs. Features such as the general stratospheric loading, the annual cycles in these tracers and the `tape-recorder' effect in H_2O are examined, and comparisons made to observational data.

MW01/W/02-A5 Poster **1150-04**

A THEORETICAL ESTIMATION OF THE EVOLUTION OF THE STRATOSPHERE AT THE BEGINNING OF THE XXIST CENTURY BY MEAN OF A COUPLED CLIMATE-CHEMISTRY MODEL

Anne DE RUDDER, Franck Lefevre, Pascal Simon (CNRM, Meteo-France, 42, avenue Coriolis, 31057 Toulouse, France, email: derudder@cnrm.meteo.fr); Hubert Teyssedre (Department of Chemistry, University of Cambridge, Lensfield Road, CB2 1EW Cambridge, UK, email: hubert@atm.ch.cam.ac.uk)

Within the next 15 or 20 years, the stratospheric content in gases emitted by the human activity is expected to change due to the increase in energy consumption and to the regulation imposed onto the production of chlorinated and brominated species. Most of these substances

having a double radiative and chemical role, the consequences of their evolution may be interestingly studied by mean of a model including both effects interactively. The 3-D global model used in this aim at Meteo-France includes an important aspect of this coupling, through the reciprocal dependence of dynamics and ozone chemistry. Two 6-year integrations of the model have been conducted, in source gases and SST conditions representative of Years 1995 and 2015 respectively. Stability and inter-annual variability of the model will be discussed, as well as its ability to reproduce the stratospheric dynamical regimes. Results corresponding to the present day atmosphere will be compared to observations. Calculated changes between the two dates will be analysed and discussed.

MW01/E/02-A5 Poster **1150-05**

EXAMINATION OF COLD BIAS IN THE POLAR WINTER STRATOSPHERE OF THE UKMO UNIFIED MODEL

D.R. JACKSON, J. Austin (both at UK Meteorological Office, Bracknell, UK, email: drjackson@meto.gov.uk)

The stratospheric version of the UK Meteorological Office Unified Model (UM) is a state of the art troposphere – stratosphere GCM with 49 levels extending from the surface to 0.1 mb. Recent improvements have been made to the UM, including the incorporation of a more comprehensive and flexible radiation scheme, which can calculate heating rates from a wider range of atmospheric constituents, including CFCs. Results from a 20 year control run for 1995 conditions indicate the presence of a cold bias in wintertime zonal mean temperatures of up to around 5K in the region of PSC formation, and the cold model vortex persists longer than observed, particularly in the southern hemisphere.
Consequently, simulations of stratospheric chemistry in this version of the UM could lead to potentially misleading results concerning predicted future ozone recovery rates. Here, possible reasons for the cold bias are examined. A comparison of model and observed planetary wave amplitudes is made and sensitivity tests of the model representation of radiative heating are carried out. In addition, tests of the representation of gravity wave drag are made. In the control run this is represented by an orographic gravity wave parametrization scheme up to the 20 mb level, and by Rayleigh friction above that level. When the level of switch - over is changed from 20 mb to 5 mb there is a clear impact on stratospheric temperatures, most strikingly in southern polar latitudes. In late southern winter, very low temperatures persist for approximately one month less than in the control run, and in early southern spring cold biases in daily polar minimum temperatures are significantly reduced.

EUGCM EXPERIMENTS WITH A UNIFIED RADIATION SCHEME

Wenyi ZHONG, Joanna D Haigh (both at Department of Physics, Imperial College, London SW7 2BZ, UK, email: w.zhong@ic.ac.uk); Warwick Norton (Department of Atmospheric, Oceanic and Planetary Physics, University of Oxford, UK, email: wan@atm.ox.ac.uk)

A unified radiation scheme has been developed which can be used throughout the troposphere and the middle atmosphere. It is based on the Morcrette (ECMWF) scheme but includes: - line-by-line precomputed LW transmission tables for CO2 15 micron band, O3 9.6 and 14 micron bands, H_2O rotation band and 6.3 micron band; - an updated parametrisation for the water vapour continuum throughout the infrared spectrum and for water vapour lines in the atmospheric window region and in the wings of the strong bands; - a representation of oxygen absorption in the Schumann-Runge bands and continuum and in the Herzberg continuum. Experiments have been carried out with several versions of the unified radiation scheme implemented in the EUGCM (the UGAMP troposphere-stratosphere-mesosphere model) to assess the impacts of the different improvements on model fields.

SELECTING METEOROLOGICAL INPUT FOR THE GLOBAL MODELLING INITIATIVE ASSESSMENTS

Susan STRAHAN (General Sciences Corp., Code 910.3 NASA GSFC, Greenbelt, MD, 20771, USA, email: strahan@dao.gsfc.nasa.gov); Anne Douglass (Code 916 NASA GSFC, Greenbelt, MD, email: douglass@persephone.gsfc.nasa.gov); Michael Prather (University of California, Irvine,CA); Larry Coy (General Sciences Corp., Code 916 NASA GSFC, Greenbelt, MD); Tim Hall (Goddard Institute for Space Studies, New York City, NY); Phil Rasch (National Center for Atmospheric Research, Boulder, CO); Lynn Sparling (Raytheon STX, Code 916 NASA GSFC, Greenbelt, MD)

The Global Modelling Initiative (GMI) science team has developed a three dimensional chemistry and transport model (CTM) to evaluate the impact of the exhaust of supersonic aircraft on the stratosphere. An important goal of the GMI is to test modules for numerical transport, photochemical integration, and model dynamics within a common framework. This work is focussed on the dependence of the overall assessment on the wind and temperature fields used by the CTM. Three meteorological data sets for the stratosphere were available to GMI: the National Center for Atmospheric Research Community Climate Model (CCM2), the Goddard Earth Observing System Data Assimilation System (GEOS-DAS),and the Goddard Institute for Space Studies general circulation model(GISS-2'). Objective criteria were established by the GMI team to evaluate which of these three data sets provided the best representation of trace gases in the stratosphere today. Tracer experiments were devised to test various aspects of model transport. Stratospheric measurements of long- lived trace gases were selected as a test of the CTM transport. This presentation describes the criteria used in grading the meteorological fields and the resulting choice of wind fields to be used in the GMI assessment. This type of objective model evaluation will lead to a higher level of confidence in these assessments. We suggest that the diagnostic tests shown here be used to augment traditional general circulation model evaluation methods.

INTERCOMPARISON OF CLIMATE MODEL SIMULATIONS OF THE RESPONSE TO THE 1991 PINATUBO VOLCANIC ERUPTION

Alan Robock, Georgiy L. Stenchikov Department of Environmental Sciences, Rutgers - The State University of New Jersey, 14 College Farm Road, New Brunswick, NJ 08901-8551, USA Phone: 732-932-9478, Fax: 732-932-8644 E-mail: robock@envsci.rutgers.edu

We have created a data set of aerosol distribution and properties needed for forcing climate model simulations of the effects of the June 1991 eruption of Mt. Pinatubo in the Philippines. Using data from SAGE II, UARS, balloons and lidar, we produced zonal-average, monthly-average loading and optical properties of the sulfate aerosols in the stratosphere from this eruption for 2 years from June 1991 through May 1993. This data set is available at any vertical and spectral resolution for general circulation model (GCM) simulations, and, as leaders of the GRIPS Pinatubo simulation task, we encourage all GRIPS participants to conduct this experiment. If the models cannot actually calculate the radiative forcing from using the radiation scheme of the model, we will provide the radiative forcing calculated with the ECHAM4 model, which can be used to drive any GCM. A complete formulation of radiative forcing includes not only changes of net fluxes at the tropopause, but the vertical distribution of atmospheric heating rates and the change of downward thermal and net solar radiative fluxes at the surface.
As a pilot demonstration project, we present simulations we conducted of the climatic response to the 1991 Pinatubo eruption with 3 GCMs, Max Planck Institut ECHAM4, GFDL climate model, and GFDL SKYHI model. With ECHAM4, we simulated climate change for the two-year period following the eruption of Mount Pinatubo in the Philippines on June 15, 1991. We calculated statistical ensembles of GCM simulations with and without volcanic aerosols for 2 years after the eruption for three different sea surface temperatures (SSTs): climatological SST, El Nino-type SST of 1991-1993, and La Nina-type SST of 1984-1986. The temperature of the tropical lower stratosphere increased by 4 K because of aerosol absorption of terrestrial longwave and solar near-infrared radiation. The heating was larger than observed, because we did not account for quasi-biennial oscillation (QBO) cooling and …

ANTARCTIC OZONE DEPLETION STUDY USING A PHOTOCHEMICALLY COUPLED MIDDLE ATMOSPHERE MODEL

Jean DE GRANDPRE, D.J. Chartrand, S.R. Beagley, J. C. McConnell (All authors in Earth and Atmospheric Sciences Department (EATS), York University, Toronto, Canada)

Middle Atmosphere Models (MAMs) coupled with photochemistry modules are powerful tools to study ozone trends and polar ozone depletion scenarios. These models represent a comprehensive approach allowing the inclusion of complex interactions between chemical, radiative and dynamical processes which is suitable to investigate long term ozone behaviour. However, there are also well known limitations to the capability of these models to reproduce the basic climatology of the middle atmosphere. For example, the understanding of the role played by gravity waves in such models is an important issue given its global impact on the strength and evolution of winter polar vortices. On the photochemical aspects, the basic representation of heterogeneous processes is also required to model an ozone climatology which is representative of the observed state in polar regions throughout the year. Nevertheless, with the development of parameterization schemes and heterogeneous photochemistry modules, such climate studies using MAMs can now be considered. In several cases, basic characteristics of the ozone annual and interannual behaviour can be reproduced with some success. The CMAM (Canadian MAM) has been used to investigate antarctic ozone hole scenarios. Results will show the capability of the model to represent the ozone hole evolution on a seasonal timescale. Studies on the potential impact of various forcing mechanisms involved will be addressed.

MW01/W/11-A5 Invited **1550**

FIRST RESULTS FROM THE RADIATION-INTERCOMPARISON PROJECT FOR GRIPS

Ulrike LANGEMATZ (Institut fuer Meteorologie, Freie Universitaet Berlin, Carl-Heinrich-Becker-Weg 6-10, 12165 Berlin, Germany, email: lang@strat01.met.fu-berlin.de)

In order to assess the impact of the representation of radiation transfer in Climate-Middle-Atmosphere-models (CMAMs) on the models' climatology and variability, an offline intercomparison of radiative codes is being performed within GRIPS (GCM - Reality Intercomparison Project for SPARC). Using standardized input data, the calculated radiative fluxes and heating rates can be compared directly thus enabling an assessment of the performance of the radiation codes. Here, first results of this intercomparison will be presented. An important question is the sensitivity of the radiation schemes to uncertainties in the distributions of trace gases, especially ozone: are differences in heating rates most sensitive to uncertainties in the parametrizations or to the ozone distribution? This issue will be discussed using a sensitivity study performed with one of the participating radiative codes.

MW01/E/01-A5 Invited **1620**

THE IMPACT OF TWO DECADES OF OZONE CHANGE ON THE STRATOSPHERE

Suzanne ROSIER, Keith Shine, Piers Forster (Department of Meteorology, University of Reading, Earley Gate, Whiteknights, Reading RG6 6BB, UK)

The `Intermediate' General Circulation Model (IGCM) developed at Reading incorporates sufficient physical processes to reproduce fundamental features of Earth's climate, yet is simple enough to simulate many decades quickly. It is a global, 3-D spectral model spanning the troposphere and stratosphere. The Morcrette radiation scheme is employed and a satellite-based 3-D seasonally-varying ozone climatology is supplied.
Results are reported of using the IGCM to investigate the effect of the last two decades of ozone change on the stratospheric climate. Ozone scenarios representative of 1979 and 1997 were estimated by combining the climatology with monthly observations of the trend in total column ozone from 1979 to 1997, taken from the 1998 WMO Ozone Assessment. The model has been run to an equilibrium using each of these scenarios and the two simulations compared. Differences in the stratospheric temperature and wind structures are of particular interest. Early results indicate that, in the annual and zonal mean, the lower stratosphere has cooled by up to 2K in the Arctic and 3K in the Antarctic. The temperature changes are further examined using a `Fixed Dynamical Heating' (FDH) version of the IGCM, in which contributions to the temperature tendency from the dynamics are held fixed at the `control' (1979) values. Differences of the experiment (1997 ozone) from the control then more clearly differentiate the radiative and the dynamical response to the ozone change.
Also of interest is the potential positive feedback in which lower stratospheric ozone loss leads to a colder lower stratosphere, a more stable winter vortex and further ozone loss. Under such conditions it might be expected that stratospheric sudden warmings occur less frequently, exacerbating the ozone loss. Whilst the IGCM currently does not allow the investigation of climate-chemistry interactions, the frequency of occurrence of sudden warmings is examined under the 1979 and 1997 scenarios reported here. Early results indicate a reduction in the frequency of sudden warmings in the ozone-depleted 1997 scenario.

MW01/E/03-A5 Invited **1650**

GCM SIMULATIONS OF STRATOSPHERIC CLIMATE CHANGE FROM 1992 TO 2051

Jeffrey KNIGHT, John Austin, Neal Butchart, Adam Scaife (Meteorological Office, London Road, Bracknell Bricks, RG12 2SZ, UK.)

Results are presented from two 60-year integrations of the troposphere-stratosphere configuration of the U.K. Meteorological Office's Unified Model with different initialisations both

representative of 1992 conditions. The Intergovernmental Panel on Climate Change scenario IS92A was used to specify changes in well-mixed Greenhouse Gas (GHGs) concentrations and sea surface temperatures (SSTs) and sea ice extents were taken from a separate coupled ocean-atmosphere experiment. Both integrations produced tropospheric warming and stratospheric cooling that increased with height, giving a trend in annual mean temperature of about -1.4 K per decade at 1.0 hPa. Trends from these integrations were in good agreement apart from in the polar winter stratosphere, where significant interannual variability arising from the sporadic occurrence of sudden stratospheric warmings prevented the identification of statistically significant trends. Even after decadal smoothing trends in the northern winter were still small compared to the variability resulting from changes in the flux of planetary wave activity from the troposphere. Unlike other studies, our use of results from two separate simulations shows the change in the frequency of warmings was due to internal variability and not the GHG or SST forcing. In the southern winter the higher wave flux from the troposphere caused increasing dynamical heating although this was offset by the trend in radiative cooling. Consequently the polar vortex became more stable, breaking-down about 10 days later by 2050. Changes in Polar Stratospheric Cloud amounts were also calculated from model temperatures, allowing the implications for future polar stratospheric ozone loss to be discussed.

GENERAL DISCUSSION **1720**

MW04 Monday 19 July

TIDAL SIMULATION IN GLOBAL MODELS (ICMA)

Location: Mechanical Engineering, G29 LT

Monday 19 July AM

Presiding Chairs: K. Hamilton (Geophys. Fluid Dynamics Lab./NOAA, New Jersey, USA), C. McLandress (York University, Toronto, Canada)

MW04/W/04-A1 0900

ATMOSPHERIC TIDES IN THE EQUATORIAL AND TROPICAL MESOSPHERE/LOWER THERMOSPHERE

R. A. VINCENT, S. Kovalam, I. M. Reid (Department of Physics and Maths Physics, University of Adelaide, Adelaide 5005, Australia, email: rvincent@physics.adelaide.edu.au); D. C. Fritts, D. Riggin (Colorado Research Associates, Boulder, CO 80301, USA, email: dave@colorado-research.com); T. Tsuda, T. Nakamura (Radio Atmospheric Science Center, Kyoto University, Kyoto, Japan, email: tsuda@kurasc.kyoto_u.ac.jp)

Radar observations of winds in the Asia/Pacific equatorial and tropical MLT region are used to explore the tidal structure as a function of latitude and longitude. Stations include Adelaide (35S, 138E), Pontianak (0N, 109E), Christmas Island (2N, 157W) and Kauai (22N, 160W). GSWM-98 model results are used as a reference to compare with climatologies of the diurnal and semi-diurnal tides at these stations. It is shown that there are significant longitudinal variations in amplitude and phase, which suggest that non-migrating modes play a role in determining tidal structure. The long-term nature of some of the observations also allows interannual variability to be studied. A QBO-like modulation of diurnal tidal amplitudes is found in certain seasons.

MW04/W/11-A1 0925

SEASONAL VARIATIONS OF THE SEMI-DIURNAL AND DIURNAL TIDES IN THE MLT: MULTI-YEAR MF RADAR OBSERVATIONS FROM 2-70N, AND THE GSWM.

Alan MANSON, Chris Meek (Institute of Space and Atmospheric Studies, University of Sask., Canada, email: manson@dansas.usask.ca); Chris Hall (Auroral Observatory, University of Tromso, Norway, email: chris.hall@phys.uit.no); Wayne Hocking, John MacDougall (Dept. of Physics and Astronomy, University of Western Ontario, Canada, email: whocking@danlon.physics.uwo.ca); Steve Franke (Space Science and Remote Sensing Laboratory, University of Illinois, USA, email: sfranke@uiwpls.ece.uiuc.edu); Dennis Riggin, Dave Fritts (Colorado Research Associates, Boulder, USA, email: riggin@colorado-research.com); Bob Vincent (Dept. of Physics and Mathematical Physics, University of Adelaide, Australia, email: rvincent@physica.adelaide.edu.au); Maura Hagan (NCAR,Boulder, USA, email: hagan@.ucar.edu); Mark Burrage (SPRL, University of Michigan, USA, email: burrage@hrdid.sprl.umich.edu)

Continuous observations of the wind field over 5-8 years have been made with 6 MF Radars: Xmas Is, 2N, Hawaii, 22N, Urbana, 40N, London, 43N, Saskatoon, 52N & Tromso,70N. 12-, 24-h tidal-wind oscillations are available from 75-95km. Comparisons with the GSWM, and the new GSWM-98, which are available for 3-month seasons are made. The new model includes an extended Gravity Wave stress scheme, and an updated background atmosphere. Monthly tidal profiles for each site, and latitudinal plots of amplitudes and phases at 80/90km are shown. For the Diurnal tide, the agreements between observations and the models are in general very good, both capturing the strong seasonal changes. These are the best agreements yet seen. In particular, the phases and wavelengths for the non winter months are now in excellent agreement. For the Semi-Diurnal tide, the strong transitions between clear solstitial states are less well captured by the GSWM. In particular the late summer/autumnal tidal maxima of mid-latitudes are observed to be larger than modelled. The new satellite 12-hr tidal data from HRDI(UARS) for mid latitudes shows useful agreement with radar observations. Finally, the longitudinal variations are shown for two other sites near 52N; amplitudes may vary considerably, but the wavelengths are remarkably similar. This is valuable information for comparisons using observations that are not global in longitude. Future plans for observations and for the GSWM are discussed.

MW04/W/01-A1 0950

CLIMATOLOGY OF THE SEMIDIURNAL TIDE AT 52 N - 56 N FROM GROUND-BASED RADAR WIND MEASUREMENTS 1985 - 1995

Ch. JACOBI, M. Lange (Institute for Meteorology, University of Leipzig, Germany, email: jacobi@rz.uni-leipzig.de); Yu.I. Portnyagin, T.V. Solovjova (Institute for Experimental Meteorology, Obninsk, Russia, email: portnyagin@iem.obninsk.ru); P. Hoffmann, W. Singer (Institute of Atmospheric Physics, Kühlungsborn, Germany, email: hoffmann@iap-kborn.de); A.N. Fahrutdinova, R.A. Ishmuratov (Radiophysics Department, Kazan University, Russia,
email: antonina.fahrutdinova@ksu.ru); A.G. Beard, N.J. Mitchell (Department of Physics, University of Wales, Aberystwyth, U.K., email: beard@aber.ac.uk); H.G. Muller (Cranfield University, RMCS Shrivenham, U.K.); D. Kürschner (Institute for Geophysics and Geology, University of Leipzig, Germany); A.H. Manson, C.E. Meek (Institute of Space and Atmospheric Studies, University of Saskatchewan, Saskatoon, Canada, email: manson@dansas.usask.ca)

Long-term wind measurements carried out at 6 northern midlatitude sites (Saskatoon, Sheffield, Juliusruh, Collm, Obninsk, Kazan) are investigated to set up a climatology of the semidiurnal tide in the mesopause region for the latitudinal range between 52 N and 56 N. Intercomparison of amplitudes and phases shows good agreement of the results from the different measuring systems. The phase gradients and the absolute phase positions are very similar for each of the measurements. The longitudinal variation of the semidiurnal tidal amplitude is small in summer, but larger in winter. The possible influence of wave-tidal interaction in the stratosphere on the inter-annual variability of this difference is discussed.

MW04/E/02-A1 1010

TIDAL SIGNATURES IN CRISTA 2 TEMPERATURE DATA

Jens Oberheide, Michael Jarisch, Martin RIESE, Dirk Offermann (all at Department of Physics, Wuppertal University, Gauss Str. 20, D-42097 Wuppertal, Germany, email: jens@wpos2.physik.uni-wuppertal.de); William E. Ward (CRESTech/CRESS, 206 Petrie Bld., York University, 4700 Keele St., North York, Canada, M4J1P3, email: william@stpl.cress.yorku.ca)

Temperature data taken during the second CRISTA mission (Aug. 7-19, 1997) show strong tidal structures from high southern to high northern latitudes and from the lower stratosphere to the upper mesosphere. Zonal means of temperatures are analyzed with respect to migrating diurnal tides. For most part, the observations are in very good agreement with the predictions of the Global Scale Wave Model (GSWM). However, zonal temperature variations at southern mid-latitudes indicate that the tidal amplitude is not uniform at all longitudes. It will be shown that this variation is associated with a wavenumber 2 planetary wave.

MW04/E/03-A1 1100

TIDAL OBSERVATIONS BY SATELLITE AND SIMULATIONS BY THE CANADIAN MIDDLE ATMOSPHERE MODEL

Charles McLANDRESS (Department of Earth and Atmospheric Science, York University, Toronto M3J 1P3, Canada, email: mcland@stpl.cress.yorku.ca)

The first part of this presentation reviews satellite observations of atmospheric tides made by the Upper Atmosphere Research Satellite (UARS). These include direct wind measurements by the High Resolution Doppler Imager (HRDI) and the Wind Imaging Interferometer (WINDII), which together span the stratosphere, mesosphere and thermosphere from about 20 to 200 m.Stratospheric temperature data from the Microwave Limb Sounder (MLS) are also presented. The migrating diurnal tide at low latitudes is the focus of the discussion, although some semidiurnal tidal results will be shown. Together these UARS observations have provided the first long term global dataset of tides in the middle atmosphere. One of the most striking results to have arisen from these observations is the presence of a strong semiannual variation in the amplitude of the propagating diurnal tide. Moreover, lower stratospheric wind measurements by HRDI reveal an intriguing correspondence between the mesospheric tidal amplitudes and the phase of the quasi-biennial oscillation (QBO) in the zonal mean winds in the tropics. The exact physical mechanism which causes the semiannual variation of the tide, however, is currently not understood. In the second part, numerical simulations of the migrating diurnal tide using the Canadian Middle Atmosphere Model (CMAM) are presented. The CMAM is a general circulation model extending from the earth's surface to approximately 100 km, which contains comprehensive physical parameterizations relevant to the different altitude regions of the atmosphere. The CMAM is found to generate a propagating diurnal tide which is in good qualitative agreement with the UARS observations. In particular it exhibits a strong semiannual amplitude signal in the mesosphere. Direct comparisons of the simulated tidal temperature fields with MLS observations in the stratosphere are also presented. We conclude the presentation with a brief examination of some of the possible mechanisms which may be responsible for causing the semiannual variation of the diurnal tide in CMAM: These include tropospheric heating, gravity wave drag and planetary wave-tidal interactions.

MW04/C/JSM01/E/14-A1 1135

THE ROLE OF GRAVITY WAVES IN MODULATING ATMOSPHERIC TIDES

H. G. MAYR (NASA Goddard Space Flight Center, Greenbelt, MD, USA); J. G. Mengel (Steven Myers and Associates Co., Vienna, VA, USA); K. L. Chan (Hong Kong University of Science and Technology, Hong Kong, China); H. S. Porter (Furman University, Greenville, SC)

We discuss results for the diurnal and semidiurnal tides obtained from our 3-D, time dependent, numerical spectral model, which incorporates Hines' Doppler spread parameterization (DSP) of small scale gravity waves (GW). In the DSP, GW momentum (and energy) are conserved. As a consequence, the GW interaction produces strong nonlinear interactions between mean zonal circulation, tides, and planetary waves. The major conclusions are: (1) Since GW momentum is deposited in the altitude regime of increasing winds, the amplitude of the diurnal tide is amplified and its vertical wavelength is reduced between 80 and 120 km. Wave filtering by the zonal circulation (with peak velocities during solstice) causes the GW flux to peak during equinox, and this produces a large semiannual variation in the diurnal tide with peak amplitudes during equinox as observed on UARS. (2) The diurnal tide in turn filters out GW preferentially during equinox, so that the semidiurnal tide at higher altitudes tends to be largest during solstice. (3) Under the influence of GW, the tides are modulated significantly by planetary waves, with periods between 2 and 30 days, which are generated preferentially during solstice in part due to baroclinic instability.

MW04/E/01-A1 1400

TIDAL SIMULATIONS WITH THE GLOBAL-SCALE WAVE MODEL (GSWM)

J.M. FORBES (Department of Aerospace Engineering Sciences, Campus Box 429, University of Colorado, Boulder, CO 80309-0429, USA, email: forbes@zeke.colorado.edu); M.E. Hagan (High Altitude Observatory, National Center for Atmospheric Research, P.O. Box 3000, Boulder, CO, 80307, USA, email: hagan@ncar.ucar.edu)

The GSWM solves the coupled momentum, thermal energy, continuity and constitutive equations for linearized steady-state atmospheric perturbations on a sphere from the surface to the thermosphere (ca. 300 km). Given the frequency, zonal wavenumber and excitation of a particular oscillation, the height vs. latitude distribution of the atmospheric response is calculated. The model includes such processes as surface friction, mean winds and meridional gradients in scalar atmospheric parameters, parameterized radiative cooling, eddy and molecular diffusion and ion drag. The advantages and disadvantages of this type of global tidal simulation are reviewed, and examples of diurnal and semidiurnal migrating and nonmigrating tides excited by various sources in the troposphere, stratosphere, mesosphere and thermosphere are discussed.

MW04/W/06-A1 1425

TIDAL OSCILLATIONS SIMULATED BY THE GFDL SKYHI GENERAL CIRCULATION MODEL

Kevin HAMILTON (Geophysical Fluid Dynamics Lab/NOAA, Princeton, New Jersey 08542, USA, Email: kph@princeton.edu)

The diurnal and semidurnal tides as simulated in the GFDL SKYHI comprehensive general circulation model will be described. Aspects to be emphasized include the seasonal cycle, day-to-day variability, effects of subgrid-scale dissipation and interaction with other explicitly-resolved waves.

MW04/W/08-A1 1450

SIMULATION OF THE TIDES IN THE EXTENDED UGAMP GCM

W. NORTON (AOPP, University of Oxford, UK, email: wan@atm.ox.ac.uk)

A global circulation model which extends from the surface to approximately 128 km has been used to examine the simulation of the tides. From a three year integration, interannual variability of the diurnal, semi-diurnal, and non-migrating tides are examined. The heating distribution is also examined.
It is shown that large two-day wave activity reduces the amplitude of the diurnal tide around the solstice. The interaction of the tides with the two-day wave produces other waves including a wave-number 4, 16 hour wave. It is shown that the amplitude of the two-day wave is controlled by the mean structure of the summer mesosphere which is strongly influenced by the strength of parameterized gravity wave breaking. Hence the parameterized gravity wave breaking has a strong indirect influence on the simulation of the tides.

MW04/W/05-A1 1545

TIDES IN THE MIDDLE ATMOSPHERE CIRCULATION MODEL AT KYUSHU UNIVERSITY

Saburo MIYAHARA, Yasunobu Miyoshi (Department of Earth and Planetary Science, Kyushu University, Fukuoka 821-8581 Japan, e-mail: sbm@rossby.geo.kyushu-u.ac.jp, miyoshi@rossby.geo.kyushu-u.ac.jp)

The Middle Atmosphere Circulation Model at Kyushu University (MACMKU) is a three-dimensional general circulation model with a domain spanning from the ground to 150 km. The model's radiation processes have a diurnal cycle, so that tidal waves are generated. Heating sources which generate tidal waves in the model are reviewed at first. After that, model's ability to simulate the generated tidal waves is discussed. Output data of the MACMKU are analyzed to study behavior of tidal waves in the MLT region. It is shown that not only the migrating tides but also non-migrating tides exist in the model, and variability of amplitudes and phases of tides are larger for the non-migrating components than the migrating tides.
Only the zonal component of zonal mean momentum flux associated with tidal waves in the MLT region usually receive much attention in connection with zonal mean wind acceleration (deceleration). However, the present analysis shows that the meridional component of zonal mean momentum flux has large magnitude in the MLT region, and affects the geostrophic balance between the Coriolis force on the zonal mean zonal wind and the zonal mean meridional pressure gradient force.

MW04/W/03-A1 1610

SIMULATION OF TIDES IN THE UK MET OFFICE UNIFIED MODEL

Sophia OLIVER (Atmospheric Physics, Oxford University, Clarendon Rd., Oxford, OX1 3PU, UK, email: oliver@atm.ox.ac.uk)

The UK Met Office Unified Model version 4.0 is used to apply a mechanistic approach to the modelling of thermally forced tides in the middle atmosphere. The model has 36 vertical levels with the highest near 110km. Physics routines have been removed from the model set-up leaving only the dynamics core. The model is initialised with zonally symmetric background temperature and zonal wind fields, and is forced with specified westward-propagating heating fields in wavenumbers 1 and 2. This approach enables clear identification of features which are due to the tides and their interaction with each other and with the mean flow. A 54 level version of the unified model with Hadam 3 physics (extended from the 49 level model by Dave Stainforth) is also being used to calculate the tides and comparisons with the mechanistic approach are made.

MW04/W/10-A1 1630

A MODEL STUDY OF UARS WIND, TEMPERATURE, AND AIRGLOW DATA: INTERANNUAL VARIABILITY OF TIDAL EFFECTS IN THE MLT REGION

Marvin A. GELLER, Valery A. Yudin, Ling Wang (State University of New York at Stony Brook, Stony Brook, NY 11794, USA, email: mgeller@notes.cc.sunysb.edu)

The UARS wind, temperature, and airglow data have been analyzed using the Tuned Mechanistic Tidal Model (TMTM) approach and compared to the long-term tidal variability obtained from radar wind observations. The global coverage of the HRDI wind measurements in the stratosphere and MLT regions allows an estimate to be made for gravity wave effects on the zonal mean flow and the tides for the different stages of the strato-mesospheric QBO. Estimated values of the effective tidal dissipation derived from UARS tidal observations have been compared to the values of the eddy dissipation calculated with gravity wave parameterizations applied to the different years of UARS observations. The possible mechanisms for interannual tidal variability, including variability in the tidal forcing, dissipation, and propagation, have been simulated using the TMTM approach for 1992, 1993, and 1994 equinox conditions with prescribed zonal mean temperatures and winds (as constrained from HRDI/MLS UARS measurements). It is shown that the UARS observed interannual tidal variability simulated by the TMTM approach can induce the year-to-year variability of oxygen airglow emission rates in the equatorial MLT region.

MW04/W/09-A1 1650

A MODEL STUDY OF UARS WIND, TEMPERATURE, AND AIRGLOW DATA: SEASONAL VARIABILITY OF TIDES AND GRAVITY WAVES IN THE MLT REGION

Valery A. YUDIN, Marvin A. Geller, Ling Wang (State University of New York at Stony Brook, Stony Brook, NY 11794, USA, email: valery@dombai.uars.sunysb.edu)

The 1992-96 UARS wind, temperature, ozone and airglow data reveals a strong semiannual variation in the mid-latitudinal and equatorial tidal fields. Several mechanisms have been suggested to interpret this semiannual variation of the diurnal tide: planetary wave-tidal interactions, variations of the effective tidal dissipation associated with gravitry wave breaking, and possible changes in the tropospheric water vapor tidal forcing. A revised version of the Tuned Mechanistic Tidal Model (TMTM) utilizing UARS wind, temperature, and ozone data has been used to study the seasonal variability of the diurnal tide due to variations in the tidal forcing, background mean fields, and tidal dissipation. The tidal influence on the seasonal variation of the nightime and daytime oxygen emissions have been simulated and compared to UARS observations. Several model case studies with prescribed zonal mean flow have been examined to show the solstice-equinox differences in the gravity wave and tidal fields for different local solar times. These have been compared to the wind and temperature structures observed by the HRDI and WINDII instruments.

MW04/W/02-A1 1710

STRATOSPHERIC TIDES AND DATA ASSIMILATION

R. SWINBANK (Universities Space Research Association, NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA; email: swinbank@dao.gsfc.nasa.gov); R.L. Orris (Anne Arundel Community College, Arnold, MD, USA; email: rlorris@mail.aacc.cc.md.us); D.L. Wu (JPL, Caltech., Pasadena, CA 91109, USA; email: dwu@mls.jpl.nasa.gov)

In the upper stratosphere, the atmosphere exhibits significant diurnal and semi-diurnal tidal variations, with typical amplitude of about 2K in mid-latitudes. In this paper we examine how well the tidal variations in temperature are represented by the Goddard (GEOS-2) data assimilation system. We show that the GEOS-2 atmospheric model is quite successful at simulating the tidal temperature variations. However, the assimilation of satellite temperature soundings significantly damps the simulated tides. The reason is because the tides are not wellrepresented by the satellite retrievals used by the assimilation system (which have a typical tidal amplitude of around 1K). As a result of this study, we suggest improvements that should be made to the treatment of satellite soundings by the assimilation system.

INFRARED RADIATIVE COOLING AND HEATING IN THE MESOSPHERE AND LOWER THERMOSPHERE AND ITS PARAMETERIZATION

Victor I. FOMICHEV (Dept. of Earth and Atmospheric Science, York University, Toronto, Canada, email: victor@nimbus.yorku.ca)

The thermal regime of the middle atmosphere is determined to a great extent by infrared radiative cooling and heating processes. To account for these processes in numerical models of the atmosphere, parameterizations that are capable of quickly and accurately calculating infrared radiative cooling and heating rates are required. These paramerizations should also include NLTE effect and allow for feedbacks by ensuring that dependencies on all input parameters are accounted for. A review of the major mechanisms responsible for the infrared cooling/heating processes in the middle atmosphere as well as recently developed parameterizations will be presented.

MW05/W/10-A2 Invited 1000

NON-LTE RADIATIVE AND CHEMICAL HEATING IN A TWO-DIMENSIONAL MODEL

Xun ZHU (JHU/APL, 11100 Johns Hopkins Rd., Laurel MD 20723-6099, USA, email: xzhu@grant.jhuapl.edu)

The conversion of radiative energy into thermal energy that drives mesospheric circulation is critically dependent on the atomic oxygen distribution in two aspects. First, the deactivation of the CO2 bending mode (15 micron band) by atomic oxygen increases the cooling rate around the mesopause region because it restores the CO2 bending mode population closer to local thermodynamic equilibrium (LTE). Second, a longer photochemical timescale of atomic oxygen than its transport timescale above the mesopause produces a non-local chemical heating rate. Since the atomic oxygen distribution is determined collectively by both dynamics and photochemistry in the upper mesosphere and lower thermosphere (UMLT), a consistent evaluation of radiative and chemical heating balance requires a fully coupled model that produces a self-consistent picture of the temperature field, net radiative heating rate, and several chemical tracer distributions needed for the chemical heating rate calculations. The recently-developed JHU/APL fully-coupled 2-dimensional model is used to evaluate the energy balance in the UMLT region. Around 95 km, it is shown that the dynamically controlled atomic oxygen distribution produces a chemical heating rate with a latitudinal gradient that counters the gradient of the net radiative heating rate. The solar cycle effect of the Lyman alpha and Schumann-Runge continuum radiation on the energy balance in the UMLT region will also be examined.

MW05/W/09-A2 Invited 1020

CARBON DIOXIDE AND ATOMIC OXYGEN IN THE LOWER THERMOSPHERE

Klaus U. GROSSMANN (Dept.of Physics, University of Wuppertal, Germany, e-mail: gross@wpos2.physik.uni-wuppertal.de)

The CRyogenic Infrared Spectrometers and Telescopes for the Atmosphere (CRISTA) experiment took measurements of several infrared emissions in the lower thermosphere during two Shuttle flights in November 1994 and in August 1997. Among the recorded emissions are the 4.3 µm band of carbon dioxide and the atomic oxygen fine structure transition at about 63 µm. From the measured altitude distribution of the 4.3 µm band intensities the F densities are derived using a non-LTE model for the CO2 emission during daylight. The atomic oxygen densities are calculated directly from the measured radiances using thermospheric temperatures from the CIRA model. The resulting data exhibit substantial

horizontal structures which are attributed to vertical movements in the lower thermosphere. The implications will be discussed.

MW05/W/03-A2 Poster 1040-01

THE CO2 NON-LTE PROBLEM TAKING ACCOUNT OF THE MULTIQUANTUM TRANSITIONS ON THE V2-MODE DURING CO2--O COLLISION

V.P. OGIBALOV (Institute of Physics, St.Petersburg State University, St.Petersburg / Petrodvorets 198904, Russia, email: vpo@lmupa.phys.spbu.ru)

The strong anisotopy of the interaction potential during CO2--O collisions can result in transitions with the CO2 state change of two- or more v2-quanta. The CO2 non-LTE problem of the Earth atmosphere, taking account of these transitions, has been solved. The results have been compared with those obtained for the usually adopted one-v2-quantum transitions during the CO2--O collisions. Increasing up to tens of Kelvin degrees of vibrational temperatures of the CO2 v2-mode manifold states in the lower thermosphere has been found, since in the case of multiquantum transitions these states can be excited by O from the ground state of the CO2 molecule. Adopting multiquantum pathway results in a considerable increase of the 15 micron band limb radiance above 100 km as compared with the one-v2-quantum pathway case. The multiquantum transitions can result in the increase of cooling rate in the 15 micron CO2 band up to 15--25 K/day at the altitudes of 125--130 km. Both these consequences are demonstrated to be caused mainly by increasing of populations of the 0200, 0220 and 1000 states of the principal isotope of CO2.

MW05/W/06-A2 Poster 1040-02

HIERARCHY OF VIBRATIONAL STATE SETS FOR SOLUTION OF THE CO2 NON-LTE PROBLEM

V.P. OGIBALOV, G.M. Shved (Institute of Physics, St. Petersburg State University, St.Petersburg-Petrodvorets 198904, Russia, email: vpo@lmupa.phys.spbu.ru)

The set of 321 excited vibrational states belonging to 7 isotopes of the CO2 molecule has been used to solve the CO2 non-LTE problem of the Earth atmosphere. Employing the Feautrier technique and accelerated lambda iteration has provided computing the state populations to a high accuracy. Using the above set as a standard, the effect of reducing the quantity of involved states on the accuracy of evaluating state populations, cooling/heating rates in the CO2 bands, and limb radiance in the both 4.3 and 15 micron CO2 bands has been studied. Criteria for the selection of state sets have been proposed. Using the criteria, three sets for estimating populations of lower vibrational states to a specified accuracy have been recommended. In order of decreasing accuracy, those are the sets of 206 and 117 states, belonging to 7 CO2 isotopes, and the set of 60 states, belonging to 5 isotopes.

MW05/E/01-A2 1115

EVIDENCE FOR NON-LTE EMISSIONS OF CO2, O3, H20, AND NO2 FROM UARS/CLAES

David P. EDWARDS (National Center for Atmospheric Research, Boulder CO, USA, email: edwards@ucar.edu); Manuel Lopez Puertas (Insituto de Astrofisica de Andalucia/CSIC Granada, Spain, email: puertas@iaa.es)

We describe observations of non-local thermodynamic equilibrium (non-LTE) limb radiance using data taken by the Upper Atmosphere Research Satellite CLAES instrument. We have studied the relative radiance contributions from CO2 and O3 in the CLAES blocker 5 region at 10.83 microns, and have examined the correlation with solar zenith angle. The diurnal variation of the measured emission points to solar dependent mechanisms selectively populating molecular vibrational levels in CO2 and O3. These processes are shown to affect the limb radiance for limb view tangent heights above about 40 km. The analysis shows good agreement between measured and calculated radiances and confirms our previous theoretical modelling of the non-LTE populations of these states.
There have been problems with the CLAES retrievals of H2O and NO2 in the blocker 3 region at 6.2 microns. This has been primarily due to uncertainties in our understanding of the radiance measurements. We present results of a study examining the daytime non-LTE enhanced stratospheric emission from excited NO2 states populated as a result of chemiluminescence and florescence processes. When examining the diurnal change in radiance, this must be considered alongside the photochemically driven change in NO2 concentration. Emission from H2O shows a daytime enhancement in the mesosphere due to non-thermal collisions and solar absorption. We discuss the implications of these studies for the future measurements of the High Resolution Dynamics Limb Sounder (HIRDLS) due to be launched on the EOS-CHEM satellite in 2002.

MW05/W/08-A2 1130

EFFECT OF OZONE NON-THERMAL EMISSION ON THE COOLING RATE IN THE MIDDLE ATMOSPHERE

Katerina KOUTOULAKI, Brian J. Kerridge (both at Rutherford Appleton Laboratory, Chilton, Didcot, Oxforshire, OX11 0QX, UK, email: a.koutoulaki@rl.ac.uk); Manuel Lopez-Puertas, Francisco J. Martin (both at Instituto de Astrofisica de Andalucia (CSIC), Apdo. 3004, 18080 Granada, Spain, email: puertas@iaa.es)

Ozone thermal emission is the second most important source of infrared cooling in the middle atmosphere, due to emission at 9.6 microns. However, ozone is chemically pumped in the middle atmosphere by the recombination reaction: O + O2 + M --> O3(v) + M This process leads to non-thermal emission from O3(v) that can potentially enhance the cooling rate, especially due to emission from ozone hot bands. The effect of this non-thermal emission on the ozone cooling rate will be investigated, between 10 mb and 0.1 mb. The vibrational populations used to calculate hot band cooling rates are those derived from the analysis of the Improved Stratospheric and Mesospheric Sounder (ISAMS) data (Koutoulaki, 1998). Furthermore, upper and lower limits on the above effect will be presented, consistent with the ISAMS data analysis. In this way, the importance of a) the nascent distribution from the recombination reaction and b) the collisional relaxation rates to the ozone cooling rate will be examined.

MW05/W/01-A2 1145

ATOMIC OXYGEN PEAK HEIGHT AND PEAK DENSITY FROM GROUND BASED NIGHTGLOW MEASUREMENTS AT 23 S

M. Stella, L. MELO, R.P. Lowe (The University of Western Ontario, Canada
e-mail: stella@danlon.physics.uwo.ca); Ian C. McDade (York University, Toronto, Canada
e-mail: mcdade@windeh.yorku.ca); Hisao Takahashi (INPE, São Paulo, Brasil,
e-mail: hisao@laser.inpe.br)

Atomic oxygen plays a fundamental role in the upper mesosphere-lower thermosphere (MLT) region. As a dominant minor constituent, it controls directly or indirectly many photochemical processes and plays an important role in the MLT energy budget through both heating and cooling processes. As its lifetime is relatively long atomic oxygen can also be used as a passive tracer of motions in the MLT. The inaccessibility of the MLT region to both balloons and satellites and the intrinsic sporadic nature of in situ rocket experiments make remote sensing of nightglow features one of the most useful techniques for obtaining information about atomic oxygen variability. However, it has generally been thought that ground-based measurements of the zenith integrated airglow intensities cannot provide useful information about vertical distributions of atomic oxygen. Here we demonstrate how ground-based measurements of selected airglow emission features may be used to determine the vertical distribution of atomic oxygen in the upper mesosphere and lower thermosphere. The technique is applied to ground-based measurements of the OI 557.7 nm green line, the O2 Atmospheric (0-1) band and the OH Meinel (9-4) band emissions made at Cachoeira Paulista (230 S, 450 W), Brazil, between 1987 and 1994. The limits of validity of such technique are exploit using nightglow profiles measured by the WINDII experiment on board UARS satellite when both the satellite on board and the ground-based instruments were observing the same region.

MW05/W/04-A2 1200

IMPACTS OF MODIFIED SOLAR AND CHEMICAL HEATING ON THE CANADIAN MIDDLE ATMOSPHERE MODEL

Chao FU, Victor Fomichev, Jean de Grandpre, John McConnell, Stephen Beagley (Department of Earth and Atmospheric Science, York University, 4700 Keele Street, North York, Ontario, M3J 1P3, Canada, email: chao@nimbus.yorku.ca)

The Canadian Middle Atmosphere Model (CMAM) is a GCM that extends from the surface to about 95 km with non-orographic gravity wave drag, solar and IR heating appropriate for the upper atmosphere. Also included is a comprehensive interactive chemical package that covers the region from 5-95 km. Recently, we have modified the heating parameterazation above 50 km to allow explicitly for chemical heating. We have calculated the chemical heating rates associated with seven exothermic reactions involving odd-oxygen and odd-hydrogen families and adjusted the ozone heating to allow for the chemical potential energy; heating in the Schumann-Runge bands and continuum has been added. The addition of a more consistent heating scheme in the mesosphere and lower thermosphere results in several improvements in the model. For example, temperatures above the mesopause are increased. The diurnal variation of heating above mesopause is much more uniform than before and this has impacts on the circulation in this region and beyond. We will present results comparing the magnitude of the heating rates for the standard and new versions of the CMAM and also detail the impact on the circulation as measured against a standard climate run.

MW05/W/07-A2 1215

DERIVATION OF THE CO2 VIBRATIONAL TEMPERATURES FROM THE LIMB RADIANCE MEASUREMENTS AND COMPARISON WITH MODEL PREDICTIONS

Vladimir KOSTCOV, Vladimir Ogibalov, Yuri Timofeyev (Research Institute of Physics, St. Petersburg State University, Ulyanovskaya 1, St. Petersburg-Petrodvorets, 198904 Russia,
email: vlad@troll.phys.spbu.ru)

The vibrational temperatures of the CO2 state 01101 for the 626, 636, 628, and 627 CO2 isotopes have been derived in the altitude range 60-130 km together with the kinetic temperature from the limb radiance spectra measured by the CRISTA instrument during 1994 mission. The measurement data inversion method did not involve an a priori information in the form of modelling of the processes driving non-LTE. The accuracy of the method has been estimated on the basis of error matrix calculations and numerical experiments. The selected for the analysis dataset included the vertical profiles of the kinetic and the vibrational temperatures for different atmospheric situations with latitudinal coverage 60S-60N and wide longitudinal coverage. On the basis of the derived kinetic temperature and pressure profiles the model vibrational temperatures for CO2 have been calculated with certain assumptions caused by lacking of complete information on the atmospheric state during measurements. These model predictions have been compared with the vibrational temperature profiles retrieved from the CRISTA spectral data. The retrieval accuracy and the results of the comparison of derived and modeled profiles are discussed.

MW05/E/03-A2 1230

NATURAL POPULATION INVERSION FOR THE CO2 VIBRATIONAL STATES IN THE EARTH'S ATMOSPHERE

V.P. OGIBALOV, G.M. Shved (Institute of Physics, St.Petersburg State University, St.Petersburg-Petrodvorets 19890, Russia, email: vpo@lmupa.phys.spbu.ru)

The non-LTE problem of populations, n, for vibrational states of CO2 molecules has been solved for the Earth's atmosphere in the daytime. The inversion of the 0001 level population with respect to the 1000 level population has been derived near the mesopause. The inversion occurs due to excitation of the 0001 level by two pumping mechanisms. The main mechanism is excitation due to solar radiation absorption in the CO2 bands. The mechanism provides the peak values of ratio [n(0001)/n(1000)] up to about 1.2 in the 95--100 km layer. The second mechanism is an energy transfer from O(1D) produced during photodissociation of O2. This mechanism can significantly increase the above ratio. However, its contribution may not be estimated with a good validity, since the number of N2 vibrational levels, excitating during the O(1D)--N2 collisions, is unknown up to now. An utilization of the natural inversion for generation of the 10.4 micron laser emission is also discussed.

TOWARDS A FULL UNDERSTANDING OF THE WINTER STORM TRACKS

Mankin MAK (Department of Atmospheric Sciences University of Illinois, Urbana, Illinois, 61801, USA)

What have been learned from the dynamical studies of the winter storm-tracks in the past 20 years will be reviewed for the purpose of identifying what are relatively well established and why some aspects remain elusive. A recently completed analysis of the relative importance of several diabatic processes will also be reported. In conclusion, we will comment on some promising unresolved issues. We will begin by reviewing the observed characteristics of the normal winter storm-tracks and their interannual variability. Then we will review the early dynamical studies that aimed at accounting for the geographical locations of the two-winter storm tracks. The answer was sought by means of linear instability of a zonally inhomogeneous baroclinic flow, highlighting the pivotal role of the two pronounced localized jets in mid-latitudes. The central issue of maintenance of the winter storm-tracks has received considerable attention, but it proves to be somewhat elusive. Although most studies focussed on the dry dynamics per se, it is not certain whether or not condensational heating plays a role of first order importance in the storm-tracks dynamics. Some studies largely introduced the all-important localised jets in the form of an external forcing a priori. Their focus was to ascertain the extent to which the storm-tracks could be simulated under such condition. Another fundamentally different approach has been to analyse the storm-tracks as a linear forced stochastical response. The extent of success and limitation of these attempts will be reviewed. We will report a recent model analysis which is intended to delineate the impacts on the maintenance of the northern hemispheric winter storm tracks by the diabatic heating (radiative forcing, surface heat flux and self-induced condensational heating) in conjunction with orographic forcing. As the constituent eddies of the storm-tracks and the accompanying planetary localised jets are treated on equal footing as unknowns, the nature of their interdependence can be more clearly delineated.

MW06/E/07-A3 1000

MID-LATITUDE STORM-TRACKS SENSITIVITY STUDIES TO SST IN A GCM

Marie DREVILLON, Philippe Rogel, Laurent Terray (CERFACS, Climate Modelling and Global Change Team, 42 avenue G. Coriolis, 31057 Toulouse cedex 1, France, email: drevillo@cerfacs.fr)

This work aims at studying the coupled interaction between SST, storm-tracks activity and the mean flow caracterized by the geopotential height at 500 hPa, and in particular at how SST anomalies and boundary layer processes may influence wave-mean flow interaction. This will be done through the following three points:
First mid-latitude storm-tracks are identified using the RMS of bandpass 2,2 to 6 day filtered geopotential height at 500 hPa, in NCEP reanalysis for the 1958-1998 period and ECMWF reanalysis for the 1979-1994 period, as well as in simulations of Meteo France ARPEGE-Climat GCM (T42). One of these simulations has a climatological and the other a month to month SST forcing. Storm-tracks variability is first addressed through an EOF analysis for each simulation and the reanalysis, which helps estimate the influence of interannual variability of sea surface temperature upon storm-tracks variability.
Second, in order to study coupled modes of variability, three two by two SVD analyses are performed on detrended datasets of SST, storm-tracks activity and geopotential height at 500 hPa. Periods with high and low covariance between those three fields are sorted out. These SVD computations are performed over monthly and winter averaged fields which allows a discussion of the results in terms of time scales ranging from intraseasonnal to interannual.
Third, these results help determine sample situations with varying covariance between storm-tracks, forcing and background circulation, for which sensitivity experiments will be performed. Preliminary experiments testing the influence of SST anomalies are presented.

MW06/W/08-A3 1020

INTERANNUAL AND INTERDECADAL VARIATION OF NORTH PACIFIC WINTER-TIME BLOCKING

Tsing-Chang CHEN, Jin-ho Yoon (Department of Geological and Atmospheric Sciences, Iowa State University, Ames, IA 50011, USA, email: tmchen@iastate.edu)

We explore inter-annual and interdecadal variations in the occurrence frequency of North Pacific (NP) wintertime (December-February) blocking using the NCEP reanalysis data for the period 1958-1997. A systematic interannual variation of NP blocking occurrence frequency emerges. Blocking occurs more often during the La Nina winters than the El Nino winters. Furthermore, a clear interdecadal increasing trend of NP blocking stands out in the past four decades, while the winter mean location of NP blocks shifts eastward. The streamfunction budget (Laplace inverse transform of the vorticity equation) analysis is used to explain the dynamic cause of these interannual and interdecadal variations.
The dynamic processes (i.e. vorticity advection and stretching) maintaining the La Nina (El Nino) anomalous circulation spatially match (mismatch) with those maintaining (suppressing) blocking in such a way that blocking occurrence was facilitated (hindered) during the La Nina (El Nino) winter. For the interdecadal variation, centers of dynamic processes maintaining the anomalous circulation pattern shifted eastward over the past four decades. This shift also results in the eastward shift of dynamic processes maintaining the NP blocks. Since both the interannual and interdecadal anomalous circulation patterns are the atmospheres response to the tropical Pacific sea surface temperature (SST) change, the interannual and interdecadal variations in NP wintertime blockings are also the consequence of the tropical Pacific SST change.

A MODELLING OF THE RESPONSE OF ATMOSPHERIC CIRCULATION TO SST ANOMALIES IN THE WINTERTIME NORTH ATLANTIC

Nikolai A. DIANSKII, A. V. Glazunov (both at Institute of Numerical Mathematics RAS, ul. Gubkina 8, 117951, Moscow GSP-1, Russia, email: dinar@inm.ras.ru)

The interaction of atmosphere and ocean in the wintertime North Atlantic was studied. For this purpose several numerical experiments with atmospheric general circulation model of INM RAS were carried out. In these experiments 360 month runs of the atmospheric model were performed in the perpetual January mode. In the first experiment a model of the upper mixed layer of ocean was coupled to the atmospheric model. It was shown that the spatial structures of leading empirical orthogonal functions (EOF) for interannual anomalies of H500 produced by the coupled model is closer to observations than these structures for the atmospheric model with the prescribed climatic SST. Two experiments were preformed with prescribed stationary and alternative sign (with prescribed temporal evolution) SST anomalies in North Atlantic extracted from the results of the coupled model simulation. It was revealed that the stationary atmospheric response to SST anomaly may contain the global response along with the localized response. It was shown that the localized response of atmospheric model to the SST anomaly has baroclinic structure. This response can be identified as the response to the SST anomaly with prescribed temporal evolution by means of the method of singular value decomposition analysis. The global response has quasi-barotropic structure and is determined by the leading low-frequency EOFs. To reveal the temporal formations of localized and global response a Monte-Carlo numerical simulation was carried out.

MW06/E/03-A3 1120

BLOCKING OVER THE SOUTH PACIFIC: THE EXTRATROPICAL ROSSBY WAVE RESPONSE TO A MOVING DIVERGENCE FORCING IN THE TROPICS?

Michael REVELL, James Renwick (both at National Institute of Water and Atmospheric Research, Wellington, New Zealand, email: m.revell@niwa.cri.nz)

Atmospheric blocking events over the South Pacific are investigated using a 39 year record of 500 hPa height fields from the NCEP/NCAR reanalysis data set. The analysis extends earlier work using a 16 year record and confirms that the occurrence of blocking over the southeast Pacific is strongly modulated by the ENSO cycle during austral spring and summer. Comparison of results at 500 hPa with the 300 hPa meridional wind component showed that blocking events are associated with large-scale wave trains lying across the south Pacific from the region of Australia to southern South America. Similar wave trains are evident in both hemispheres in singular value decomposition analyses between 300 hPa meridional wind components and tropical Pacific outgoing longwave radiation (OLR) anomalies.
The hypothesis that the divergence associated with tropical OLR anomalies forces an extra-tropical wave response which results in enhanced blocking over the southeast Pacific was tested using a linearised, barotropic vorticity equation (BVE) model. Observed 300 hPa mean flow fields and divergence forcing which matched the anomalous OLR were used to drive the BVE model. The resulting pattern of meridional wind and stream function anomalies agrees closely with observations.
When the tropical OLR anomaly is given an eastward phase speed of 5 degrees per day, the extra-tropical response agrees even better with observations. This suggests that linear Rossby wave propagation provides an important link between anomalous convection in the tropics and the occurrence of blocking over the southeast Pacific Ocean.

MW06/W/01-A3 1140

EFFECT OF MIDLATITUDE SST ANOMALIES ON STORM TRACK POSITION AND AMPLITUDE - AN IDEALISED STUDY

David N. BRESCH (Massachusetts Institute of Technology, 77 Massachusetts Av, Cambridge, MA 02139, USA, email: bresch@mit.edu); Rene Fehlmann (Swiss Federal Institute od Technology, ETH Hoenggerberg, CH-8093 Zuerich, Switzerland, email: fehlamnn@atmos.umnw.ethz.ch); Huw C. Davies (Swiss Federal Institute of Technology, ETH Hoenggerberg, CH-8093 Zuerich, Switzerland, email: davies@atmos.umnw.ethz.ch)

The contrasting properties of ocean and atmosphere render the coupled system of significant importance for the understanding of midlatitude climate variability. Indeed the linkage between oceanic and atmospheric fluctuations is an important component of the climate system, and has far-reaching practical implications, particularly in the realm of extended-range prediction of weather and climate. In this study, consideration is given to the effect of selected midlatitude SST anomalies on the atmospheric flow evolution in an idealised model setting, yielding insight on the (non-linear) interaction of ocean and atmosphere. A SVD analysis of observed coupled patterns of SST and storm track is both used to define the SST perturbations and for the purpose of model verification. An examination of the possible effect of the distinctive SST patterns formed the basis for a sequence of simulations with an idealised primitive equation model. The imposition of a dipole SST pattern leads to an intensification of the storm track and a concomitant strengthening of the (stationary) trough in the geopotential height field which bears some resemblance to the NAO dipole structure. While the anomalous atmospheric response does not perfectly project on the corresponding statistically derived coupled (SVD) patterns, particular features of the idealised model results do relate to the overall structure of the first coupled mode. This indicates that the SST dipole forces limited features of the whole coupled atmospheric patterns. Furthermore, the modelled atmospheric response is shown to be both non-linear and highly sensitive to the precise location of the SST anomaly.

MW06/E/06-A3 1200

THE DYNAMICS OF THE ANTARCTIC CIRCUMPOLAR WAVE

Peter G. BAINES (CSIRO Atmospheric Research, PMB No. 1, Aspendale, 3195, Australia)

The Antarctic Circumpolar Wave (ACW) is a large scale coupled atmosphere-ocean disturbance in the region of the Southern Ocean. Observations show that it consists of a zonal wave number two pattern in sea surface temperature, sea surface height, and sea ice extent from the Antarctic coast, with associated patterns of atmospheric sea level pressure and wind stress curl. It circles the globe with a period of approximately nine years, and a local period of about 4.5 years. It seems likely that the ACW has a significant effect on the climate (temperature and rainfall) of southern Australia, comparable with that of El Nino. A manifestation of this phenomenon has been observed in the CSIRO Mark 2 coupled model. A simple model that explores the dynamics of the ACW is presented. This consists of a baroclinic atmosphere and a two-layer ocean with the lower layer at rest, in which the atmosphere and ocean affect each other by wind stresses and heat fluxes. Perturbation equations describing the velocity and temperature fields in the atmospheric and oceanic layers show that unstable disturbances (implying positive feedback) can exist, with the most rapidly growing disturbances having properties consistent with those of the observations. The primary interaction exists between long barotropic Rossby waves in the atmosphere driving the ocean flow pattern by wind stress, and the ocean forcing the atmosphere by the effect of surface heat flux on the atmospheric vorticity. Growth times are of the order of 4 years for the inviscid case, and 22 years if viscosity and diffusion (with values equalling those in the CSIRO coupled model) are included.

THE SEESAWING VARIATIONS BETWEEN THE TROPICAL AND SUBTROPICAL MONSOON IN EAST ASIA

QingYun ZHANG (Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing 100029, China)

Based on the wind data at 2OOhPa and 85OhPa level from the ECMWF datasets and Tbb data of Japan (JMA) Geostationary Meteorological Satellite (GMS) during 1980-1989, two convergence zones in East Asia, one over the South China Sea (called monsoon trough), the other over the Yangtze River Basin and Japan (called the MeiYu or Baiu front) were studied.
There is the seesawing variation for the intensity between the two convergence zones. The tropical monsoon trough weakens and the MeiYu front strengthens; the MeiYu front weakens and the tropical monsoon trough strengthens . The westerly (easterly) wind anomalies at 85OhPa during summer appear over the MeiYu front region, the MeiYu front intensifies (weakens); the westerly (easterly) wind anomalies at 85OhPa during summer appear over the monsoon trough region, the monsoon trough intensifies (weaken).
The rainfall patterns in Eastern China during summer are greatly dependent on the intensity of the two convergence zones (the tropical monsoon trough and MeiYu front over East Asia). The study shows that when the MeiYu front over East Asia strengthened (weakened), the Rainfall over Yangtze River Valley is above (below) anomaly.

DYNAMICAL MECHANISM OF INTRASEASONAL OSCILLATION IN THE MID-HIGH LATITUDES

Li Chongyin (LASG, Institute of Atmospheric Physics, CAS, P.O. Box 2718, Beijing 100080, China, email: lcy@lasgsgi4.iap.ac.cn)

The intraseasonal oscillation is also an important atmospheric system in the mid-high latitudes and obviously different in the structure and activity from that in the tropical atmosphere. The dynamical mechanism of intraseasonal oscillation in the mid-high latitudes has been studied from various angles. A comprehensive review will be given in this paper, it is shown that the dynamical mechanism of intraseasonal oscillation in the mid–high latitudes can be able to sum up several points as follows:
1. Low-frequency remote responses of the atmosphere to external forcings (the SSTA and so on).
2. The atmospheric circulation pattern caused by instability of basic flow in the atmosphere.
3. Non–linear interaction in the atmosphere, such as the resonant interaction of the waves and the modons.
4. Influences of tropical atmospheric anomalies, especially the convection activity in the tropics.

MW06/W/05-A3 1430

INSTABILITY MECHANISMS AND LOW FREQUENCY ATMOSPHERIC DISTURBANCES

Carsten S. FREDERIKSEN (Bureau of Meteorology Research Centre, GPO Box 1289K, Melbourne, Victoria 3001, Australia, email: C.Frederiksen@bom.gov.au); Jorgen S. Frederiksen (CSIOR Atmospheric Research, PB1, Mordialloc, Victoria 3195, Australia,
email: Jorgen.Frederiksen@dar.csiro.au)

During the last decade or so, normal mode instability theory, generalized to analyse disturbances growing on three-dimensional flows has provided insights into many aspects of large-scale atmospheric dynamics. Early studies used barotropic or multi-level quasi-geostrophic models. Recently, an extension of the theory to the full primitive equations and including a Kuo-type cumulus convection parameterization has been successfully applied to studies of monsoon disturbances, intraseasonal oscillations, circulation anomalies associated with Australian Northwest Cloudband disturbances, and low frequency anomalies.
Here, we present an overview of three-dimensional instability theory and the role of eigenmodes and adjoint eigenmodes in the development of atmospheric disturbances, and review some of these recent studies. In particular, we focus on the roles of barotropic instability, baroclinic instability and convection in the formation and structures of intraseasonal oscillations, low frequency anomalies and teleconnections, Northern and Southern Hemisphere blocking and Australian Northwest Cloudband disturbances. We also discuss possible future development and application of the theory.

MW06/W/02-A3 1500

PIECEWISE TENDENCY DIAGNOSIS OF INTRASEASONAL LOW FREQUENCY VARIABILITY

Robert X. BLACK, Katherine J. Evans (School of Earth and Atmospheric Sciences, Georgia University of Technology, Atlanta, Georgia 30332-0340, USA, email: rxblack@voir.ias.gatech.edu)

A new diagnostic approach, piecewise tendency diagnosis (PTD), is employed to study the dynamics of intraseasonal low frequency variations occuring during Northern Hemisphere Winter. PTD extends piecewise potential vorticity inversion by first partitioning the local time tendency of quasi-geostrophic potential vorticity (QGPV) into an array of advective and nonconservative forcing terms. These forcing terms are then inverted separately to obtain the associated three-dimensional height tendency. The diagnostic is based upon the QGPV balance and conservation relations and is used to isolate individual mechanistic influences upon the atmospheric height tendency. This provides a quantitative methodology for assessing the contribution of individual dynamic and physical sources towards local height tendency. We extend PTD to include the effects of diabatic heating, ageostrophic forcings, and spherical geometry. In our study PTD is applied to study both the composite and individual case dynamics of the formation of persistent cyclonic circulation anomalies over the North Pacific. Our results indicate that the calculated height tendency patterns matches the observed tendency of the individual case and composite very well. In both situations, linear geostrophic advective terms provide the largest dynamic forcing. In particular, both the individual and composite cases develop largely from linear baroclinic processes, with spatial deformation processes providing a smaller first-order contribution. PTD analyses of the composite events provide results that are consistent with previous synoptic and diagnostic studies. For both the composite and case analyses, QG non-linear and non-QG advection terms played secondary but nonnegligible roles in intensification. The non-QG vertical advection of stratification anomalies generally opposes development, but is weak. The effect of diabatic heating was small in both cases, acting to intensify the low in the individual case and slow the development in the composite.

MW06/W/03-A3 1520

MIDLATITUDE MESOPAUSE REGION WINDS AND THEIR CONNECTION WITH EUROPEAN AND ASIAN TROPOSPHERIC PARAMETERS

Christoph JACOBI (Institute for Meteorology, University of Leipzig, Germany,
email: jacobi@rz.uni-leipzig.de)

Comparison of long-term measurements of winter mesopause region zonal winds has shown a connection of northern hemisphere tropospheric parameters, as temperature and rainfall, and mesopause region dynamics. These are on one hand due to a connection of the stratospheric polar vortex and the North Atlantic Oscillation and on the other hand steered by a coupling of the lower stratosphere and the upper mesosphere/lower thermosphere region. The connection between European and Asian winter climatological parameters and the North Atlantic Oscillation leads to the fact, that the signal of Eurasian winter conditions can be found in the interannual variability of mesopause winds. Some of these winter tropospheric parameters influence the strength of the Indian monsoon in the following summer, and this leads to a correlation between winter mesopause winds and summer Indian rainfall, so that the midlatitude mesopause winter dynamics can be used as a precursory signal of the strength of the Indian monsoon.

MW06/E/05-A3 1600

INTERPRETING LOW FREQUENCY MODES OF SOUTHERN HEMISPHERE ATMOSPHERIC VARIABILITY AS THE ROTATIONAL RESPONSE TO DIVERGENT FORCING

Michael REVELL, John Kidson (both at National Institute of Water and Atmospheric research, Wellington, New Zealand, email: m.revell@niwa.cri.nz); George Kiladis (Aeronomy Lab, NOAA, Boulder, Colorado, USA, email: gkiladis@al.noaa.gov)

The principal, low frequency, modes of atmospheric circulation variability in the Southern Hemisphere have been calculated using a 39 year record of 200 hPa wind fields from the NCEP/NCAR reanalysis data set. Many of these modes show strong correlations with tropical convection as inferred from outgoing longwave radiation (OLR). We attempt to interpret these modes as the rotational response to a divergent forcing. For a range of mean states we use the linearised barotropic vorticity equation (BVE) to solve the CHI problem for the divergent wind that would generate these rotational modes. We find that several of these low frequency modes can be generated by forcing the BVE with fairly simple divergent wind fields that could be interpreted as resulting from anomalous convection. In particular we find divergence patterns that correspond well to the MJO and ENSO. These results are further evidence that linear Rossby wave propagation provides an important link between anomalous convection in the tropics and the occurrence of low frequency circulation anomalies in mid-latitudes and vice-versa.

MW06/W/06-A3 1620

MULTI-YEAR VARIABILITY IN A MIDLATITUDE OCEAN-ATMOSPHERE MODEL OF INTERMEDIATE COMPLEXITY

Ernst VAN DER AVOIRD, Henk A. Dijkstra (both at the Institute for Marine and Atmospheric research Utrecht (IMAU), Princetonplein 5, 3584 CC Utrecht, The Netherlands, email: avoird@phys.uu.nl, h.a.dijkstra@phys.uu.nl)

The problem of interannual midlatitude climate variablity is approached using dynamical systems theory applied to a quasi-geostrophic coupled ocean-atmosphere model of intermediate complexity. The model consists of a two-layer rectangular ocean basin underlying a two-layer zonal atmospheric channel. A constant depth mixed layer within the top layer of the ocean model with variable sea surface temperature determines the thermodynamic coupling. Simple parameterizations are proposed to represent the air-sea interaction which lead to non-local relations between SST-anomalies and the anomalous atmospheric flow pattern. The associated coupling parameters are estimated from data- analyses in the North Atlantic region. The stability of the mean flow consisting of the zonal atmospheric jet overlying the double gyre ocean circulation is investigated. Low frequency modes are found and described with the help of the perturbation structures at critical points in parameter space.

MW06/W/04-A3 1640

THE IMPACT OF THE ANNUAL CYCLE UPON THE EXTRATROPICAL RESPONSE TO ANOMALOUS TROPICAL HEATING

Matthew NEWMAN (NOAA-CIRES Climate Diagnostics Center, University of Colorado, Boulder, CO 80309, USA, email: men@cdc.noaa.gov); Prashant D. Sardeshmukh, Christopher R. Winkler (both at NOAA-CIRES Climate Diagnostics Center, University of Colorado, Boulder, CO 80309, USA, email: pds@cdc.noaa.gov, crw@cdc.noaa.gov)

The impact of the annual cycle in the zonally, meridionally, and vertically varying base state upon the extratropical response to anomalous heating is considered in the context of a linear baroclinic model. Using a diagnostic tool called the influence function, it is shown that the most sensitive areas of heating for producing a large local geopotential height response change from month to month. Over North America, this change is most dramatic in spring and fall. Also, as spring progresses, there is a marked increase in the sensitivity to smaller scale heating, particularly over the west Pacific.
These results suggest that the impact of the annual cycle must be taken into account in any complete theory of low-frequency variability. The impact is large enough to raise the possibility of significant interactions across time scales. In other words, it is possible for a steady forcing to produce an unsteady response, and equally, for an unsteady forcing to produce a seasonal-mean response. In such situations, particularly during the northern spring and fall seasons, investigating low-frequency anomalies as departures from 3-month seasonal climatologies may lead to confusion, and may not be useful.
A similar analysis is made in a linearized multi-level baroclinic model, showing the impact of the seasonally varying base state upon the North American response to MJO-like heating anomalies. Again, this impact is greatest during spring, but even during winter there are noticeable differences.

MW06/P/1-A3 1700

THE RELATION BETWEEN THE PRECIPITATION OF SOUTHWEST CHINA (YUNNAN) IN MAY AND THE INTRASEASONAL OSCILLATION BEFORE MAY

Xiao ZINIU, Wen Min (Yunnan Meteorological Observatory, Kunming 650034, Yunnan, China)

Yunnan is in the south-west of China and influenced by the South Asia Monsoon. The precipitation in May reflects the time of the rainy season beginning in the area and it is very

important to agriculture there, based on black body temperature (TBB) data and Yunnan precipitation data, the relation between Yunnan precipitation in May and intraseasonal oscillation (30-60 days) over the equatorial Indian Ocean and the South Asian monsoon area before May is studied. The results revealed that the intensity of intraseasonal oscillation activities in winter over the equatorial Indian Ocean and the South Asian monsoon area has a close relation to the Yunnan precipitation in May. When the oscillation is stronger and the range of the activity extends eastward and northward obviously, the precipitation is more than usual; when the oscillation is weaker and it doesn't extend eastward and northward obviously, the precipitation is less than usual. Therefore, the amount of the precipitation of Yunnan in May is mainly influenced by south Asia monsoon. The precipitation of Yunnan in May is closely related to the intraseasonal oscillation activity over south Asia monsoon region in previous period. The intensity of the intraseasonal oscillation over the equatorial Indian Ocean in winter may be an important factor to forecast the precipitation of Yunnan in May and the beginning of Yunnan rainy season in next year.

OBSERVATIONS OF CONVECTIVELY GENERATED GRAVITY WAVES IN THE STRATOSPHERE

Leonhard PFISTER (NASA/Ames Research Center Moffett Field, CA, 94035-1000 USA)

Gravity wave motions are an important driver of the stratospheric circulation. This arises from their ability to transport momentum through the atmosphere over long distances in the vertical. When the waves break, that momentum is deposited, effectively exerting a force that can drive the overall transport circulation. The location of the breaking region in the stratosphere depends on the gravity wave phase speed and amplitude, while the magnitude of the force depends on the gravity wave momentum flux. The amplitude, momentum flux, and phase speed spectra of topographically generated gravity waves are reasonably well known, with the phase speed spectrum being particularly simple (i.e., quasi-stationary). This is not true for convectively generated gravity waves, where one expects a much richer spectrum due to the transient nature of the convective forcing. In fact, a variety of techniques (satellite temperatures, radiosondes, aircraft, radar), which are sensitive to different portions of the spectrum of vertical scales, horizontal scales, and phase speeds have all detected strong gravity wave variance. Ultimately the goals are: (1) to produce a coherent picture of momentum flux as a function of phase speed and horizontal scale and (2) to link this spectrum quantitatively to mechanisms operating in convective systems and (on a synoptic scale), clusters of convective systems. This paper will review observations of convectively generated gravity waves and the role of various parts of the spectrum in the stratospheric momentum budget. The emphasis will be on mesoscale waves (up to 500 km horizontal wavelength) in the tropics as observed by aircraft, though the larger scales will be discussed as well. Among the new findings are: (1) clear observations of gravity waves in the tropics with vertical wavelengths at least marginally comparable to the ~10 km predicted by convective cloud models; (2) a case study showing the very short residence time of some convectively generated waves in the lower stratosphere; and (3) observations of inertia-gravity waves as seen in a horizontal view (as opposed to vertical profiles). These waves are seen to actually generate thin clouds near the tropopause, suggesting a role in the stratospheric water budget as well as the momentum budget.

MW07/E/04-A4 0900

GRAVITY WAVE GENERATION IN A HIGH-RESOLUTION NUMERICAL MODEL OF DEEP TROPICAL CONVECTION

Todd P. LANE, Michael J. Reeder (Centre for Dynamical Meteorology and Oceanography, Monash University, Australia and Cooperative Research Centre for Southern Hemisphere Meteorology, Australia)

Convective clouds are known to generate internal gravity waves. Indeed, such waves are thought to be important in adjusting the unsaturated environment of the cloud, and in shaping the mean flow in the middle atmosphere. However, the way in which convective clouds generate gravity waves is not well understood. The present study seeks to clarify the dynamics of wave generation using a high-resolution numerical model. The numerical calculations presented explicitly resolve both the mesoscale convective cloud cluster and the gravity waves generated. As the convective clouds evolve, they generate prominent gravity waves in both the troposphere and stratosphere. The source location is variable in time and space, but is related to the development of individual convective cells. The largest amplitude gravity waves are generated when the cloud tops reach the upper troposphere. The stratospheric momentum flux shows a distinct temporal cycle associated with the transient nature of the wave source.
A new analysis technique is introduced in which the non-linear terms in the governing equations are taken as the forcing for linear gravity waves. The analysis shows that neither the shear nor the diabatic heating are the dominant mechanisms for wave generation. Instead, the wave source is most easily understood when viewed in a frame of reference moving with the level of neutral buoyancy, whereupon the source may be described as a vertically oriented, oscillating convective up-draught. This description is consistent with the properties of the modelled stratospheric waves.

MW07/W/08-A4 0920

MOMENTUM TRANSPORT BY CONVECTIVELY GENERATED WAVES

Carol ROADNIGHT, Stephen Mobbs (both at The Environment Centre, The University of Leeds, Leeds, LS2 9JT, UK, email: carol@lec.leeds.ac.uk)

Vertically propagating waves, excited by deep convective systems, can transport momentum to higher levels in the atmosphere and thus exert a significant acceleration, or deceleration, on the mean flow at levels of dissipation. The inclusion of this, apparently important, process in larger models has received much less attention than the related problem of momentum transport by orographically generated gravity waves.
A study of these convectively generated waves and their contribution to the vertical transport of horizontal momentum will be presented using results from large-eddy simulations of the convective boundary layer and an overlying stable layer. A variety of idealised and realistic flow profiles are used to investigate the effects of convective intensity, wind shear and stability of the atmosphere on gravity wave generation and establish which conditions are associated with strong convective momentum transport.

MW07/W/02-A4 0940

RADIOSONDE OBSERVATIONS AND MODELLING OF GRAVITY WAVES OVER THE TROPICAL INDIAN OCEAN AND THEIR EFFECTS IN THE STRATOSPHERE

M. Joan ALEXANDER, Robert A. Vincent (Colorado Research Associates, 3380 Mitchell Lane, Boulder CO 80301, USA, email: alexand@colorado-research.com)

High resolution radiosonde observations of temperature and winds from twice-daily launches over Cocos Island (12S, 97E) have been analyzed for information on gravity waves in the lower stratosphere. The observations span a six-year period 1992-1998. The results include measurements of the monthly-mean energy density and estimates of the momentum flux, as well as information on the intrinsic frequencies, horizontal and vertical wavelengths, and phase speeds of the waves. As in any data set, these observations will emphasize waves with certain properties while other waves may be present but go unobserved. These effects are taken into account in a corresponding model study of gravity wave propagation using the observed background stability and wind structure as model inputs. The results of the data analysis were used to constrain the model, and the model/data combination provide a unique tool for interpretation of these data and evaluation of the wave effects on the atmosphere. The model study shows that these data place strong constraints on many of the details of the source spectrum of gravity waves crossing the troposphere that includes interesting variations of the monthly-mean properties of the waves. A broad parameter space describing the wave sources was investigated and best agreement between modeled momentum flux and energy density time series were obtained with wave parameters similar to those determined independently from hodograph analyses of the data. The model is then further used to investigate the limitations of the observations for inferring wave effects on the mean flow.

MW07/W/21-A4 1000

OBSERVATIONS OF GRAVITY WAVE GENERATION BY CONVECTION

Tobias KERZENMACHER (The Environment Centre, University of Leeds, Leeds LS2 9JT, UK, email: Tobias@lec.leeds.ac.uk)

The parameterization of gravity wave drag due to convection is investigated using high resolution radiosonde ascent data (~10 m) and radar data taken at mid-latitudes. In order to understand the physical processes behind wave generation by convection, the data are analyzed using a set of mathematical tools developed to detect gravity waves and convection in the data.
The importance of convection as a wave generation mechanism in the mid-latitudes is discussed based on the prevalence of simultaneous convection and gravity wave events in the data set. Furthermore inertial waves often develop after gravity wave events. These inertial waves may have a significant influence on the momentum budget. The occurrence of inertial waves has also been investigated and results will be presented.

MW07/W/03-A4 Invited 1040

SHEAR EXCITATION OF INTERNAL WAVES, AND THEIR STABILITY

B.R. SUTHERLAND (University of Alberta, 539 Central Academic Building, University of Alberta, Edmonton, AB T6G 2G1 Canada, email: bruce.sutherland@ualberta.ca)

Linear theory and the results of nonlinear numerical simulations have shown that strong coupling between radiating internal gravity waves and unstable stratified shear flow is anticipated if the stratification is sufficiently weak where the shear is strong and the stratification is sufficiently strong elsewhere. To examine these dynamics in the laboratory, experiments have been performed in a recirculating tank filled with salt-stratified water and driven near the surface by a Kovasznay pump to create a shear flow. The flow passes over a tall thin barrier spanning the width of the test-section of the tank, and the generation of internal waves from the mixing region in the lee of the barrier is observed. In the early stages of the flow development, internal waves are observed to couple with spanwise-coherent vortices that are shed in the wake of the barrier. Using a new technique, the amplitude of the excited waves is non-intrusively measured continuously in space and time. This analysis shows that large amplitude waves are generated when the mixing region is sufficiently weakly stratified and that these extract up to 7 percent of the momentum from the mean flow.
In experiments of uniformly stratified flow over the barrier, small amplitude internal waves are generated initially. Over time, however, the stratification in the mixing region becomes weaker and transient bursts of large amplitude internal waves are observed. Although the frequency spectrum of the internal waves excited by the turbulent mixing region can be broad in theory, they are observed to propagate typically at angles between 30 to 45 degrees to the vertical. A simple argument based on weakly nonlinear theory is proposed to help explain this phenomena. Specifically, it is proposed that an internal wave is unstable if the ratio of its maximum vertical displacement to its horizontal wavelength is greater than sin(2 Theta)/(pi sqrt(8)), in which Theta is the angle of the wave characteristics to the vertical. In particular, waves that propagate at very large or very small angles to the vertical are stable only if they are of infinitesimal amplitude. The predicted stability boundary is in excellent agreement with numerical simulations of horizontally periodic internal waves. However, horizontally compact waves are found to be stable at larger amplitudes than predicted if their angle of propagation to the vertical is moderately smaller than 45 degrees.

MW07/W/14-A4 1110

GRAVITY WAVE EXCITATION BY SPATIALLY AND TEMPORALLY VARIABLE BODY FORCES IN A SPHERICAL GEOMETRY

David C. FRITTS, Sharon L. Vadas (Colorado Research Associates, 3380 Mitchell Lane, Boulder, CO 80301, USA)

A spherical compressible model is used to study the radiation of large-scale gravity waves from sites of localized body forcing due to small-scale wave dissipation. This source can be viewed alternatively as the ageostrophic radiation of gravity waves accompanying geostrophic adjustment. In both cases, the radiated wave scales are imposed by the source geometry, with smaller horizontal scales suggesting more local effects at higher altitudes and larger horizontal scales implying more global responses. Because of the scales of such motions, there is a potential that they may play a role in momentum transport, induced circulations, and thermal and constituent responses well into the thermosphere.

Presiding Chair: David C. Fritts (Colorado Research Associates, Boulder, USA)

MW07/W/04-A4 1130

OBSERVATION OF STRATOSPHERIC INERTIA-GRAVITY WAVES ASSOCIATED TO AGEOSTROPHIC FLOW IN THE UPPER TROPOSPHERE

Albert HERTZOG (Service d'Aeronomie du CNRS, BP3, F-91371 Verrieres-le-Buisson Cedex, France; email: albert.hertzog@aerov.jussieu.fr); Claude Souprayen (Department of Applied Mathematics and Theoritical Physics, University of Cambridge,Silver Street, Cambridge, CB3 9EW, England; email: c.souprayen@damtp.cam.ac.uk); Alain Hauchecorne (Service d'Aeronomie du CNRS, BP3, F-91371 Verrieres-le-Buisson Cedex, France; email: alain.hauchecorne@aerov.jussieu.fr)

Inertia-gravity waves are often observed in the mid-latitude lower stratosphere. Those low frequency waves, whose amplitude can reach several m/s, may induce important horizontal displacements of air parcels, and thus be involved in dispersion of tracers in the "surf zone" or at the vortex edge. Some recent observations of high amplitude inertia-gravity waves made in the south of France by Doppler Lidar will be presented. In order to determine the mechanism responsible for the generation of such waves, a 3D non-stationary ray tracing model has been developed. Backward trajectories of gravity wave packets have been simulated with atmospheric thermo-dynamical fields coming from the ECMWF T106 model and wave spectral parameters estimated on Lidar data. Those trajectories show retro-propagations to regions located in the upper troposphere and characterized by high baroclinic activity. Our results support the excitation of inertia-gravity waves by geostrophic adjustment.

MW07/E/05-A4 1150

ENHANCED AND INHIBITED GRAVITY WAVE SPECTRA

James A. WHITEWAY (Department of physics, University of Wales, Aberystwyth, SY23 3BZ, UK, email: jjw@aber.ac.uk)

Meteorological balloon measurements were applied to investigate gravity wave activity in the upper troposphere and lower stratosphere above the Canadian High Arctic. These observations reveal that there are specific atmospheric conditions in which the spectrum of gravity waves is enhanced at all vertical wavelengths larger than 100 m; and that there are other distinct conditions in which the spectrum is inhibited. It will be shown that an enhancement in spectral magnitude in the lower stratosphere occurred only when tropospheric conditions were favourable for the generation and upward propagation of mountain waves. Otherwise, growth in spectral magnitude at the tropopause was inhibited and there was no response to the change in background atmospheric conditions between the troposphere and stratosphere. The enhanced spectra are consistent with the current gravity wave paradigm but the inhibited spectra are not so readily explained. Measurements will also be shown that demonstrate how large scale meteorological patterns influence the amount of gravity wave activity above the high Arctic. It was found that enhancements in wave activity were associated with the tropospheric jet stream and also the stratospheric polar vortex.

TOPOGRAPHICALLY FORCED INTERNAL GRAVITY WAVES IN TIME DEPENDENT SHEAR WINDS

Kwok-Aun TAN (School of Mathematics, University of New South Wales, Sydney, NSW 2052, Australia, email: K.Tan@unsw.edu.au); Stephen Eckermann (Code 7641.2, Naval Research Laboratory, Washington, DC 20375, USA, email: eckerman@map.nrl.navy.mil); Dave Broutman (School of Mathematics, University of New South Wales, Sydney, NSW 2052, Australia and Computational Physics, Inc., Fairfax, VA 22031, USA, email: D.Broutman@unsw.edu.au); Lance Leslie (School of Mathematics, University of New South Wales, Sydney, NSW 2052, Australia, email: L.Leslie@unsw.edu.au)

The flow of stable stratified air over topography generates internal gravity waves that can exert a drag on the atmosphere. The vertical propagation of these mountain waves can be affected by time-evolving shear flows in the atmosphere. In the present study, we investigate the effect of unsteady shears on mountain wave forcing and propagation. In particular, we consider shear flows that are transient and exhibit wind reversals. We use a non-hydrostatic numerical model that solves the non-linear, fully compressible Euler equations of the atmosphere using a split-time explicit scheme. The simulated mountain wave fields are compared to previous studies and predictions based on ray-tracing techniques. Mechanisms for unsteady mountain wave generation are discussed.

MW07/W/06-A4 1230

EFFECT OF A WEAKLY DIRECTIONALLY SHEARED FLOW ON GRAVITY WAVE DRAG

Maria Antonia VALENTE, Ian N. James (Department of Meteorology, University of Reading, PO Box 243, Earley Gate, RG6 6BB Reading, UK, email: antonia@met.reading.ac.uk, i.n.James@reading.ac.uk)

Several experiments were performed with a mesoscale 3D non-hydrostatic, non-linear model simulating a stably stratified directionally sheared flow over an isolated bell-shaped circular mountain. The wind turns monotonically with height from southerly at z=0 to westerly at z=6km, maintaining the speed constant with height. Various mountain heights were tried, from h=10m to 3km, to obtain an extensive range of flow regimes, from linear flow to splitting flow, passing through breaking wave regimes (Froude number Fr varying in the range 13.2 to 0.44). Directional shear makes the flow more steady, but the surface drag magnitude is very similar to the drag for a uniform flow over the same mountain. The drag regimes are not significantly altered by the directional shear. In contrast, the vertical fluxes of horizontal momentum rotate with height following the wind turning and imposing an acceleration on the mean flow, even for linear regimes. The linear theory for a directionally sheared flow, stating that the momentum flux vector rotates with height in such a way that the acceleration is at right angles with the wind for each height, was tested for the different flow regimes. The simulations show that it is verified for linear flow regimes (Fr>1). The theory starts to fail for Fr near 1, but high drag regimes still have an acceleration vector turning as predicted by the theory. For low drag regimes, when the low level flow splits around the mountain, the theory is not valid. According to these results, directional shear effects should be included in parametrizations of GWD. The linear theory is adequate to parametrize linear drag regimes and could be useful for certain characteristics of high drag regimes. This theory is not useful for parametrizing flow splitting low drag regimes.

MW07/E/03-A4 1400

STRATOSPHERIC GRAVITY WAVES MEASURED FROM SPACE BY CRISTA: VERTICAL WAVELENGTHS, DAILY VARIATIONS AND SOURCES

Peter PREUSSE (Department of Physics, Wuppertal University (BUGW); Gauss Str 20, D-42097 Wuppertal, Germany, email: preusse@wpos2.physik.uni-wuppertal.de); Stephen D. Eckermann (E. O. Hulburt Center for Space Research, Code 7641, NRL, Washington DC 20375-5352, USA, email: eckerman@ismap4.nrl.navy.mil); Martin Riese, Bernd Schaeler, Dirk Offermann (all three at Wuppertal University, Germany)

During shuttle missions STS-66 (November, 1994) and STS-85 (August, 1997) the CRISTA instrument measured around 14 days of temperature and constituent data with very high spatial resolution. Vertical profiles of Kalman-detrended temperatures and trace gases measured by CRISTA are analysed using a combination of MEM and harmonic analysis. The results are binned according to vertical wavelength. Zonal-mean values of gravity wave activity are calculated and compared to gravity wave variances inferred from other satellite data. Good agreement is found with the results obtained from the LIMS instrument (NIMBUS 7), as well as with radiance fluctuations recorded by the MLS instrument (UARS). The apparent discrepancies between LIMS and MLS are discussed. CRISTA variances reveal high spatial correlation between mountain ridges and observed wave patterns, most notably near the southern tip of South America, indicating that large-scale stratospheric mountain waves are present in these regions. In addition, strong gravity wave activity is observed at the equator and near the edge of the polar vortex. The findings will be compared to model simulations of global gravity wave activity during the mission days, obtained by coupling the NRL/MWFM and the GROGRAT model.

MW07/W/19-A4 Invited 1420

GLOBAL MODELLING OF GRAVITY WAVES IN THE MIDDLE ATMOSPHERE: COMPARISONS WITH CRISTA DATA

Stephen D. ECKERMANN, E. O. Hulburt (Center for Space Research, Code 7641.2, Naval Research Laboratory, Washington, DC 20375, USA); Peter Preusse, Bernd Schaeler, Dirk Offerman (Physics Department, University of Wuppertal, Germany)

Small-scale temperature variances in the middle atmosphere have been derived from data acquired by the CRISTA instrument. CRISTA flew on the CRISTA-SPAS satellite during shuttle missions STS-66 (3-14 November, 1994) and STS-85 (7-19 August, 1997) (see the presentation by Preusse et al.). Preliminary analysis indicates that much of this variance could be produced by gravity waves. We investigate this using two global gravity-wave models: the Naval Research Laboratory Mountain Wave Forecast Model (NRL/MWFM) and the Gravity Wave Regional or Global Ray Tracer (GROGRAT). We use the models in conjunction with assimilated global winds and temperatures for each mission day to generate global maps of gravity wave activity in the middle atmosphere. Specific bursts in stratospheric temperature variance observed during both CRISTA missions are also generated in the model runs. Enhanced variance near the southern tip of South America is produced in the simulations by long wavelength f forced by flow over the Andes. Increased variance at the equator also arises due to effective transmission of nonzero phase speed waves into the middle atmosphere. We also show that effective interpretation of the data requires consideration of the spatial filtering characteristics of the measurement, supporting similar arguments by Alexander (1998) in reference to gravity waves inferred from the MLS instrument on the Upper Atmosphere Research Satellite.

MW07/E/08-A4 1450

GRAVITY WAVE SOURCES INFERRED FROM SATELLITE TEMPERATURE DATA

Charles McLANDRESS (Department of Earth and Atmospheric Science, York University, Toronto M3J 1P3, Canada, email: mcland@stpl.cress.yorku.ca); M. Joan Alexander (Colorado Research Associates, Boulder CO 80301, USA, email: alexand@colorado-research.com); Dong L. Wu (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109-8099, USA, email: dwu@mls.jpl.nasa.gov)

Gravity wave activity in the troposphere is inferred from high resolution temperature data from the Microwave Limb Sounder (MLS) on board the Upper Atmosphere Research Satellite. Global climatologies of temperature variance in the stratosphere are computed using six years of observations obtained from the instrument's limb-tracking and limb-scanning modes of operation. The summer hemisphere variances exhibit large spatial variations, with the maxima of both datasets located over the continental land masses at mid-latitudes and in the subtropics. The winter southern hemisphere is dominated by a region of large variance over the tip of South America. The variances for northern hemisphere winter are also located over the continents at high latitudes but the geographical positions of the individual maxima in the track and scan datasets differ more significantly.
A linear gravity wave ray model is used to interpret the observed temperature variances and determine whether information about the geographical distribution of gravity wave sources in the troposphere can be obtained. Realistic background wind and temperature fields which correspond to the MLS observing periods are used, and the model variances are filtered in a manner which qualitatively simulates the instrument's response to wavelike temperature perturbations. Source information is inferred by specifying a spatially-uniform spectrum of waves in the troposphere and comparing the simulated results in the stratosphere to the observations. Spectra representing both convectively- and orographically- generated gravity waves are tested. The model is able to reproduce the latitudinal variations of the observations, indicating that the MLS data yield little information about the latitudinal dependence of gravity wave sources. Longitudinal variations of the observations in the summer hemisphere, however, are most likely representative of variations in convective forcing since the model results exhibit much less variation in this direction. Simulations using the orographic spectrum exhibit large spatial variations as a result of critical level filtering by the background westerlies. This makes interpretation of the observed wintertime variances difficult. The large variances observed over the tip of South America, however, are most probably linked to orographic forcing since that is the only longitudinal sector containing any significant topography.

MW07/W/18-A4 1510

GRAVITY WAVES EFFECTS ON 4.3 MM DATA APPLICATION TO HIRS DATA

Gabriel CASTELAIN, Pierre Simoneau, Véronique Achard Onera (France)

Effect of gravity waves on atmospheric radiances in the 4,3 mm band of CO2 was studied for satellite nadir observations. The SHARC-3 and FASCODE-3 codes (developed by Phillips Laboratory) were used to compute vibrational temperatures and radiances. In an other hand, NOAA-12 HIRS 16 and 17 data will be studied to attempt to detect gravity waves on the

Western Europe area. TOVS data are processed using AAPP software (EUMETSAT). Preliminary line by line computations show variations reaching more than 10 % discrepancy on radiances near 4.33 mm, for a gravity wave with a maximum temperature amplitude of 30 K at around 50 km of altitude. Taking into account the TOVS filters width, we can expect variations from 1 to 2 % on channel HIRS-16, and from 1 to 4 % on channel HIRS-17.

MW07/W/17-A4 Invited 1530

MOUNTAIN WAVES PARAMETERIZATION

F. LOTT (LMD-CNRS, Paris 6- case courrier 99, 4 Place Jussieu, 75252 Paris Cedex 05, France, email: flott@lmd.jussieu.fr)

The problem of the representation of subgrid-scale orography (SSO) in General Circulation Models (GCM) is presented. The presentation of a particular parameterization scheme is then given, it allows to represent non-linear low-level "blocked" flow drag and gravity waves drag. Its realism is evaluated with field data, its impact and its limitation are evaluated with different sets of GCM simulations.

MW07/W/20-A4 1620

ANISOTROPY IN THE PARAMETERIZATION OF DRAG DUE TO FREELY PROPAGATING GRAVITY WAVES AND NEAR-SURFACE-FLOW DYNAMICS

John SCINOCCA, Norm McFarlane (Canadian Centre for Climate Modelling and Analysis Atmospheric Environment Service University of Victoria E-mail: john.scinocca@ec.gc.ca http://www.cccma.bc.ec.gc.ca)

A new orographic gravity-wave drag (GWD) parameterization is derived for implementation in the Canadian Climate Centre GCM. The new scheme is comprised of three principle components. The first component is a parameterization of the freely propagating gravity wave field forced by the unresolved topography (UT) in the GCM, and its interaction with the mean flow. Two waves are employed to represent the gravity-wave field launched by the UT in each GCM grid cell. The properties of each wave are derived from the linear-theory spectral density of horizontal momentum-flux for stratified flow over an elliptical obstacle (Phillips 1984). In this way, anisotropy in the gravity-wave field is represented by the direction and magnitude of momentum flux associated with each wave. The second component of the new scheme is a parameterization of drag associated with low-level wave breaking and downslope flows. The final component of the new scheme employs form drag to parameterization the drag resulting from near-surface-flow dynamics (e.g. blocking and lee-vortices). This drag is applied independently to the components of the low-level wind which are parallel and anti-parallel to two-dimensional ridge-like structure in the UT in each GCM grid cell. Consequently, in addition to retarding the flow, the form drag in the new scheme has the potential to deflect the flow along prominent unresolved topographic ridges. The Climate resulting from the implementation of the new scheme is compared with the climate obtained with the current GWD scheme (McFarlane 1987). The comparison indicates an improved tropospheric circulation with reduced anomalies from the observed climate.

MW07/W/07-A4 1640

EFFECTS OF GRAVITY WAVE DRAG INDUCED BY CUMULUS CONVECTION ON ATMOSPHERIC GENERAL CIRCULATION

Hye-Yeong CHUN, Myung-Duk Song, Jeong-Woo Kim (Department of Atmospheric Sciences and Global Environment Laboratory, Yonsei University, Seoul, 120-749, Korea, email: chy@atmos.yonsei.ac.kr); Jong-Jin Baik (Department of Environment Sciences and Engineering, Kwangju Institute of Science and Technology, Kwangju, Korea, email: jjbaik@aromi.kjist.ac.kr)

Effects of gravity wave drag induced by cumulus convection on the zonally averaged fields and planetary waves are investigated using an atmospheric general circulation model, YONU AGCM ST15. Gravity wave drag induced by convection (GWDC) is parameterized based on the method proposed by Chun and Baik (1998, JAS). In this scheme, the stress at individual cloud top is calculated explicitly based on the linear theory of thermally induced internal gravity waves, and the vertical distribution of the stress is determined by a saturation hypothesis using a Richardson-number-dependent wave breaking formulation.
Two one-year integrations with and without GWDC parameterization for perpetual run in July are performed, and the last 90 day-averaged fields are used for analysis. The control simulation without GWDC parameterization reveals a systematic bias both in the zonally averaged temperature and wind. There is cold bias in the midlatitude-to-polar region of the Southern Hemisphere and polar region of the Northern Hemisphere and warm bias in the tropical lower stratosphere. Related to this temperature bias, polar jets are too strong compared with observations and no separation between the polar and subtropical jets is detected in the Southern Hemisphere. The simulation with GWDC parameterization shows that the magnitude of the stress on the cloud top is large near the Western Pacific and North Africa mainly by deep cumulus convection in the inter-tropical convergence zone. Even though the tendency of the zonal wind by GWDC is large in the regions of strong stress on the cloud top, the effects of GWDC in the zonally averaged wind and temperature are dominant in the midlatitude of the Southern Hemisphere. This is because GWDC activates the vertically propagating planetary waves in the westerly region and increases the southward transport of eddy momentum flux, hence reducing the westerly jet in the Southern Hemisphere. The stronger westerly bias in the Southern Hemisphere polar jets is alleviated by 7 m/s/day, and cold bias in the midlatitude-to-polar regions in the Southern Hemisphere and polar region in the Northern Hemisphere by 1 K.

MW07/E/06-A4 1700

SENSITIVITY OF THE UKMO UNIFIED MODEL TO A PARAMETERIZED GRAVITY WAVE SPECTRUM

Adam A. SCAIFE (U.K. Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SZ, UK, email: aascaife@meto.gov.uk); Christopher D. Warner (Centre for Atmospheric Science, D.A.M.T.P., University of Cambridge, Silver Street, Cambridge CB3 9EW, UK.); Neal Butchart, John Austin (U.K. Meteorological Office, London Road, Bracknell, Berkshire, RG12 2SZ, UK.)

The effects of non-orographic gravity waves are represented in the UKMO Unified Model using a simplified version of Warner and McIntyre's full power spectral model (Warner and McIntyre, 1996). The domain of the model is extended through the mesosphere to 1Pa to capture the effects of gravity wave breaking in the mesosphere. The launch height for the waves and the launch spectrum are both prescribed in this scheme. Multiannual integrations with a range of launch levels and launch spectra are used to investigate the sensitivity of the planetary scale flow to changes in the parametrized waves. Results are also compared to a control simulation where Rayleigh friction is used to moderate winds in the mesosphere. Significant effects on the model simulations are found in the tropical stratosphere at the level of the observed QBO and also in the polar night jet in the upper stratosphere. The effect on the model's cold polar bias will also be discussed.

MW07/W/13-A4 1720

EIKONAL THEORY FOR THE SPECTRAL DISTRIBUTION AND TRANSFER OF ENERGY IN THE ATMOSPHERIC GRAVITY WAVEFIELD

Claude SOUPRAYEN (Department of Applied Mathematics and Theoretical Physics, DAMTP, University of Cambridge, Siver Street, UK, email: C.Souprayen@damtp.cam.ac.uk); Albert Hertzog, Alain Hauchecorne (Serviced'Aeronomie du CNRS, Verrieres-Le-Buisson, FRANCE, email: A.Hertzog@aerov.jussieu.fr); Jacques Vanneste (Dept of Mathematics &Statistics, University of Edinburgh, UK, email: vanneste@maths.ed.ac.uk)

The parameterization of gravity waves in the atmosphere relies on an accurate description of the spectral distribution of their pseudo-energy and pseudo-momentum and of the transfer of such quantities toward the small dissipative scales. The weakly non-linear off-resonant interaction that could be responsible for the observed spectra is studied using an eikonal description for the wave action transport and ray-tracing techniques. The formation and maintenance of gravity wave spectra during the dispersive propagation of the wave field in realistic 3D "random" background wind and temperature fields is analysed; the commonly observed spectra are emerging from arbitrary wave sources distribution. In a simplified 1D stochastic model of the vertical propagation, it is shown that the transport (and the dissipation) is strongly related to the mean, the variance and the vertical correlation length of the vertical shear of horizontal wind. Deposition of pseudo-energy and pseudo-momentum results from the continuous spectral transfer toward and a removal by dissipation at small scales.

MW07/W/05-A4 1740

PARAMETERIZATION OF THERMAL EFFECTS OF SATURATING GRAVITY WAVES

A.S. MEDVEDEV, G .P. Klaassen (York University, Toronto, Canada)

Breaking/saturating gravity waves (GWs) do not only provide drag on the mean flow due to their momentum deposition, but also affect the background thermally because of the associated energy flux divergence. We present a rigorous derivation of terms describing thermal effects of GWs on the mean flow. The parameterization is based on the corresponding energy cycle for wave/mean flow interactions, and on our recent non-linear theory of GW spectra. The combined effect of saturating GW is to produce both the differential heating/cooling by inducing a downward wave heat flux, and an irreversible wave energy loss into a heat. The former effect can also be represented as a thermodiffusion acting on the mean potential temperature, although there is no mean momentum diffusion counterpart exists. The parameterization requires the source GW spectrum as the only tunable parameter. Results of numerical simulations with the Canadian Middle Atmosphere Model will be shown, which demonstrate an important role of GW thermal effects in the strato- mesosphere.

MW08/W/02-A2 1405

OBSERVATIONAL STUDIES OF THE QUASI-DECADAL OSCILLATION

Lon HOOD (Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721, USA, email: lon@lpl.arizona.edu)

Previous studies have identified evidence for a quasi-decadal oscillation (QDO) of meteorological parameters and ozone in both the lower and the upper stratosphere. Here, we report a new statistical study of updated NCEP/NCAR reanalysis data and satellite-derived ozone data in order to investigate further the origin and characteristics of this oscillation. The analysis is limited to the period from 1979 to the present during which the data are highest in quality and upper stratospheric data are available. In the upper stratosphere, where photochemical and radiative forcing by solar UV flux variability is most direct, an in-phase QDO in ozone and temperature is present at low latitudes over nearly two 11-year cycles. An associated modulation of the mid-latitude zonal wind near the stratopause occurs during the early winter. In the lower stratosphere, geopotential heights exhibit a QDO with maximum amplitude near 30 mb and near 30 degrees latitude in each hemisphere. An associated modulation of column ozone and zonal wind is also present at low and middle latitudes, respectively. The derived characteristics of the stratospheric QDO represent important potential constraints on sun-climate models.

MW08/E/03-A2 1430

THE INFLUENCE OF THE SUNSPOT CYCLE ON THE GLOBAL STRATOSPHERE

Harry VAN LOON (National Center for Atmospheric Research, P.O. Box 3000, Boulder, Colorado, USA); Karin Labitzke (Freie Universitat Berlin, Carl-Heinrich-Becker-Weg 6-10, 12165 Berlin, Steglitz, Germany)

The NCEP/NCAR re-analyses of the global data have made it possible to examine the influence of the 11-year sunspot cycle on the stratosphere as high as the 10-hPa level (about 30 km above sea level). The correlations between the solar cycle and the 30-hPa heights on the Northern Hemisphere, using a 40-year data set from the Freie Universitat Berlin, showed a strong signal which is repeated in the NCEP/NCAR data. The correlation pattern on the Southern Hemisphere is similar to the one on the Northern Hemisphere, not only at 30 hPa but at all the available levels in the stratosphere.
The largest correlations with the geopotential heights move poleward from winter to summer within each hemisphere, and the largest temperature correlations move from one summer hemisphere to the other. The first eigenvector in a principal component analysis of the 30-hPa heights in summer and in the annual mean has the same areal shape as the correlation between the solar cycle and the heights, and the time series of its amplitude is in phase with the 11-year solar cycle.

MW08/E/02-A2 1500

THE QBO'S INFLUENCE ON THE SOLAR SIGNAL IN THE GLOBAL STRATOSPHERE DURING THE NORTHERN WINTER

Karin LABITZKE (Freie Universitat Berlin, Carl-Heinrich-Becker-Weg 6-10, 12165 Berlin, Steglitz, Germany); Harry van Loon (National Center for Atmospheric Research, P.O. Box 3000, Boulder, Colorado, USA)

The talk deals with correlations between the re-analyzed NCEP/NCAR, global stratospheric data below 10hPa and the 11-year solar cycle. In the northern summer the correlations with the temperatures and geopotential heights are strong and positive on the Northern Hemisphere and as far south as 30S, whereas they are weaker in the southern summer all over the earth. If, however, the northern winter data are stratified according to the phase of the QBO in the lower stratosphere, the correlations in the Arctic are large and positive in the west years, but only zero to 0.3 over the rest of the globe. In the east years, however, the arctic correlations are negative and to the south the correlations are positive and strong in the tropical and temperate latitudes of both hemispheres, as they are in the unstratified data during the other seasons. Qualitatively, this difference between east and west years stems form the fact that teleconnections in the stratosphere and the solar influence work in the same direction in the east years but oppose each other in the west years.

MW08/W/01-A2 1530

SOLAR CYCLE VARIABILITY, OZONE, AND CLIMATE

Drew SHINDELL, David Rind, Nambeth Balachandran (NASA Goddard Institute for Space Studies and Center for Climate Systems Research, Columbia University, 2880 Broadway, New York, NY, USA 10025); Judith Lean_, Patrick Lonergan_ (Center for Space Research, Naval Research Laboratory, Washington DC, USA 20375); E.O. Hulburt (Space Science and Applications, Inc., 2880 Broadway, New York, NY, USA 10025)

Solar variability's capacity to influence climate, both on decadal and century time scales, is among the most controversial issues in global climate change. Previous modelling and observational studies have suggested a correlation between solar cycle variability and surface climate, but have failed to convince the community since the models could not reproduce observed quasi-decadal variations. In this study, we show how upper stratospheric ozone changes amplify observed, small 11-year solar cycle irradiance changes in the Goddard Institute for Space Studies (GISS) tropospheric/stratospheric general circulation model (GCM). Circulation changes initially induced in the stratosphere subsequently penetrate into the troposphere, affecting climate, demonstrating a dynamical coupling between the stratosphere and troposphere. The model reproduces observations, including the well-documented geopotential height variations, implying that observed 11-year oscillations are likely driven, at least partially, by solar variability.

MW08/W/04-A2 1630

GLOBAL DYNAMICAL EFFECTS OF THE QBO

Mark P. BALDWIN (Northwest Research Associates, Bellevue, WA, USA)

This talk will provide an overview of the dynamical effects of the equatorial quasi-biennial oscillation (QBO) on the extratropical circulation of the stratosphere. Observations show that the wintertime Northern hemisphere stratospheric polar vortex is modulated by the phase of the equatorial QBO. The high-latitude stratospheric vortex tends to be stronger during the winter, and sudden warmings are less likely when the QBO is in its west phase at 40 hPa. Modulation of the Southern hemisphere vortex is confined to middle latitudes at the edge of the polar vortex during May–October. The difference between west and east phase composites of zonal mean wind during November, at the time of the final warming in the southern hemisphere, are comparable to January in the northern hemisphere. Southern hemisphere effects are best seen using 25-hPa equatorial winds.
Observations of effects from the QBO are supported theoretically by a mechanism involving modification of the wave guide for upward and equatorward propagating planetary waves. When the QBO is in its east phase, the wave guide in the northern hemisphere is narrower, and waves tend to be more focused toward the polar cap, where their convergence results in a deceleration of the zonal-mean wind. Studies with mechanistic 3-D models and GCMs confirm this mechanism. During winter in the northern hemisphere, the QBO appears to excite the Arctic Oscillation (AO), a deep, largely zonally symmetric mode which couples the stratosphere and the troposphere. AO anomalies are observed to propagate downward through the stratosphere and troposphere on a time scale of less than a month. This downward propagation may be a general mechanism for downward communication of stratospheric circulation anomalies associated with the QBO or other forcings.

MW08/E/01-A2 1700

QUASI-DECADAL, QUASI-BIENNIAL, AND BIENNIAL OSCILLATION IN THE NORTHERN WINTER STRATOSPHERE

C. MARQUARDT (Freie Universität Berlin, Institut für Meteorologie, Carl-Heinrich-Becker-Weg 6-10, 12165 Berlin, Germany, email: marq@strat01.met.fu-berlin.de)

The Quasi-Decadal (or Ten-to-Twelve Year) Oscillaton (QDO, or TTO) was discovered as a modulation of the tropical Quasi-Biennial Oscillation's (QBO) influence on high latitude dynamics during northern hemisphere winter. Later on, statistical evidence was found that a global QDO has been in phase with the solar cycle for more than three decades irrespective of the state of the tropical QBO.
But the issue of a possible interaction between QBO and QDO during northern hemisphere winter has not yet been resolved. Instead, statistical evidence has been presented supporting both (1) a unique QBO effect in high latitudes (as proposed by Holton and Tan) as well as (2) a coupled QBO/QDO phenomenon (as proposed by Labitzke and Labitzke and van Loon). And recently, (3) an additional Biennial Oscillation (BO) has been found to dominate stratospheric frequency spectra at high latitude; the BO has been used as an argument against the reality of the QDO. Unfortunately, the physical cause of the extratropical BO is as uncertain as the origin of the QDO, and why the latter should be related to the solar cycle.
In this paper it is demonstrated that the extratropical BO can also be understood as a consequence of the interaction between annual cycle, tropical QBO and QDO. Contradictions between previously published statistical studies (Holton/Tan vs. a coupled QBO/QDO) will be resolved by showing that the development of wintertime dynamics follows a two stage process: During early and mid winter, a Holton/Tan-like oscillation dominates, but gets superseded by a Labitzke/van Loon-like behaviour propagating from upper levels into the mid and lower stratosphere during late winter.

MW08/W/06-A2 1730

EFFECTS OF SOLAR CYCLE VARIABILITY ON THE LOWER STRATOSPHERE AND THE TROPOSPHERE

Nambath K. BALACHANDRAN, David Rind, Patrick Lonergan, Drew T. Shindell (all at Goddard Institute for Space Studies, 2880 Broadway, New York, NY 10025, U.S.A.,
email: cdnkb@giss.nasa.gov)

The effects of solar irradiance variability on the lower stratosphere and the troposphere are investigated using observed and general circulation model (GCM) generated 30 mb and 100 mb geopotential heights. The annual and seasonal averages of the height differences between solar maximum and solar minimum conditions are evaluated. In the sub-tropics, observations indicate statistically highly significant increased geopotential heights during solar maximum, compared to solar minimum, in composite annual and seasonal averages. The model simulates this feature reasonably well, although the magnitude and statistical significance of the differences are often weaker than in observations, especially in summer. Both the observations and the model results show a strong di-pole pattern of height differences when the data are partitioned according to the phase of the QBO, with the pattern reversing itself with the change in the phase of the QBO. The solar effects on the lower atmosphere are interpreted as resulting from the effects of UV change on E-P flux divergence in the stratosphere and the associated circulation change below.

IMPACT OF LAND-USE CHANGE ON NUTRIENT LOADS FROM DIFFUSE SOURCES (ICWQ, ICCE, ICASVR)

SMALL SCALE FIELD STUDIES OF LAND USE IMPACT ON WATER QUALITY

HS3/W/01-A1 0900

SIMPLIFIED CLASSIFICATION OF HYDROLOGICAL TERMINOLOGY FOR PHOSPHORUS TRANSFER

Neil PREEDY (Institute of Grassland and Environmental Research, North Wyke, Okehampton, EX20 2SB, UK) Louise Heathwaite (Department of Geography, University of Sheffield S10 2TN, UK, email: a.l.heathwaite@sheffield.ac.uk) Phil Haygarth and Rachel Matthews (Institute of Grassland and Environmental Research, North Wyke, Okehampton, EX20 2SB, UK)

Understanding the importance of surface and subsurface hydrological pathways is critical to effectively manage diffuse transfers of phosphorus (P) from agricultural soils. However, limited understanding of the complexities inherent within the hydrological regime and unfamiliarity with hydrological terminology, can sometimes be a source of confusion for agronomists and soil scientists concerned with P transfer. Consistent use of terminology can help eliminate confusion and the use of ambiguous terms such as "runoff" and "leaching" that are commonly misused. The hydrological terms and processes defined here are identified at the spatial and temporal scales where they occur, and the potential of vertical and lateral water flows for P transfer, both over and through the soil, are discussed.

COMPARISON OF NUTRIENT OUTPUTS FROM TWO LOWLAND WATERSHEDS WITH DIFFERENT AGRICULTURAL PRACTICES

Kazimierz BANASIK (Department of Hydraulic Structures, Warsaw Agricultural University, ul. Nowoursynowska 166, 02-787 Warsaw, Poland, email: banasik@alpha.sggw.waw.pl) J. Kent Mitchell, Sharyl E. Walker (Department of Agricultural Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801, USA) Elzbieta Rudzka (Environmental Protection Laboratory of the "Pronit" Factory, 26-600 Pionki, Poland)

Results of four-year water quality monitoring programmes carried out in two small, lowland agricultural watersheds with different agricultural practices, the Upper Little Vermilion River (ULVR) located in central Illinois and the Zagozdzonka River located in central Poland, were analysed. Nitrate and orthophosphate concentrations and loads are presented and discussed in relation to meteorological conditions and hydrological responses of the watersheds. The watershed with intensive agricultural practices (ULVR) generates runoff with higher nutrient concentrations. Concentrations of the considered nutrients were, in the case of N-NO3 about 7.6 times, and in the case of P-PO4 about 2.3 times higher in the ULVR than in the Zagozdzonka River.

HS3/W/03-A1 0950

THE NITROGEN COMPOSITION OF STREAMS DRAINING GRASSLAND AND FORESTED CATCHMENTS: INFLUENCE OF AFFORESTATION ON THE NITROGEN CYCLE IN UPLAND ECOSYSTEMS

P. J. CHAPMAN, A.C. Edwards (Macaulay Land Use Research Institute, Craigiebuckler, Aberdeen AB15 8QH, UK, email: p.chapman@mluri.sari.ac.uk) B. Reynolds (Institute of Terrestrial Ecology, Deiniol Road, Bangor, Gwynedd LL57 2UP, UK) C. NEAL (Institute of Hydrology, Wallingford, Oxfordshire OX10 8BB, UK)

The nitrogen (N) composition of streams draining three moorland and three plantation forest catchments in mid-Wales was investigated and compared. Samples of stream water were collected every four weeks over one year and analysed for total dissolved nitrogen (TDN), nitrate (NO3), ammonium (NH4), dissolved organic nitrogen (DON) and dissolved organic carbon (DOC). There was no significant difference in TDN concentrations between forested and moorland streams. However, NO3 concentrations were significantly larger in the forested streams and DON and DOC concentrations were significantly larger in the moorland streams. Nitrate and DON also displayed contrasting seasonal patterns: NO3 concentrations were largest in the winter, while the opposite was observed for DON and DOC. The results confirm conclusions from other studies that afforestation of upland semi-natural vegetation can promote nitrification within the soil system, which is reflected in a change in the TDN composition of stream water. The results also emphasize the need to consider both inorganic and organic forms of N in studies that assess the impact of land management strategies on N cycling in terrestrial and aquatic ecosystems.

General Aspects of Nutrients in Waters

HSA3/W/05-A1 1015

LOSS OF NITROGEN THROUGH LEACHING AND RUNOFF FROM TWO POTATO LAND-USE SYSTEMS ON DIFFERENT SOILS

U. C. SHARMA (ICAR Research Complex for NEH Region, Barapani, Meghalaya 793103, India)

Field experiments conducted for two years on three soils varying in texture, planted with potatoes grown by two methods of cultivation—terraced and bun (traditional method on hillslopes) revealed that nitrogen loss through leaching and runoff increased with increased application of nitrogen and was significantly influenced by the nature of the soil, the amount of rainfall received and the method of cultivation followed. The mean N loss was 14.2, 16.5 and 30.3 kg ha-1 through leaching and 5.8, 5.5 and 4.0 kg ha-1 through runoff in terraced and 7.1, 9.8 and 19.9 kg ha-1 in leaching and 19.5, 19.4 and 33.7 kg ha-1 in runoff in bun method from soils S1, S2 and S3, respectively. The NO3-N content of the soil was observed to be higher near the surface (0–20 cm) compared to lower depths (20–40 cm and 40–60 cm) in both methods of potato cultivation and it increased with increased application of nitrogen. Applied nitrogen increased the dry matter yield (tuber + shoots) of potato, and productivity was found higher in light textured soil.

HSA3/W/05-A1 1110

NITRATE LOSSES UNDER VARIOUS CROPPING SYSTEMS

J. Kent MITCHELL, Sharyl E. Walker, Michael C. Hirschi and Richard A. C. Cooke (Department of Agricultural Engineering, University of Illinois at Urbana-Champaign, 1304 West Pennsylvania Avenue, Room 332, Urbana, Illinois 61801, USA, email: j.k.m.@sugar.age.uiuc.edu)

The effectiveness of nitrogen management systems in reducing the movement of nitrate in surface and subsurface flow in the Little Vermilion River watershed is presented. Nitrate in subsurface tile flow have been monitored for six years from fields with various tillage and cropping management practices. Water samples have also been obtained along the mainstream of the watershed. Concentrations of nitrate differed little among specific sampling locations along the river, but they definitely followed a seasonal cycle. The pre-plant anhydrous-N application systems with average nitrogen application of 108 kg ha-1 year-1 had a mean concentration of nitrate-N of 16.8 mg l-1 while the side-dress and manure application systems with average nitrogen application of 92 kg ha-1 year-1 had a mean concentration of nitrate-N of 10.2 mg l-1. The mean concentration of nitrate-N from a permanent meadow field was 1.0 mg l-1.

Phosphorus in Waters

HS3/W/06-A1 1135

TRANSFER OF PHOSPHORUS FROM SMALL AGRICULTURAL BASINS WITH VARIABLE SOIL TYPES AND LAND USE

P. J. A. WITHERS (ADAS Bridgets, Martyr Worthy, Winchester, Hampshire SO21 1AP, UK, email: paul_withers@adas.co.uk) R. M. Dils (Environment Agency, National Centre for Ecotoxicology and Hazardous Substances, Evenlode House, Howbery Park, Wallingford, Oxfordshire OX10 8BD, UK) R. A. Hodgkinson (ADAS Boxworth, Boxworth, Cambridge, Cambridgeshire CB3 8NN, UK)

Three small rural basins in England with different soil types and farming systems were monitored from November 1994 to July 1998 to determine the amounts, forms, timing and pathways of diffuse phosphorus (P) transfer in land runoff. Annual loads of total phosphorus (TP) measured in two lowland and one upland basin ranged up to 4.2 and 1.4 kg ha-1, respectively and were heavily dependent on basin flow. In all three basins, most P was transported in particulate (PP) form during high flow rates in winter when stream biological activity is low. However, comparison of two monitoring programmes in one basin also indicated elevated loads of soluble P under lower intensity storms. Monitoring of individual field tile drains in the two lowland basins indicated that much of the P transfer was agriculturally derived. The amount of flow needed to generate P transfer was greater, and the concentration of P in the runoff under equivalent flows was lower, under upland grass than under arable or mixed arable/grass cropping.

HS3/W/07-A1 1200

INVESTIGATIONS ON PHOSPHORUS LEACHING FROM SANDY SOIL

T. TISCHNER (Institute of Freshwater Ecology and Inland Fisheries, Rudower Chaussee 6a, D-12484 Berlin, Germany, email: tischner@igb-berlin.de)

Investigations on phosphorus leaching were conducted at a field site with sandy soil. From soil sample analyses a linear relationship was found between total phosphorus (Pt) and the amount of water-soluble phosphorus (Pw). Regardless of soil depth and sampling point location only approximately 5% of Pt is water soluble. At a small test site at the border of the field, soil solution was extracted using ceramic- and nylon suction cups. The soil solutions showed that the concentration of total dissolved phosphorus (TDP) decreased significantly with depth. An averaged concentration of around 0.8 mg l-1 was found at a depth of 30 cm, whereas at 180 cm about 0.1 mg l-1 was observed. Phosphorus input to the groundwater is in the range of 0.1 kg ha-1 year-1). At that site organic P forms are more important for phosphorus leaching than inorganic fractions. Since the start of investigations no more fertilizer has been applied at the small test site which has led to decreasing ionic strength in the topsoil (30 cm). In contrast, at a depth of 30 cm a continuous increase in the concentration of soluble phosphorus was observed. It is shown that this increase in the concentration of soluble P should be attributed to declining ionic strength and especially to declining Ca concentration. As a consequence changing land use from cultivation to fallow land may lead to enhanced mobilization of previously accumulated phosphorus.

HS3/W/08-A1 1225

PHOSPHORUS TRANSPORT FROM DIFFUSE AGRICULTURAL SOURCES: SHALLOW SUBSURFACE PATHWAYS IN GRASSLAND SOILS

R. M. DILS (Environment Agency, National Centre for Ecotoxicology and Hazardous Substances, Evenlode House, Howbery Park, Wallingford, Oxfordshire OX10 8BD, UK, email: r.dils@qub.ac.uk) A. L. Heathwaite (Department of Geography, University of Sheffield, Sheffield S10 2TN, UK)

Phosphorus (P) can be transferred from grassland soils along a number of surface and subsurface hydrological pathways. Currently, our understanding of subsurface transport mechanisms for P is limited. This research examines P transport in shallow subsurface pathways (matrix and macropore flow) under controlled laboratory conditions, and under true field conditions. Simulated rainfall experiments were performed on triplicate soil cores (0.01 m3) extracted in summer and winter from an intensively managed grazed grassland field. Matrix and macropore flow samples were collected in situ in this field. Despite the differences in sampling approach, the forms and amounts of P transported in matrix and macropore flow exhibited distinct similarities. In summer matrix flow, for example, total P (TP) concentrations ranged from 47–185 µg l-1 in the field and from 76–163 µg l-1 in leachate from cores, with soluble P constituting 65% and 61% of TP, respectively. These findings further current understanding of field-scale P transport processes.

REGIONAL SCALE MONITORING STUDIES OF LAND USE IMPACT ON WATER QUALITY

General Aspects of Nutrients in Waters

HS3/W/09-A1 1400

NUTRIENT DISCHARGE BY GROUNDWATER AND RIVERS INTO LAKE BIWA, JAPAN

Makoto TANIGUCHI (Department of Earth Sciences, Nara University of Education, Nara 630-8528, Japan, email: makoto@nara-edu.ac.jp) Norio Tase (Institute of Geoscience, University of Tsukuba, Ibaraki 305-8571, Japan)

Nutrient discharges not only by rivers but also by groundwater have been evaluated in Lake Biwa basin, Japan. In the eastern part of the basin, the densely populated urbanized areas and many agricultural fields have brought a large amount of nutrients such as NO3-, SO42-, Cl- and Na+ into Lake Biwa. The NO3- concentration of the groundwater discharged from the lake bottom is three times larger than that of river water. A high concentration of Ca2+ in three rivers and groundwater near those rivers was also found in the areas where the main geology consists of limestone. Land use, population, geology and groundwater flow systems are keys to understanding the nutrient discharge into the lake by rivers and groundwater.

HS3/W/10-A1 1425

THE EFFECTS OF INTENSIVE DAIRY FARMING ON STREAM WATER QUALITY IN NEW ZEALAND

Harvey J. E. RODDA (National Institute of Water and Atmospheric Research—NIWA, PO Box 11-115, Hamilton, New Zealand; now at Risk Management Solutions Ltd, 10 Eastcheap, London EC3M 1AJ, UK, email: harvey.rodda@riskinc.com) Robert J. Wilcock (NIWA, PO Box 11-115, Hamilton, New Zealand) Ude Shankar (NIWA, PO Box 8062, Christchurch, New Zealand) Bruce S. Thorrold (AgResearch, Private Bag 3123, Hamilton, New Zealand)

This paper describes a three-year study on the effects of intensive dairy farming on the water quality of the Toenepi basin, near Hamilton in New Zealand's North Island. The study incorporated a detailed programme of water quality and flow monitoring, land use surveys, soil surveys, and stream ecology surveys. The monitoring not only generated a better understanding of the effects of intensive dairy farming on stream water quality, but also provided input and calibration data for a distributed basin-scale water quality model, which was set up to test the effects of a number of land-use change scenarios. The results of the monitoring programme showed higher levels of nutrients compared to other New Zealand streams, but sediment levels were not particularly high. The model scenario testing confirmed that any further intensification of land use could lead to stream nitrate-nitrogen concentrations above WHO guidelines.

HS3/W/11-A1 1450

NUTRIENT CONCENTRATIONS AND FLUXES IN TRIBUTARIES TO THE SWAN-CANNING ESTUARY, WESTERN AUSTRALIA

Norman E. PETERS (US Geological Survey, 3039 Amwiler Road, Suite 130, Atlanta, Georgia 30360, USA, email: nepeters@usgs.gov) Robert Donohue (Waters and Rivers Commission, Hyatt Centre, East Perth, Western Australia 6004, Australia)

In Western Australia, catchment nutrient availability on an areal basis is primarily controlled by the disposal of animal waste and the type and rate of fertilizer application, particularly in coastal areas. The coastal areas receive notably higher rainfall and have more intense horticulture and animal production than inland areas, and are undergoing rapid urbanization, particularly adjacent to the estuary. Also, the surficial aquifers on the coastal plain are generally sandy having a low nutrient retention capacity and rapidly transmit soluble and colloidal material through the subsurface. In the Swan-Canning basin, high air and soil temperatures and seasonally arid conditions cause rapid mineralization of nitrogen and phosphorus. The nutrients are subsequently available for transport during the onset of seasonal wet weather, which typically begins during the period from late April to June. In addition to the rapid mobility of nutrients in streamwater from agricultural areas during the wet season, drains in urban areas, which typically have high nutrient concentrations, also are an important source of nutrients as the drains flow directly to the estuary throughout the year.

HS3/W/12-A1 1515

STUDIES OF EROSION AND SOIL LOSS IN THE SEMIARID NORTHEASTERN REGION OF BRAZIL

Vajapeyam S. SRINIVASAN, José de Araújo Pereira and Carlos de Oliveira Galvão (Department of Civil Engineering, Centre for Sciences and Technology, Federal University of Paraíba, Campus II, Campina Grande 58100-970, Paraíba, Brazil, email: srinivas@rechid.ufpb.br)

The effects of land clearing and some of the cultivation practices are analysed for a semiarid region in the northeast of Brazil, in terms of the runoff generated and the soil erosion caused. The data collected in an experimental basin with microbasins of about 0.5 ha in area and various erosion plots were utilized. The response of these micro-basins and plots to the events of rainfall as well as the influence of such factors as land cover, slope, etc. are presented. The most significant result is the ability of the native vegetation in preventing the soil erosion in spite of its sparse nature and fragility.

HS3/W/13-A1 1615

CHANGE IN DISSOLVED LOADS AND BIOGEOCHEMICAL PROCESSES LINKED TO THE AIR TEMPERATURE FROM LOW MOUNTAINOUS TO SUB-ALPINE WATERSHEDS

Tomohiro NARUOKA (Institute of Environmental Science, University of Tsukuba, 1-1-1 Tennodai, Tsukuba, Ibaraki 305-8572, Japan, email: lemieux@qb3.sonet.ne.jp) Shin'ichi Onodera (Department of Natural Environmental Sciences, Hiroshima University, 1-7-1, Kagamiyama, Higashi-hiroshima, Hiroshima 739-8521, Japan)

In order to clarify the effect of air temperature on biogeochemical processes in various environments, we confirmed the changes in dissolved load fluxes and biogeochemical processes with air temperature from low mountainous to sub-alpine watersheds in a part of Kanto mountains, west of Tokyo. The solute concentrations in spring water and soil water increased with a decrease in elevation. The organic acids concentrations in the surface soil showed not only seasonal variations but also variations depending on altitude change. This result suggests that organic acids, produced by microorganisms in the surface soil, especially in the summer season cause the seasonal variations in the solute concentrations. Concentrations of organic acids were extremely low around the elevation of 1500 m where the soil temperature at a depth of 10 cm was below 15ºC in summer. The relationship between solute concentrations and temperature was clear in the deeper soil. This result suggests that the variation in the reaction rate of chemical weathering is related to temperature.

HS3/W/14-A1 1640

NITRATE IN GROUNDWATER OF THE MIDWESTERN UNITED STATES: A REGIONAL INVESTIGATION ON RELATIONS TO LAND USE AND SOIL PROPERTIES

Dana KOLPIN (US Geological Survey, 400 S. Clinton Street, Iowa City, Iowa 52244, USA, email: dwkolpin@usgs.gov) Michael Burkart (National Soil Tilth Laboratory, 2150 Pammel Drive, Ames, Iowa 50011, USA) Donald Goolsby (US Geological Survey, Box 2506, Denver Federal Center, Lakewood, Colorado 80225, USA)

The intense application of nitrogen-fertilizer to cropland in the midwestern United States has created concern about nitrate contamination of the region's aquifers. Since 1991, the US Geological Survey has used a network of 303 wells to investigate the regional distribution of nitrate in near-surface aquifers of the midwestern United States. Detailed land-use and soil data were compiled within a 2-km radius of 100 unconsolidated wells in the regional network to determine relations to nitrate concentrations in groundwater. For land use, the amount of irrigated land was directly related to nitrate concentrations in groundwater. For soils, the general water table depth and soil factors associated with rates of water movement were directly related to nitrate concentrations in groundwater.

HS3/W/15-A1 1705

SOURCES OF NITRATE IN WATER FROM SPRINGS AND THE UPPER FLORIDAN AQUIFER, SUWANNEE RIVER BASIN, FLORIDA

Brian G. KATZ (US Geological Survey, 227 N. Bronough Street, Suite 3015, Tallahassee, Florida 32301, USA, email: bkatz@usgs.gov) H. David Hornsby (Suwannee River Water Management District, 9225 County Road #49, Live Oak, Florida 32060, USA) Johnkarl F. Bohlke (US Geological Survey, 431 National Center, Reston, Virginia 20192, USA)

In the Suwannee River basin of northern Florida, nitrate-N concentrations are 1.5 to 20 mg l-1 in waters of the karstic Upper Floridan aquifer and in springs that discharge into the middle reach of the Suwannee River. During 1996–1997, fertilizers and animal wastes from farming operations in Suwannee County contributed approximately 49% and 45% of the total N input, respectively. Values of d15N-NO3 in spring waters range from 3.9‰ to 5.8‰, indicating that nitrate most likely originates from a mixture of inorganic (fertilizers) and organic (animal waste) sources. In Lafayette County, animal wastes from farming operations and fertilizers contributed approximately 53% and 39% of the total N input, respectively, but groundwater near dairy and poultry farms has d15N-NO3 values of 11.0–12.1‰, indicative of an organic source of nitrate. Spring waters that discharge to the Suwannee River from Lafayette County have d15N-NO3 values of 5.40–8.39‰, which are indicative of both organic and inorganic sources. Based on analyses of CFCs, the mean residence time of shallow groundwater and spring water ranges between 8–12 years and 12–25 years, respectively.

MODELLING THE IMPACT OF LAND USE ON NUTRIENT BEHAVIOUR IN SMALL SCALE WATER QUALITY STUDIES

Nitrogen in Waters

HS3/W/16-A1 1730

RELATING POTENTIAL DENITRIFICATION RATES TO STREAMFLOW VARIABILITY

Bente CLAUSEN (Department of Civil Engineering, University of Canterbury, Private Bag 4800, Christchurch, New Zealand; previously at: Department of Earth Sciences, Aarhus University, Denmark; email: b.clausen@civil.canterbury.ac.nz) Charles P. Pearson and Malcolm T. Downes (National Institute of Water and Atmospheric Research (NIWA), PO Box 8602, Christchurch, New Zealand)

Measurements of denitrification enzyme activity (DEA) were made in riparian zones within 27 subcatchments of a 114 km2 catchment in Denmark during summer 1996, and the rates were related to the hydrological regime of the subcatchments. The hydrological regime was characterized spatially by the specific mean flow (QMEAN) and the baseflow index (BFI), which were almost linearly related. DEA was significantly higher in the top 50 cm soil samples compared with the samples taken from between 50 and 100 cm depth. DEA and BFI were found to be weakly related with higher DEA rates in upstream subcatchments with lower QMEAN and BFI (higher proportion of quickflow).

HS3/W/17-A2 0900

A SIMPLE MODELLING APPROACH TO IDENTIFY PROCESSES CONTROLLING STREAM NITRATE IN AN AGRICULTURAL CATCHMENT

S. M. DUNN, P. Domburg, A. C. Edwards and R. C. Ferrier (Macaulay Land Use Research Institute, Craigiebuckler, Aberdeen AB15 8QH, UK, email: mi586@mluri.sari.ac)

The processes involved in nitrate generation at the catchment scale are highly complex. This paper investigates whether it is possible to use a modelling approach to derive a simplified set of processes that explain the temporal variability of stream nitrate. The approach is tested on an agricultural catchment where the majority of stream nitrate originates from diffuse runoff from the land. A simple nitrate transport model is combined with a hydrological model and different scenarios to describe potential nitrate leaching mechanisms are tested as drivers of the model. The resulting predictions of stream nitrate are compared with data from continuous sampling. The results suggest that in this catchment mineralization is a more important process in determining nitrate leaching than direct losses following fertilization of crops.

HS3/W/18-A2 0925

MATHEMATICAL MODELLING FOR ESTIMATING THE SEASONAL CHANGES IN STREAMWATER NO3--N CONCENTRATION

Takao TAMURA (Department of Civil Engineering, Takamatsu National College of Technology, 355 Chokushi-cho, Takamatsu City, Kagawa 761-8058, Japan, email: tamu@takamatsu-nct.ac.jp) Hiromu Yoshida and Michio Hashino (Department of Civil Engineering, The University of Tokushima, 2-1 Minami-jousanjima-cho, Tokushima City, Tokushima 770-8506, Japan)

A NO3--N runoff tank model was developed for describing seasonal changes of NO3--N concentration of streamwater in forested mountain basins. Three hydrochemical and biochemical processes, namely advection, solute exchange between mobile and immobile regions in the soil and nitrification are considered in the model. Three model types, Models A, B and C respectively, were applied to data obtained in a forested mountain basin in Japan. "Model C" which takes account of all three processes effectively described seasonal changes of NO3--N concentration in streamwater. However, "Model A" which represents only the advection process, and "Model B" which includes both advection and solute exchange processes, could not. It is suggested that it is necessary to take all three processes into consideration if any model is to be regarded as valid.

HS3/W/19-A2 0950

MODELLING THE IMPACT OF LAND-USE CHANGE ON WATER QUALITY IN LOWLAND CATCHMENTS: THE ROLE OF DYNAMIC NITROGEN RESERVOIRS

F. WORRALL (Department of Geological Sciences, South Road, Durham DH1 3LE, UK, email: fred.worrall@durham.ac.uk) T. P. Burt (Department of Geography, South Road, Durham DH1 3LE, UK)

The consequences of a decline in soil nitrogen following ploughing of permanent pasture are explored in terms of nitrate export at the catchment scale. The release and build up of reserves of organic nitrogen developed in grassland soils is modelled as a first-order kinetic decay and shows supply-limited hysteresis. In comparison with observed data, overestimates are achieved at times of maximum release of nitrogen reserves, implying that new sinks of nitrogen or the form of nitrogen release needs to be explored.

HS3/W/20-A2 1015

MODELLING WATER AND NITROGEN BALANCE ON A CULTIVATED FIELD: A CHARACTERISTIC HILLSLOPE APPROACH

Harri Koivusalo, Maija Paasonen-Kivekäs, Tuomo Karvonen and Pertti Vakkilainen (Laboratory of Water Resources, Helsinki University of Technology, PO Box 5200, FIN-02015 HUT, Finland, email: hkoivusa@ahti.hut.fi)

The objective was to develop computational tools to simulate runoff generation and nitrogen leaching in agricultural areas under subsurface drainage. The hillslope was taken as a basic modelling unit corresponding to the scale where cultivation practices and the full range of hydrological processes occur. A quasi-two-dimensional model was used to describe water movement along a characteristic hillslope, which represented a typical cross-section of the fields. The nitrogen leaching with subsurface drainage flux and surface runoff was modelled using a simplified representation of the nitrogen cycle. The characteristic hillslope model was used together with measured runoff and water quality data to evaluate water and nitrogen balance during winter rye cultivation in southern Finland from 1995 to 1996. The results showed that most of the nitrogen was leached through subsurface drains, even if leaching with surface runoff may become important just after fertilizer applications.

HS3/W/21-A2 1110

NITROGEN TRANSPORT VIA SURFACE AND SUBSURFACE FLOW IN AN AGRICULTURAL FIELD

Maija Paasonen-KIVEKÄS, Harri Koivusalo, Tuomo Karvonen, Pertti Vakkilainen and Johanna Virtanen (Helsinki University of Technology, Laboratory of Water Resources, PO Box 5200, FIN-02015 HUT, Finland, email: mpaasone@ ahti.hut.fi)

Nitrogen in runoff waters and in soil was monitored in a clay field, in southern Finland. Subsurface drainage accounted for 51% of the total runoff (439 mm) and 79% of the total N losses (30 kg ha-1) in June 1994–December 1996. Nitrate nitrogen (NO3-N) formed 32–96% of the total N load. NO3-N in the subsurface drainage water rapidly increased from 2 to 60 mg l-1 after the sequence of fertilization and rainfalls. NO3-N in the soil water indicated prominent preferential flow from the top layer into the tile drains. Total N in the runoff waters remained below 5 mg l-1 during the snowmelt and below 10 mg l-1 in the autumn. In these seasons, the determining factor in N transport was the high water volumes of surface runoff and subsurface drainage. The preferential flow paths are likely caused by both macropores and the drainage trench itself.

HS3/W/22-A2 1135

IMPACT OF LAND-USE CHANGE ON NUTRIENT FLUXES IN A STRUCTURED CLAY-LOAM SOIL

Lubomír LICHNER, Ivan Mészáro_ (Institute of Hydrology, Slovak Academy of Sciences, Racianska 75, PO Box 94, 830-08 Bratislava, Slovakia, email: lichner@uh.savba.sk) Peter F. Germann, Abdallah Mdaghri Alaoui (Institute of Geography, Bern University, Hallerstrasse 12, CH-3012 Bern, Switzerland) Miloslav _ír (Institute of Hydrodynamics, Czech Academy of Sciences, Podbabská 13, 166-12 Prague 6, Czech Republic) Pavol Fa_ko (Slovak Hydrometeorological Institute, Jesénio va 17, 83-315 Bratislava, Slovakia)

Accepted management practices influence the distribution of surface-vented macropores and thus the nutrient fluxes in soil. Two ways to assess the impact of land-use change on nutrient fluxes in soils are presented: (a) estimating the bypassing ratio at the interface between the root zone and subsoil, and (b) monitoring the non-reactive tracer relative concentration vs depth distributions in the course of infiltration experiment. The 1993–1996 small-scale field experiments have shown that the bypassing ratio varied from 19 to 55% in a structured clay-loam soil. Impact of land use on the tracer relative concentration vs depth distributions was significant for small and medium cumulative infiltration (I = 40–54 mm) but not so significant for the bigger cumulative infiltration (I = 100–108 mm).

MODELLING THE IMPACT OF LAND USE ON WATER QUALITY IN REGIONAL SCALE STUDIES

HS3/W/33-A2 1200

A CONCEPTUAL MODEL FOR SIMULATION OF CATCHMENT SCALE NITRATE TRANSPORT

Y. Van Herpe, P. A. Troch and L. Callewier (Laboratory of Hydrology and Water Management, University of Ghent, Coupour Links 653, B-9000 Ghent, Belgium, email: yves.vanherpe@rug.ac.be)

A conceptual catchment-scale model for simulating nitrate transport in rural watersheds is presented. The model consists of a hydrological part and a nitrate transport module. The latter comprises two functions: a production function controlling nitrate release from the unsaturated zone and a transfer function controlling the discharge of nitrate in the surface water. The production function simulates surface runoff and nitrate leaching towards the saturated zone in response to effective rainfall, duration of the leaching period and initial soil nitrate content of the leaching period. The transfer function defines a proportional relation between the catchment soil saturation deficit and the nitrate concentrations in the surface water. The model is found to be applicable for two different catchments under humid temperate climatic conditions.

HS3/W/24-A2 1225

MODELLING NITROGEN TRANSPORT IN SWEDEN: INFLUENCE OF A NEW APPROACH TO RUNOFF RESPONSE

Berit Arheimer and Sten BERGSTRÖM (Swedish Meteorological and Hydrological Institute, S 60176 Norrköping, Sweden, email: berit.arheimer@smhi.se)

The Swedish HBV-N model is aimed to be a decision-support tool to counteract eutrophication in the marine environment. It has recently been applied in several Swedish rivers for large-scale retention mapping, source apportionment, and optimization of measure allocation. The model proved to have difficulties in capturing the N dynamics of some rivers with low baseflow conditions and few lakes. The rigidity of the response function of the HBV model was questioned, and a new routine was developed. It was found out that the simple variability parameter for soil moisture in the hydrological HBV model also could be linked to percolation and recession coefficients, and thereby significantly improve low flow simulations. This resulted in rather modest impacts on the water discharge, but changed internal variables drastically, which improved N simulations of concentrations in rivers with unusual concentration patterns. The hydrological response function was found to be especially important when modelling low flow concentration dynamics which originate from diffuse pollution in catchments.

FACTORS AFFECTING NITROGEN EXPORT FROM DIFFUSE SOURCES: A MODELLING STUDY IN THE ELBE BASIN

Valentina KRYSANOVA, Dieter Gerten, Beate Klöcking, and Alfred Becker (Potsdam Institute for Climate Impact Research (PIK), PO Box 601203, D-14412 Potsdam, Germany, email: valen@pik-potsdam.de)

To investigate the factors affecting nitrogen export from diffuse agricultural sources of pollution, the model SWIM was applied in two mesoscale river basins located in the Elbe drainage area: the Stepenitz (gauge Wolfshagen, 575 km2) in the Pleistocene lowland subregion, and the Zschopau (gauge Lichtenwalde, 1504 km2) in the mountainous subregion. Significant parts of both basins are occupied by cropland, but they are different in relief and soil types. The modelling results show the pathways of nitrogen loss from different soils in cropland, and the influence of climate and agricultural practices (fertilization rates and timing, rotation schemes) on nitrogen export. The differences in nitrogen cycling for different soils and management practices revealed by the simulation provide a basis for further scenario evaluation and eventually for recommendations on improving agricultural practices.

HS3/W/26-A2 1425

SCENARIO CALCULATIONS OF REGIONAL SUBSURFACE TRANSPORT OF PHOSPHORUS IN A SUB-BASIN OF THE SPREE RIVER NEAR BERLIN

S. PUDENZ and G. Nützmann (Department of Ecohydrology, Institute of Freshwater and Fish Ecology, Rudower Chaussee 6a, D-12484 Berlin, Germany, email: step@igb-berlin.de)

The assessment of the potential eutrophication of surface waters in the northeastern lowlands of Germany depends on the phosphorus input from the basin. Therefore scenarios dealing with regional transport of phosphorus are helpful tools to calculate a prognosis for the diffuse loading of surface waters. In this study the compartment model MORPHO is applied to simulate the leaching of phosphorus in the unsaturated zone in a sub-basin of the Spree River near Berlin. The water soluble phosphorus content in the pore water indicates a strong relation between P leaching and water solubility of P. The calculated average mean annual TDP (total dissolved phosphorus) concentration of 187 mg l-1 in a certain area of the sub-basin overestimates the mean annual measured concentration (112 mg TDP l-1) in drainage waters. However, the results of two scenarios averaged over the whole basin (0.56 and 1.39 kg TDP ha-1 year-1) are of the same order of magnitude as values estimated in similar basins (0.25 and 1.15 kg TDP ha-1 year-1). Finally the results indicate that managing agriculture without P fertilizing in the basin is not an efficient strategy to reduce P loading of drainage waters.

EVALUATING STRATEGIES TO REDUCE NITRATE AND PHOSPHATE LOSS TO SURFACE WATER FROM AGRICULTURAL LAND ON JERSEY

R. J. PARKINSON, J. E. Lott, M. P. Fuller (Department of Agriculture and Food Studies, Seale-Hayne Faculty, University of Plymouth, Newton Abbot, Devon TQ12 6NQ, UK,
email: rparkinson@plymouth.ac.uk) L. Beattie (Department of Agriculture and Fisheries, PO Box 327, Howard Davis Farm, Trinity, Jersey JE4 8UF, UK)

Nitrate concentrations in reservoirs on the island of Jersey consistently exceed 11.3 mg l-1 nitrate-nitrogen (NO3-N). In the 3.4 km2 drainage basin of the Val de la Mare Reservoir

selected for this study, arable crops, predominantly early potatoes, in combination with a second crop, a cover crop or fallow, accounted for 53% of the total land use in both 1995 and 1996. Export coefficient modelling was used to calculate the total nitrogen delivered to the Val de la Mare reservoir annually. The model predicted that land allocated to early potatoes accounted for 86–87% of the total nitrogen lost to the reservoir from agricultural land during 1996 and 1997. Field trials were conducted during the 1997/98 winter drainage season to evaluate the effectiveness of various crop management strategies designed to limit nutrient losses from agricultural land within the drainage basin. Mean NO3-N and molybdate reactive phosphorus (MRP) concentration in soil water under a cauliflower/early potato crop during 1997/98 were 17.1 mg N l-1 and 49.2 m g P l-1 respectively, in comparison with 2.4 mg N l-1 and 14.3 m g P l-1 under ungrazed permanent grass.

HS3/W/28-A2 1515

THE IMPACT OF LAND USE CHANGES 1820–2020 ON WATER QUALITY AND QUANTITY IN SOUTHEAST MICHIGAN

Andrew J. BRENNER, Paul L. Richards (School of Natural Resources and Environment, University of Michigan, 430 E. University, Ann Arbor, Michigan, 48109-1115, USA) Mike Barlage and Peter Sousounis (Atmospheric, Oceanic and Space Sciences, Space Research Building, 2455 Hayward, University of Michigan, Ann Arbor, Michigan, 48109-2143, USA)

Since changes in land use and climate are impacting river systems around the world, there is a need to build models that enable integration of atmospheric and hydrologic models. This paper shows an adaptation to the soil curve number approach for continuous rainfall input, and the event mean concentration approach to simulate stream loading of total suspended solids, phosphorus (P) and Kjeldahl nitrogen. Simulated P loads were within 4.5% of measured values. Simulation using 1820, 1990 and predicted 2020 land covers showed that runoff has increased by 3.5 times since 1820, but will change little in the future. However, it appears that the large increases in pollutant loads that have occurred in the last 170 years will increase in the future. This emphasizes the need to implement non-point source pollution controls in the studied watershed.

General Aspects of Water Quality

HS3/W/29-A2 1615

SURFACE WATER POLLUTION FROM DIFFUSE AGRICULTURAL SOURCES AT A REGIONAL SCALE

Piet GROENENDIJK (DLO Winand Staring Centre, Institute for Integrated Land, Soil and Water Research, PO Box 125, 6700 AC Wageningen, The Netherlands, email: p.groenendijk@sc.dlo.nl) Paul Boers (Institute for Inland Water Management and Waste Water Treatment, PO Box 17, 8200 AA Lelystad, The Netherlands)

The approach used in the leaching models to assess the nutrient load on minor surface water systems at the regional scale in The Netherlands is presented. Regional spatially distributed patterns of soil type, land use and hydrology are schematized by a number of homogeneous subregions. In the model a sub-region is represented by a single vertical soil column. Lateral groundwater fluxes are used to compose a regional average discharge concentration. Results of the model approach are discussed for the study on the quantification of the nitrogen and phosphorous load on surface waters at a national scale, as has been conducted in the framework of the Fourth National Policy Document on Water Management in The Netherlands. The aim of the study was to analyse the impact of fertilizer management on N and P discharges to Dutch surface waters. It is concluded that hydrological insight into the system and an associated understanding of the relation between groundwater flow and the loading of surface water is of the utmost importance.

HS3/W/30-A2 1640

MODELLING SPATIAL AND TIME DEPENDENT NUTRIENT FLOW DYNAMICS BY DELINEATION OF VARIABLE CHEMICAL HYDROLOGICAL RESPONSE UNITS (VCRUS) WITH A GIS

Ulrike BENDE-MICHL (Department of Geography, Institute of Geoinformatics, Geohydrology and Modelling, Friedrich-Schiller University Jena, D-07743 Jena, Germany,
email: c5ulbe@geogr.uni-jena.de)

Modelling hydrochemical contaminant catchment dynamics in heterogeneous basins is dealing with the detection and the quantification of spatially-distributed and time-variable impacts—known as nonpoint sources and the knowledge of their transformation and translocation into the output of the catchment. The concept of time and spatially variable chemical hydrological response units (VCRUs) through GIS analysis and the physically-based solute model WASMOD were linked to monitor the magnitude of export rates and dynamics of nutrients at the catchment outlet at different time and spatial scales. VCRUs are defined as areas having unique or similar hydrochemical dynamics related to physiographic catchment characteristics and to land-use strategies within a variable defined time sequence. Furthermore the time sequence was delineated according to the dominant hydrological pathways, the solute source and its determinant transformation process. The concept was applied to the 216 km2 Broel River basin, Germany, which has been intensivly mapped and digitized for GIS analysis. Data collection included water samples for dissolved solids, fertilizer application and catchment characteristics. Hydrological and chemical balances were modelled for different time series and the results were compared with the measured output at the gauging station. Modelling results showed a good fit during unique hydrological conditions whereas VCRUs were adapted to. Therefore the approach is validated to monitor and control land-use changes and its effects on the magnitude of nutrients losses at a basin-scale.

HS3/W/31-A2 1705

THE USE OF HIGH RESOLUTION DIGITAL TERRAIN MODELS TO REPRESENT WASH-OFF IN NATURAL AND MAN INFLUENCED ENVIRONMENTS

Paul QUINN (Water Resource Systems Research Laboratory, Department of Civil Engineering, University of Newcastle, Newcastle Upon Tyne NE1 7RU, UK, email: p.f.quinn@ncl.ac.uk) Steven Anthony (ADAS Research and Development, Wergs Road, Wolverhampton, WV6 8TQ, UK)

Modelling the wash-off of diffuse surface pollutant sources and sediment requires an accurate representation of flow pathways. The main problem of flow representation within models is one of scale. In reality processes that mobilize and transport pollution are highly localized and controlled by small-scale natural and manmade features. These features are essentially hydraulic structures that control the volume, direction and energy regime of the flow. However, at the larger scale, "hydrological" phenomena are used to represent the general flow accumulation of flow and pollutants. Recently, digital terrain maps (DTMs) have been used to depict flow paths, gradients and erosion indices (using grid resolution of 50–300 m in some examples). There needs to be therefore, some form of simplification and some generalization of our flow assumptions. This poster paper seeks to investigate the scale problem by creating high resolution DTMs. In essence we are trying to create DTMs that are at a scale approaching "reality". This paper shows: the importance of local topography form on flow; the importance of manmade features controlling flow and the implication of grid resolution choice when modelling flow, erosion and sedimentation.

HS3/W/32-A2 1730

MODELS FOR EVALUATING WATER QUALITY AND BMP EFFECTIVENESS AT THE WATERSHED SCALE

Ray WHITTEMORE (National Council of the Paper Industry for Air and Stream Improvement—NCASI, Tufts University, PO Box 53015, Medford, Massachusetts 02153-0015, USA,
email: rwhittemore@tufts.edu) George Ice (NCASI, Corvallis, Oregon, USA)

The Environment Protection Agency (EPA) and other water resource agencies have identified the need to develop watershed-scale assessments to evaluate progress in meeting the goals of the Clean Water Act. The forestry community has been a leader in developing these watershed evaluation techniques. While watershed-scale, monitoring, adaptive management assessments, and modelling combinations are all used effectively in the US, this paper emphasizes realistic modelling. Models can be used to test different alternatives and are not confounded by the weather or watershed variability associated with even well paired adjacent basins. Examples of watershed-scale models frequently used in forestry for assessing water quality response are DHSVM, BOISED, and BASINS2.0.

A COMBINED TRACER–HYDROMETRIC APPROACH TO ASSESS THE EFFECT OF CATCHMENT SCALE ON WATER FLOW PATH, SOURCE AND AGE

Jeff McDONNELL (State University of New York, College of Environmental Science and Forestry, Syracuse, New York 13210, USA, email: jemcdonn@mailbox.syr.edu); Lindsay Rowe (Landcare Research, PO Box 69, Lincoln, New Zealand); Mike Stewart (IGNS, PO Box 31312, Lower Hutt, New Zealand)

The scaling of water source contributions to channel stormflow is not well understood. We collected rainfall–runoff data along with streamflow and rainfall d 18O information for four nested catchments in the Maimai watershed, South Island, New Zealand. The catchments ranged in size from 0.1 to 920 ha. Water source contributions and water age spectra were assessed for an 87 mm rainfall event using a new model by Stewart & Rowe (1999). We found that (a) the source contributions of new water increased with increasing catchment area for catchment scales above the representative elementary area of the system, and (b) water age (flow time) showed some increase with increasing catchment size (beyond the zero-order catchment scale), and peak water fraction increased linearly with catchment area. This work has implications for how we model stream water chemistry since it is affected by both the mixing of different catchment end members and contact time.

HYDROMETRIC APPROACHES

HS4/W/02-A4 1015

HYDROMETRIC APPROACHES TO GAIN A BETTER UNDERSTANDING OF SATURATION EXCESS OVERLAND FLOW

Gerd PESCHKE and Christoph Sambale (International Graduate School, Department of Environmental Sciences, Markt 23, D-02763 Zittau, Germany, email: peschke@ihi.htw-zittau.de)

This paper examines how hydrometric approaches can be used to obtain information about the spatial variability of runoff processes, especially saturation overland flow. This quick runoff component reflects the interaction between subsurface and surface flow and catchment features such as topography and soil properties, weather characteristics like rainfall intensity and amount, and antecedent soil moisture. We measured transects across the stream with both spatially integrated measurements and point measurements. This kind of experimental investigation provides data of a new quality and additional process knowledge needed for a better understanding of runoff production. With detailed mapping of the dominant runoff processes in combination with the most important influencing parameters, an improved construction of submodels becomes possible.

HS4/W/03-A4 1045

EFFECT OF A PERMEABLE BEDROCK ON RUNOFF GENERATION IN STEEP MOUNTAINOUS CATCHMENTS IN THE KANTO MOUNTAINS, JAPAN

Kunihide MIYAOKA (Faculty of Education, Bunkyo University, 3337 Minami-Ogishima, Koshigaya, Saitama 343, Japan, email: miyaoka@koshigaya.bunkyo.ac.jp); Shinichi Onodera (Faculty of Integrated Science, Hiroshima University, 1-7-1 Kagamiyama, Higashihirosima, Hiroshima 739, Japan); Takashi Hirose (Faculty of Law and Literature, University of Ryukyu, 1 Senhara, Nishiharamachi, Chuto-gun, Okinawa 903-01, Japan)

We estimated the effect of the permeable bedrock on the runoff generation in two steep mountainous catchments west of Tokyo, using hydrological observation and hydrogeological surveys. Two small catchments, one underlain by granite bedrock, and the other with sedimentary bedrock were studied. Runoff decreased after the first peak in the granite

catchment, while it reached 5 times the initial peak value after 6 h in the sedimentary catchment. Runoff ratios were 12% in the granite catchment and 65% in the sedimentary rock catchment. Because the regolith layer is thinner in the sedimentary catchment than in the granite catchment, this observed secondary peak of runoff suggests the existence of significant flow-through fissures. Event water amounts in both catchments were estimated to be very low, using the natural tracers Cl- or d18O. These results indicate the contribution of pre-event water to storm runoff. The electrical sounding and infiltration experiments suggest that rainwater percolates into the fractured bedrock, mixes with soil water in the regolith, and discharges quickly in the sedimentary rock catchment.

HS4/W/04-A4 1105

QUANTITATIVE EVALUATION OF FOREST FLOOR EVAPORATION AND TRANSPIRATION REVEALED BY SOIL WATER CONTENT OBSERVATION IN HUMID TEMPERATE PINE FORESTS

Jun SHIMADA (Department of Earth Sciences, Faculty of Science, Kumamoto University, 2-39-1, Kurokami, Kumamoto 860-8555, Japan, email: j-shimada@sci.kumamoto-u.ac.jp); Takashi Yonesaka (196-11 Misono-cho, Yoichi machi, Hokkaido 046, Japan); Qi You Zhou (Doctoral Programme in Geoscience, University of Tsukuba, 1-1-1 Tennodai, Tsukuba 305-8571, Japan)

The combined monitoring of soil water content by soil heat conductivity probes and soil matrix potential by tensiometers was done at a Japanese red pine forest site during summer 1997. The total potential distribution during the study period revealed the existence of two separate zero flux planes at depths of 20 and 70 cm. The depth of the shallower zero flux plane was influenced by rainfall events, while the deeper zero flux plane was stable. The deeper zero flux plane was considered to be mainly influenced by the absorption of soil moisture through the root system of the Japanese red pine based on root depth distribution. The daily soil water content recorded by the soil heat conductivity probes was used to evaluate the day-to-day variations of soil water content at the monitored soil depth. The decreasing variations should be the influence of forest floor evaporation, or transpiration through root, or downward soil water infiltration to recharge the groundwater. The total potential distribution monitored by tensiometers can be used to separate those soil water reducing components by the direction of the soil water flow. The combination of the daily soil water content variations, and the soil water flux revealed by the total potential distribution, makes it possible to evaluate the quantitative separation of the forest floor evaporation and the transpiration.

HS4/W/05-A4 1225

WATER AND COMPONENT MASS BALANCES IN THE CATCHMENT OF LAKE STECHLIN

E. HOLZBECHER, G. Nützmann and G. Ginzel (Institute of Freshwater Ecology and Inland Fisheries, Department of Ecohydrology, Rudower Chaussee 6A, Building 21.2, D-12484 Berlin, Germany, email: holzbecher@igb-berlin.de)

Surface water and groundwater are hydraulically connected in the Lake Stechlin catchment. Therefore, there is an urgent need to study unsaturated and saturated flow and related major ion transport processes and exchange with the surface water to analyse the influence on the aquatic chemistry, especially on calcite precipitation in the lake. Based on long-term measured hydrological data, in an integrated approach a steady-state regional groundwater model was developed and fluid mass balances were calculated. Chemical analyses show higher concentrations of major components (Na+, K+, Ca2+, Mg2+, Fetot, Cl-, SO42-, NO3-, HCO3-) in groundwater than in lake water. Based on the computed subsurface water balance it can be deduced that groundwater has a strong influence on the composition of the surface water, especially for Ca2+ and HCO3-.

REMOTE SENSING APPROACHES

HS4/W/06-A4 1400

SNOWMELT RUNOFF CONCEPTUALIZATION BASED ON TRACER AND SATELLITE DATA

Jaroslav MARTINEC (Alteinstrasse 10, CH-7270 Davos-Platz, Switzerland); Albert RANGO (USDA Hydrology Laboratory, BARC-West, Building 007, Room 104, Beltsville, Maryland 20705, USA, email: alrango@hydrolab.arsusda.gov)

As a result of thermonuclear test explosions in the atmosphere, tritium concentrations in precipitation in the sixties and seventies varied strongly from year to year as well as in the winter and summer half years. This paper illustrates how the contrasting tritium concentration in snow and in groundwater was used to develop a snowmelt runoff model (SRM). A new insight into the runoff mechanism and the role of the recession flow provided a concept of transforming the snowmelt into river flow on a daily basis. The adopted deterministic approach, without calibration of parameters, requires snow cover monitoring by satellites. While tritium tracing contributed to the model design, remote sensing enables the SRM model to be used around the world.

HS4/W/07-A4 1430

UNDERSTANDING HYDROLOGICAL PROCESSES IN CATCHMENTS USING REMOTELY SENSED TRACERS AND GEOGRAPHICAL INFORMATION SYSTEMS

Serwan M. J. BABAN (GRRU Group, Geography, School of Natural and Environmental Sciences, Coventry University, Priory Street, Coventry CV1 5FB, UK, email: s.baban@coventry.ac.uk)

Soil erosion and water degradation problems are currently major environmental problems. Attempting to solve them will require a clear understanding of the hydrological processes involved at the appropriate scale. Remote sensing techniques can provide information about areas prone to erosion and the subsequent sediment load in water bodies within a catchment area. This is usually based on the deduced spatial and temporal distribution of turbidity, suspended material and associated pollutants, acting as natural tracers. This paper explores the possible usage of remote sensing and geographical information systems (GIS) techniques in catchment studies. Remotely sensed tracer information is then used within a GIS framework to present a holistic approach that takes into consideration the causes as well as the effects of soil erosion and water degradation problems in hydrological catchments. This approach can easily be used to promote a clearer conceptual understanding of hydrological processes and to develop, monitor and simulate management strategies aiming at minimizing the magnitude of these problems within catchments.

APPLIED REMOTE SENSING FOR PARAMETERIZING SOLUTE TRANSPORT AND SEDIMENT MODELS IN THE ARSGISIP PROJECT

Bettina MÜSCHEN, Wolfgang-Albert Flügel (Institute for Geography, Department of Geoinformatics, Hydrology and Modelling, Friedrich-Schiller-University of Jena, Löbdergraben 32, D-07743 Jena, Germany, email: arsgisip@geogr.uni-jena.de); Friedrich Quiel (Environmental and Natural Resources Information Systems, The Royal Institute of Technology, Brinellvägen 32, S-10044 Stockholm, Sweden);.Giuliano Rodolfi (Dipartimento di Scienza del Suolo e Nutrizione della Pianta, Università di Firenze, Piazzale delle Cascine 15, I-50144 Firenze, Italy)

The EU project ARSGISIP applies remote sensing techniques and GIS analyses to parameterize hydrological, erosion, and solute transport models. Activities of the first project stage are presented, emphasizing the common environmental problem of nutrient leaching within three representative European drainage basins located in Italy, Germany, and Sweden. Physically-based simulation models used by project partners are briefly described and the contribution of optical and radar remote sensing techniques for model parameterization is discussed. The scientific approach concentrates on deriving physical parameters characterizing soil and vegetation by means of land use/land cover classifications using Landsat TM, IRS-1C LISS, and ERS-2 SAR data. First results are quite promising: (a) agricultural crops and Mediterranean vegetation could be classified with optical and radar data, and (b) model parameters describing the distributed features of the test basins vegetation–soil–topography interface (VSTI) could be derived.

HS4/W/09-A4 1510

INTEGRATING TRACER WITH REMOTE SENSING TECHNIQUES FOR DETERMINING DISPERSION COEFFICIENTS OF THE DMBOVITA RIVER, ROMANIA

Mary-Jeanne ADLER, George Stancalie and Cristina Raducu (National Institute of Meteorology and Hydrology, Sos Bucuresti-Ploiesti 97, 71552 Bucharest, Romania, email: adler@meteo.inmh.ro)

Knowledge of dispersion coefficients in longitudinal, lateral and vertical flow directions is of utmost importance when evaluating the time–concentration distribution of pollutants at any point in a stream. Remotely sensed field data (from NOOA and teledetection) were used to identify the river sector for a dye tracing experiment. The main criteria were to locate a sector without significant anthropogenic influence and with similar hydraulic conditions. The sector selected for sampling was 2.5 km long. The longitudinal and three-dimensional dispersion coefficients were determined. The time–concentration curve for rhodamine dye obtained under different hydraulic conditions of flow (different stages) was measured on the Dâmbovita River. The stage was nearly constant for each experiment but different in each case, therefore it was possible to obtain information for different regimes. Additional information needed to make use of the one-dimensional and three-dimensional mathematical models of dispersion was obtained at the Malu cu Flori gauging station (continuos stage recording and stage–discharge curve). Finally, the experimental data were used to verify the mathematical dispersion model proposed for the Dâmbovita River.

HS4/W/10-A4 1530

APPLICATION DE LA THERMOGAPHIE INFRAROUGE AEROPORTEE A L'ETUDE DE L'HETEROGENEITE D'UNE ZONE HUMIDE RIVERAINE D'UN COURS D'EAU

Hocine BENDJOUDI, Celine Pinet (Laboratoire de Géologie Appliquée, Université Pierre et Marie Curie, 4 Place Jussieu, F-75252 Paris, France, email: bdj@biogeodis.jussieu.fr); Roger Guerin (Département de Géophysique Appliquée, Université Pierre et Marie Curie, Paris, France)

La compréhension du fonctionnement des zones humides riveraines du cours moyen des rivières passe par la reconstitution et la modélisation de la mise en place des alluvions qui leur servent de substrat. Sur les zones humides des vallées de l'Aube et de la Seine, une prospection thermique aéroportée a ainsi été mise en œuvre, dans le but de fournir des images dans le visible et le thermique lointain. Suite aux premiers résultats obtenus—distinction entre les zones d'eau libre et les zones d'eau stagnantes, localisation rapide et à grande échelle des anciens réseaux hydrographiques—un site test d'une superficie de 1 ha a été sélectionné sur un des axes de vol. Les mesures électromagnétiques et les sondages réalisés sur ce site ont révélés une concordance des résultats sur les sols vierges de toute pratique agricole. D'autres investigations géophysiques mais également géochimiques (traceurs), permettraient à l'avenir de définir les paramètres hydrauliques de cette zone humide.

TRACER APPROACHES

HS4/W/11-A4 1600

INTEGRATION OF TRACER INFORMATION INTO THE DEVELOPMENT OF A RAINFALL–RUNOFF MODEL

Stefan UHLENBROOK and Christian Leibundgut (Institute of Hydrology, University of Freiburg, Fahnenbergplatz, D-79098 Freiburg , Germany, email: uhlenbro@uni-freiburg.de)

A conceptual rainfall–runoff model has been developed for the mountainous Brugga basin (39.9 km2) situated in the Black Forest, south-western Germany. This model contains an extensive, physically realistic description of the runoff generation, considering seven unit types each with characteristic dominating runoff generation processes. The processes are conceptualized by different linear and non-linear reservoir concepts. Tracer concentrations (i.e. dissolved silica) are attributed to reservoir outflows, according to tracer hydrological investigations. A study period of 20 months showed a reasonable agreement between simulated and observed discharge. The simulated amounts of different runoff components also agreed well with calculations based on measurements of natural tracers. The tracer simulations were less accurate, whereas the general behaviour of the tracer concentrations and short time periods were modelled well.

HS4/W/12-A4 1630

ISOTOPE HYDROLOGICAL STUDY OF MEAN TRANSIT TIMES AND RELATED HYDROGEOLOGICAL CONDITIONS IN PYRENEAN EXPERIMENTAL BASINS (VALLCEBRE, CATALONIA)

Andreas HERRMANN, Susanne Bahls (Institute for Geography and Geoecology, Technical University Braunschweig, Langer Kamp 19c, D-38106 Braunschweig, Germany, email: a.herrmann@tu-bs.de); Willibald Stichler (Institute for Hydrology, Research Centre for Environment and Health (GSF), Ingolstädter Landstr. 1, D-85764 Neuherberg, Germany); Francesc Gallart and Jerome Latron (CSIC Institute of Earth Sciences Jaume Almera, Lluís Sole Sabarís s/n, SP-08028 Barcelona, Spain)

Measurements of tritium and oxygen-18 concentrations in water samples from streams at low discharge, wells, and permanent springs are used to provide insight into hydrogeological conditions, storage properties, runoff formation, and flow partitioning of Pyrenean experimental basins 100 km north of Barcelona. Transit times as derived from tritium range between 8–11.5 years for wells, 8.5–13.0 years for streams, to 10.5–13.5 years for springs. These results are twice the usual values which suggests low permeability of the bedrock formations. Minimum groundwater reserves can be determined from low discharge and mean transit times, and groundwater plays an important role in flood generation. Tritium is still found to be a useful tracer provided that transit times are high enough and geological information is available.

HS4/W/13-A4 1650

HYDROLOGICAL PROCESSES IDENTIFICATION BY THE COMBINATION OF ENVIRONMENTAL TRACING WITH TIME DOMAIN REFLECTOMETRY MEASUREMENTS

C. JOERIN, A. Musy and F. Pointet (Soil and Water Management Institute, Swiss Federal Institute of Technology, CH-1015 Lausanne, Switzerland, email: christophe.joerin@dgr.epfl.ch)

This study begins with the application of environmental tracing in order to identify hydrological processes in the Haute-Mentue basin. The application of a three-component model, based on concentrations of silica and calcium demonstrates that the groundwater and soil water dominate streamflows. Mixing models identify volumes, but not water pathways. In this context, in order to specify which physical properties or mechanisms are responsible for the important contribution of subsurface flows, an experiment based on a time domain reflectometry system and additional measurements within the basin (piezometers and rainfall simulator) was conducted. The association of these experiments allows demonstrating that preferential flows are certainly responsible for the important contribution of soil water. Furthermore according field observations and a rainfall simulator experiment, it seems that macropores are at the origin of these preferential flows.

HS4/W/14-A4 1710

THE USE OF TRACER HYDROLOGICAL TIME PARAMETERS TO CALIBRATE BASEFLOW IN RAINFALL–RUNOFF MODELLING

Jens MEHLHORN and Christian Leibundgut (Institute of Hydrology, University of Freiburg, Fahnenbergplatz, D-79098 Freiburg, Germany, email: mehlhorn@imbdec1.bau-verm.uni-karlsruhe.de)

This paper discusses the use of tracer time parameters to calibrate the baseflow time concentration in a conceptual rainfall–runoff model. A comparison showed that the modelling approaches in tracer hydrology and rainfall–runoff modelling were mathematically equivalent. Therefore, it was assumed that tracer time parameters were suitable to calibrate baseflow runoff models. It can be shown that this is possible if the mobile and immobile water volumes in the groundwater system are considered. In a case study, the tracer time parameter of baseflow was 920 days. This value indicates the age of all water in the groundwater system and has no influence on the shape of the hydrograph. Recession analyses led to a turnover time of the mobile water in the groundwater system of 340 days. Coupling the water age and turnover time made it possible to simulate the baseflow with more detail. The calculated baseflow reflects correctly the dynamics of the groundwater system and the age of the baseflow.

HS4/W/15-A4 1730

SEASONAL HYDROLOGY OF OXYGEN-18 IN THE ALLT A' MHARCAIDH, SCOTLAND: IMPLICATIONS FOR WATER MOVEMENT AND RESIDENCE TIMES

C. SOULSBY, R. Malcolm (Department of Geography, University of Aberdeen, Aberdeen AB24 2UF, UK, email: c.soulsby@abdn.ac.uk); R. C. Ferrier, R. C. Helliwell (Macaulay Land Use Research Institute, Aberdeen AB15 8QH, UK); A. Jenkins (Institute of Hydrology, Wallingford, Oxfordshire OX10 8BB, UK)

The seasonal variation of oxygen-18 has been observed in precipitation, groundwater and streamwater in the Allt a' Mharcaidh catchment, Cairngorm mountains, Scotland. Precipitation showed strong seasonal variation in its isotopic signature over the 1995–1998 study period. As anticipated, such variation was substantially damped in groundwater and surface water. Nevertheless, 18O proved a useful tracer, indicating the influence of spring snowmelt events and summer rainfall on stream waters. Detailed examination of the seasonal variation in d 18O levels in various catchment waters provided an insight into mixing processes and a first approximation of mean residence times. Preliminary estimates for the latter are <180 days for (inferred) near-surface soil water and storm runoff, 2.5 and >5 years for shallow and deeper groundwater respectively. These longer-term data sets demonstrate the ability of the catchment to effectively mix new precipitation with resident soil and groundwater over the hydrological year. This implies that the influence of groundwater on the hydrology and hydrochemistry upland catchments has been underestimated.

TRACER APPROACHES

HS4/W/16-A5 0900

INTEGRATION OF TRACER TECHNIQUES AND HYDROMETRIC APPROACHES IN CATCHMENT HYDROLOGY: RESEARCH ON HYDROLOGICAL PROCESSES IN THE KAWAKAMI EXPERIMENTAL BASIN, CENTRAL JAPAN

Tadashi TANAKA (Institute of Geoscience, University of Tsukuba, Ibaraki 305-8571, Japan, email: tadashi@atm.geo.tsukuba.ac.jp); Maki Tsujimura (Department of Environmental Earth Sciences, Aichi University of Education, Aichi 448-8542, Japan)

The Kawakami experimental basin, located in the mountain region of central Japan, has been monitored since 1985. Complex hydrological processes occurring in the forested mountain catchment were studied using both isotope and chemical tracers and hydrometric approaches. Tritium concentration data of soil water, groundwater, and stream water provided information on residence times of each as well as the mixing ratio of stream water with soil water and groundwater. Stable isotope data, such as deuterium and oxygen-18, showed the spatial characteristics of each stream water source. Additionally, hydrometric data including tensiometric and piezometric potentials revealed the physical dynamics of subsurface water in the catchment. All these data are necessary for consideration of flow mechanisms in the catchment, especially for stormflow and water quality studies.

HS4/W/17-A5 0930

WATER FLUXES THROUGH CLAY AND SANDY SOILS: INTEGRATION OF TRACING AND SOIL WATER DATA

Mary MOSUGU and Chris Bradley (School of Geography and Environmental Science, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK, email: mem672@novell5.bham.ac.uk)

This paper considers infiltration studies in a cracking clay and a sandy loam soil at two sites in the UK. Changes in water potential during infiltration under natural and simulated rain events are determined using tensiometer nests within plots of 9 m2. An anionic tracer (Br-) was applied at a controlled rate, following which samples of soil water were collected at regular intervals from porous cup samplers within the two soil profiles. Br- concentrations were determined using HPLC ion chromatography. The results indicate substantial differences in timing and rate of infiltration and redistribution between the two soil types, and significant internal variability within the same soil. The results are analysed to assess seasonal changes in the nature and magnitude of water movement.

IN SITU EXPERIMENTS ON WATER INFILTRATION IN SAND DUNES TRACED BY TEMPERATURE

Changyuan TANG (Graduate School of Science and Technology, Chiba University, 1-33 Yayoi-cho, Inage-ku, Chiba 263, Japan, email: cytang@rsirc.cr.chiba-u.ac.jp); Shizuo Shindo (Centre for Environmental Remote Sensing, Chiba University, 1-33 Yayoi-cho, Inage-ku, Chiba 263, Japan); Yosuo Sakura and Isao Machida (Faculty of Sciences, Chiba University, 1-33 Yayoi-cho, Inage-ku, Chiba 263, Japan)

Knowledge of the mechanisms of water infiltration in sand dunes and wadis is the key to understanding the hydrological conditions in arid and semiarid regions. In order to trace infiltration processes in sand dunes, two sites were chosen in Al Ain, United Arab Emirates. An artificial rainfall infiltration experiment was conducted at one site. The other was left in its natural state. The variations in temperature between the sites were compared with soil water tension as well as soil water content at the same depths. Field observations showed that the temperature of the sand dune at the experimental site was more greatly affected by air temperature than that at the natural site, which means that the temperature distribution in the sand dune is closely related to the water content. The vertical distribution of temperature correlated well with the water movement in the sand dune, from which the average velocity of infiltration has been estimated as 3 cm h-1. The results showed that water infiltration in sand dunes is not continuous but stepped, and suggested the possibility of tracing water movement in sand dunes using temperature.

CONTRASTING RAINFALL–RUNOFF PROCESS BETWEEN GEOLOGY USING HYDROMETRIC AND TRACER APPROACHES IN STEEP, LARGE RELIEF MOUNTAINS

Maki TSUJIMURA (Department of Environmental Earth Sciences, Aichi University of Education, Kariya, Aichi 448-8542, Japan, email: mktsuji@auecc.aichi-edu.ac.jp); Yuichi Onda, Jun'ichi Fujiwara (School of Agricultural Sciences, Nagoya University, Nagoya, Aichi 464-8601, Japan); Jun Ito (Department of Environmental Earth Sciences, Aichi University of Education, Kariya, Aichi 448-8542, Japan)

Hydrometric and tracer approaches have been applied to investigate the rainfall–runoff process in two headwater basins underlain by shale and granite. Four small basins were monitored; two in shale and two in granite. The rainfall peak was followed by the runoff peak in the shale basin, whereas peak runoff coincided with rainfall peak in the granite basin. Tensiometric data from hillslopes indicate that subsurface water percolated into the bedrock even during the rainstorm in the shale basin, whereas lateral saturated subsurface flow was often observed during heavy rainstorms in the granite basin. Considering the isotopic data from water, subsurface flow with relatively long residence times through the bedrock should be dominant so that the delayed runoff response was observed during the rainstorm in the shale basin, whereas lateral subsurface stormflow in the soil mantle should be dominant so that the quick response of runoff was observed during rainstorms in the granite basin.

HS4/W/20-A5 1030

USE OF ENVIRONMENTAL TRITIUM TO STUDY CATCHMENT DYNAMICS: CASE STUDY FROM THE DANUBE RIVER BASIN

Yuecel YURTSEVER (Department of Nuclear Sciences and Applications, International Atomic Energy Agency (IAEA), Wagramer Strasse 5, PO Box 100, A-1400 Vienna, Austria, email: y.yurtsever@iaea.org)

Use of environmental isotopes, particularly, oxygen (18O) and hydrogen (2H and 3H) offers unique methodologies for investigations related to rainfall–runoff relationships and catchment dynamics. Using long-term tritium (3H) data in the Danube River, observed temporal variations in the river water have been simulated through a compartmental (mixing cell) modelling approach to estimate the fluxes of surface flow and groundwater to total river discharge and to characterise the transit time distribution of these component flows. The findings of this approach are compared to the results of an earlier simulation model based on the Artificial Neural Network (ANN) approach using the same long-term tritium data. The two approaches provide comparable results for the characteristics travel time of the water in the basin providing improved confidence for the results.

HS4/W/21-A5 1100

STUDY OF RAINFALL DISTRIBUTION AND GROUNDWATER FLOW USING THE CL- ION AND STABLE ISOTOPES ON A VOLCANIC ISLAND IN JAPAN

Isao MACHIDA (Graduate School of Science and Technology, Chiba University, 1-33 Yayoi-cho Inage-ku, Chiba 263-0022, Japan, email: isao@rsirc.cr.chiba-u.ac.jp); Shizuo Shindo (Centre of Environmental Remote Sensing ,Chiba University, 1-33 Yayoi-cho Inage-ku, Chiba 263-0022, Japan)

Using the stable isotope and water quality method, we investigated groundwater movement in Hachijojima Island, a volcanic island located about 290 km south of Tokyo Bay, Japan. Rain samples for analyses of oxygen-18 and Cl- were collected by 20 evenly distributed precipitation collectors during a one-year period (April 1997–April 1998), with a sampling interval of 45 days. A hydrological survey was carried out, and more than 50 groundwater and surface water samples were also collected. We found: (a) Cl- in springs is a suitable tracer for groundwater study in this island; however, we could not estimate recharge area using oxygen-18 because the altitude effect (of precipitation isotope) is small; (b) Cl- concentration in springs and well water was more than 2 times higher than Cl- concentration of precipitation; we could

not calculate the recharge area, comparing Cl- concentration in precipitation with that in groundwater; (c) groundwater quality is classified into several groups, which reflect the different groundwater flow processes.

HS4/W/22-A5 1120

FAN ISOTOPIC STUDY OF THE GROUNDWATER REGIME OF A SEEPAGE CALDERA LAKE DISTRICT, SOUTHERN JAPAN

Masaya YASUHARA, Yoshihisa Kawanabe and Atsunao Marui (Hydrology Research Group, Geological Survey of Japan, 1-1-3 Higashi, Tsukuba, Ibaraki 305-8567, Japan, email: masaya@gsj.go.jp); Tadashi Kohno (Research Centre of Environmental Science and Technology, Nippon Bunri University, 1727 Ichiki, Ohita 870-0397, Japan); Yoshinori Satoh (Division of Social Studies, Joetsu University of Education, Joetsu, Niigata 943-8512, Japan)

The 233-m deep Lake Ikeda is a seepage caldera lake with no surface outflow or inflow. During February–March 1998 water samples were taken from lakes, rivers, wells, hot springs, and springs. They were analysed for dD, d18O, and Cl- concentration to determine the contribution of lake water to river discharge and down-gradient groundwater field. The results indicate that the influence of leakage from Lake Ikeda is confined to the area east-south of the lake, where a mixing of lake water, local rainwater, and sea water takes place. For certain rivers and springs, lake water contributes more than 80% of the discharge. Many of the wells and hot springs represent a 7–100% lake-water contribution. Leakage of lake water is most likely to occur through the southern caldera walls, where thick volcanic aquifers are hydraulically connected to Lake Ikeda. The study showed that leakage from Lake Ikeda was found to play a predominant role in the groundwater regime of the district.

HS4/W/23-A5 1140

PRELIMINARY ANALYSIS OF BORON ISOTOPE RATIOS IN LEACHATE-CONTAMINATED GROUNDWATER

Eduard HOEHN (Swiss Federal Institute of Water Science and Technology (EAWAG), CH-8600 Dübendorf, Switzerland, email: hoehn@eawag.ch)

Boron isotope ratios of municipal solid waste leachate and groundwater yielded values between –7.0 and 16.6‰. We feel that these ratios have the potential to be used as a tracer for the assessment of mixing of leachate-contaminated groundwater. The values were interpreted as a mixture of waters of a different origin. This interpretation is corroborated by independent findings from a hydrogeological site assessment.

HS4/W/24-A5 1200

FLOW MODELLING, TRACER METHODS, AND HYDROMETRIC TESTS IN THE RIVER VAH BASIN, SLOVAK REPUBLIC

Jozef HULLA, Emilia Bednarova and Danka Gramblickova (Department of Geotechnics, Slovak Technical University, Radlinskeho 11, 813-68 Bratislava, Slovak Republic, email: hulla@us.svf.stuba.sk)

Fifty-four reservoirs have been built in the basin of the River Vah, Slovak Republic, over various geological formations. The reservoirs are used for flood protection, drinking water supply and hydroelectric power. The grouting curtains were a serious problem during dam construction. Maximum seepage was estimated for the Liptovska Mara and Turcek dams and ranged between 0.060 and 0.070 m3 s-1. The real seepage, and implications for the subsoil stability were questionable. Borehole tracer methods were used to address this problem. The results show that maximum real seepage was 0.030 m3 s-1, and filtration velocities have never reached critical values for the filtration stability of fine fills in rock fissures or gravel pores.

HS4/W/25-A5 1220

COMBINATION OF TRACER TECHNIQUES AND NUMERICAL SIMULATIONS TO EVALUATE THE GROUNDWATER CAPTURE ZONE

Makoto TANIGUCHI (Department of Earth Sciences, Nara University of Education, Nara 630-8528, Japan, email: makoto@nata-edu.ac.jp); Kunimitsu Inouchi (Centre for Cooperative Research and Development, Ehime University, Matsuyama 790-8577, Japan); Norio Tase and Jun Shimada (Institute of Geoscience, University of Tsukuba, Ibaraki 305-8571, Japan)

The groundwater flow system and capture zone were evaluated using the combination of stable isotopes, continuous measurements of groundwater seepage rate, and numerical simulations by a 2-D unsaturated–saturated three-layer model. The inland effect of d18O of the precipitation was used as a tracer to detect the capture zone. The depth of the groundwater which discharges near the lake shore is estimated to be deeper than 100 m below the surface even though the clay layer exists from a depth of 10 to 20 m below the surface. The combination of tracer methods and numerical simulations enabled us to understand the groundwater flow system and the capture zone of the groundwater in the Lake Biwa basin.

A CALL FOR HYDROLOGICAL MODELS BASED ON REMOTE SENSING, TRACERS AND OTHER MODERN HYDROMETRIC TECHNIQUES

Gert A. SCHULTZ (Institute of Hydrology, Water Resources Management and Environmental Techniques, Ruhr University Bochum, D-44780 Bochum, Germany,
email: gert.a.schultz@rz.ruhr-uni-bochum.de)

Modern hydrological models of the distributed system type subdivide the drainage basin into many area elements and do the computations of the vertical and lateral fluxes for each area element on the basis of digital maps, digital terrain models and remote sensing data. Although these more sophisticated models quite often provide a high accuracy as far as runoff volumes are concerned, they obviously do not represent the various flow components (surface, subsurface groundwater) correctly. Such knowledge was acquired only in recent times due to the successful application of tracer techniques. They show that subsurface flow, i.e. interflow and groundwater flow, plays a much more important and different role than usually assumed in hydrological models. In this paper close cooperation between hydrological modellers and tracer experts is postulated with the goal of producing new types of sophisticated hydrological models, in which the flows, particularly the subsurface flows, are simulated according to their true physical processes.

HS4/W/28-A5 1430

RECENT TECHNIQUES IN LARGE ARID CATCHMENTS—WAYS TO OVERCOME MODEL CALIBRATION

Jens LANGE, Christian Leibundgut (Institute of Hydrology, University of Freiburg, Fahnenbergplatz, D-79098 Freiburg, Germany, email: jlange@uni-freiburg.de); Asher P. Schick (Department of Geography, The Hebrew University of Jerusalem, 91905 Jerusalem, Israel)

Advanced techniques were applied to determine the spatial distributed parameter values of a non-calibrated rainfall–runoff model in a large arid catchment. Channel dimensions and infiltration characteristics were determined by air-photo analysis and verified by careful fieldwork. A GPS device was used for positioning during field surveys and channel transmission losses were studied by artificial tracers. During one high intensity event (October 1991) rainfall radar yielded the spatial pattern of rainfall intensities, while during another (October 1979) the input rainfall was traced back by the model using a physically-based description of convective arid rainfall. Due to its physical basis, the model could combine different sources of information: basin characteristics determined by field surveys and remote sensing, results of existing experiments, and general scientific experience. Compared with calibrated conceptual models, this resulted in a higher flexibility facilitating applications to basins or events with poor data records, urgently needed for many parts of the arid zone.

HS4/W/29-A5 1450

APPLICATION OF GIS-BASED DISTRIBUTED HYDROLOGICAL MODELLING FOR ESTIMATION OF WATER RESIDENCE TIMES IN THE SMALL SWISS PRE-ALPINE CATCHMENT RIETHOLZBACH

Tomas VITVAR, Joachim Gurtz and Herbert Lang (Swiss Federal Institute of Technology (ETH), Department of Geography, Winterthurerstrasse 190, CH-8057 Zurich, Switzerland,
email: vivtar@geo.umnw.ethz.ch)

A concept of water residence time distributions in the pre-alpine catchment Rietholzbach in northeastern Switzerland has been developed. The catchment covers an area of 3.18 km2 and ranges from 680 to 960 m a.s.l. It is part of the Upper Freshwater Molasse overlaid by Quaternary deposits. The study combines runoff modelling with the use of the isotope 18O and consists of two parts. In the first part, runoff simulation over the period 1983–1997 was carried out using the model PREVAH-ETH. For the spatial data distribution, 100 m grid data were aggregated into hydrotopes by means of a GIS. An approach including the topographical index was integrated into the model, improving the simulation of runoff components. In the second part, the calculated groundwater recharge rates were used for the weighting of d 18O input functions. They served to estimate groundwater residence times at selected sites in the catchment over the period 1994–1997. The mean groundwater residence times range up to 2.5 years and depend on the mixing efficiency within the aquifers. The results form a contribution to the understanding of the water turnover processes in hilly pre-alpine basins with porous structures, as investigated using areal distributed hydrological modelling coupled with tracer techniques.

HS4/W/30-A5 1510

HYDROGRAPH SEPARATION OF RUNOFF COMPONENTS BASED ON MEASURING HYDRAULIC STATE VARIABLES, TRACER EXPERIMENTS, AND WEIGHTING METHODS

Markus WEILER, Simon Scherrer, Felix Naef and Paolo Burlando (Institute of Hydromechanics and Water Resources Management, Swiss Federal Institute of Technology Zurich, CH-8093 Zurich, Switzerland, email: weiler@ihw.baum.ethz.ch)

Hydrograph separation with natural tracers or isotopes has become a popular method to gain comprehensive insights into runoff processes. The mass balance approach, which uses the measured chemical signature of the rainfall as the signature of the event water, is generally used for this purpose. However, temporal variations in the composition of rainfall must be taken into account by an appropriate weighting technique that describes the time response of event water in a drainage basin. A conservative tracer was added to an artificially simulated intense rainfall event on a small-forested hillslope plot. A simple mass balance approach coupled with an appropriate weighting technique was used to separate the event and pre-event water fractions of the surface and subsurface flow. Runoff processes and their relation to mixing between event and pre-event water are identified for both flow paths by means of a detailed survey of both soil water changes and soil properties, as well as through a dye tracer experiment. The experiment demonstrates the importance of event water contributions to subsurface runoff by preferential flow.

HS4/W/31-A5 1630

IMAGE ANALYSIS AND WATER TRACING METHODS FOR EXAMINING RUNOFF PATHWAYS, SOIL PROPERTIES AND RESIDENCE TIMES IN THE CONTINUOUS PERMAFROST ZONE

William L. QUINTON and Philip Marsh (National Water Research Institute, Saskatoon, Saskatchewan, Canada S7N 3H5, email: bill.quinton@ec.gc.ca)

This paper integrates remote sensing and a tracer technique with existing information obtained from hydrometric measurements in order to improve the understanding of soil properties, runoff pathways and residence times on arctic tundra hillslopes in the continuous permafrost zone. Low altitude aerial photographs were analysed in order to quantify physical attributes of earth hummocks. These images were also used in a particle tracking procedure to determine the average tortuosity of inter-hummock channels. Image analysis was also conducted at a much smaller scale on thin sections extracted from soil cores to determine changes in physical properties with depth. Tracer experiments were repeated several times to determine the residence times for different saturated layer elevations. The subsurface drainage efficiency depends upon the physical attributes of the hummock cover, due to the influence of these attributes on the tortuosity of inter-hummock channels. The variations of the total and active porosity, and pore size with depth in the peat are important variables governing residence

times, due to their impact on the hydraulic conductivity. Average residence times increased from ~0.3–0.5 day to as high as ~38 days, as the saturated layer subsided into increasingly decomposed peat.

REQUIRED INTEGRATED APPROACH TO UNDERSTAND RUNOFF GENERATION AND FLOW-PATH DYNAMICS IN CATCHMENTS

Alfred BECKER, Andreas Güntner and Daniel Katzenmaier (Potsdam Institute for Climate Impact Research (PIK), PO Box 601203, D-14412 Potsdam, Germany, email: alfred.becker@pik-potsdam.de)

During the last 20 years, much has been learned about runoff generation processes and lateral flow along different pathways, especially at hillslope to small catchment scales. Nevertheless, this knowledge has only to a small extent contributed to modify model formulations/parameterizations describing runoff generation at the catchment scale. In this paper, we focus on a few examples where detailed field studies describe the essential elements of runoff generation and thus help to achieve a more realistic representation of the underlying mechanisms within process-oriented rainfall–runoff models.

STUDY OF THE INTERCONNECTION BETWEEN A LAKE AND SURROUNDING SPRINGS USING ENVIRONMENTAL TRACERS IN THE KUMAUN LESSER HIMALAYAS

Rm. P. Nachiappan and Bhishm KUMAR (National Institute of Hydrology, Roorkee 247667, Uttar Pradesh, India, email: bk@nih.ernet.in)

The interconnection between Lake Nainital, located in the Kumaun Lesser Himalayas, and the springs issuing in the vicinity of the lake, was investigated using hydrochemistry. The lake water and most of the downstream springs have a high concentration of MgHCO3. Although, the downstream springs that issue in the Kailakhan area southwest of the lake are dominated more by MgSO4, d 18O data confirmed the interconnection between the lake and the springs. The springs in the Balia ravine located south of the lake are also dominated by MgHCO3. However, the springs located in the area to the west of the lake are not hydrologically connected to the lake, as deduced from the stable isotope data. Based on the vertical profiles of the water chemistry and isotopic composition of the lake, we hypothesize that the leakage from the lake takes place from the epilimnion zone. The study highlights the usefulness of stable isotope data combined with water chemistry in identifying recharge sources.

MODIFIED QUANTITATIVE ESTIMATION MODEL OF EROSION AND DEGRADATION IN FOUR MOUNTAINOUS BASINS

Dimitrios A. Emmanouloudis (Department of Forestry, Technological Educational Institute of Drama, Proastio 66100, Drama, Macedonia, Greece); Evangelos I. FILIPPIDIS (Department of Forestry and Natural Environment, AUT, 54006 Thessaloniki, Macedonia, Greece, email: efilippi@for.auth.gr)

This paper presents a new version of a well-known stochastic model to quantitatively assess drainage basin degradation in order to determine erosion in four torrential mountainous basins. This new three-dimensional version, combined with using geographical information systems for data processing, can provide a quantitative assessment of the degradation of any torrential basin in a very short time. Although this system was originally designed for these four particular basins, its flexibility enables it to be adapted for any torrential basin.

HS4/L/03-A4 Poster **0930-03**

SPATIAL DELINEATION OF ZONES WITH THE SAME DOMINATING RUNOFF GENERATION PROCESSES

Eckhard RUTENBERG, Stefan Uhlenbrook and Chris Leibundgut (Institute of Hydrology, University of Freiburg, Fahnenbergplatz, D-79098 Freiburg, Germany, email: rutenb@uni-freiburg.de)

A spatial delineation of the dominating runoff generation processes, based on previous tracer experiments, was conducted in a mountainous area in the Black Forest in southwestern Germany. On saturated areas and boulder trains, rapid runoff is generated (Güntner et al., 1998; Mehlhorn, 1998). The area is dominated by periglacial drift cover on moderate to steep hillslopes, producing mainly delayed runoff (Leibundgut et al., 1998). Rainfall on hilly uplands and consolidated moraines results in slow runoff components (Lindenlaub, 1998). Characteristics of the drift cover and slope serve as main criteria for the differentiation of runoff generation processes. With the aid of a geographical information system, eight classes of spatial units with a characteristic runoff behaviour are defined.

IDENTIFYING MAJOR SOURCES OF ORGANIC MICROPOLLUTANTS AND HEAVY METALS DURING FLOOD EVENTS IN A PARTLY URBANIZED HEADWATER CATCHMENT

Andreas KREIN, Reinhard Bierl (University of Trier, Department of Hydrology, D-54286 Trier, Germany, email: krein@uni-trier.de)

Since 1988 we have investigated flood events in a headwater catchment. Dissolved and particle-bound solids were analysed as well as particle characteristics. By surveying all the data, pollutant profiles and hydrograph patterns, different sources of pollutants can be identified and related to particular locations in the basin. The influence of main roads and sewer systems is obvious. Heavy metals are additionally mobilized from pore water during resuspension of sediments. There is also a clear tendency for a fast and distinct response of smaller polycyclic aromatic hydrocarbons (PAH) with higher solubility, which could be explained by a gradual enrichment of these partly mobile molecules at locations along the flow path. Patterns of PAH chemographs are further determined by chemical alteration and season. The maximum contents during flood events are controlled by pre-event climatic and hydrological conditions with storm intensity and duration controlling inputs of unpolluted material causing dilution. Experiments with artificial flood releases give some indications of in-channel source reactions.

HS5/W/02-A1 **1425**

SPATIAL VARIATION OF METALS IN BED SEDIMENTS OF AN URBAN DRAINAGE BASIN, HAWAII

Ross A. SUTHERLAND (University of Hawaii, Geomorphology Laboratory, Department of Geography, 2424 Maile Way, Honolulu, Hawaii 96822, USA, email: sutherla@hawaii.edu)

Fish from the Manoa Stream, Hawaii, have consistently shown the highest Pb concentrations and some of the highest Cu contents in nationwide surveys by the National Contaminant Biomonitoring Program (NCBP). To investigate the source(s) of these trace metals, a detailed systematic programme was instituted to collect bed sediment samples from 5.8 km of the Manoa Stream. Bed material <63 m was examined for a variety of elements; those reported here include Al, Cu, Ni, Pb and Zn. All statistical analyses and contaminant indices point to minor anthropogenic contamination for Cu and Zn; mineralogical control for Ni; and a very strong contamination signal for Pb. Maximum Pb concentrations (up to 1080 mg kg–1) were associated with anthropogenic material dumping in minor tributaries, storm sewer sediments and sediments in the "lower" section of the basin.

HS5/W/03-A1 **1445**

METALS IN SEDIMENTS OF SUSTAINABLE URBAN DRAINAGE STRUCTURES IN SCOTLAND

Kate HEAL (Institute of Ecology & Resource Management, University of Edinburgh, Darwin Building, King's Buildings, Mayfield Road, Edinburgh EH9 3JU, UK, email: kate.heal@ed.ac.uk)

Sustainable urban drainage solutions increasingly use structures, such as wetlands and ponds, to improve water quality. Previous studies have demonstrated the effectiveness of these structures in removing metals from runoff, but the fate of the captured contaminants has been neglected. Whilst organic contaminants and nutrients may biodegrade and be taken up by plants, metals are expected to accumulate in sediments. EDTA-extractable cadmium, chromium, copper, lead, nickel and zinc were measured in sediment sampled from three urban drainage structures (a wetland and two ponds receiving industrial and residential storm drainage) in Scotland, UK. Metal concentrations showed considerable variability within each structure, probably reflecting short-circuiting of flow. Zinc, chromium and cadmium concentrations were at very low levels at all sites, but copper, nickel and lead exceeded background concentrations for aquatic sediments. An index of metal contamination showed that the metal content of sediments increased with the age of the structure.

HS5/W/04-A1 **1505**

EVALUATION OF STREAM WATER QUALITY IN ATLANTA, GEORGIA, AND THE SURROUNDING REGION (USA)

Norman E. PETERS (US Geological Survey, 3039 Amwiler Rd, Atlanta, Georgia 30360-2824, USA, email: nepeters@usgs.gov); Stephen J. Kandell (Atlanta Regional Commission, 3715 Northside Pkwy, Atlanta, Georgia 30327, USA)

A water-quality index (WQI) was developed from historical data (1986–1995) for streams in the Atlanta Region and augmented with "new" and generally more comprehensive biweekly data on four small urban streams, representing an industrial area, a developed medium-density residential area and developing and developed low-density residential areas. Parameter WQIs were derived from percentile ranks of individual water-quality parameter values for each site by normalizing the constituent ranks for values from all sites in the area for a base period, i.e. 1990–1995. WQIs were developed primarily for nutrient-related parameters due to data availability. Site WQIs, which were computed by averaging the parameter WQIs, range from 0.2 (good quality) to 0.8 (poor quality), and increased downstream of known nutrient sources. Also, annual site WQI decreased from 1986 to 1995 at most long-term monitoring sites. Annual site WQI for individual parameters correlated with annual hydrological characteristics, particularly runoff, precipitation quantity, and water yield, reflecting the effect of dilution on parameter values. The WQIs of the four small urban streams were evaluated for the core-nutrient-related parameters, parameters for specific dissolved trace metal concentrations and sediment characteristics, and a species diversity index for the macro-invertebrate taxa. The site WQI for the core-nutrient-related parameters used in the retrospective analysis was, as expected, the worst for the industrial area and the best for the low-density residential areas. However, macro-invertebrate data indicate that although the species at the medium-density residential site were diverse, the taxa at the site were for species tolerant of degraded water quality. Furthermore, although a species-diversity index indicates no substantial difference between the two low-density residential areas, the number for macro-invertebrates for the developing area was much less than that for the developed area, consistent with observations of recent sediment problems probably associated with construction in the basin. However, sediment parameters were similar for the two sites suggesting that the routine biweekly measurements may not capture the short-term increases in sediment transport associated with rainstorms. The WQI technique is limited by the number and types of parameters included in it and therefore, should be used with caution.

HS5/W/05-A1 **1525**

WATER QUALITY AND ECOLOGY OF WATER BODIES IN URBAN TERRITORIES: ST. PETERSBURG AS A CASE STUDY

Sergei KONDRATYEV, Ludmila Efremova (Institute of Limnology, Sevastyanova 9, St. Petersburg, Russia, email: kond@lake.spg.org); Tatiana Gronskaya, Irina Varfolomeeva (State Hydrological Institute, 2 - liniya 23, St. Petersburg, Russia)

The ecological state of small water bodies located in large cities is the best indicator of the degree of environmental pollution within urban territories. This paper presents data and results on the ecological state of the water system of Lake Lakhtinsky Razliv and its drainage basin located in the northwestern part of St. Petersburg, Russia. The research has evaluated the critical state of the urban water bodies, which are regarded as being in stages of ecological regress. The water bodies intercept, transform, and accumulate in their bottom sediments, the anthropogenically-derived pollutants coming in from the upper part of the drainage system. However it is considered that the water bodies still have not totally lost their possibility for self-purification.

Identifying and Measuring Impacts

HS5/W/06-A1 1610

EVAPOTRANSPIRATION RATES IN URBAN AREAS

C. S. B. GRIMMOND (Climate and Meteorology Program, Department of Geography, Indiana University, Bloomington, Indiana 47405, USA, email: grimmon@indiana.edu); T. R. Oke (Atmospheric Science Program, Department of Geography, University of British Columbia, Vancouver, British Columbia, Canada)

For a significant number of urban hydrological issues, notably, water supply, water quality, groundwater recharge, saline intrusions, and flood runoff, knowledge of evapotranspiration (ET) rates is required. However, because little is known about the magnitude of urban ET rates and their spatial variability, broad assumptions have to be made in many applications. In this paper we present direct measurements of the magnitude and variability of ET rates using micrometeorological techniques (eddy correlation), in seven North American cities. The data demonstrate the importance of urban ET, and illustrate clear differences with land use. Simple relations between ET and measures of land cover are shown.

HS5/W/07-A1 1630

IMPACTS OF URBAN GROWTH ON SURFACE WATER AND GROUNDWATER QUALITY IN THE CITY OF DESSAU, GERMANY

U. RIEMANN (HGN Hydrogeologie GmbH, Rothenburgstraße 10-11, D-99734 Nordhausen, Germany, email: u.riemann@hgn-online.de)

From the mid 19th century, the city of Dessau (Germany) developed as an economic centre. The development of new residential and industrial areas changed the natural landscape having an adverse impact on the surface water, soil water and groundwater regimes. Between 1965 and 1990, public water supply, industry and agriculture pumped some 60 000 m3 d-1 groundwater out of the Dessau aquifer. As a result, groundwater levels fell by 2–3 m over large areas. Since 1990, extraction for drinking water supply, industry and agriculture has decreased from about 60 000 m3 d-1 to as little as about 5000 m3 d-1. As a result of this, in some parts of the city groundwater levels are now only 0.5–1.0 m below the surface. The rising groundwater levels have caused flooding of existing buildings and structures over large areas. To minimize or prevent damage, extensive engineering studies and works have been carried out to keep the groundwater level as low as necessary. Extensive pollution of both groundwater and soil has been observed in a highly industrialized area at Dessau. Further impacts on groundwater quality are caused by gas stations, petrochemical production plants and related depots. The main pollutants are volatile organic compounds (VOCs), monocyclic aromatic hydrocarbons which include benzene, toluene, ethylbenzene and the three xylenes (m-, o- and p). Local contamination exceeds defined limit values for drinking water. A further problem is the concentration of heavy metals (arsenic, zinc, cadmium and nickel) in these areas.

HS5/W/08-A1 1650

DEVELOPMENT AND WATER QUALITY IN THE KAM TIN BASIN, HONG KONG

Mervyn PEART (Department of Geography, University of Hong Kong, Pokfulam Road, Hong Kong)

The economic development of Hong Kong has meant that some once rural areas have been transformed. Low-density housing, open storage and makeshift factories, in addition to agriculture have characterized them. This change in land use may have consequences for water quality especially as many areas are not connected to mains sewerage. In the Kam Tin basin, under baseflow conditions, water samples from the river in the developing lowland are characterized by much higher concentrations of calcium, magnesium, potassium, nitrate-nitrogen and dissolved phosphorus, than an undisturbed upland tributary. The Kam Tin River also has much greater suspended solids concentrations than the upland stream and significant amounts of floating debris and rubbish which is never seen in the upland tributary. More attention needs to be given to sewerage and waste disposal in the basin. Runoff pH appears little influenced by the acid rain input.

STORMWATER MANAGEMENT PROBLEMS IN A TROPICAL CITY – THE BELO HORIZONTE CASE STUDY

Nilo Oliveira NASCIMENTO, Márcio Benedito Baptista (Federal University of Minas Gerais, Av. Contorno, 842, Belo Horizonte, MG, 30110-060 Brazil, email: niloon@ehr.ufmg.br); Luiz Augusto Kauark-Leite (SAFEGE, Consulting Engineers, 15/27, rue du Port, F-92007 Nanterrre, France)

In developing countries urban stormwater management shows a set of particularities when compared to that of developed countries. These particularities are mostly related to the lack of adequate urban planning and regulation, operation and maintenance of drainage systems, economic, health, educational, demographic and social questions. In the present paper, these questions are analysed and discussed using the Brazilian city of Belo Horizonte as a case study. The role of stormwater master planning as an instrument to adequately handle the reported problems is a major conclusion of the paper.

HS5/W/10-A1 1730

AN INTEGRATED APPROACH TO THE MANAGEMENT OF WATER QUALITY IN A DEVELOPING SOUTH AFRICA

E. PRETORIUS (Department of Civil Engineering and Building, Technikon Free State, Private Bag X25305, Bloemfontein 9300, South Africa, email: ipretori@eng.tofs.ac.za); G. du T. de Villiers (Department of Geography, University of the Orange Free State, PO Box 339, Bloemfontein 9300, South Africa)

The majority of South Africans live in rapidly developing communities with inadequate or poorly functional services. Pollution from these developing communities has severe economic and health implications for downstream users and impacts on the natural functioning of river ecosystems. Water quality problems from developing communities arise where wastes produced in the community, reach the surface or groundwater resource, or where destruction of the riparian zone and river habitats occur. The key to sustainable management of pollution from developing communities lies in addressing the physical causes of water quality problems while the sustainability of these physical interventions rests on addressing the institutional and socio-economic factors contributing to the problem.

NUTRIENT STORAGE IN URBAN WETLANDS

Tom Shatwell (Sinclair Knight Merz, 100 Christie Street, St Leonards, Sydney 2065, Australia); Ian CORDERY (School of Civil and Environmental Engineering, The University of New South Wales, Sydney 2052, Australia, email: i.cordery@unsw.edu.au)

A pond in Sydney's Centennial Park is fed by stormwater from a 120 ha catchment that has predominantly residential land use. Over a period of several months the pond inflow and outflow were monitored to observe flow rate, suspended solids and total phosphorus concentration. In all runoff events, the inflows were characterized by rapid increases in the concentration of both suspended solids and phosphorus. It appears that significant amounts of phosphorus and sediment accumulate in the pond during the small, more frequent rainfall events. In most small to medium size winter flood events, 60% of phosphorous and 80% of suspended sediments were deposited in the pond. The implication for use of ponds for stormwater treatment would appear to be that ponds can be effective in arresting the downstream movement of sediment, but may not significantly reduce the downstream movement of phosphorus.

HS5/W/12-A2 0920

THE USE OF CONSTRUCTED WETLANDS FOR REDUCING THE IMPACTS OF URBAN SURFACE RUNOFF ON RECEIVING WATER QUALITY

Michael REVITT, Brian Shutes and Lian Scholes (Urban Pollution Research Centre, Middlesex University, Bounds Green Road, London N11 2NQ, UK, email: m.revitt@mdx.ac.uk)

The design criteria for constructed wetlands for the treatment of urban runoff are described and particular attention is paid to pre- and post-treatment components, sizing considerations and the substrate structure. The pollutant removal performances of two constructed wetlands are discussed and the predicted maximum outflow pollutant concentrations are compared to existing water quality criteria. Suspended solids represent the main concern with higher outlet concentrations being discharged due to re-suspension processes. This problem highlights both the need for regular maintenance, particularly with respect to the emptying of sedimentation tanks, and the benefits of incorporating an overflow channel to reduce sediment mobilization during high flow conditions.

HS5/W/13-A2 0940

DESIGN CONSIDERATIONS FOR THE USE OF VEGETATIVE CONTROLS FOR THE TREATMENT OF HIGHWAY DISCHARGES

J. Bryan ELLIS (Urban Pollution Research Centre, Middlesex University, Bounds Green Road, London, N11 2NQ, UK, email: b.ellis@mdx.ac.uk)

The design of highway drainage in the UK has traditionally provided for the rapid removal of surface runoff from the carriageway with positive discharges being directly routed either to a roadside soak away system or to the nearest receiving water course. Such systems pay little attention to the potential pollution loads generated from rainfall-runoff events or their potential deleterious impacts upon receiving waters. Increasing regulatory agency concern over such discharges is leading to a review of such conventional drainage systems and an interest in the potential use of vegetative systems for the control and treatment of highway runoff quality. The paper identifies the range of pollutant removal efficiencies achieved by vegetative best management practice (BMP) controls and reviews available design procedures for grass-lined channels (swales) and constructed wetlands. Recommended design guidance for swales rarely specifically considers water quality criteria and usually results in over-design capacities; "over-the-edge" trough systems are preferred over conventional swale geometries. For wetland design, a multi-cell approach is recommended with sizing providing the critical control parameter in terms of performance efficiency and a quantitative comparison is given of hydraulic and kinetic sizing design approaches.

HS5/W/14-A2 1000

SUSTAINABLE MANAGEMENT OF CHRISTCHURCH'S WATERWAYS AND WETLANDS USING STORMWATER SOAKAGE DISPOSAL

Peter CALLANDER (Pattle Delamore Partners Ltd, PO Box 389, Christchurch, New Zealand, email: peter.callander@pdp.co.nz); Robert Watts and Tony Oliver (Christchurch City Council, PO Box 237, Christchurch, New Zealand)

The western margins of Christchurch City, New Zealand, are located on a large alluvial flood plain including areas of free draining gravel strata. In settings such as this, the disposal of stormwater via ground soakage will minimize the disruption that urban development causes to the hydrological cycle. The gravel strata also form part of a productive aquifer used (by wells) to provide the city water supply. The discharge of stormwater into a drinking water aquifer, rather than a surface aquatic environment, indicates that faecal coliforms are likely to be the main contaminant of concern, along with protection against chemical spillages. Removal of suspended sediments is also important to maintain the soakage capacity of the disposal system. An appropriate treatment and disposal system involves separate soakage of roof stormwater, reticulation of other stormwater using vegetated swales, and disposal via soil adsorption basins and rapid soakage overflow chambers. The location and shape of these components are designed with appropriate landscape and planting considerations to create an aesthetic enhancement to the urban environment.

HS5/W/15-A2 1020

TOWARDS INTEGRATED STORMWATER-MELTWATER MANAGEMENT IN THE COASTAL PART OF NORWAY

Sveinn T. THOROLFSSON (Department of Hydraulic and Environmental Engineering, The Norwegian University of Science and Technology, N-7034 Trondheim, Norway,
email: sveinn.thorolfsson@bygg.ntnu.no); Magnar Sekse (The Municipality of Bergen, Division for Water Supply and Water Environment, Bergen City Hall, N-5002 Bergen, Norway)

New directions in urban runoff and water environmental management in the coastal part of Norway are being introduced. The goal is to manage the total urban runoff (wastewater and stormwater) so that environmental damage is avoided and the goals for the receiving water are achieved at reasonable cost. It is mostly based on the results from the research programme carried out in the Birkeland basin and the subcatchment Sandsli, in Bergen, since 1981, where use of the blue-green concept and the Sandsli-system has been successful. The green trend in urban stormwater management utilizes the capabilities of nature to store huge stormwater-meltwater volumes and to reduce the pollution content in the water. In the planning process, blue areas like lakes, rivers and brooks are to be kept in their natural condition.

Management & Planning Approaches

HS5/W/16-A2 1100

IMPROVING DEGRADED URBAN WATER COURSES IN EASTERN SCOTLAND: A CASE STUDY

Chris JEFFERIES (Wastewater Technology Centre, University of Abertay, Dundee, DD1 1HG, UK, email: c.jefferies@abertay-dundee.ac.uk); Anna Govier (ABB Power T&D Ltd., East Kingsway, Dundee, DD4 7RP, UK)

The outcome of a range of studies of the Lyne Burn in eastern Scotland is presented. This is a typical water course which has become degraded in the past from discharges directly related to urban influences. Changes include reduced low flows due to mining and at the same time increased washoff of pollutants from industry and sewerage, a major housing and commercial development and new highways. The drainage improvement actions and initiatives undertaken are also presented. Details of pollution causes and impacts are presented together with the changes in the water course quality mirroring the various initiatives. It is concluded that the index of stream classification has not changed and that a water course of this type can only be improved in the long term if source control measures are implemented in a wide range of areas and continual attention is paid to the causes of pollution.

HS5/W/17-A2 1120

WATER-SENSITIVE URBAN PLANNING: THE CASE OF ISRAEL'S COASTAL AQUIFER

Uri SHAMIR (Faculty of Civil Engineering, Technion - Israel Institute of Technology, Haifa 32000, Israel, email: shamir@tx.tecnion.ac.il); Naomi Carmon (Faculty of Architecture and Town Planning, Technion - Israel Institute of Technology, Haifa 32000, Israel)

Urban development above a phreatic aquifer can reduce substantially the amount of water that infiltrates and recharges the water resource. In Israel's coastal plain, the area of which is about 1900 km2, 650 km2 are already urban, and another 625 km2 are expected to be urbanized by 2020. This paper presents the motivation, methodology and results of estimating the present and expected future loss of recharge to the aquifer, as a consequence urban development above it. The paper ends with recommendations for implementing Water-Sensitive Urban Planning.

HS5/W/18-A2 1140

STORMWATER MASTER PLANNING IN DEVELOPING TROPICAL COUNTRIES

Luiz Augusto KAUARK-LEITE (SAFEGE, Consulting Engineers, 15/27, rue du Port, F-92007 Nanterre, France, email: luiz_kauarkleite@safege.fr); Nilo Oliveira Nascimento and Márcio Benedito Baptista (Federal University of Minas Gerais, Av. Contorno, 842, 30110-060 Belo Horizonte,MG, Brazil)

In the present paper a methodology to design urban drainage master plans suited to cities located in tropical regions of developing countries is presented. The role of master planning in urban drainage and its objectives are reviewed and discussed. Fundamental methodological principles that should guide master planning are presented and a structure for its elaboration is suggested. A discussion is presented on the main actions and programmes that a master plan could lead to such as technical, institutional and legal initiatives.

HS5/W/19-A2 1200

THE ALLOCATION OF RESOURCES TO STORMWATER POLLUTION CONTROL

S. Brown, S. Shrestha and S. J. RILEY (School of Civic Engineering and Environment, University of Western Sydney Nepean, PO Box 10, Kingswood NSW 2747, Australia, email: s.riley@uws.edi.au)

Limited resources for ameliorating stormwater pollution in urban areas raises the issue of selecting and implementing appropriate methods of pollutant reduction. An effective stormwater management programme should consist of strategies that will achieve the goal at the minimum cost, thereby making the best use of limited available resources. This paper presents an optimization scheme that sizes various stormwater pollution control options. The options include a wide range of strategies, from street sweeping to constructed wetlands. The objective is to select the most effective strategies for limited funds. The non-linear problem is solved using LINGO, a non-linear problem solver. A heuristic method is used to select various possible options. The algorithm is applied to Plumpton Park in Blacktown, a suburb in Western Sydney, Australia.

HS5/W/20-A2 1220

USE OF WEATHER RADAR FOR COMBINED CONTROL OF AN URBAN DRAINAGE SYSTEM AND A SEWAGE TREATMENT PLANT

Markus QUIRMBACH, Gert A. Schultz (Institute for Hydrology, Water Management and Environmental Techniques, Ruhr-University Bochum, Universitätsstr. 150, D-44780 Bochum, Germany, email: markus_quirmbach@ruhr-uni-bochum.de); Torsten Frehmann (Institute for Urban Water Management, University of Essen, Universitätsstr. 15, D-45141 Essen, Germany)

In present practice, the design and operation of urban drainage systems, and the corresponding sewage treatment plants, are usually independent. In this paper an approach is presented, the aim of which is joint operation of an urban drainage system and the corresponding sewage treatment plant. This operation will be based on real-time flood forecasts, which are computed with the aid of radar rainfall measurements. The goal of this control is to minimize the combined negative effects of the hydraulic load (water quantity) and the pollution load (water quality) in the receiving waters during floods. In growing urban areas, higher imperviousness is the cause of increased flood peaks and volumes in the receiving water. In the test basin used, an industrial area with a high imperviousness strongly effects the control of the total system.

National Perspectives

HS5/W/21-A2 1405

GROUNDWATER IN URBAN DEVELOPMENT—A REVIEW OF LINKAGES AND CONCERNS

S. S. D. FOSTER (British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK, email: s.foster@bgs.ac.uk); B. L. Morris and P. J. Chilton (British Geological Survey, Wallingford, Oxfordshire, OX10 8BB, UK)

Urban population growth in Asia and Latin America is occurring on a scale, and at a rate, unprecedented in human history. Many of the cities are sited on unconfined or semi-confined aquifers, depend on groundwater for much of their water-supply, and apply or dispose of most of their liquid effluents and solid residues to the ground. Urbanization causes radical changes in groundwater recharge, modifying existing mechanisms and introducing new ones. Concomitantly groundwater quality degradation is reported from a wide range of geographical locations, both within the urban area itself and in downstream alluvial aquifers. Its severity varies considerably with hydrogeological environment, development level and coverage of waterborne sewerage, but it is often the cause of increasing freshwater scarcity, escalating water-supply costs and a growing human-health hazard. As such it is an issue that urgently needs to be addressed.

HS5/W/22-A2 1425

IMPACT OF GROUNDWATER ON URBAN DEVELOPMENT IN THE NETHERLANDS

Frans VAN DE VEN (Delft University of Technology, Civil Engineering and Geosciences, Land and Water Management, Stevinweg 1, 2628 CN Delft, The Netherlands, and Institute for Inland Water Management and Wastewater Treatment (RIZA), PO Box 17, 8200 AA Lelystad, The Netherlands, e-mail: f.h.m.vdven@riza.rws.minvenw.nl); Michiel Rijsberman (Delft University of Technology, Civil Engineering and Geosciences, Land and Water Management, Stevinweg 1, 2628 CN Delft, The Netherlands, and, DHV Water BV, PO Box 484, 3800 AL Amersfoort, The Netherlands)

Although existing urban areas in the Netherlands suffer from groundwater nuisance, the groundwater system seems to be a neglected part of the urban water system. This also is the case in recent plans for new urban areas, which constitute a substantial growth of the total Dutch urban area. Groundwater related problems include hazards to public health, unwanted effects on the environment and economic attenuation. For these problems a number of causes and effect are identified. These include problems with groundwater quantity and quality, besides geological problems and organizational problems. The impact of groundwater on present Dutch urban development planning is too small, as groundwater related problems are not given proper attention.

HS5/W/23-A2 1445

GROUNDWATER CONTAMINATION BY ORGANIC CHEMICALS IN INDUSTRIALIZING COUNTRIES: THE UNSEEN THREAT

Oliver T. N. SILILO (Cape Water Programme, Environmentek, CSIR, PO Box 320, Stellenbosch 7599, South Africa, email: osililo@csir.co.za)

Industrialization brings with it a high production of wastes. Many of these are disposed of in the environment and can have a serious impact on groundwater. In developed, industrialized countries, hierarchical approaches to investigating contamination problems are generally well established. In many instances, individual organic chemicals have been identified as being critical in pollution plumes. On the other hand, in many industrializing countries, individual organic contaminants are rarely determined during groundwater pollution investigations. The reasons for this include low level of awareness, lack of analytical facilities and cost constraints. Three case studies are presented from the Western Cape, South Africa, where although organic contaminants were suspected, the investigation concentrated on inorganic contaminants. It is concluded that there is need for increased awareness of the potential impact of organic contaminants on groundwater and ultimately guidelines need to be developed for principal organic contaminants that should be analysed for at contaminated sites.

HS5/W/24-A2 1505

PROBLEMS OF GROUNDWATER QUALITY RELATED TO THE URBAN ENVIRONMENT IN GREATER CAIRO

Nahed E. El ARABI (Nile Basin Dept., Research Institute for Groundwater, El Kanater El Khairia, Egypt)

Greater Cairo is faced with increases in population and unplanned extensions in urbanization. This has not been followed by an equal expansion in water supply and sanitary drainage, thus resulting in poor environmental conditions. Cairo covers 300 km2 with intensive and varied urban land uses and encompasses the oldest industrial areas of Egypt, such as Shubra-Mostorad and Helwan. In addition, new industrial communities are located in the western desert fringe of Greater Cairo with many industrial areas located in zones of highly vulnerable groundwater. Pollution sources of industrial origin threatening groundwater occur in a wide variety of both large and small industrial areas. Moreover using sewage (waste) water for irrigation is reclaiming the desert fringes of Cairo. The adverse environmental impacts of unplanned urban expansion and industrial and agricultural activities could lead to deterioration in groundwater quality. This has dictated quick interventions based on groundwater quality monitoring systems designed to detect pollution sources and their spatial extension. This

paper presents groundwater quality indicators for domestic, agricultural and industrial pollution at representative sites within Greater Cairo.

HS5/W/25-A2 1525

DETERIORATION OF GROUNDWATER QUALITY IN THE COASTAL PINGTUNG PLAIN, SOUTHERN TAIWAN

Chung-Ho WANG (Institute of Earth Sciences, Academia Sinica, PO Box 1-55, Nankang, Taipei, Taiwan 11529, ROC, email: chwang@earth.sinica.edu.tu); Chung-Jung Chiang (Central Geological Survey, PO Box 968, Taipei, Taiwan 23557, ROC); Tsung-Ren Peng (Department of Soil and Environmental Sciences, National Chung Hsing University, Taichung, Taiwan 40227, ROC); Wen-Cheh Liu (Department of Horticulture, Taiwan Sugar Research Institute, Tainan, Taiwan 70123, ROC)

Population growth, urban expansion and economic development have persistently raised the demand for water supply and consequently, greatly increased the exploitation of groundwaters in the Pingtung Plain of southern Taiwan over past decades. Over-pumping of groundwaters due to booming freshwater aquaculture and agricultural activity has caused the groundwater level to fall and land to subside below sea level in some coastal areas. Isotopic and chemical groundwater analysis has verified the deterioration in coastal groundwater quality due to active seawater intrusion through the offshore outcrops of both unconfined and confined aquifers since 1980. The greatest extent of seawater encroachment has been estimated to be as far as 8.5 km inland with an affected area of about 104 km2 for the deep confined aquifer in 1996. Remedial measures need to be immediately enforced to effectively restrain sea water encroachment and to alleviate groundwater salinization.

HS5/W/26-A2 1545

GROUNDWATER QUALITY MANAGEMENT: POLLUTION PERSPECTIVES

R. RAMESH (Institute for Ocean Management, Anna University, Chennai, India, email: auiomrr@md2.vsnl.net.in

Water scarcity has been one of the most serious problems in Chennai, India for many years. In particular there has been a decline in both groundwater table level, and groundwater quality over recent years. This paper focuses on the distribution of major and trace elements in groundwater of the Chennai basin. It is seen that the concentration of major ions such as Na and Cl are predominantly influenced by anthropogenic activities, whereas natural processes control other major elements. The concentration of trace metals at a few wells along the waterways are high and in general there is a decrease in the relative concentration from summer to monsoon due to local precipitation and seepage which dilutes the concentration of trace metals and aids their migration. This study also highlights the impact on groundwater of urban growth in Chennai.

Modelling & Methods 1

HS5/W/27-A2 1635

MODELLING OF NITROGEN DYNAMICS IN THE SUB-SURFACE ENVIRONMENT

A. Jake GUSMAN (URS Greiner Woodward Clyde, 2020 East First Street, Suite 400, Santa Ana, California 92705, USA, email: jake_gusman@urscorp.com); Miguel A. Marino (Dept. of Land, Air, & Water Resources and Dept. of Civil & Environmental Engineering, University of California, One Shields Avenue, Davis, California 95616-8628, USA)

This paper presents a physically-based model (RISK-N) to simulate nitrogen cycling in soils, and nitrate transport and fate in soils and groundwater. The soil is separated into upper-root, lower-root, sub-drainfield, and intermediate vadose zones, each with uniform properties. Transport in each soil zone is modelled on the basis of complete mixing, by spatially averaging the related partial differential equation. Transport in the aquifer, however, is modelled using a two-dimensional advection-dispersion equation. Two example problems demonstrate and validate the use of the RISK-N model: (a) an irrigated and fertilized corn plot, and (b) a suburban area with septic tank systems and fertilized turfgrass.

HS5/W/28-A2 1655

GROUNDWATER MODELLING IN URBAN AREAS AS A TOOL FOR LOCAL AUTHORITY MANAGEMENT: BARCELONA CASE STUDY (SPAIN)

E. Vázquez-Suñé, X. SÁNCHEZ-VILA (Dept. Enginyeria del Terren, Universitat Politècnica de Catalunya, 08034 Barcelona, Spain, email: dsanchez@etseccpb.upc.es)

Urbanization poses some threats to both the availability and quality of groundwater resources in large cities worldwide, with corresponding significant social, environmental and economic implications. A good knowledge of urban hydrology requires a detailed quantitative analysis of water fluxes, but also of the quality of the resources. In any real case study one has to face at least three aspects: (a) process identification, (b) aquifer characterization and modelling, and (c) water resources management. This three-fold methodology has been applied to the city of Barcelona. The outcome is a groundwater model which among other things may become a management tool, as it allows definition, characterization and quantification of the potential risk to aquifers, as well as to urban structures, with all the implications for the population. This is an important step towards convincing city managers to consider groundwater as one of the topics to be taken into account in city planning.

HS5/W/29-A2 1715

THE VULNERABILITY OF THE DUPI TILA AQUIFER OF DHAKA, BANGLADESH

M. Kamrul Hasan, William BURGESS (Department of Geological Sciences, University College London, Gower St., London WC1E 6BT, UK, email: william.burgess@ucl.ac.uk); Jane Dottridge (Komex Clarke Bond, 129 Cumberland Road, Bristol BS1 6UY, UK)

Dhaka relies almost exclusively on groundwater for its water supply. Intensive abstraction from the Dupi Tila aquifer has led to induced recharge from rivers and enhanced vertical leakage from regions containing contaminated land. Low quality water has invaded the aquifer from a polluted stretch of river. Vertical hydrochemical profiles show that urban pollution has reached the upper levels of the aquifer within the city, but not the level of groundwater abstraction except in isolated cases. The aerobic environment of the aquifer may support the natural attenuation of contaminants. Contaminant transport modelling demonstrates that a general deterioration of groundwater quality is inevitable even if all sources of contamination are removed immediately. The model could be used to guide groundwater quality monitoring as part of a protection policy for this strategically important aquifer. A programme of waste management should be based on factors identified as governing aquifer vulnerability.

HS5/W/30-A2 1735

ECOLOGICAL INDICATORS AND INDICES OF SUSTAINABLE DEVELOPMENT

Anna BELOUSOVA (Water Problems Institute, Russian Academy of Sciences, 3 Gubkina Str., Moscow 117971, Russia, email: anabel@eolss.msk.ru)

A system of ecological Pressure-State-Response (PSR) indicators has been developed. The first indicator, characterizing an impact in the PSR system, must take into account all time peculiarities of the impact on the underground hydrosphere. However, this will not help to fully assess the whole ecological situation in terms of groundwater in complex natural-anthropogenic conditions. Pressure indicators must be subdivided into Present (current) and Retarded (or delayed) Pressure Indicators. An additional indicator, the Foresight Indicator makes it possible to avoid confusion in assessing ecological consequences at present, with those in the near and remote future. State Indicators characterize changes in the hydrosphere under the impact of negative events (Present and Future State Indicators). Response Indicators characterize political, social and economical decisions. Index groups can characterize each of these indicators.

LOADINGS OF NON-AGRICULTURAL NITROGEN IN URBAN GROUNDWATER

David N. LERNER (Groundwater Protection and Restoration Group, Civil and Structural Engineering, University of Sheffield, Mappin Street, Sheffield, S1 3JD, UK, email: d.n.lerner@shef.ac.uk); Yuesuo Yang (Environmental Engineering Centre, Queens University, Belfast, BT7 1NN, UK); Mike H. Barrett (Robens Centre for Public and Environmental Health, University of Surrey, Guildford, Surrey, GU2 5XH, UK); John H. Tellam (School of Earth Sciences, University of Birmingham, Edgbaston, Birmingham, B15 2TT, UK)

In the groundwater under Nottingham, nitrate concentrations are as high as they are in the surrounding rural groundwater. Fertilizer and agricultural practices are the main sources of rural nitrates, but are insignificant in the city environment. Urban sources of nitrogen in groundwater include leaking sewers, leaking water mains, landfills and industrial chemical spillages. We have recently completed a major field and modelling study of Nottingham to identify and quantify recharge sources and amounts, and loadings of solutes. A novel approach of combining a water balance with multiple solute balances provided the first estimates for a UK city. Sewers contribute about 13% of the nitrogen loading. The size of the nitrogen loading from leaking water mains is more important at about 36% of the total, because they provide over half the recharge in the urban area. The remaining 50% of the N loading includes parks, gardens, landfills and industrial spillages.

HS5/W/32-A3 0920

GROUNDWATER PROTECTION INCORPORATED INTO LAND USE PLANNING: A STUDY FROM CEBU CITY, THE PHILIPPINES

Ian HOLMAN, Robert Palmer (Soil Survey and Land Research Centre, Cranfield University, Silsoe, Bedfordshire, MK45 4DT, UK, email: i.holman@cranfield.ac.uk)

Municipal water suppliers to many Asian mega-cities rely on imports of surface water because recent rapid urban expansion threatens local groundwater quality. However, shallow groundwater resources beneath these cities are still utilized by private wells irrespective of health implications. If the quality of shallow resources is to be maintained, potentially polluting activities must be encouraged to locate in areas where groundwater is naturally protected. Groundwater vulnerability techniques are an appropriate, low cost management tool for defining both areas of natural protection and areas requiring strict land use controls. The UK vulnerability methodology, adapted for Philippine conditions, enables land to be zoned according to: soil and aquifer properties, depth to groundwater, and proximity to perennial rivers. The resulting 16 groundwater vulnerability zones have been simplified, for routine regulatory use, into a four-zone Development Constraint Map, which identifies the planning controls necessary to protect groundwater quality.

AUTOPSY OF AN AQUIFER: A CASE STUDY OF AL HAYMA, YEMEN.

Chris D HANDLEY (School of Oriental and African Studies, Russell Square, London WC1H 0XG, UK, email: chris@chrishandley.freeserve.co.uk)

Despite the absence of a unique solution, a combination of the following methods permits an assessment of "who stole the water?" from the main aquifer on which a city of 400 000 people depends: (a) the Penman-Monteith method for deriving crop and soil evaporation, (b) the US Soil Conservation Service curve number method for calculating runoff, and (c) groundwater flow modelling to match historical water level trends.

HS5/W/34-A3 1000

SULPHATE ISOTOPE SIGNATURES IN BOREHOLE WATERS FROM THREE URBAN TRIASSIC SANDSTONE AQUIFERS, UK

Anwen J. Hughes, John H. TELLAM, John W. Lloyd, Kim A. Stagg (Earth Sciences, Birmingham University, Birmingham B15 2TT, UK, email: j.h.tellam@bham.ac.uk); Simon H. Bottrell, Andrew P. Barker (Earth Sciences, Leeds University, Leeds LS2 9JT, UK); Michael H. Barrett (Robens Centre, Surrey University, Guildford, Surrey, GU2 5XH UK)

This paper outlines an investigation of the use of 34S and 18O data in provenancing sulphate in groundwaters of urban UK Triassic sandstone aquifers. The isotopic composition of potential S sources (precipitation, industrial acids, plating bath effluents, various building materials, public supply water, detergents, road salt, and geological materials) were determined. The isotopic data from pumped sampling in the Birmingham aquifer confirmed previous interpretations based on elemental concentrations, identifying natural and various anthropogenic sources. Detailed resolution of the anthropogenic sources was not possible, partly because of the common source of many man-made sulphur compounds in the aquifers studied (Triassic evaporites), and the mixed nature of the groundwater samples. However, the

isotope data set from Birmingham, Nottingham, and Liverpool all show that sulphide oxidation commonly occurs in the shallow subsurface: this has important implications for the attenuation of other pollutants. No sulphate reduction was apparent in any of the waters sampled from the three aquifers.

HS5/W/35-A3 1045

A STABLE CARBON ISOTOPE STUDY ON DIRECT PRECIPITATION RECHARGE TO THE AQUIFER IN THE CITY OF YAMAGATA, NORTHERN JAPAN

Masaya YASUHARA and Kohei Kazahaya (Hydrology Studies Group, Geological Survey of Japan, 1-1-3 Higashi, Tsukuba, Ibaraki 305-8567, Japan, email: masaya@gsj.go.jp); Hiroyuki Higuchi and Toshifumi Ueda (International Department, Kyowa Engineering Consultants Co. Ltd., 2-26-2 Sasazuka, Shibuya, Tokyo 151-0073, Japan)

A dynamic image of a shallow (<100 m below the surface) unconfined aquifer in the City of Yamagata, northern Japan has been obtained by d13C and major element analyses of groundwater and river water. The chemical and isotopic composition of groundwater show significant variations across the study area, as a result of mixing, in varying proportions, of waters of different origin. A successive mixing of the infiltrated precipitation (direct precipitation recharge) with the infiltrated Mamigasaki river water takes place beneath the downtown area of the city. Although about 70–80% of the surface has already been rendered impermeable, groundwater beneath the downtown area shows strong evidence of precipitation inputs. In the immediate area of the Mamigasaki River, less than 10% of groundwater can be attributed to water of precipitation origin. With an increasing distance downslope, the infiltrated precipitation has an increasing influence on groundwater. A couple of kilometres away from the river, the results are indicative of a 40% precipitation contribution. This suggests that the direct precipitation recharge is still of great significance even in the highly urbanized areas like the City of Yamagata.

HS5/W/36-A3 1105

MONITORING SOLVENTS IN THE BIRMINGHAM AQUIFER (UK): 1987, 1998 AND ON TO THE NEXT MILLENNIUM

Lynda Taylor, Michael RIVETT (School of Earth Sciences, University of Birmingham, Edgbaston, Birmingham, B15 2TT, UK, email: m.o.rivett@bham.ac.uk)

Chlorinated solvents are exceedingly common groundwater contaminants in aquifers that underlie urban areas. A case study is presented of the Birmingham aquifer (UK) using data from two surveys of solvent occurrence conducted a decade apart (1987 and 1998). Active abstraction boreholes (mainly industrial-use) were used to obtain groundwater samples. The suitability of such boreholes to observe relevant contaminant hydrogeological processes and provide long-term monitoring is illustrated. Although the Birmingham data set is relatively sparse, interpretations may nevertheless be offered on solvent occurrence, persistence of solvent source zones, effects of changing groundwater abstraction, solvent attenuation in the aquifer and trends in solvent mass removal by groundwater abstraction. It is concluded that active abstraction boreholes may provide useful data on urban groundwater quality trends and their use in the next millennium should not be overlooked.

EVIDENCE FOR SEWAGE CONTAMINATION OF THE SHERWOOD SANDSTONE AQUIFER BENEATH LIVERPOOL, UK

Emily Whitehead, Kevin HISCOCK, Paul Dennis (School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, UK, email: k.hiscock@uea.ac.uk)

Urbanization of the Liverpool area in northwest England began in 1207 and the area was prosperous by the 1700s. As an area with a long history of urbanization, the objective of this study was to map the water quality of the underlying major Sherwood Sandstone aquifer with special attention to whether leaking sewers are contaminating the groundwater. The sewerage system in Liverpool has been extensive since the late nineteenth century, expanding along with the city. Twelve samples were collected from sites in Liverpool and analysed for several markers of sewage contamination, including the nitrogen isotope composition of dissolved nitrate, microbiological indicators, boron and major ions such as nitrate and potassium. The results showed saline intrusion and widespread contamination of the aquifer. The sewage "fingerprint" was positively identified and provides the first conclusive evidence for sewer-derived contamination of Liverpool's groundwater.

GROUNDWATER LEVEL EVOLUTION IN THE MILAN AREA: NATURAL AND HUMAN ISSUES

Tullia BONOMI (Dipartimento di Scienze dell'Ambiente e del Territorio, Università degli Studi Milano Bicocca, Milano, Via Emanueli 15, I-20126 Milano, Italy, email: bonomi@alpha.disat.unimi.it)

The history of groundwater level development in Milan province and in Milan city is analysed. It is very well recorded by piezometric data from a monitoring network of 284 wells, with a monthly frequency. In 1915 the water table depth, quite close to Milan city, was about 1 m below ground surface. The groundwater table has since fallen rapidly, with an historical minimum in the 1970s, some 40 m below ground surface. However, a rapid increase is now occurring and in recent years (1993–1997) the situation in Milan is getting worse. Many areas of the town's subsurface (parking, underground, houses, hospitals) are now flooded by groundwater. A study of the Milan hydrogeological system has been carried out to analyse the natural and human causes determining the groundwater level evolution. The historical sequences of all the different factors of the mass transfer, from the beginning of the century through to 1997, have been analysed to evaluate their synergistic relationships.

HS5/W/39-A3 1205

LOSS OF GROUNDWATER RESOURCES FOLLOWING MAJOR QUARRYING ACTIVITY IN URBAN AREAS: THE GALERIA-MAGLIANA QUARRY BASIN (ROME, ITALY)

Giuseppe Capelli, Renato Funiciello, Daniela Iorio, Roberto SALVATI (Department of Geological Sciences, University of Rome TRE, L.go S. Leonardo Murialdo 1, I-00146 Roma, Italy, email: salvati@uniroma3.it)

In this paper we present the results of a study aimed to define the environmental impacts of quarry activities in the suburban belt of Rome. The hydrological and hydrogeological modifications induced by the quarry activities receive particular attention and can be summarized as (a) disruptive groundwater lowering as a result of quarrying activity below groundwater level; (b) dewatering of large parts of the area as a consequence of quarry site back-filling with low permeability materials, morphological alteration and soil degradation, with consequent loss of environmental structure in large parts of the area; and (c) river system alteration or its complete disruption as a result of dispersed and unplanned site development. The study has been developed through a multidisciplinary approach using sedimentological, geomorph-ological and hydrogeological methods.

ASSESSMENT OF GROUNDWATER POLLUTION IN THE PATANCHERU INDUSTRIAL DEVELOPMENT AREA AND ITS ENVIRONS, MEDAK DISTRICT, ANDHRA PRADESH, INDIA

V. V. S. GURUNADHA RAO, K. Subrahmanyam, P. Yadaiah and R. L. Dhar (National Geophysical Research Institute, Hyderabad-500007, India, email: director@nngri.wiprobt.ems.vsnl.net.in)

A number of chemical and pharmaceutical industries have opened since 1978 in the Patancheru Industrial Development Area of Medak district, Andhra Pradesh, India. Both treated and untreated effluents from these industries are discharged to the Nakkavagu and Peddavagu streams and the former also receives effluents from an adjacent Industrial Development area. Groundwater level and water quality monitoring have been carried out on 30 observation wells over the last two years in Patancheru and its environs covering a 120 km2 area, and a number of aquifer parameters were estimated at various pumping wells. Groundwater flow and mass transport models were prepared using visual MODFLOW software, allowing the extent of contaminant migration from Nakkavagu and other streams to be assessed for the last 20 years. The stream-aquifer interaction was found to be responsible for faster migration of contamination in the over exploited area around Nakkavagu in Arutla village.

IMPACT OF CHEMICAL GROUT INJECTION ON URBAN GROUNDWATER

Matthias EISWIRTH, Renke Ohlenbusch and Klaus Schnell (Department of Applied Geology, University of Karlsruhe, Kaiserstr. 12, D-76128 Karlsruhe, Germany, email: matthias.eiswirth@bio-geo.uni-karlsruhe.de

In many urban areas, grout injections have been used to seal porous soil within the last decades. Silica hydrogels have been particularly applied in foundation engineering practice due to their wide applicability and economic advantages. For example in the City of Berlin between 1990 and 1995 about 100 000 m3 of silicate gels were injected into porous aquifers. Therefore the environmental authority of Berlin insisted on detailed investigations of potential groundwater contamination risks. This paper presents the results of detailed investigations on an excavation site over a period of two years. Two main topics are the use of artificial and natural tracers as well as transport modelling to quantify potential changes in groundwater chemistry and to predict both longevity and toxicity of silica grouts.

HS5/W/42-A3 1420

THE IMPACT OF URBAN INDUSTRIAL GROWTH ON GROUNDWATER QUALITY IN VISAKHAPATNAM, INDIA

C. SUBBA RAO & N. V. Subba Rao (Department of Geophysics, Andhra University, Visakhapatnam-530003, India)

The process of urbanization and industrial expansion has been phenomenal in the port city of Visakhapatnam since 1940. In addition to the port, major industries such as shipyards, petroleum refineries, zinc smelter plants, fertilizer units, ceramics and polymers have started in the city heartland. Forty percent of the one million population lives in the industrial belt within which the quality of groundwater has become seriously polluted. Fifteen percent of the industrial well waters have recorded more than 3000 _ s level of conductivity and major ions have crossed the "safe" limits at many places. Toxic elements including lead, chromium, arsenic, zinc, cobalt have been traced in large amounts in the groundwaters of the industrial zones, with a zinc plant being identified as the worst offender followed by the port and polymer facilities. The extent of effluent contamination has been delineated using geo-electrical techniques.

HS5/W/43-A3 1440

MODELLING CONTAMINATION OF A DRINKING WATER SUPPLY WELL IN THE SABARMATI RIVER BED AQUIFER, AHMEDABAD, INDIA

V. V. S. GURUNADHA RAO (National Geophysical Research Institute, Hyderabad 500007, India, email: postmast@ngri.globemail.com); S. K. Gupta (Physical Research Laboratory, Ahmedabad 380009, India)

Drinking water supply wells in Ahmedabad city were constructed in the Sabarmati river bed aquifer using radial pipes; they are known as French Collector wells. Groundwater contamination from one of the French wells near Sabarmati railway bridge was noticed during 1992. The suspected pollution sources are Duff-nala of Shahibaug and two other sources from slum dwellings on either side of Sabarmati River. A combined groundwater flow, pathlines and mass transport model was constructed covering an area of 9 km2 to analyse the capture zone of the French well under two different scenarios. Dry river bed condition was simulated under Scenario 1 and controlled flow in the river bed was simulated under Scenario 2. The groundwater velocity and migration of contaminant particles from sources was analysed in the pathline model. The computed pathlines and TDS concentration contours indicate likely migration of contaminant plumes from pollutant sources to the French well during 300 days under both scenarios. The modelling study emphasized the necessity of controlled release of surface water from the Dharoi reservoir to the Sabarmati riverbed throughout the year.

HAZARDS DUE TO MIGRATION OF SEPTIC TANK LEAKAGES IN PERI-URBAN SETTLEMENTS

H. K. Ramaraju, M. Venkatachalappa and G. RANGANNA (UGC-DSA Centre, Department of Mathematics, Bangalore University, 560 001 Bangalore, India, email: dsamath@blr.vsnl.net.in); C.

Sadashivaiah, N. Manamohan Rao (Department of Civil Engineering, Bangalore University, Jnanabharathi, 560 056 Bangalore, India)

Whilst it is widely accepted that a healthy environment is essential for human survival and sustainable development, two thirds of people living in developing countries still do not have adequate sanitation facilities. A field study carried out at three selected sites within the Bangalore peri-urban area has been undertaken to assess the contamination status of domestic well waters. The two-year study revealed that water quality of the domestic wells is deteriorating fast as partly indicated by very high nitrate levels. Thirteen wells out of 19 were found to be severely contaminated, five wells are marginally contaminated with only one well being considered fit for use. In some cases the nitrate level of the well waters has reached 495 mg l-1 during summer months, which is far in excess of WHO stipulations. Based on two years of field data, certain measures are suggested for safe domestic waste disposal in the study areas in order to achieve a congenial groundwater environment and to provide long term protection for the health status of the local population.

THE URBAN GROWTH OF MOMBASA COASTAL TOWN AND ITS IMPLICATION FOR SURFACE AND GROUNDWATER RESOURCES

John Kioko MUSINGI, Shadrack Mulei Kithiia, Boniface Nzuve Wambua (Department of Geography, University of Nairobi, Box 30197, Nairobi, Kenya)

Mombassa is the second largest urban centre in Kenya after the city of Nairobi. The historical development of the town dates from the 15th century during the Arabian rule of the coastal strip. The town, which is about 500 km south east of Nairobi, is situated on Mombasa Island with an extension on the mainland. It has the largest harbour in eastern Africa with good sheltered harbour facilities at Kilindini port and is the gateway to the East and Central African region. The major industrial activity is associated with oil refining but the town is a major tourist destination due to its natural clean beaches. The city experiences acute water shortages due to increased demands from both industrial and population growth. This paper describes the historical and current growth of Mombasa town in terms of population and industrial activities as it affects water demand and use. The geology is examined as a means of quantifying groundwater resources and pollutant sources and the overall effects are examined in view of suggesting possible strategies to ensure continued urban growth without further environmental degradation impacts.

HS5/W/46-A3 Poster **1545-02**

WATER RESOURCES UTILIZATION AND ITS INFLUENCE ON THE ECO-ENVIRONMENT IN THE ARID ZONE OF NORTHWEST CHINA

Wang GENGXU (Geology Department of Lanzhou University, and Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou, 730000, P. R. China, email: liusy@ns.lzb.ac.cn); Cheng Guodong (Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou, 730000, P. R. China)

Over the last 50 years exploitation of water and land resources in the arid northwest regions of China has been expanding to support the sustainable development of industrial and agricultural production. As a result river discharges have been drastically reduced (even dried-up), river courses shortened, and terminal lakes have contracted or dried-up. In the lower reaches of some inland river basins, desertification is rapidly developing at an annual rate of 3.5–6.9%. Economical and effective use of water resources and harmonization of eco-environment benefits with economic benefits are the only fundamental ways to achieve sustainable development of arid northwest China.

HS5/W/47-A3 Poster **1545-03**

DYNAMICS AND QUALITY OF WATER RESOURCES IN THE NIGER DELTA

T. K. S. ABAM (Institute of Geosciences and Space Technology, Rivers State University of Science and Technology, P.M.B. 5080, Port-Harcourt, Nigeria)

The Niger Delta is a large and ecologically sensitive region, in which various water species (including surface and groundwater, saline and fresh waters) are in a dynamic equilibrium. Physical environmental attributes of these waters and the nature of their changes as well as the resultant adjustments in hydrodynamic and ecological boundaries are described. Groundwater over-abstraction in the urban coastal areas has resulted in increased aquifer salinity. The inland incursion of tidal waters has been strengthened by the reduction of fresh water discharge due to impoundment in upstream dams and reservoirs.

HS5/W/48-A3 Poster **1545-04**

A MODEL OF THE FLOOD TRANSFORMATION IN THE AMUDARYA RIVER

Victor E. CHUB (The Main Administration of Hydrometeorology of Republic of Uzbekistan, 72, K. Makhsumov Str. 700052, Tashkent, Republic of Uzbekistan, email: uzhymet@hmc.tashkent.su); Sergey V. Myagkov (Department of Hydrological Forecast, Central Asian Regional Research Hydrometeorological Institute, 72, K.Makhsumov Str. 700052, Tashkent, Republic of Uzbekistan)

On the basis of modelling the flood transformation for a river with a deformed channel, a technique has been developed for short-range forecasting of the Amydarya River discharge. The model takes into account the relationship between the lag time of the flood peak and the water discharge as well as the deformational instability of the river channel. A description of the model and techniques of flow adjustment with a strongly deformed river channel and dynamic changes of the hydraulic bonds are presented.

HS5/W/49-A3 Poster **1545-05**

CONTEMPORARY STATUS OF SURFACE WATER QUALITY OF THE ARAL SEA BASIN

E. I. CHEMBARISOV, E. I.Chembarisova (Institute of Water Problems, Uzbek Academy of Sciences, 700000, Uzbekistan, email: root@pwater.tashkent.su

The problems of the Aral Sea desiccation and associated deterioration in ecology have now acquired a global importance. Estimates of ecological condition have been made using methods of systems and budget analysis, statistics and cartography. Surface water volume and quality in different regions of the Aral Sea basin have been determined together with optimum variants for irrigation systems. Means of decreasing the extent of river water pollution and reducing the number of collector- drainage water discharges into rivers have been developed as well as principles for hydro-ecological zoning of territories.

THE USE OF DRASTIC MODELLING INDICES FOR THE ASSESSMENT OF GROUNDWATER POLLUTION POTENTIAL

M. Chandra SEKHAR & K. Karuna Kumar (Water & Environment Division, Regional Engineering College, WARANGAL 506 004, India, email: mcs@recw.ernet.in)

The vulnerability of groundwater to pollution depends on various factors such as depth to water table, net recharge, aquifer media, soil media, topography, impact of vadose zone, hydraulic conductivity of the aquifer, cropping pattern etc. The Kakatiya canal area studied in this investigation was found to have polluted groundwater aquifers requiring immediate counter-measures and integrated management of pollution. However, some of the investigated factors, termed "DRASTIC" factors, constitute varying risks for pollution of the aquifer groundwaters. The vulnerability of groundwater pollution is estimated by giving suitable weights and rating to these "DRASTIC" factors which are determined from the collected seasonal study data.

HS5/W/51-A3 Poster **1630-02**

IMPACT OF URBANIZATION ON THE KHASH AQUIFER, AN ARID REGION OF SOUTHEAST IRAN

E. KHAZAI (Department of Civil Engineering, University of Sistan and Baluchestan, Zahedan, Iran, email: khazai@hamoon.usb.ac.ir); M. G. Rigi (Sistan and Baluchestan Regional Water Authority, Zahedan, Iran)

This paper investigates both the quantitative and the qualitative impacts of urbanization on the Khash aquifer. The results indicate a general fall in the groundwater level and deterioration of groundwater quality. However, there are cases of improvement in the groundwater quality owing to reductions in evaporation effects.

HS5/W/52-A3 Poster **1630-03**

URBAN IMPACTS ON GROUNDWATER QUALITY IN THE DELHI REGION

R. B. SINGH (Department of Geography, University of Delhi, Delhi 110 007, India)

In recent years, water supply and groundwater resources in India have become threatened following uncontrolled disposal of urban waste into water bodies, open waste dumping and poorly designed landfills. Within the urban fringe zones of Delhi, the contamination of groundwater by industrial and domestic effluents now presents serious challenges. Subsoil waters in the area through which effluents from major industries infiltrate, are already polluted more or less permanently. Wells in many residential areas are contaminated with nitrate, detergents and high salinity levels with the high content of fluoride also posing severe health hazards in surrounding regions.

A REVIEW OF GLOBAL HYDROLOGIC DATA SETS IN RELATION TO THE GCOS/GTOS PLAN FOR TERRESTRIAL CLIMATE-RELATED OBSERVATIONS

JURATE LANDWEHR (USGS, 431 National Center, Reston VA 20192, USA;
Email: jmlandwe@usgs.gov); Josef Cihlar (Canada Centre for Remote Sensing, 588 Booth Street, Ottawa, Ontario, Canada K1A 0Y7; Email: josef.cihlar@ccrs.nrcan.gc.ca)

TOPC (Terrestrial Observation Panel for Climate) is a joint activity of the Global Climate Observing System (GCOS) and the Global Terrestrial Observing System(GTOS), both of which are initiatives of WMO, UNEP, and ICSU. IOC of UNESCO also sponsors GCOS, and UNESCO and the FAO, GTOS. The purpose of GCOS is to provide a forum for the development of a comprehensive long-term global observing system to improve our capability to detect, predict and assess climate change. GTOS was established to provide policy makers, resource managers, and researchers data needed to detect, quantify, and give early warning of changes in the capacity of terrestrial ecosystems to support sustainable development and improvements in human welfare. TOPC has produced an analysis of data and actions needed to address these goals jointly. The GCOS/GTOS plan for terrestrial climate-related observations has been published and is available via the internet at http://www.wmo.ch/web/gcos/pub/topv2_1.html The TOPC plan not only identifies key hydrospheric, cryospheric and biospheric parameters but also compares their relative importance for their respective climate purposes and suggests methods and actions for obtaining this information. For example, for the hydrologic sector, the plan provides a detailed

rationale for the following variables: atmospheric water content near the surface (relative humidity), biogeochemical transport from land to oceans, discharge (runoff), evapotranspiration, ground water storage fluxes, precipitation, sediment load at large river mouths, snow cover area and snow water equivalent, soil moisture and surface water storage. TOPC is actively seeking to identify which data is available digitally to satisfy the above requirements. In this presentation, we will review which hydrologic data sources have been identified globally, and discuss the general availability and compatibility of this information, as well as gaps in the geographic or thematic coverage for the above variables.

GLOBAL DATA BASES IN SUPPORT OF THE NEWLY-CREATED IGBP WATER GROUP

Michel MEYBECK (UMR SISYPHE CNRS, Université de Paris VI, Place Jussieu, 75257 Paris FRANCE, e-mail: meybeck@biogeodis.jussieu.fr) Charles Vörösmarty (Institute for the Study of Earth, Oceans, and Space, University of New Hampshire, Durham NH 03824, USA, e-mail: charles.vorosmarty@unh.edu)

The terrestrial water cycle has played a central role in several of the individual Program Elements of the IGBP. In recognition of the key role that water plays in the Earth System, IGBP is now integrating its ongoing water-related activities through the newly-formed IGBP Water group. This group is carrying forward an analysis of Continental Aquatic Systems which are defined as all surface and subsurface waters participating in the hydrological cycle across the continents. The analysis focuses on understanding the past, contemporary, and future state of terrestrial water systems together with the biogeochemical constituents they store, transform, and transport to the coastal oceans. Central to this is an understanding of the role of humans in defining the status and use of these continental water resources. IGBP has developed different global data bases on river basins (IGBP-BAHC) and on the coastal zone (IGBP-LOICZ), including geo-referenced data sets for water discharge, chemical constituents, biophysical and socio-economic data depicting the world's drainage basins. The IGBP intends to launch an electronic River Archive Series to integrate existing data sets relevant to the analysis of drainage basin change at the global scale. These information resources are now being used to build a TYpology of Global RIver Systems (TYGRIS-BAHC). The IGBP Water Group is also proposing to other organizations having such data repositories (e.g. WMO/GRDC, WHO/GEMS-Water, UNESCO/FRIEND) to construct a common data base on GLObally-SIgnificant Basins (GLOSIBA) which will combine both present-day basin attributes, long-term mean observations of river fluxes, and full time series over a minimum period of 20 years. The time series is intended to include water discharges, water chemistry, sediment discharge, and changing human pressure. The selection criteria for stations may combine basin size, length of record, and representativity of basins with regard to biophysical attributes and human impacts. Smaller pristine basins fully monitored over a long period may also be considered. The GLOSIBA is regarded as a data base common to all participating institutions with free on-line access.

DATA FOR THE GLOBAL WATER AVAILABILITY AND USE MODEL WATERGAP

Petra DOELL and Joseph Alcamo (Center for Environmental Systems Research, University of Kassel, Kurt-Wolters-Str. 3, D-34109 Kassel, Germany, Tel. +49 561 804 3913, FAX +49 561 804 3176, e-mail: doell@usf.uni-kassel.de)

In order to assess the impact of global change on the problem of water scarcity, we are developing a global model of water availability and water use in drainage basins (spatial resolution 0.5° by 0.5°) . Such a model is highly constrained by the availability of global data sets. Time series of gridded monthly climatic variables from 1901 to 1995 are provided by the Climate Research Unit at the University of East Anglia (New et al., 1998). These data sets are the first to allow a global-scale analysis of temporal variability of water availability, and, together with discharge data from the Global Runoff Center (Grabs et al., 1996), a calibration and validation of the model. A very important but highly uncertain parameter in runoff modeling is the water capacity of the soil, which was assigned using a WISE data set (Batjes, 1996) who derived it from the FAO Soil Map of the World and more than 4000 soil profiles.
85% of the global water consumption is used for irrigation. Based on international and national sources, we generated the first digital global map of irrigated areas, which shows the percentage of each 0.5° grid cell that is irrigated in the reference year 1995. This map enables us to compute cell-specific irrigation requirements. With respect to domestic and industrial water use, we need to rely on very heterogeneous values of national water uses. Efforts should be undertaken to encourage an improved and standardized collection of water use data by the individual countries.

THE ARCSS DATA COORDINATION CENTER (ADCC) AT THE NATIONAL SNOW AND ICE DATA CENTER (NSIDC), USA: A DATA AND INFORMATION RESOURCE FOR ARCTIC HYDROLOGY AND CRYOSPHERIC STUDIES.

Matthew D. CROSS and Christopher K. McNeave (both at CIRES/NSIDC, University of Colorado, Campus Box 449, Boulder, CO. USA, 80309, email: mcross@kryos.colorado.edu)

The National Science Foundation's (NSF) Arctic System Science (ARCSS) Program is a multi-disciplinary approach to understanding polar processes for climate and global change. ARCSS is the only element of the U.S. Global Change Research Program specifically concerned with the arctic region. By focusing on understanding Arctic processes in great detail, investigators are better able to characterize global changes through the improvement of global scale models and other research tools. The ARCSS Data Coordination Center (ADCC) at the National Snow and Ice Data Center (NSIDC), USA, is funded by NSF to archive and disseminate data and information generated from the ARCSS program. Through this endeavor the ADCC strives to be a catalyst for system science and integration within ARCSS.
A major concern of the research community is the availability of reliable data for research. Working with ARCSS investigators, the ARCSS Committee and NSF, the ADCC is continually acquiring data and developing data products appropriate and useful for the research community. Integrating data and information from among the ARCSS ocean based, land based, ice core, paleoclimate and human dimension communities is a high priority at the ADCC. Many of the data sets available at the ADCC are directly applicable to hydrological studies within the Arctic (river runoff, land forms, vegetation cover, vegetation type, ice and snow accumulation, temperature, precipitation, etc.). We also work with other national and international data centers so as to provide optimum accessibility to data and information from the ARCSS archive.
The ADCC strives to provide the most contemporary means of data accessibility to the scientific community. The ARCSS home page (http://arcss.colorado.edu/) at the ADCC has become an important tool for data accessibility and integration within ARCSS. Data and information are also distributed on other media (CDROM's, disks, data catalogs, etc.) when appropriate. The ADCC also maintains a complete backup of the ARCSS archive to ensure data and information collected from the program are available on a long-term basis.
This paper summarizes the data and information currently available at the ADCC, and details the mechanisms by which investigators can access these data.

HW1/W/01-A4 1130

THE AVHRR POLAR PATHFINDER 1.25 KM DATA SET: HYDROLOGIC AND POLAR CLIMATE APPLICATIONS

Ted A. Scambos and Terry HARAN (both at National Snow and Ice Data Center, University of Colorado, Boulder CO 80309-0449, USA, email: haran@kryos.colorado.edu)

Visible and thermal infrared image data from the AVHRR sensor on the NOAA polar orbiting satellites have been archived at the National Snow and Ice Data Center since 1993, covering both polar regions at 1.1 km resolution. Now these data have been reprocessed to provide twice-daily composite images of albedo, surface temperature, cloud cover, and the calibrated separate channels, and once-daily sea ice motion vectors. The composite data, resampled to 1.25 km per grid cell, are designed to be used in conjunction with passive microwave data from the SSM/I Polar Pathfinder: the data are in an equal-area projection, the polar EASE-Grid, and the grid scale is an integer multiple (20) of the coarser (25 km) SSM/I grid. We intend to continue to archive the image data and generate products for at least one year after launch of the MODIS sensor on the EOS AM-1 platform.
The high resolution of the data also supports detailed regional studies; individual islands, small polynas, small ice caps, or river drainages may be monitored. Historical in situ data may be related to the regional pattern in the images. The data are especially useful in supporting field programs, allowing locally accurate field measurements to be extended to areas away from the field site. We will demonstrate some of these applications in selected regions of the northern hemisphere.

HW1/L/08-A4 1130

THE ANALYSIS OF LONG-TERM CHANGES OF SNOW COVER, CLIMATE AND HYDROLOGICAL PROCESSES IN THE NORTH OF RUSSIA - THE DATABASE GENERATION

L. Kitaev, A. Krenke, E. Barabanova, Institute of Geography, Russian Academy of Sciences, Russia, Moscow, 109017, Staromonetny per. 29, e-mail: climat@ipcom.ru

A data base and analysis system defining long-term changes in the land surface hydrology of Northern Russa is presented. An observational period spans one hundred years, but in particular the most recent 30 years are targetted since these are most representative of contemporary conditions.
To analyse conjugate changes of land surface variables efficiently and with a sufficient degree of confidence, a special geoinformational technique was formulated. Initial conditions and forcings encompassed surface-based snow cover, weather and other hydrological observations. The database with its information retrieval system permits searches over a full spectrum of quantitative and spatial identifiers.
To reveal the interaction between climatic and hydrological properties as well as temporal and spatial snow cover changes a special technique was developed. This study revealed that the character of snow cover distribution corresponds well to both air temperature and precipitation changes. Also, the spring flood snow component conforms well to the snow character. Snow cover thus plays an important role in linking both climatic and hydrological processes.

HW1/W/02-A4 1130

A LONG-TERM HYDROLOGIC DATA BASE FOR THE UNITED STATES

Thomas H. YORKE and Kenneth J. Lanfear (both of the U. S. Geological Survey, 12201 Sunrise Valley Drive, Reston, VA, 20192, USA; email: thyorke@usgs.gov; lanfear@usgs.gov)

The U. S. Geological Survey (USGS) recently completed an evaluation of the streamgaging network that it operates in the United States in cooperation with more than 800 other Federal, State, and local agencies. The evaluation focused on the major Federal goals of the network, which include measuring streamflow across state and national boundaries, determining river basin water budgets, providing data for flood mitigation and warning, determining water-quality trends, and documenting long-term changes to the hydrologic regime. A set of quantitative metrics was established to measure the extent to which each goal was achieved over time. The geospatial data base that was used for the analysis included: the locations of 18,000 streamgaging stations operated by the USGS; traces of 60,000 stream segments in the conterminous United States; boundaries of 329 major river basins and 2,100 small watersheds; boundaries of physiographic sections and ecoregions; locations of 3,000 flood forecasting points; and the locations of 15 million people at risk from riverine flooding.

The evaluation examined the effectiveness of the network in providing data for documenting long-term changes to the hydrologic regime. The results of the evaluation show that representative streams were being monitored in 76 percent of the ecoregions (areas with similar land use, land-surface form, potential natural vegetation, and soils) in 1996. Since 1976, however, there has been a decline in the number of representative streams in river basins and ecoregions throughout the conterminous United States. There also has been a decline in the number of stations with 30 or more years of record. In the 1990s, about 4 percent of the long-record stations were discontinued each year.
The USGS further refined the evaluation by analyzing the parts of the network that were represented by the USGS Benchmark station network and the USGS Hydro-Climatic Data Network. These networks consist of currently operated stations that have 30 or more years of record and represent watersheds that have little or no flow regulation and, thus, are suitable for the study of the relationships among climate, land use, and streamflow. A subset of stations that are part of these two special networks and that are spatially distributed within the major river basins, physiographic sections, and ecoregions of the United States have been identified as high priority long-term stations.

RIVER MASS LOAD ESTIMATION FROM UK NATIONAL RIVER FLOW AND QUALITY DATABASES

I.G. Littlewood, Institute of Hydrology, Centre for Ecology and Hydrology, Wallingford, Oxon, OX10 8BB, United Kingdom

Recent developments related to the need for, and systematic production of, river mass load estimates are outlined, with particular reference to the UK national river flow and quality databases. Selected details of the first effective merger of these two large databases for systematic river mass load estimation are given. Some results from recent work to derive time series of annual river mass loads discharged from the aggregated freshwater-monitored area of Great Britain are presented. Comments arising from this work are made which may be relevant to the management and use of other large river flow and water quality databases.

THE GLOBAL HYDROLOGICAL ARCHIVE AND ANALYSIS SYSTEM (GHAAS): HYDROGRAPHIC DATA SETS AVAILABLE ON-LINE

Charles VÖRÖSMARTY, Balazs Fekete, Richard Lammers, Michael Routhier, and Pamela Green. (Institute for the Study of Earth, Oceans, and Space, University of New Hampshire, Durham NH 03824, USA, e-mail: charles.vorosmarty@unh.edu)

The Global Hydrological Archive and Analysis System (GHAAS) provides a computerized framework which supports a wide array of Earth Systems studies. The system is organized into individual modules that handle a variety of GIS-related functions in a hydrographic context. Modules include the Data Manager pre-processor, Data Analyzer to assemble model components, and River-GIS modeling tool for topologically-organized simulated river networks and drainage basin analysis.
The GHAAS initiative also encompasses the preparation and distribution of hydrometeorological data sets for wide distribution to the water sciences community. A brief synopsis of several of these data sets will be offered. Specific holdings include a gridded river network topology for potential river flow paths at 30-minute spatial resolution (STN-30p); climatologically-averaged station data for discharge co-registered to STN-30 (WMO/GRDC-UNH Composite); discharge and meteorological station time series in geographic coordinates (RivDIS v1.1; R-ArcticNET; R-HydroNET); and, gridded climate (R-HydroNET) and runoff fields (WMO/GRDC-UNH Composite; WBM-USA). All data are available free of charge and without restriction at http://www.csrc.sr.unh.edu/hydro/welcome.html. Portions of the GHAAS data base are also made available through WWWeb sites and CD-ROMs maintained by the Oak Ridge National Laboratory NASA-DAAC (Oak Ridge, Tennessee USA), National Snow and Ice Data Center (Boulder, Colorado USA), and WMO Global Runoff Data Center (Koblenz GERMANY).

HW1/L/07-A4 1430

UTILIZATION OF GLOBAL RIVER DISCHARGE DATA FOR THE VALIDATION OF LAND SURFACE MODELS THROUGH TOTAL INTEGRATING PATHWAYS (TRIP)

Taikan OKI and Katumi Musiake., Institute of Industrial Science, Univ. of Tokyo 7-22-1 Roppongi, Minato-ku, Tokyo 106-8558, Japan, e-mail: taikan@iis.u-tokyo.ac.jp

Land surface models (LSMs) are used within numerical atmospheric models to represent physical and biological processes at land surface. Calibration and validation of LSMs have been carried out mainly using observational data from enhanced observations of surface fluxes and physiological variables depicting the biosphere. However, these observations are limited both in space and time. In contrast, river discharge represents integrated runoff within the drainage area and it is the only direct measurement of areal mean hydrological response available on a large scale. Thus, river discharge has recently been used for validation of water balances calculated by LSMs.
To utilize river discharges for the validations of LSMs, three components are required. These are:

- digital information of river channel networks,
- a numerical model of river routing, and
- discharge data.

These together form a "digital river" for the validation of estimated water balances at the land surface. A 1deg. X 1deg. global mesh was used for validation of 11 LSMs in the Global Soil Wetness Project (GSWP). Under GSWP,the global soil moisture distribution for 1987 and 1988 was simulated in anoffline mode. Even though observations and analyses from ISLSCP Initiative I CD-ROM were used as for forcing data, validation studies are necessary because LSMs may not simulate the water balance accurately.
A global river channel network, named Total Runoff Integrating Pathways (TRIP) was developed in 1deg. X 1deg. global mesh. A simple linear river routing model was prepared, as well. Even though river discharge data at only 20 gauging stations were available for 1987 and 1988 in the ISLSCP Initiative I CD-ROM, monthly river discharge data at 250 gauging stations in 150 river basins of the globe were collected and used for the validation of LSMs after error-checking.
As a result, river runoff information was found to be very effective for the validation of water cycling at the continental scale. Based on this study, it is clear that efforts to collect and prepare more comprehensive data sets of historical river discharge, as well as the promotion of international exchange of river discharge data in near real time, are highly recommended not only for the hydrological sciences but also for global climatological studies.

HW1/E/03-A4 1430

DERIVATION OF GLOBAL GCM BOUNDARY CONDITIONS FROM 1 KM LAND USE SATELLITE DATA

STEFAN HAGEMANN, Michael Botzet, Lydia Dumenil and Bennert Machenhauer; Max Planck Institute for Meteorology, Bundesstrabe 55, D-20146 Hamburg, Germany, e-mail: Hagemann@dkrz.de

The coupling between atmosphere and biosphere is of particular importance over land surfaces from both the atmospheric and hydrological point of view. For adequate modelling of processes at the land surface boundary to the atmosphere an accurate representation of the land surface is necessary. The initial description of the land surface is a significant problem in global and regional climate modelling. The available datasets are particularly inaccurate in some regions of the world and up to now their spatial resolution was too coarse to fit the demands of high resolution limited area models. Remote sensing is a relatively new technique to measure land surface characteristics with a very fine spatial resolution which offers the possibility to create new datasets of land surface parameters.
At a resolution of 1 km a global distribution of major ecosystem types(according to Olson, 1994) was prepared by the U.S. Geological Survey which was derived from International Geosphere Biosphere Programme 1 km AVHRR data. From this global distribution a global dataset of land surface parameters is constructed by allocating parameters to the ecosystem types. These parameters are: background surface albedo, surface roughness length due to vegetation, fractional vegetation cover and leaf area index for the growing and dormancy season, forest ratio, plant-available soil water holding capacity, and volumetric wilting point. This global dataset is provided for the use in global and regional climate modelling.

A PLEA FOR INCREASED DATA COLLECTION

IAN CORDERY (School of Civil and Environmental Engineering, The University of New South Wales, Sydney, 2052, Australia, email: i.cordery@unsw.edu.au).

It has been shown that for a fairly typical stream-flow data collection operation the value of the collected data can be about ten times the cost of collecting and archiving. Where data are not available planning and design exercises are dependent on intuitive approaches or (equally uncertain) importation of information from another region. Examples of the problems of using intuitive approaches and imported data will be given. Even greater problems occur for planners and regulators when there is a need to assess the current and likely future states of aquatic parameters which are currently only measured for research purposes, such as sediment and nutrient loads, and aquatic flora and fauna species diversity and population densities. Not only is little data available on many of these parameters but even less is known about their interrelationships and their interactions with parameters which are more likely to be measured. In the past changes to one aspect of the natural regime (eg to flow by construction of a reservoir, to chemical and biological properties by urbanisation or intensive farming) have, in some instances had dramatic effects on a range of other parameters. Sadly, most of these changes were not measured and in most cases it is not now possible to estimate what the former, natural conditions were. Currently efforts are being made to manage water extraction, land use changes and wastewater releases to ensure maintenance of "natural" conditions. But what were the natural conditions? What man-induced changes have occurred? Unless data collection is increased considerably, without the ever-present need for short-term economic justification, our ability to assess what changes are occurring and to maintain our living environment will continually diminish. We must collect more of the data we already collect, -at more locations and for longer-, and different types of data, -some of which may have no

apparent immediate usefulness. For example who, in the 1880s foresaw the value of collecting river salinity levels at the time when modern irrigation was just beginning?

COUPLING OF PARALLEL RIVER AND GROUNDWATER MODELS TO SIMULATE DYNAMIC GROUNDWATER BOUNDARY CONDITIONS

Guy CARABIN (Laboratoires de Géologie de l'Ingénieur, d'Hydrogéologie et de Prospection éophysique (L.G.I.H.), University of Liège Bat. B19, B-4000 Liège, Belgium, email: carabin@lgih.ulg.ac.be), Alain Dassargues (L.G.I.H., University of Liège Bat. B19, B-4000 Liège, Belgium, email: adassarg@lgih.ulg.ac.be)

For groundwater modeling, interactions with the other parts of the water cycle (atmosphere, river and ocean) are usually taken into account with prescribed external input/output boundary fluxes. This is often considered as convenient in most of the studied cases when exchanges can 'a priori' be estimated. How could we take the interactions into account, when variations of water levels and solute concentrations in the river must also be computed. The proposed solution is based on a parallel run of the Groundwater Model (GWM) and the River Model (RM). The exchanged water and solute mass fluxes through the contact interface are calculated by a junction on basis of the received results from each model at each time step. These calculations are made using a Fourier boundary conditions. As each model has its own time and space discretizations, the junction must organize the data exchanges, including various time and space interpolation schemes. The tests on a real case study, show the importance of these interactions on the computed groundwater quantity and quality in an alluvial aquifer where important pumping is made. The junction river-aquifer is being used in the scope of a research project entitled 'Integrated modeling of the hydrological cycle in relation to global climate changes', and it has already been used for the SALMON project (Sea Air Land Modeling Operational Network) designed to describe water and contaminant fluxes in a whole system (including marine, river, groundwater and atmospheric inputs) at regional scale.

HW5/W/10-A3 **0920**

NUMERICAL SIMULATION OF GROUNDWATER - SURFACE WATER INTERACTION AND CONTAMINANT TRANSPORT AT A FRESHWATER COASTAL BARRIER BAR.

Allan S. CROWE, Steven G. Shikaze and Carol J. Ptacek (National Water Research Institute, Canada Centre for Inland Waters, Box 5050, 867 Lakeshore Road, Burlington, Ontario, L7R 4A6, Canada)

Recent field work at Point Pelee, Ontario, Canada, has shown that the groundwater flow regime within the barrier bars is controlled by the width of the bar, the distribution and rate of recharge, and the seasonal fluctuations of the water levels in Lake Erie and the Point Pelee marsh. As a result, the flow system behaves in a complex, transient manner with seasonal reversals in the direction of flow in a portion of the barrier bar. Because of this complexity, A 2-D numerical model has been developed to simulate transient groundwater flow and contaminant transport in this environment, to aid in determining (1) the nature and extent of the hydraulic connection between the lake and the marsh, and (2) the potential for groundwater to transport septic-system derived contaminants to the marsh. The model presented here overcomes limitations with existing techniques, with respect to numerical accuracy, conceptual accuracy, and groundwater-wetlands boundaries. In our approach, the position of the water table (and shape of the groundwater domain) rises or falls in response to infiltration, evapotranspiration, and shorelines which can fluctuate both vertically and laterally in response to changes in the wetland or lake level fluctuations. Nodes and elements are added to or removed from a finite element mesh as a result of a rising or falling water table, respectively, thus maintaining accuracy with respect to the size and shape of the groundwater domain. Contaminant transport within the groundwater regime is simulated by either a particle tracking algorithm or by a standard Galerkin finite element solution to the advection dispersion equation.

HW5/W/11-A3 **0940**

INTERACTION BETWEEN SHALLOW GROUNDWATERS AND SALINE SURFACE WATER IN A SEASONAL ESTUARY: THE SWAN RIVER SYSTEM

J.V.TURNER, W.R. Linderfelt, L.R. Townley, G.A Bartle, and G.D Watson, CSIRO Land and Water, Centre for Groundwater Studies, Private Bag, PO Wembley WA 6014, Australia.

The Swan and Canning River system is a seasonally and tidally forced system which converges to form an estuary in contact with the Indian Ocean. The perception that the occurrence of nuisance algal blooms has increased in frequency in recent years has prompted the present investigation into the interaction of the shallow groundwater system with the Swan River. The principal aim is to determine the extent to which this interaction contributes nutrient delivery to the river system. It has been identified that groundwater interaction with the upper reaches of the Swan River occurs at three length scales. From the smallest scale upwards, these interactions are at the scale of the river-bed sediments (i.e. < 10m), at the scale over which tidal forcing of the river is transmitted into the adjacent aquifer (10's to several hundred meters) and at the regional or catchment scale (100's to 1000's m). Two dimensional groundwater flow modelling in plan covering the regional domain of the upper Swan River from the Causeway to Guildford shows that there is a net annual groundwater discharge to the Swan River of groundwater discharge of about 80,000 m3/day, or about 29 million m3/year. In 1996, the surface water flow entering the Swan River from the Avon was about 715 million m3, thus groundwater discharge contributed approximately 4% of the total river flow. Although this is a small percentage, nutrient concentrations, particularly ammonium, within the sediment pore fluids underlying the river are very high relative to concentrations in the river such that even low groundwater discharge rates introduce significant nutrient loadings to the river especially in summer when surface water inflow to the Swan River from the Avon effectively ceases. The nitrogen load to the Swan River derived from groundwater discharge is conservatively estimated at between 30 and 60 tonnes per year, meaning groundwater is one of the highest single inputs of nitrogen to the Swan River, contributing about 10% of the total nitrogen load entering this reach of the river. Seasonal and diurnal tidal forces increase the complexity of the system and may act to increase the presence and availability of groundwater-derived nutrients in the estuary system.

HW5/W/12-A3 **1040**

SIMULATING HILLSLOPE HYDROLOGY AND INTERFLOW DYNAMICS FROM TEST SLOPES IN A MIDDLE MOUNTAIN CATCHMENT IN GERMANY

Wolfgang-Albert FLÜGEL; Geographisches Institut, Universität Jena, Löbdergraben 32, D-07743 Jena, Germany, tel +49 - 3641 - 948 850; fax +49 -3641 948 852, e-mail: c5wafl@geogr.uni-jena.de

Between 1993 and 1996 detailed process studies of the dynamics of interflow were carried out on two test slopes within the catchment of the River Bröl (A = 216km2) located in the Rheinische Schiefergebirge, a middle mountain range characterized by gentle slopes and an oceanic type climate. Mean annual rainfall varies with elevation between 900 and 1200mm averaging to about 1070mm. Dominant land use is rangeland, coniferous, deciduous and mixed type of forest. The soils have greyish mottles above the impermeable bedrock indicating a distinct hydromorphic influence resulting from lateral interflow drainage. For simulating water balance and lateral interflow dynamics the HILLS-model developed by the USDA was applied and improved. HILLS is simulating unsaturated water fluxes by means of the RICHARDS equation and is routing interflow laterally using a kinematic wave approximation. The concept of the "Dynamic Storage" developed by the author was used to connect the hydrological dynamics observed in the valley floor with that of the contributing slopes. The concept makes use of the matrix potential and links the saturated groundwater aquifer with the overlaying unsaturated soil zone. Both are intersecting with the footslope region on the one side and draining into the adjacent river on the other side. The following results can be presented so far: (1) Soil water dynamics in the unsaturated zone is not only influenced by the rainfall distribution but intensively from the interaction with the rooting vegetation; (2) understanding and simulating this dynamics must integrate plant physiological model in a much greater extend than it is done so far; (3) the HILLS-model is capable to simulate the hillslope drainage and interflow dynamics together with the groundwater fluctuations in the adjacent valley floor; (4) specific model extensions are necessary link the river system to the groundwater dynamics; (5) further research based on the HRU-concept is required to regionalize the approach to the catchment of the River Bröl.

HW5/E/05-A3 1100

EPISODIC RISING IN NITRATE CONCENTRATION OF STREAMWATER BY PARTIAL WITHER OF PINE FOREST CATCHMENT IN TEMPERATE REGION IN JAPAN

Naoko Tokuchi, Nobuhito Ohte, Asami Nakanishi, Masanori Katsuyama, and Yuko Asano (School of Agriculture, Kyoto University, Kyoto, 606-8502, Japan, email: nobu@bluemoon.kais. kyoto-u.ac.jp); Misuzu Hamada (Asia Air Survey Co. Ltd., Atsugi, 243, Japan)

The forest decline as an impact of environmental pollution is one of the major concerns not only of Japanese forestry community, but also for ordinary residents who utilise the water resources from forest catchments. The decline of pine forest has been extensively spread in the western part of Japan past thirty years, and environmental pollution has been considered as one of their important causes in addition to physiological and pathological conditions. The purpose of this study is to clarify the mechanism of changes in streamwater chemistry caused by episodic partial wither of pine forest. We focused on the disturbance of nitrogen dynamics in the scale from soil-profile to whole catchment. The intensive hydrochemical observations and in-situ lysimeter experiments at small head water catchment have been conducted since 1990. The partial (20% of the catchment area) wither of pine trees started in 1993, and continued until the fall of 1995. Before the wither events, the average nitrate concentration of streamwater was 0.04 meq/l, and much smaller than that of rainwater concentration. The cut-off of nitrate uptake by pine roots and nitrate supply with litters of dead trees brought about the three times higher nitrate concentration of subsurface groundwater and streamwater compared to those before the wither event. It was found that there was a remarkable two-year time lag between start of the event and the time when the concentration reached the highest level. The time lag and rising process of nitrate concentration can be explained by velocity of solute transport in unsaturated infiltration zone and mixing processes of soil water and saturated groundwater in riparian zone of catchment.

HW5/E/08-A3 1120

UZBEKISTAN: INTERACTIONS BETWEEN SURFACE AND GROUNDWATER QUANTITY AND QUALITY

Valentina Khaydarova (Institute of Water Problems, Uzbek Academy of Sciences, Uzbekistan, 700000, Tashkent, Ya. Kolas, 24B. Tel./Fax: +7 371 1391237) Lev POBEREJSKY (Association «Vodproject», Uzbekistan, 700000, Tashkent, Malyasov Street, 3, Tel.: +7 3712 340983, email: lena_60@usa.net)

Uzbekistan, which is settled down in the drainage basins of Syrdarya and Amudarya rivers, takes actually the whole runoff of those rivers for the maintenance of the irrigated agriculture jointly with neighboring states. Groundwater is being formed by the filtration losses from watercourses and canals in the greater part of Uzbekistan, which is a plain. The portion of the surface runoff in the groundwater resources is equal to 78.7% or 669.7 m3/sek changing from 50% in the territory before mountains to 100% in the downstream area of Amudarya River.
The damage of surface runoff by the groundwater exploitation is estimated for the planning of economic measures. Because of the difference in orographical conditions such damage in the Syrdarya basin is equal to 90% and it is equal to 77% in the Amudarya basin. The potential damage to surface runoff is equal to 646 m3/sek (85%) under the whole exploitation groundwater supplies. As a quantity the groundwater quality is the close correlation to the surface water quality. Mineral fertilizer, the poisonous chemical substances, pesticides pollutes the surface runoff, which enter to the water system jointly with the water return. Therefor the groundwater rapidly losses their drinking quality. For example, the whole groundwater supplies in Amudarya lower course are polluted so much as they present itself a risk for the human health. Under this cause the Aral-Amudarya area is announced officially as a zone of ecological disaster.

HW5/W/13-A3 1140

QUALITY ASSESSMENT OF SURFACE AND SUBSURFACE WATER OF DAMODAR RIVER BASIN, INDIA

ABHAY KUMAR SINGH and Syed I. Hasnain, School of Environmental Science, Jawaharlal Nehru University, New Delhi-110 067, INDIA, email: singhak@yahoo.com

Damodar is the main river of south Bihar and West Bengal and it runs through India's richest coal deposit belt. Damodar receives pollution load from various sources like domestic sewage, thermal power plants, steel plants, fertilizer factories and coal washeries. The water quality of Damodar river has swiftly deteriorated in recent years due to unplanned mining, urbanization and industrialization and it poses one of the major environmental problem that is drawing attention in recent years. As the increased mining activities and population in Damodar valley, so did the garbage, sewage and mining wastes which found their way directly into the Damodar river. This invited health hazards brought on basically by contaminated drinking water and also restrict its suitability for irrigation uses. The river Damodar constitutes the major source of water for south Bihar and Bengal and a large population and agriculture, especially in the lower valley are depend on the Damodar. Therefore regular monitoring and preservation of the quality of this river is a very important responsibility for everybody. In this paper the quality assessment of surface and subsurface water of Damodar river basin and its suitability for domestic and irrigation purpose will be presented. Besides that the source of dissolved ions and mechanism controlling water chemistry of Damodar river will also be discussed.
Calcium and bicarbonate are the dominant cation and anion in surface water, while in subsurface water calcium is replaced by sodium in cationic abundance. The TDS content of subsurface water is two to three times higher than the surface water. The higher TDS of subsurface water may be due longer residence time, favoring acquisition of solutes through rock weathering. Gibbs variation diagram shows that chemistry of the Damodar river basin is mainly controlled by rock weathering. The higher concentration of sulphate and phosphate at some sampling sites indicate the impact of mining and anthropogenic activities on the water quality of the basin. Quality assessment study of Damodar river basin water shows that with few exceptions, subsurface water is suitable for drinking and domestic uses. Based on sodium adsorption ratio (SAR), residual sodium carbonate (RSC) and percent Na the surface water are fall within the excellent to good quality class and subsurface water within the good to permissible limit and it can be used for irrigation without any hazard. However the high %Na, RSC and SAR values at a few sites restrict its suitability for irrigation purpose. Ca-Na-HCO3 is the dominant hydrochemical facies in surface water while Na-Ca-HCO3 is the common hydrochemical facies in subsurface water.

HW5/W/14-A3 1400

DRAINAGE CONDITIONS IN IRRIGATED LANDS WITHIN A SEMIARID REGION: A CASE STUDY

L. B. RODRÍGUEZ and C.A. Vionnet, Facultad de Ingeniería y Ciencias Hídricas, Universidad Nacional del Litoral, Casilla de Correo Nro. 217 - 3000 Santa Fe Argentina,
email: leticia@fich1.unl.edu.ar

Usually the interaction between rivers and aquifers in semiarid regions is very intense and, under natural conditions, the exchange of water through the streambed follows the natural cycles induced by all the intervening processes. However, man's intervention can considerably alter the natural flow patterns. In this work we consider a semiarid area where land has been put into agricultural use, with pears and apples as the main crops. Due to the scanty precipitation, fruit production is only possible under irrigation with water diverted from the river that traverses the study area. On the other hand, the same river has been controlled for energy production, creating a conflict regarding water uses. Regulations exist to limit streamflows to allow the proper drainage of the irrigation fields. In spite of these regulations, the lowland portions of the study area, characterized by soils with poor drainage capacity, are still adversely affected during high surface water levels. Numerical modeling is being used to simulate the hydrodynamics of the surface water component, the groundwater component and their interaction. Computer simulations are instrumental in getting a better understanding of the system as a whole, and in particular, of the interrelationship between river, aquifer, and drainage system. Data collected during the past 2-3 years is used to calibrate the model to present conditions. The calibrated model is then used to explore different alternatives, among then pumping, to improve the drainage conditions in the area.

HW5/E/07-A3 1420

PHYSICAL MODELING OF THE INFILTRATION PROCESS OF RIVERINE SURFACE WATER INTO THE GROUNDWATER

Hubert HOLZMANN and Hans Peter Nachtnebel (Department of Water Management, Hydrology and Hydraulic Engineering, University of Natural Sciences BOKU, Muthgasse 18, A-1190 Vienna, Austria, email: holz@edv2.boku.ac.at)

At the IWHW hydraulic laboratory a model for assessing the infiltration process of ephemeral streamflow into the soil was constructed. The objectives of the experiment are twofold: First to provide estimates of the infiltration capacity as a function of the water level (head) of the surface (riverine) water and (saturated) groundwater and as a function of sediment component (hydraulic conductivity, particle distribution, clogging layer). Second to test the applicability of measurement equipment for field measurements in the laboratory.
This measurement tool includes tank lysimeters for collection of the infiltrated discharge. Two types of infiltration experiments were carried out, once under unsaturated condition with air entrapment. This reflects the situation of the beginning runoff event. Second the infiltration under saturated condition which can be observed after longer duration of runoff. This situation can be achieved in the experiment by filling the flume from the bottom of the soil layer. Due to these situations, the design of the tank lysimeters uses either simple filter material (fine sand) or a ceramic plate for water extraction.
The presentation will describe the model design, experiences with the observation devices and instrumentation and will give recommendations for the field experiment.

HW5/W/14-A3 1440

228RA/226RA/224RA AND 87SR/86SR ISOTOPE SYSTEMATICS FOR DETERMINING INTER-ACTIONS BETWEEN GROUND AND RIVER WATER

Jost EIKENBERG1, Guido Vezzu and Max Ruethi (Paul Scherrer Institute 5232 Villigen, Switzerland, e-mail: eikenberg@psi.ch), Aude Tricca (California Institute of Technology, Pasadena, CA 91125, USA, e-mail: tricca@)gps.caltec.edu

Ground and river waters of the Upper Rhine Valley (Alsace, France) were investigated for chemical composition of the major elements, Sr-isotopes and radionuclides from the U and Th series. In particular, the isotope ratios and concentrations of Ra and Sr were used as geochemical tracers to distinguish between different types of water and their interactions. The surface waters in the Rhine Valley can be described as strong mixtures between Ca-Na-HCO3 rich plaine ground-water and less mineralized river waters which have been migrated through crystalline (mainly granitic) basement rocks of the Voges mountains. Mixing of these waters yield positive correlations between bulk Sr, U, Ra and HCO3, indicating that carbonate rich sediments are the main source for U and (non-radiogenic) Sr in the plain aquifers. With increasing distance from the plain the 87Sr/86Sr ratios continuously increase from 0.708 to highly radiogenic ratios up to 0.725. For both end member types linear arrays between 226Ra and 224,228Ra can be observed, however, with different slopes. The almost constant (but different) 224Ra/226Ra and 228Ra/226Ra ratios in each end member type therefore indicate homogeneous U/Th isotopic composition in the corresponding source rocks which are in contact with the waters. Mixing ratios of non pure end-member waters were determined using three isotope diagrams (i.e. 224Ra/226Ra vs. 228Ra/226Ra) and the results obtained using the Ra isotope system are consistent to the data using isotopic Sr mixing relationships (i.e. 87Sr/86Sr vs. 1/Sr).

HW5/E/04-A3 1500

USE OF SULFUR HEXAFLUORIDE, A CONSERVATIVE TRACER, TO INVESTIGATE GROUNDWATER/SURFACE WATER INTERACTIONS IN THE FLORIDA KEYS

Jeffrey CHANTON, Kevin Dillon, William Burnett and Reide Corbett, (Department of Oceanography, Florida State University, Tallahassee, Florida 32306-4320, USA, email: jchanton@mailer.fsu.edu.;), Lee Kump, (Department of Geoscience, Penn State University, University Park, PA 16802, USA.)

The Florida Keys has experienced rapid development. The main sewage disposal method is ground water injection through some 600 injection wells at 10-30m. Additionally there are some 24,000 septic tanks and an estimated 5,000 illegal cesspits which contribute to nutrient loading to the shallow groundwater aquifer. Both Florida Bay, which borders the Keys to the north, and the Key's reef tract to the south (ocean side of the Keys) have experienced significant environmental degradation of late including nuisance algal blooms, coral disease and seagrass die offs. We used SF6 to test the hypothesis that water injected into septic tanks and 20-30m injection wells could rapidly migrate through the subsurface and reach surficial waters. We also conducted experiments to determine if non-conservative compounds (e.g. nitrate, phosphate) might be retarded by the carbonate framework relative to our inert tracer. Two types of experiments were conducted in differing limestone types. In Miami Oolite on Big Pine Key, where there is a shallow freshwater lens overlying a saline aquifer groundwater, transport rates were constrained to be between 0.11 to 1.87 m/hr. The second type of experiment took place on Key Largowhere there is no freshwater aquifer and the matrix of the aquifer is solely the more porous Key Largo limestone. Here, groundwater transportrates were as great as 3.7 m/hr and were controlled by the Atlantic tide. SF6 laden groundwater plumes moved back and forth due to tidal pumping. Our results indicate that wastewater injected into the Keys can travel rapidly and may reach marine surface waters within hours to days. There is evidence, however, that the limestone matrix retards phosphate, while allowing nitrate to pass with the wastewater.

ASSESSMENT OF STREAM DEPLETION EFFECTS CAUSED BY GROUNDWATER ABSTRACTION

Peter CALLANDER (Pattle Delamore Partners Ltd, P O Box 389, Christchurch, New Zealand, Email: peter.callander@pdp.co.nz) Dr Bruce Hunt (School of Engineering, University of Canterbury, Private Bag 4800, Christchurch, New Zealand)

In many areas of New Zealand the effect of groundwater abstractions on nearby surface waterways has historically been managed by defining arbitrary zones around streams and assuming that groundwater abstractions within this zone are equivalent to an abstraction direct from the surface water body.
However, since 1991 the focus of New Zealand's environmental legislation has been based on the "Resource Management Act" which requires an assessment of the actual effects arising from any groundwater abstraction. A consideration of these effects clearly demonstrates that in addition to the separation distance between a pumping well and a surface waterway, the duration and rate of groundwater pumping and the aquifer characteristics also have a key role in determining stream depletion rates.
Practical and accurate methods of calculating stream depletion rates have proved difficult for staff in regulatory agencies. The analytical solutions by Theis (1941) and Glover and Balmer (1954) are easy to apply but are considered to conservatively over-estimate stream depletion effects due to the assumption of a stream which fully penetrates the aquifer with perfect connection. Similarly the solution by Hantush (1965) is seen as requiring an unrealistic low permeability vertical layer along the stream edge.
Numerical modelling assessments undertaken by Spalding and Khaleel (1991) and Sophocleous et al. (1995) emphasise the uncertainty in the analytical methods described above. They identify streambed clogging and partial penetration of the stream as the key areas of inaccuracy. Whilst numerical models can most accurately quantify groundwater abstraction effects they are not practically accessible tools for many regulatory staff. Furthermore, the necessary site parameters for an accurate definition of the model parameters cannot be readily obtained.
As a practical alternative, Hunt (1998, in press) has derived a solution for unsteady flow from a well to a stream that only partially penetrates the aquifer and has a clogging layer around the wetted perimeter of the stream. A solution has also been derived for the draw-down at any point within the aquifer. This may be matched with field data from a pumping test with observation wells to obtain estimates for both aquifer and streambed leakage parameters. This is seen as a realistic representation of stream/aquifer interactions, which can be practically applied by regulatory staff.

HW5/W/16-A3 1600

DIRECT MEASUREMENT OF GROUNDWATER EXCHANGE IN THE SWAN RIVER USING AN ELECTRONIC SEEPAGE METER

David HERNE, CSIRO Land and Water, Private Bag, P.O. WEMBLEY WA 6014, Australia, email: David.Herne@per.clw.csiro.au

An instrument that measures the rate of groundwater exchange with surface water in the Swan River, Perth, Western Australia has been constructed by CSIRO Land and Water. The device, an electronic seepage meter, operates autonomously, measuring seepage rates at pre-defined intervals. The current prototype stores data on a notebook computer located nearby but a next-generation design incorporates onboard data processing and data logging.
In operation, a section of the riverbed is confined under a dome which is vented through an instrument package. The rate at which water flows through the instrument package, attached to the crown of the dome, is measured accurately and corresponds to seepage of water into the groundwater or conversely, into the river. Measuring the speed of water flowing through the instrument package gives a direct measure of groundwater seepage rates. Flow speed is measured by applying a short burst of heat to the water (about 1/3 of a second) and measuring the time it takes to travel through a tube inside the instrument package. The method is very sensitive and has currently permitted seepage rates as low as 2cm per day to be measured. All signals produced by sensors in the tube are measured by an electronics system built into the seepage meter, under the control of two microcontrollers. Separate power supplies for the electronics and heater are provided by sealed lead acid batteries housed on the seepage meter.
The seepage meter has returned rates of seepage of groundwater into the Swan River along a section of river bed at Garvey Park that agree strongly with model predictions made by this group.

HW5/E/06-A3 1620

CALIBRATION OF MEASUREMENT TECHNIQUES FOR SUBMARINE GROUNDWATER DISCHARGE IN THE COASTAL ZONE

William C BURNETT and Jeffrey P. Chanton (Department of Oceanography, Florida State University, Tallahassee, FL 32306-4320, USA, email: wburnett@mailer.fsu.edu; Makoto Taniguchi(Department of Earth Sciences, Nara University of Education, Nara 630-8528, Japan, email: makoto@nara-edu.ac.jp; Jaye E. Cable(Coastal Ecology Institute, Department of Oceanography, Louisiana State University, Baton Rouge, LA 70803, USA, email: jcable@unix1.sncc.lsu.edu

Quantitative estimates of submarine groundwater discharge (SGD) in the coastal zone have been made by a variety of approaches. Basically, the techniques fall into one of two groups: (1) hydrological; and (2) oceanographic. A standard hydrological approach is typically based on measurements made from monitor wells on land and flow is estimated via Darcy's Law. Coastal discharge may also be assessed using water balance considerations, assuming the data are sufficiently complete. A typical oceanographic approach has emphasized use of seepage meters, mini piezometers, and geochemical tracers - all measurements that are made within the coastal system itself. Thus, hydrogeologists (dry) and oceanographers (wet) tend to approach the same problem from different ends. Rarely are the methodologies combined.
Other measurement issues concern limits of detection as well as differences in spatial and temporal scales measured by various techniques. Certain types of tracers, for example, integrate over large time and space scales. Seepage meters, on the other hand, monitor only very small-scale processes. Yet seepage meters are essentially the only direct measurement of SGD available for use in the coastal zone and valuable information has been obtained by use of automated meters and/or use of multiple devices. The Scientific Committee on Oceanic Research (SCOR) and the Land-Ocean Interactions in the Coastal Zone (LOICZ) Project has recently formed a working group to evaluate the state of knowledge regarding groundwater flow into the coastal zone. The primary goal is to define more accurately and completely how submarine groundwater discharge (SGD) influences chemical and biological processes in the coastal ocean. An important shorter-term task has been set to examine questions relating to the measurement and sampling of SGD in the coastal zone. To this end, we are currently working on the design for an experiment to perform an intercalibration exercise using as many measurement techniques as possible. The results of our progress will be reported in this presentation.

NON-AXISYMMETRIC MAGNETOHYDRODYNAMIC SHEAR LAYERS IN A ROTATING SPHERICAL SHELL

Andrew SOWARD (School of Mathematical Sciences, University of Exeter, Exeter, EX4 4QE, UK, Email: A.M.Soward@exeter.ac.uk) Rainer Hollerbach (Department of Mathematics, University of Glasgow, Glasgow, G12 8QW, UK, Email: rainer@maths.gla.ac.uk)

Constant density electrically conducting fluid is confined to a rapidly rotating spherical shell and is permeated by an axisymmetric magnetic field of either dipole or quadrupole parity; the regions outside the shell are insulators. A prescribed non-axisymmetric body force drives slow steady non-axisymmetric motion. Linear solutions of the governing magnetohydrodynamic equations are derived in the small Ekman number limit analytically for values of the Elsasser number less than order unity and they are compared with new numerical results. The analysis extends Kleeorin etal.'s (1997) study in the axisymmetric dipole case of the various shear layers on the equatorial tangent cylinder attached to the inner sphere. There are two new key results. Firstly, the quasi-geostrophic layers, which occur at small Elsasser number, have a new structure resulting from the asymmetry of the motion. Secondly, though at moderate Elsasser number the ageostrophic character of the Hartmann-Stewartson layer stumps attached to the equator of the inner sphere remains unchanged for asymmetric flow, motion is strongly supressed by quadrupole magnetic fields with nonzero radial component at the equator.

GA1.01/W/04-A5 0930

HELICITY AND ALPHA-EFFECT DUE TO COMPOSITIONAL PLUMES

I.A. ELTAYEB (Department of Mathematics and Statistics, College of Science,SQU, Al-Khodh 123, Muscat, Sultanate of Oman)

The solidification of the heavy iron component of the fluid alloy occupying the outer core of the Earth is believed to occur in the neighbourhood of the inner core surface. The light component of the alloy released as a result of the solidification of the heavy component rises in the form of plumes to the upper reaches of the outer core. The flow giving rise to such plumes is discussed and its stability to infinitesimal perturbations is examined. In particular, the helicity and alpha-effect produced by the perturbations are investigated and their dependence on the rotation rate and the amplitude of the ambient magnetic field is examined in detail.

GA1.01/W/21-A5 0945

TURBULENT TRANSPORT IN THE EARTH'S CORE

Masaki MATSUSHIMA (Department of Earth Planetary Sciences, Tokyo Institute of Technology, Meguro-ku, Tokyo 152-8551, Japan, email: mmatsush@geo.titech.ac.jp) Takahiro Nakajima (Tono Geoscience Center, JNC, Gifu 509-5102, Japan, email: takahiro@tono.pnc.go.jp) Paul H Roberts (IGPP, UCLA, Los Angeles, CA 90095, USA, email: roberts@math.ucla.edu)

Fluid motions in the Earth's outer core are likely to be turbulent because of very small molecular diffusivities. Such small-scale motions are considered to be highly anisotropic, since they are strongly influenced by the Earth's rotation and the magnetic field. Large-scale fields are then transported by anisotropic turbulence. It is therefore important to understand the effect of such anisotropies on the geodynamo.
We have been examining anisotropic turbulence in the core by direct numerical simulation to understand the effect of the small-scale motions. We have found that the turbulent flux has a preferred direction, determined by the directions of the rotation axis, the imposed strong magnetic field and the gravitational force. The magnitude of turbulent flux is determined by the local values of the nondimensional parameters.
We here derive a transport equation for turbulent heat flux using a second order closure model. Then we compute the turbulent flux using the equation. It turns out that the turbulent flux thus estimated well approximates the one computed through direct numerical simulation.

GA1.01/W/34-A5 1000

NUMERICAL MODELLING OF CONVECTIVE TURBULENCE IN THE EARTH'S CORE

Emmanuel Dormy (I.P.G.P., 4 place jussieu, 75252 Paris Cedex 05, France, email: dormy@ipgp.jussieu.fr) Paul Roberts (I.G.P.P.-U.C.L.A., 405 Hilgard Avenue, Los Angeles Ca 90095-1567, USA, email: roberts@math.ucla.edu)

Direct numerical simulations of turbulence, including all scales of motion (from the largest to the Kolmogorov dissipation scale), are limited to Reynolds numbers too low to describe geophysicaly relevant situations. MHD convection in the Earth's core is turbulent despite the stabilizing tendency provided by the Earth's rotation and magnetic field. Rotational and magnetic effects however make small scale turbulence in the core highly anisotropic with respect to the directions of the angular velocity and magnetic field. Only recently could numerical simulations give a first insight into phenomena occuring in the core, implicit in those simulations were assumptions concerning the way that the small scale turbulent flow, which could not be numerically resolved, affected the large scale flow and field. The object of our work is to investigate numerically, on massively parallel computers, the behavior of the small scale motions in rapidly rotating MHD convective turbulence, to gain understanding of the nature of turbulent transport in the Earth's core and how it affects dynamo action that creates the Earth's magnetic field.

GA1.01/W/26-A5 1015

ASYMPTOTIC BIFURCATION ANALYSIS FOR A NONLINEAR ALPHA- OMEGA-DYNAMO

K. KUZANYAN (IZMIRAN, Solar-Terrestrial Dept., Troitsk, Moscow Region, 142092 Russia, email: kuzanyan@dnttm.ru) M. Reshetnyak (United Institute of the Physics of the Earth, Moscow, Russia, 123810, email: rm@uipe.srcc.msu.su) D. Sokoloff (Department of Physics, Moscow State University, Moscow, Russia, 119899, email: sokoloff@dds.srcc.msu.su)

The generation of magnetic field in astrophysical bodies can be described by the induction equation. So far the solution of this equation grows exponentially with time and one may take into account the feedback of the magnetic field onto the flow. Usually the so-called alpha- and omega-quenching is considered as such feedback. The asymptotic analysis of this quenching at the threshold of generation of the magnetic field (in the vicinity of the critical dynamo number D) can be an important source of information on the nature of the solution in general. On the example of Parker's migratory dynamo we perform bifurcation analysis of the equations for different types of alpha- and omega-quenching. We consider both the algebraic and dynamic quenching of the effects. The link between these forms in the limiting case of weak field is discussed. Our analysis shows that the relation between some factors of the quencing mechanism and the form of quenching controls the regime of bifurcation: the so-called soft (direct) and rigid (inverse) bifurcation scenarios may occur. Possible applications to the solar and geo-dynamos are considered.

GA1.01/W/32-A5 1100

SHARP SOLUTIONS IN THE ANELASTIC MODEL OF GEODYNAMO

Alexander ANUFRIEV, Geophysical Institute of BAS

Turbulent diffusivities of entropy and light constituent in the liquid Earth's core are usually supposed to be of order of magnetic diffusivity, η. Therefore dimensionless numbers associated with them are also of order of $R_m = Vd/\eta$, where d is a typical space scale of the core and V is its typical velocity. This number in the anelastic model we estimate using experimental data about superadiabatic heat flux. Its value obtained on this base is $R_m \sim 10^3$, which is well consistent with the results of computer simulations of Glatzmaier and Roberts (GR). Analysis of the equations of the anelastic model shows that together with smooth distribution of entropy, light constituent and magnetic field with space scale d, it has to exist disturbed sharp solutions, characterized by small space scale across the main flow of order of $d/R_m^{1/2}$. Though the amplitudes of these solutions are small, being of order of $R_m^{-1/2}$ in comparison with smooth solutions, they play crucial role in the problem. In the equations for entropy and light constituent, they create large diffusional fluxes which is an essential feature of the GR solution. In the induction equation they create an α effect for generation of magnetic field. Though value of this effect, formally estimated, is of order of $R_m^{1/2}$, it vanishes in the main approximation. Finally its value turns out to be of ~ 1. Estimations based on comparison of azimuthal and meridional magnetic fields in GR solutions support this conclusion. Estimations show that the Lorentz forces for sharp solutions are of order of the Arhimedean ones. They suppress the rise of sharp velocity, creating quenching for α effect. We suppose that this is just the mechanism, restricting enhance of the magnetic field. Typical time values of sharp solutions are of order of $(d^2/)\eta R_m^{1/2} \sim 2 \time 10^3$ years. It could be supposed that they are related to the secular variations of geomagnetic field. Together with the sharp solutions with small amplitudes, the sharp solutions with big amplitudes exist as well. In the distributions of entropy and light constituent these solutions typically arise on the core boundary, enhancing their fluxies into (out of) the core. In the solutions of magnetic field they can exit outside the boundaries as it can be observed from the figures of GR.

GA1.01/W/22-A5 1115

WHAT THE CHARACTERISTIC AMPLITUDES DEPEND ON IN THE SOLUTION OF ANELASTIC GEODYNAMO MODEL?

Alexander P. Anufriev (Geophys. Inst. Bulg. Acad. Sci., 1113 Sofia, Bulgaria, email: anufriev@geophys.bas.bg) Ivan Cupal (Geophys. Inst. Acad. Sci. Czech Rep., 141 31 Prague 4, Czech Republic, email: ic@ig.cas.cz)

Braginsky and Roberts (1995) presented energy and entropy balance equations which are applicable for 3D geodynamo model in anelastic approximation by Glatzmaier and Roberts (1997). These slightly modified equations allow us to discuss expected characteristic amplitudes in the solution of the model. We show that the whole energy balance of the dynamo does not participate in obtaining the characteristic amplitudes of the solution. The amplitudes are primarily influenced by the flux of light constituent and by the overadiabatic heat flux. On this basis we obtain the characteristic amplitudes of entropy, light constituent and velocity which are in good agreement with the solution by Glatzmaier and Roberts. The obtained characteristic amplitude of the magnetic field rather relates to the axisymmetric part of their solution. Our analysis also suggests suitable dimmensionless units as a measure of individual quantities while solving the model.

GA1.01/W/08-A5 1130

ARE THE GEODYNAMO PROCESSES INTRINSICALLY UNSTABLE ?

Keke ZHANG, (School of Mathematical Sciences,University of Exeter, EX4 4QE, UK),David Gubbins (School of Earth Sciences,University of Leeds, LS2 9JT)

Recent studies show a new picture of the geomagnetic field: both intensity and direction of the field suffer many substantial changes in the shorter time scales (Langereis et al,1997).This paper attempts to shed light on the following related questions: Can the changes of the field affect the core dynamics significantly? Why can the geomagnetic field vary so rapidly and dramatically? Are the geodynamo processes intrinsically unstable? The subtlety of magneto hydrodynamics in the liquid core is investigated. It is found that the size of the magnetic Reynolds number in the core can change drastically in response to small fluctuations of the field, suggesting that the geodynamo processes are intrinsically unstable. Rapid variations in the geomagnetic field including collapses of the field may be a fundamental characteristic of the Earth's dynamo. The results may also explain why one encounters formidable difficulties ins imulating geodynamo while there seems no such difficulties in the corresponding non-magnetic problem.

GA1.01/W/13-A5 1145

A NEW APPROACH TO GEODYNAMO MODELS:CUBED SPHERICAL SHELL AND QUASI-UNIFORM GRIDS

SHI-ZHUANG MA, (Institute of Geophysics, Chinese Academy of Sciences, Beijing 100101, China)K. Zhang and C. A. Jones(School of Mathematical Sciences, University of Exeter, UK)

It is becoming increasingly recognised that the computational inefficiency of theLegendre transform and its global nature are of major disadvantagesto the spectral method on modern massively parallel computers.We use an algorithm that allows an efficientimplementation on the parallel computers to develop a newnumerical geodynamo model.The primary feature of the algorithm is to divide a spherical shell into the six identical ``cubic'' regions with quasi-uniform grids in which the coordinatesingularities are eliminated.Furthermore, we use half-staggered mesh in thelateral direction and the standard staggered mesh in the radialdirection.The centered Crank-Nicholson scheme is adopted for temporal evolution of the system.We can run the numerical model either with one single cube of the spherical shellwith periodic boundary conditionsor with the six coupled cubes as the wholespherical shell.We will report some preliminary results from our new model.

GA1.01/W/35-A5 1200

SPHERICAL SPECTRAL ANALYSIS OF LINEARISED MHD MODELS FOR THE EARTH'S CORE

David IVERS (School of Mathematics and Statistics, University of Sydney, NSW 2006, Australia; email: david@maths.usyd.edu.au) and Collin Phillips (Mathematics Learning Centre, University of Sydney, NSW 2006, Australia)

Linear stability models of the Earth's core complement and offer some advantages over fully-dynamical dynamo models. In particular they provide information about the time-behaviour and strength of the magnetic field, and allow investigation of parameter regimes inaccessible to time-stepping dynamical codes. The present model consists of the linearised rotating Boussinesq induction, momentum and heat equations for a uniformly-conducting spherical-shell fluid outer core with a conducting or non-conducting inner-core, non-conducting exterior and no-slip or stress-free boundary conditions. The basic state is steady and possibly three-dimensional, and may include both meridional and azimuthal velocity components. We use a vector and tensor spherical harmonics analysis of the equations, together with poloidal-toroidal representations of the velocity and magnetic fields. Vector spherical harmonics have been successfully used to solve laminar and mean-field dynamo problems with difficult interactions, such as the laminar induction term, anisotropic alpha-effects and anisotropic diffusion. Vector and tensor spherical harmonic representations produce concise systematic equations, which are readily coded into computer algebra programs to produce Bullard-Gellman type spectral equations or directly coded into numerical programs. A further advantage is that terms with the same structure, such as vector products and their curls, use precisely the same subroutines. This allows a large part of the code to be checked with simple analytical models such as free-decay. Both finite-differences and Chebychev collocation methods are used for the radial discretisation method. We have exploited the vector and tensor spherical harmonic approach to allow easy extension of numerical code to include a light component, the anelastic approximation and anisotropic diffusion.

GEOPHYSICAL EXPERIMENTAL DYNAMO

NATAF H-C., D. Jault, Ph. Cardin and D. Brito L.G.I.T. ,Observatoire de Grenoble, Université Joseph Fourier BP 53, 38041 Grenoble Cedex 9, France.

We are designing an experimental set-up to study the dynamics of a spherical cavity filled with liquid sodium in presence of both rotation and strong magnetic field. We have put this investigation under the umbrella of the French effort "Ampère" to build an homogeneous fluid dynamo. Such an experiment is interesting from the geophysical point of view because the physical properties (Prandtl number, magnetic Prandtl number) of liquid metals inside the inner cores of telluric planets are similar to the properties of liquid metals in the laboratories at the Earth's surface. We plan to begin with a prototype experiment.
The liquid sodium is enclosed between two rotating spheres respectively of radius 10 cm and 30 cm. Fluid motion arises in response to the differential rotation of the inner sphere (200 revolutions per minute) with respect to the outer sphere (400 revolutions per minute). A permanent magnet (out of rare earth) is set inside the inner sphere. It yields a magnetic field of 0.2T. in the bulk of the fluid cavity. The dimensionless numbers of such experiment are: Magnetic Reynolds number Rm = UR/l = 18, Reynolds kinematic number Re = UR/n = 3.6 106, Rossby number Ro = tW /tJoule = 1.7 (rotation time over magnetic diffusion time), Elsasser number L= sB2/ rW = 8, Ekman number E = n/W R2 = 1.4 10-7 . We will also be able to vary the rotation of the two spheres and to remove the inner magnet.
Then, we hope to be able to advocate a larger experiment (a few cubic meters of liquid sodium) which would allow us to witness the dynamo effect. We can dream to record a lot of reversals because the magnetic diffusion time would be only 1 s.

OBSERVATIONS: FROM REVERSALS TO JERKS

GA1.01/W/10-A5 1400

TEMPORAL ASPECTS OF A GEOMAGNETIC REVERSAL

Kenneth A. HOFFMAN (Physics Department, Cal Poly State University, San Luis Obispo, CA 93407 USA, email: khoffman@calpoly.edu & Institut für Geophysik, ETH-Hönggerberg Zürich 8093, Switzerland)

Paleomagnetic studies of polarity transitions typically are concerned with the spatial character of the reversing field. We demonstrate that the distribution of virtual geomagnetic poles (VGPs) may be a reliable proxy regarding temporal aspects of the process as well. Our analysis of the VGPs contained in the select "MBD97" database for the Matuyama-Brunhes reversal reveals a global distribution of virtual poles so distinct that inferences concerning both the temporal nature as well as the energetics of the dynamo process can be drawn. The data clearly indicate the existence of four major groupings of virtual poles, suggesting that transitional fields in a state of quasi- equilibrium dominated the reversal process. Yet, while the VGP must cross the equator at least once during the polarity transition, a remarkable sparsity of low latitude poles in MBD97 is also observed. We propose that a formidable potential barrier exists between transitional field states where the VGP must change hemispheres. When this barrier is successfully surmounted VGP movement across the equator takes place at an apparently rapid rate of speed. That this stage of fast field change is a non-diffusive, driving process of Earth's dynamo is an almost certain conclusion. Indeed, the process of frozen-in flux may largely dictate the configurational structure of directional behavior midway into a geomagnetic reversal.

GA1.01/W/18-A5 1430

PALEOSECULAR VARIATION DURING BACK-TO-BACK GEOMAGNETIC REVERSALS FROM O'AHU, HAWAII, USA

Emilio HERRERO-BERVERA (SOEST-HIGP 2525 Correa Rd. Honolulu, Hawaii, 96822, U.S.A., email: herrero@soest.hawaii.edu)Jean-Pierre Valet (Institut de Physique du Globe de Paris IPGP 4, Place Jussieu, 75252 Paris CEDEX 05, France, email: valet@ipgp.jussieu.fr)

Paleomagnetic directions measured from 175 lava flows recorded in four volcanic sequences on the island of O'ahu (Hawaii) cover about 0.3 Ma of geomagnetic field changes and include detailed records of the sucessive Gilbert-Gauss (3.57 Ma) and Lower Mammoth reversals (3.33 Ma). The dominant pattern of the directional changes is the presence of large inclination variations with increasing amplitude and steep values during the transitional periods. The morphology of these recurring features during different transitions remind the characteristics of the zonal non-dipole field inferred from studies of paleosecular variation in the Pacific. These observations are consistent with transitional mechanisms yielding the emergence of non-dipole components with similar characteristics as during periods of stable polarity. Scatters of transitional pole positions are not reproducible between parallel sections and thus appear to be linked to local eruptions rather than to long-lived states of the transitional fields.

GA1.01/E/06-A5 1445

HEMISPHERICAL ASYMMETRY IN REVERSAL TRANSITION FIELDS

Ji-Cheng Shao and Mike FULLER (HIGP-SOEST, U. Hawaii, Honolulu, Hawaii, 96822, USA, email: mfuller@soest.hawaii.edu)

The morphology of the Brunhes-Matuyama transition field has been obtained from inversion of the records from the Reversal Atlas of Athanassopoulos (Athanassopoulos, 1994) and those in the recent compilation of Love and Mazaud (1998). The method of inversion is standard with the exception that we use a Virtual Geomagnetic Pole constraint from Maxwell pole theory (Shao, 1998, Shao et al., 1999) in place of the more usual smoothest possible field on the core-mantle boundary. Analysis of the transitional field during the Brunhes-Matuyama reversal has revealed hemispherical asymmetry in its morphology. This result is robust in that it is found whether the all the records given in the Athanassopoulos Atlas (Athanassopoulos 1994), the small number of preferred data of Love and Mazaud (1997), or subsets obtained by elimination of different records from the Atlas, are used. The field model inverted from the Love-Mazaud data set was found to predict successfully records in the Atlas not used in the inversion. The low order asymmetry found is independent of the detailed alignment of the records. The changes which bring about the reversal appear to be dominated by strong radial field features which cross the equator close to the prime meridian, whereas there are no such features in the Pacific Hemisphere. The asymmetry is consistent with the predominance of VGP paths in the hemisphere centered on the prime meridian and with the clusters of poles in that hemisphere. The hemispherical asymmetry is similar to that seen in the present field and appears to be an important feature of the geodynamo suggesting that the processes which generate the field are more active in the hemisphere centered on the prime meridian.

GA1.01/W/15-A5 1500

PHENOMENOLOGICAL MODELS OF THE REVERSING GEOMAGNETIC FIELD

Jonathan M.G. GLEN (Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709 USA, and Earth Sciences Department, University of California, Santa Cruz, CA, 95064, USA, email: jglen@bgc.org) and Lionel Hongre (Earth Sciences Department, University of California, Santa Cruz, CA, 95064, USA, email: lhongre@earthsci.ucsc.edu)

We present new results from a family of phenomenological models of the reversing geomagnetic field. The models, which are based in part on observations of the historic geomagnetic field, produce strongly confined virtual geomagnetic pole (VGP) paths quite similar to what is observed in records of the real field. This confinement is surprising given that the transitions consist of nondipole fields. We have found that simple models furnish useful guidelines for interpreting reversal records, and for building criteria for data selection. For example, they reveal that the duration of transitions largely depends on the site locality. As a result, a record with few transitional VGPs may contain valuable space-time information critical to constraining reversal models. In other words, the often-used criteria that accept only records that contain a certain number of intermediate poles could be a poor measure of whether a record is reliable or not. We also find that grouping similar transitional poles into a single pole may obscure information on the site-dependent rates of field change. In addition, the results suggest why existing data seemingly support arguments for both geographically confined and site-dependent VGP paths. The models also render significantly different VGP paths for some sites that are in close proximity: this may explain the existence of rapid jumps of VGPs in existing records. A comparison of our model results with the existing data will be given.

GA1.01/W/25-A5 1515

INVERSION OF PALEOMAGNETIC DATA TO OBTAIN THE MEAN PALEOMAGNETIC FIELD FOR THE LAST 5 MA

Masaru Kono (Institute for the Study of the Earth's Interior, Okayama University, Misasa, Tottori-ken 682-0193, Japan)

Description of the mean paleomagnetic field in terms of Gauss coefficients have already been derived from paleomagnetic data of the last 5 Ma by Kelly and Gubbins (GJI, 1997) and Johnson and Constable (GJI, 1997). However, it can be shown that they are not satisfactory because they neglect the fact that the mean of the field directions are affected not only by the means but also by the variances of the parameters (Gauss coefficients). Kono, Tanaka and Tsunakawa (JGR, 1999) presented the inversion of paleointensity data, which avoids this problem because data in this case are linearly related to model parameters. In their study, the inversion of data was carried out separately for the means and variances. In this study, I will present a new approach to the inversion of paleomagnetic data. Unlike Kono et al. (1999), we determine the means as well as the variances of the parameters at the same time. For this purpose, each single paleomagnetic datum is considered to be a sample drawn from the ensemble of models. The models have parameters which are samples of random variates normally distributed with unknown means and variances. The most plausible model parameters are determined by maximizing the likelihood function. This method was applied to paleomagnetic data from the last 5 Ma. The mean and fluctuation of the magnetic field thus determined will be discussed.

GA1.01/W/19-A5 1600

ANGULAR DISPERSIONS OF FIELD AND VGP FROM THE MODELS OF PALEOMAGNETIC FIELD

Hidefumi TANAKA (Faculty of Education, Kochi University, Kochi 780-8520, Japan, email: hidefumi@cc.kochi-u.ac.jp) Hideo Tsunakawa (Department of Earth & Planetary Sciences, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo 152-8551, Japan, email: htsuna@geo.titech.ac.jp) Masaru Kono (Institute for Study of the Earth's Interior, Okayama University, Misasa, Tottori-ken, 682-01, Japan, email: mkono@geoph.s.u-tokyo.ac.jp)

Angular standard deviation (ASD) of paleomagnetic field shows clear variation to the latitude of the observation site; the higher the latitude, the smaller in field and the larger in VGP. Among the various models so far proposed to explain this feature, Constable and Parker (1988) first introduced a statistical model in which Gauss coefficients are zero mean random variables (except g10). Kono and his colleagues further developed a mathematical expressions of this model called a homogeneous background model (HBM), and pointed out that contribution of g21 (or h21) should be large to explain the latitude variation of ASD.
This study examines various statistical models of paleosecular variation (PSV) by a computer simulation in which random numbers are given to each Gauss coefficient. Importance of large variation in g21 (or h21) is so far ascertained, but we will also examine dependency of ASD on longitude of observation site. We will further apply the computer simulation to the models of time averaged paleomagnetic field which several authors studied by least squares methods. It is shown so far that the latitude variation of ASD is determined solely by how much variance is given to each Gauss coefficient as long as the model is close to an axial dipole field.

SECULAR VARIATION MODELS, TANGENTIAL GEOSTROPHY, AND LOCAL COMPUTATION OF THE PRESSURE AT THE TOP OF THE CORE

Arnaud CHULLIAT, Gauthier Hulot (Institut de Physique du Globe de Paris, Laboratoire de Geomagnetisme, 4 place Jussieu, 75252 Paris cedex 05, France, email: chulliat@ipgp.jussieu.fr)

There are strong arguments for neglecting the horizontal component of the Lorentz force in the dynamical budget of the fluid at the top of the core. This tangentially geostrophic approximation reduces the degeneracy of the inverse problem for the determination of the flow from the secular variation data. It further makes it possible to compute the local value of the pressure at the CMB (Chulliat and Hulot, 1998). But these computations are quite sensitive to possible incompatibilities between the SV models and the tangentially geostrophic assumption. Furthermore, it is still not clear how close to tangential geostrophy the flow at the CMB actually is. In an attempt to address these difficulties, we have derived a newset of necessary conditions for the secular variation to be consistent with both the frozen-flux and the tangentially geostrophic assumptions. Following standard approaches developped for testing the frozen-flux approximation alone, we have computed SV models that : (a) satisfy these constraints, and (b) fit the SV data with the precision allowed by the present accuracy of the observations. Preliminary results show that the tangentially geostrophic approximation does not seem to be contradicted by the existing data. These new ``geostrophic'' SV models can also be used for computing the local pressure at the top of the core in a fully consistent way.

GEOMAGNETIC SECULAR VARIATION FROM 1500

Bondar Tatiana N, Burdelnaya Irina A and GOLOVKOV Vadim P (all at IZMIRAN, 142092 Troitsk, Moscow region, Russia, email: golovkov@izmiran.rssi.ru)

Global space-time model of the geomagnetic field has been produced for time interval 500 years from 1500. Navigational observations of the magnetic declinations as well as observations of the inclinations and the horizontal component of the geomagnetic field were used as a data set for analysis. A new algorithn for these data joint analysis was developed. It is based on the SH coefficient expansion into the Legendre polynomies to degree 3. Uniqueness of the solution was reached with usage of the modern SH model as a reference one. Adequacy of the model was tested with step by step increasing of the time interval under analysis from one to five hundred years. Main results of the model being the almost stable position of the magnetic poles and the latitudinal dependence of the westword drift are discussed.

GA1.01/W/31-A5 1645

CHAOS IN THE SECULAR VARIATION OF THE RECENT GEOMAGNETIC FIELD

DE SANTIS A. and Tozzi R. (both at the Istituto Nazionale di Geofisica, Roma, Italy, email: desantisag@ing750.ingrm.it), Barraclough D. (British Geological Survey, Edinburgh, UK, email: DRBAR@wpo.nerc.ac.uk)

A non-linear forecasting analysis has been applied to the secular variation of the three-component annual means of 14 observatories, unevenly distributed over the Earth's surface (12 in the northern and 2 in the southern hemisphere) and spanning the last 150 years. All results were in agreement, either in terms of possible evidence of chaos (against hypothesis of white or coloured noise), or in terms of the Kolmogorov entropy, confirming previous results obtained with only three European observatories. New tests and evidences are presented to support a non-linear chaotic behaviour underlying the observed secular variation of the recent geomagnetic field.

GA1.01/W/29-A5 1700

A DESCRIPTION OF THE 1991 GEOMAGNETIC JERK

Paola De Michelis (Istituto Nazionale di Geofisica, via di vigna Murata 605, 00143 Roma, Italy, email: demichelis@marte.ingrm.it) Lili Cafarella (Istituto Nazionale di Geofisica, via di vigna Murata 605, 00143 Roma, Italy, email: cafarella@ing750.ingrm.it) ANTONIO MELONI (Istituto Nazionale di Geofisica, via di vigna Murata 605, 00143 Roma, Italy, email: meloni@marte.ingrm.it)

The analysis of the temporal behaviour of the secular variation in the last fifteen years, carried out on 110 observatories widely distributed all over the world, clearly showed the existence of a jerk around 1990. A point of rapid change in the slope of the secular variation is almost always present in all examined magnetic observatory data. A complete quantitative description of this jerk is now shown. Contour plates of the distribution of the secular acceleration discontinuity for the three magnetic field components, which provide information on the worldwide intensity distribution of the jerk and contour plates of the jerk time occurrence distribution in the magnetic field component are shown and discussed. Finally, a spherical harmonic analysis is presented to reconfirm the internal nature of the jerk and to study the trend of the energy density spectrum as function of the order n.

GA1.01/W/37-A5 1715

ON THE EXTERNAL NATURE OF JERKS IN GEOMAGNETIC SECULAR VARIATIONS

Vsevolod Shapiro and Albina Akhmetzanova (Institute of Geophysics, 100 Amundsen str., Ekaterinburg,620016, Russia. Fax:+7 3432 678872 Email: seva@maglab.mplik.ru)

Based on magnetic observatory data we have compiled annual total force isoporic maps for the secular variation foci of Northern hemisphere. In the course of analysis of these maps we have revealed short period variation - jerks of two types: variations observed at the phase of solar activity growth and changes of secular variation at the solar activity maximum. Jerks in other components of the field were occured at the same phases of solar cycles too. The peculiarities of discovered jerks such as their global character, morphology of variation and the evident correlation with phases of solar activity leads us to conclusion about external nature of these variations. The parameters of investigated jerks are obviously specified by solar activity changes, its 11- and 22-years periodicities. The study has shown that during 1923-1995 (solar cycles 16-22) the jerks in the total force and north component of magnetic field similar to described were occured both at the phases of solar activity growth and phases of its maxima. It is likely that another short-period changes in the structure of secular variation are induced by the solar activity. The obtained results made it possible to predict the behaviour of secular variations and to forecast jerks of revealed types during forthcoming solar activity cycles. The successful attempt of such prediction of the jerk on the period of maximum of the 22nd solar activity cycle was proved to be the case.

NUMERICAL SIMULATION OF DYNAMO

GA1.01/W/23-A6 0900

NUMERICAL MODELLING OF THE GEODYNAMO AND CORE-MANTLE COUPLING

Jeremy BLOXHAM (Department of Earth & Planetary Sciences, Harvard University, Cambridge, MA 02138, USA. Email: Jeremy_Bloxham@harvard.edu)

Of the various components of the Earth system, the most remote is the geodynamo operating in the Earth's core. The concomitant scarcity of observations is exacerbated not only by the complexity of the physics of the geodynamo but also by the inaccessibility of the dynamical regime of the core to direct numerical investigation. The almost vanishingly small role played by viscosity and the almost equally small, but nonetheless important, role played by inertia renders the system one that presents a great challenge to numerical studies.
Nonetheless, significant progress has been made over the last few years in the development of numerical models of the geodynamo, though none of the models is free of approximations, some of which are, unfortunately, introduced more for numerical expediency than for sound geophysical reasons. Here we review this progress and comment on the effect of these approximations on the solutions.
An additional complicating factor is that the geodynamo cannot be considered in isolation from the rest of the Earth system. The transport of heat from the core - which drives the geodynamo – is controlled by the mantle, and the pattern of mantle convection imposes lateral variations in the heat flux from the core. We show that this thermal core-mantle coupling influences the pattern of magnetic field at the core-mantle boundary, and that the pattern of mantle convection inferred from seismic tomography gives rise to a certain observed features in the magnetic field.

GA1.01/W/11-A6 0930

CONVECTION DRIVEN GEODYNAMO MODELS: REVERSAL MECHANISMS

C.A.JONES and G.R.Sarson, School of Mathematical Sciences, University of Exeter, Exeter EX4 4QE, UK

Numerical models of convection driven geodynamos show reversals with many similarities to those of the actual geomagnetic field. Sarson and Jones (1998) analysed the nature of the solution in the core during one reversal process. The 2.5 dimensional model,which severely truncates the number of modes in the azimuthal direction was used in this investigation.
The reversal of the field was found to be strongly associated with changes in the axisymmetric component of the meridional circulation, driven by an instability of the buoyant convection located within the tangent cylinder. Analysis of the kinematic dynamos produced by a typical flow suggested that the drop in meridional circulation was sufficient to turn the dynamo from an essentially steady dipole into a reversing dipole, for the duration of the reduction in the meridional flow. Roberts (1972) first noted the role of meridional circulation in determining whether kinematic dynamos are steady or oscillatory.
In our more recent calculations, we have investigated more reversals and used more azimuthal modes, thus moving from 2.5 dimensional models to 3 dimensional modelling. The results of these new calculations, and comparison with palaeomagnetic data on reversals will be discussed.

GA1.01/E/04-A6 0945

THE INFLUENCE OF DIFFERENT DRIVING MODES IN DYNAMO MODELS

Carsten KUTZNER, Ulrich Christensen (Institute of Geophysics,University of Goettingen, Herzberger Landstrasse 180, 37075 Goettingen, Germany, e-mail: carsten@willi.uni-geophys.gwdg.de)

We use a 3-D numerical model of convection-driven dynamos in a spherical shell to study the influence of various sources of buoyancy on the magnetic field generation. In particluar, we compare (1) fixed temperatures on both the inner and outer boundaries, (2) internal heat sources in the outer core or, equivalently, secular cooling, and (3) homogeneous sinks in the outer core with zero flux through the core-mantle boundary, which is meant to represent chemical convection. Both for fixed temperatures and for chemical convection we obtain strong dipole-dominated magnetic fields. The condition of internal heating or secular cooling leads to weaker fields with quadrupolar symmetry at lower Rayleigh number, changing to irregular field structures dominated by short wavelengths at higher Rayleigh number. Comparison with the geomagnetic field supports a predominantly compositional driving mechanism for the geodynamo.

THREE-DIMENSIONAL KINEMATIC DYNAMOS WITH THERMAL WIND FLOWS

Graeme R. SARSON, (School of Mathematical Sciences, University of Exeter, Exeter EX4 4QE, UK. Email: sarson@maths.ex.ac.uk)

Most three-dimensional kinematic dynamos studied to date have been chosen without reference to the magnetohydrodynamics applicable to the geodynamo; none of the simple cases in the literature are consistent with the magnetostrophic balance expected of the Earth's core. A simple flow is constructed which can be driven by the thermal-wind term present in the magnetostrophic regime. The kinematic dynamo action of this flow is investigated numerically, both via direct three-dimensional calculations, following the formalism of Bullard and Gellman, and via alpha-omega calculations, using the axisymmetric limit of Braginsky. The heat-source distribution necessary to drive this velocity is calculated; although in the present case artificial, this form allows comparisons with possible heat-distribution within the Earth, or in laboratory-scale experimental dynamos.

GA1.01/W/06-A6 1015

THE EFFECT OF INERTIA ON 2.5D HYDROMAGNETIC DYNAMOS

Graeme MORRISON and Prof. D. R. Fearn (Both at Department of Mathematics, University of Glasgow, Glasgow, G12 8QW, Scotland. Email: gm@maths.gla.ac.uk)

This study examines the effect of inertia in a 2.5D dynamo which has been produced by reducing the azimuthal truncation and then suitably modifying an existing fully 3D dynamo model. Despite including only one non-zero azimuthal mode, this model is self-consistent and will run at significantly lower computational effort than a 3D model, making it perfect for investigating the effects of individual parameters. When the inertial term is included, its relative size is given by the Rossby number, Ro, which has a geophysical value of O(10-9). This small value has resulted in the inertial term being neglected (i.e. Ro=0) in previous 2.5D dynamo studies, although it is included in the 3D models of Glatzmaier and Roberts (GR) and Kuang and Bloxham (KB), and indeed most other 3D models. The (GR) dynamo models includes only the zonal, axisymmetric part of the inertial term with Ro of O(10-9), while the (KB) model includes the full axisymmetric part of the inertial term, with Ro of O(10-5). The choice of Ro may play a crucial role in determining the type of solution obtained, and the different solutions obtained by the (GR) and (KB) dynamos are perhaps due to the different choice of Ro. The full inertial term is already included in this 2.5D model, while a finitely conducting inner core, which is free to rotate about the vertical axis, has been incorporated to aid comparison with existing dynamo solutions. Both of the implemented changes have been rigorously tested and benchmarked against a well-established 2.5D code, which is itself capable of reproducing qualitatively the results of the Boussinesq (GR) model. Solutions are obtained for a tractable range of values of Ro. These are of interest in their own right, in addition to providing a useful complement to the more computationally intensive 3D studies.

FORCE BALANCES IN THE CORE AND GEODYNAMO SIMULATION

Weijia KUANG (Space Geodesy Branch, Code 926, NASA Goddard Space Flight Center, Greenbelt, MD 20731, USA, email: Kuang@santafe.gsfc.nasa.gov)

One unavoidable issue in geodynamo simulation is the approximations on the force balances in the Earth's core, in particular the torque balance on the co-axial cylindrical surfaces across the fluid outer core. Due to the computational constraints, we are far from simulating the geodynamo with the parameters appropriate for the Earth's outer core. Several approximations have been applied on the torque balance in numerical modelling.
We have examined extensively these approximations and the corresponding strong-field dynamo solutions with a model in which the solid inner core is electrically conducting and rotates subject to the Lorentz torque and (optionally) the viscous torque on the inner-core boundary (ICB). We found that the structures of the core flow and the magnetic field vary significantly when a strong viscous coupling (relative to that appropriate for the core) on the ICB is introduced. In particular, the thermal wind and the magnetic wind inside the tangent cylinder (the co-axial cylindrical surface tangent to the inner core at the equator) change greatly with the viscous coupling (provided that the inertia of the inner core is sufficiently small), thus altering the differential rotation of the inner core. We find also that torsional oscillations are also affected by the approximations: when a strong viscous coupling is retained, the torsional oscillations in the core are strongly damped by viscous dissipation inside the tangent cylinder; they almost disappear outside the tangent cylinder.
To improve the force balance approximations, we introduce new asymptotic boundary conditions with which we are able to reduce significantly the strength of viscous coupling in modelling. We have implemented in our geodynamo model and examined the strong-field dynamo solutions for various parameters. We also examined the possibility of forecasting the geomagnetic field with the new model.

GA1.01/E/02-A6 1115

MAGNETOCONVECTION IN A RAPIDLY ROTATING ANNULUS

Michael PROCTOR (DAMTP, University of Cambridge, Silver St. Cambridge CB3 9EW UK; email: mrep@damtp.cam.ac.uk) Chris Jones (Dept. of Mathematics, University of Exeter, Exeter EX4 4QE UK; email: CAJones@maths.exeter.ac.uk)

Recent numerical simulations of dynamo models in cartesian geometry have shown the importance of the separation that occurs in the strong-field regime between regions of high (zonal) field strength and corresponding long length scale motion, and relatively field free areas with short length scales. To model this process we adopt the annulus model of Busse, and impose a strong zonal magnetic field. The geometrical constraints on the motion mean that variations parallel to the angular velocity vector can be ignored; then the only (but important) contribution of the rotation is the so called beta-effect from the tilted boundaries. In the limit of rapid rotation and with
appropriate magnitude of the field strength the zonal length scale is much shorter than the radial one, leading to the possibility of a mean-field theory for the effects of convection on the mean fields and flows. The resulting reduced system of equations is integrated numerically, so as to show the mechanism for the production of net mean flows, and the conditions for onset of self-sustained modulations in the zonal direction.

GA1.01/W/14-A6 1130

A NUMERICAL EXPERIMENT OF MAGNETOCONVECTION IN A ROTATING SPHERICAL SHELL FLUID

Ataru SAKURABA, Masaru Kono (Department Of Earth And Planetary Physics, University Of Tokyo)

The dynamic interaction between magnetic field and fluid flow and the resulting deformation of convective rolls are investigated through a numerical experiment of magnetoconvection in an electrically conductive rotating spherical shell fluid to which a uniform magnetic field parallel to its spin axis is imposed. A uniform heat source in the sphere drives a time-independent thermal convection in which the maximum magnetic Reynolds number is 92. The Elsasser number measures the strength of the externally imposed magnetic field. In the course of the numerical experiment, the Elsasser number is increased discretely from 0.2 to 5.0 through several intermediate values.
An abrupt change of the mode of magnetoconvection occurred when the Elsasser number was about 0.5; the pattern of the fluid flow changed from geostrophic to magnetostrophic ones. At the same time, the induced magnetic energy jumped up to a higher level and the kinetic energy of the fluid also increased. The transition from geostrophic to magnetostrophic balances is responsible for the deformation of the anti-cyclonic convective rolls in which the fluid circulates in the opposite fashion to the rotation of the sphere so that the Coriolis force works inward. The lines of magnetic force in the equatorial plane are converged into the anti-cyclonic rolls due to the compensation flow of the Ekman pumping at the outer fluid-solid boundary. As the imposed magnetic field increases, the equatorial part of the anti-cyclonic roll expands because of the outward Lorentz force around there caused by the converged lines of magnetic force. The deformation of the convective rolls is a natural result of the effective thermal convection and the confinement of magnetic flux in the fluid shell. This study provides a basic idea to consider the dynamic structure in the Earth's outer core.

GA1.01/E/15-A6 1145

ROTATING MAGNETOCONVECTION IN VARIOUSLY STRATIFIED LAYERS IN DEPENDENCE ON BOUNDARY CONDITIONS

J. BRESTENSKY, S. Sevcik, J. Simkanin, Dept of Geophysics, Faculty of Maths And Physics, Comenius University, Bratislava, Slovakia

Hydromagnetic instabilities, developing in the rapidly rotating horizontal fluid layer permeated by the azimuthal magnetic field linearly growing with the distance from the vertical rotation axis, are investigated for ranges of parameters (Elsasser, Roberts, Ekman number,) which can be roughly related to the Earth's core conditions. Both horizontal boundaries are thermally infinitely conducting and are either free or rigid ones with infinite or finite (Earthlike) electrical conductivities.
Cases of uniform and non-uniform stratification of the layer are considered with various widths of the upper stably stratified sublayer for the non-uniformly stratified layers. The lower sublayers are unstably stratified as in the Earth's core.
Frequencies of the instabilities, running in the azimuthal direction, are comparable to typical frequencies of the Geomagnetic Secular Variations only for order one values of Roberts number, the ratio of the times of ohmic and thermal diffusion. The question is, how the results for uniformly stratified layer are modified in various cases of the non-uniformly stratified layer. E.g. in uniformly stratified layer at stronger magnetic fields the finite electrical conductivity causes the development of MC waves, i.e. instabilities able to exist without the buoyancy. Furthermore, the rigid boundaries induce the marked competition of modes in viscous fluid. Moreover, the viscosity plays an important role in the dynamics of instabilities of greater azimuthal wave number.

MAGNETIC INSTABILITIES IN A SPHERICAL SHELL WITH FINITELY CONDUCTING INNER CORE

FOTHERINGHAM, Paul, University of Glasgow

Continuing the work of Hollerbach and Jones(1993), in which they studied the weakly super-critical axisymmetric solutions of an alpha squared dynamo, I investigate the behaviour in the strongly super-critical regime. In particular, I will focus on the next symmetry breaking bifurcation in the sequence, which, for the alpha effect used by Hollerbach and Jones is to a fully non-axisymmetric solution. Given the possible importance of sub-critical instabilities in geomagnetic reversals, results confirming the nature of the bifurcations will be given.

GA1.01/E/03-A6 1215

INVERSION FOR FLUID FLOW AT THE CORE SURFACE -A TEST WITH RESULTS FROM DYNAMO MODELLING

Steffen RAU, Ulrich Christensen, Johannes Wicht (Institute of Geophysics, University of Goettingen, Herzberger Landstrasse 180, 37075 Goettingen, Germany, e-mail: srau@willi.uni-geophys.gwdg.de)

Using the frozen flux approximation, secular variation data have been inverted for the horizontal flow v_h at the surface of the Earth's core. The non-uniqueness of the inversion problem must be removed by making additional assumptions for the velocity field. Here we invert the magnetic fields of 3-D numerical dynamo models for the near-surface velocity and compare the results with the actual velocity distribution. We find that the frozen-flux assumption is reasonably well satisfied at magnetic Reynolds numbers of order 100. Inversion schemes that employ only a regularisation condition (smooth flow), or that additionally assume purely toroidal flow, perform poorly in recovering the original velocity field. We find a decent correlation when using the assumption of tangentially geostrophic flow, even though a large fraction of the field v_h*B_r is divergence-free, i.e., in the null-space of the inversion problem. The results justify cautious optimism concerning the retrieval of the long-wavelength part of flow near the top of the core.

THE MODEL OF ALPHA-QUENCHING IN GEODYNAMO

A.Anufriev (Geophysical Institute, Bulgarian Acad. Sci., Bonchev str., bl. 3, 1113 Sofia, Bulgaria, email: anufriev@geophys.acad.bg); M.RESHETNYAK (United Institute of the Physics of the Earth, Moscow, Russia, 123810, emails: pavlov@uipe-ras.scgis.ru and rm@uipe.srcc.msu.su); D.Sokoloff (Department of Physics, Moscow State University, Moscow, Russia, 119899, email: sokoloff@dds.srcc.msu.su)

We believe that process of geomagnetic field generation can be described in terms of the mean-field dynamo theory. Usually, the equilibrium between the magnetic Em and kinetic Ek energies is proposed: this is the case of the stars and the Galaxy. After the magnetic energy exceeds the state of equilibrium the quenching of the magnetic field starts. It corresponds to equilibrium of inertial and Lorentz terms in Navie-Stokes equation. So far the energy of the small scale motions is much smaller then the energy concerned with the large-scale kinetic energy, the alpha quenching is of the crucial importance. In the same time the observations of the geomagnetic field as well as it's numerical simulations (Glatzmaier and Roberts, 1995) indicate that magnetic energy exceeds the kinetic energy more then three orders of magnitude. Thus, following the previous scenario the magnetic field had to suppress the flow motions and as a consequence to damp the process of the magnetic field reproduction. Here we propose the possible explanations of this phenomenon. Following the model alpha-quenching starts when the balance between the Coriolis and Lorentz forces in the Navie-Stokes equation is fulfilled. Then the ratio of Ek/Em~Ro, where Ro is the Rossby number.

CURRENT LOOPS MODEL OF THE GEOMAGNETIC FIELD SOURCE

Vsevolod V. BOTVINOVSKY (Institute of Geophysics SB RAS, Koptyug av., 3, Novosibirsk 630090, Russia; e-mail: botvin@uiggm.nsc.ru)

We attempted to model the geomagnetic field by fields of several quasi-independent space-separated sources. Magnetic dipoles and current loops are used as sources of magnetic field. If we use single source located approximately in the Earth's center and four additional sources located under the world magnetic anomalies then the morphology of the simulated field is fitted in a good way to morphology of the real geomagnetic field. It allows to suppose the existence of relatively independent sources generating the main field (dipole form) and fields of the world anomalies (Canadian, Siberian, Brazilian and Antarctic).
It was found that using current loops with opposite current flows it is possible to create the model of quasi-symmetrical source of the main geomagnetic field. In order to attain the real tilt of geomagnetic axis and real asymmetry of intensity of the geomagnetic field it is enough to incline the loops at 1-2 degree to the equator plane and to shift the loops at 35 km apart from the Earth's center. These values are much less than that used in the model of displaced magnetic dipole.

MAGNETO-CONVECTION IN A ROTATING SPHERE OF LIQUID GALLIUM

D. BRITO, Nataf H-C., B. Pascal and Ph. Cardin L.G.I.T. ,Observatoire de Grenoble, Université Joseph Fourier BP 53, 38041 Grenoble Cedex 9,France

Although numerous numerical studies are devoted to magneto-convection in a rotating sphere, there has been no experimental confirmation. We propose to study experimentally the magnetohydrodynamics of such a flow where Coriolis and Lorentz forces play an important role, as in the Earth's core.
We have built an experimental set-up where a 22 cm-diameter sphere is filled with liquid gallium and spun at up to 1000 revolutions per minute. Water is circulated at high flow rates in a cylinder inside the sphere, keeping the inner temperature constant and slightly above the melting point of gallium (29.8˚C). The device is located in a 2 m-side cabin in which air is kept at a higher temperature (up to 50˚C). This enables thermal convection to develop between the inner cylinder and the outer sphere. A 30 mT azimuthal magnetic field is created by a toric copper solenoid consisting in 360 loops being passed inside the inner cylinder and then along the outer sphere.
The Prandtl number is 0.027, the Ekman number is around 5.10-7, the Rayleigh number is expected to be a few times critical, and the Elsasser number is around 10-2. We expect convective velocities of a few millimeters per second, electrical potential differences of a few microvolts, and induced magnetic fields of the order of 20 mT.
We will measure convective velocities in opaque gallium using an ultrasonic Doppler velocimeter; prior velocity measurements obtained with this technique in a vortex of gallium will also be presented. Using platinum-constantan thermocouples, we plan to measure simultaneously the temperature fluctuations and the electrical potentials on the walls. We will also measure the induced magnetic field close to the outer surface of the sphere.
We will present a preliminary study of thermal convection in water as well as the first results of magneto-convection in gallium.

GA1.01/W/27-A5 Poster **0900-04**

2.5D-MODEL OF GEODYNAMO WITH RESOLVED EKMAN LAYER

Ivan Cupal and Pavel Hejda (Geophys. Inst. Acad. Sci. Czech Rep., 141 31 Prague 4, Czech Republic, email: ic@ig.cas.cz Maxim Reshetnyak (Inst. Phys. of the Earth, Russian Acad. Sci., Moscow, 123810 Russia, email: rm@uipe.srcc.msu.su)

The model is based on mean field approach (MFA), which has been applied by Jones et al. (1995). We decompose the quantities into axially symmetric and non-axisymmetric parts and in the azimuthal direction we take into account only several harmonics of the Fourier expansion (2.5 D approximation). In this approach mean values of non-axisymmetric magnetic field and velocity over azimuthal direction vanish. However, we resolve Ekman layer analytically and it enables to obtain solutions for Ekman numbers smaller than 0.000001. The numerical method is a special combined grid-spectral method which was successfully tested with a kinematic case. The first calculation of the model are performed without the inner core to be taken into account.

GA1.01/W/20-A5 Poster **0900-05**

IS THE EARTH'S MAGNETIC FIELD POLARITY REVERSAL A SELF ORGANIZED CRITICAL PHENOMENON?

Paola DE MICHELIS (Istituto Nazionale di Geofisica, via di Vigna Murata 605, 00143 Roma, Italy, email: demichelis@marte.ingrm.it)Giuseppe Consolini (Istituto di Fisica dello Spazio Interplanetario, via del Fosso del Cavaliere snc, 00133 Roma, Italy, email: giuseppe@sunago2.ifsi.rm.cnr.it)Antonio Meloni (Istituto Nazionale di Geofisica, via di Vigna Murata 605, 00143 Roma, Italy, email: meloni@marte.ingrm.it)

The geomagnetic field property, best documentated by paleomagnetism, is that the Earth's magnetic field has reversed its polarity hundred times in the Earth's history. It is generally considered that the polarity reversal intervals have an exponential distribution. Here, the geomagnetic polarity reversal record, for the past 165 Ma, is analyzed and a new approach to the study of the magnetic field time reversals, based on concepts coming from Self-Organized Criticality (SOC), is presented. More in detail, the occurrence of $1/f$-noise (also called pink noise) in the Power Spectral Density (PSD), relative to geomagnetic field time reversals, and of a Zipf's law for the cumulative distribution of chrono duration are investigated. The obtained results are compared with those coming from prototypical models of dynamical systems, exhibiting SOC, and discussed in the context of fluid motions acting within the Earth's outer liquid core.

NUMERICAL MODELLING OF FINITE AMPLITUDE CONVECTION IN RAPIDLY ROTATING SPHERICAL SHELLS. INTERACTIONS WITH THEORITICAL WORK AND EXPERIMENTAL DATAS

Dormy Emmanuel I.P.G.P., 4 place Jussieu, 75252 Paris cedex 05, FRANCE. Dominique Jault and Philippe Cardin L.G.I.T., U.J.F. Grenoble, 1381 rue de la piscine, Grenoble, FRANCE. C.N.R.S., FRANCE.

We present a numerical study of finite amplitude convection in rapidly rotating spherical shells with rigid boundary conditions. Solutions in a range of Taylor number (2 Omega r^2/nu)^2 from 10^7 to 10^12 are discussed, great care is taken to make sure boundary layers are correctly resolved. Different kind of heatings and gravities are used. We study how the numerics compare with previously available experimental data. We discuss also the results expected from the Gallium experiment under development in Grenoble. Caracteristics of the flow such as the critical mode, the phase velocity and its dependence on the Rayleigh number are investigated. Attention is given to the effects of the widely used centrifugal gravity. A comparison with the analytical (Soward 1977) description of finite amplitude convection and criticality of the bifurcation is performed with stress free boundary conditions.

THE EFFECT OF DIFFERENT ROTATIONS OF INNER CORE AND MANTLE ON GEOMAGNETIC FIELD

Bejo DUKA Faculty of Natural Sciences, Tirana, Albania

The existence of the difference between the angular velocities of Inner Core and Mantle is now an accepted fact (Glatzmaier and Roberts, 1996). Another interesting fact, drawn from seismological observations (Su Wei-jia and Dziewonski, 1995), is that the Inner Core has an axis of symmetry, which is tilted (about 10.5 degree) from the Earth's rotation axis. Supposing that the rotation of Inner Core is about its axis of symmetry, we modeled the motion of Outer liquid Core as the fluid flow inside a spherical shell where the inner and outer spheres rotate about different axes, with different angular velocities. Solving Navie-Stokes equations in spherical geometry, we found the velocity field. The presence of gravitational and magnetic field changes the hydrodynamic equations, but the gravitational field contributes only to the radial dependence of the pressure and does not influence the velocity field, while the Lorentz force is considered small and the velocity field is considered known from the solution of Navie-Stokes equations. Substituting the velocity field to the kinematic dynamo equation with known boundary conditions for the geomagnetic field, we discussed about the solution of the equation without claiming to find the exact solution.

A TIDE-DRIVEN DYNAMO - A PROPOSAL FOR A SYNTHESIS OF SEISMIC AND GEOMAGNETIC OBSERVATIONS, AND OF EARTH'S ROTATION ANOMALIES

Giovanni P. GREGORI (IFA-CNR, via Fosso del Cavaliere 100, 00133 Roma, Italy; e-mail: gregori@atmos.ifa.rm.cnr.it), Wen Jie Dong and Xiao Qing Gao (Lanzhou Institute of Plateau Atmospheric Physics, Academia Sinica, Lanzhou, Gansu Province, P. R. of China) , and Fabrizio T. Gizzi (Istituto Internazionale di Studi Federiciani, Tito Scalo, Potenza, Italy)

Three kinds of objects exist in our galaxy: (1) stellar (all plasma), (2) cold (comets, meteorites, the Moon,), and (3) intermediate, i.e. having interior layers that can slide with respect to each other. Such last objects, when are subject to a tide, have an internal dynamo, a magnetic field, a magnetosphere, endogenous Joule's heating, volcanism, gas exhalation, and an atmosphere protected by their magnetosphere. II - The electric currents of the dynamo flow on the outermost possible internal layers, i.e. wherever they experience an abrupt step-like relative drop of the electrical conductivity. In the case of the Earth there are 3 such layers, i.e. ICB, CMB, ALB. III - Outward propagation of endogenous heat can hardly occur within such a bad t hermal conductor as the Earth. It rather occurs by Hamilton's principle ("electric soldering iron mechanism"; cfr. Gregori, PEPI, 77, 39, 1993), thus feeding volcanoes. IV - The radii of the ICB, CMB and ALB can thus be computed either by seismology (dur i ng the last several tens years) or by geomagnetism (since ~1400 AD for ICB and CMB). The Earth appears to behave almost like a car-battery, recharging and discharging itself, solar modulated (for periods longer than solar cycle's) with a typical decay ti m e of ~110 years. V - Such comparatively rapid internal transformations of state, imply: (i) large variations of the outer core pressure within an almost rigid mantle and lithosphere and a constant-radius Earth, and (ii) a time variation of the Earth moment of inertia, thus explaining the relation between the geomagnetic secular variation and the length of day (in progress). VI - Also lunar palaeo-magnetism and -volcanism fit very well within such a model.

DYNAMICAL GEODYNAMO CODES ON A NETWORK

David IVERS, Les Farnell, Ron James and David Galloway (School of Mathematics and Statistics, University of Sydney, NSW 2006, Australia; email: david@maths.usyd.edu.au)

We report on the development of a low cost fully dynamical computer code to model the Earth's magnetic field. Various codes are being tested. The prototype geodynamo model underlying these codes consists of an electrically-conducting solid inner core, free to rotate about the geographic axis, and an electrically-conducting Boussinesq fluid outer core surrounded by a stationary insulating mantle. The convection is thermally driven by prescribed temperatures or heat fluxes at the inner and outer core boundaries. The magnetic, viscous and thermal diffusivities are uniform. The fields are governed by the magnetic induction, heat and momentum equations in a rapidly rotating frame with Coriolis, Lorentz, buoyancy and viscous forces, and may include inertia. The numerical methods use either spherical harmonics or Fourier expansions in colatitude and longitude, finite differences in time, and either finite differences or a Chebychev tau method in radius. Fast Fourier and Gauss-Legendre methods are used to transform fields between physical and spectral spaces. Finite differences in radius allow efficient job-splitting across a distributed network of cpu's for increased execution speed. Against this Chebychev methods in radius offer greater accuracy for a given truncation level. Higher-order including maximal order finite-difference schemes are being explored for increased accuracy. The codes are implicit in the linear diffusion terms for stability, and explicit in the nonlinear terms for reduced cost. At present the message handling program PVM is used for job-splitting between CPU's. So far a finite-difference code for the magnetic induction and heat equations have been completed, including both laminar and mean field dynamo effects but with either a non-conducting inner-core or no inner-core at all. A Chebychev-tau

code for the magnetic induction equation has also been completed. These codes have been tested on a 10-cpu network against known models, where either the exact solution or accurate numerical solutions are known. Currently a finite-difference code for the momentum equation is being developed and has been tested in the non-magnetic case. The fully-dynamical case is currently being tested.

STRUCTURES OF THE MAGNETIC AND THE VELOCITY FIELDS WITHIN BOUNDARY LAYERS

J. S. KATAYAMA, M. Matsushima, and Y. Honkura (all at Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Meguro-ku, Tokyo 152-8551, Japan, Email:jsato@geo.titech.ac.jp)

We have been performing numerical simulations for an MHD dynamo model in a rotating spherical shell. We have investigated structures of the magnetic and the velocity fields under a condition that the Rayleigh number is slightly larger than the critical one for exciting a thermal convection. Columnar convection cells aligned in parallel to the rotation axis characterise the structure of velocity field. The structure of magnetic field is characterised by a strong toroidal field generated near the equatorial region close to the outer surface and by a poloidal field generated by convective columns.
We have so far examined these structures on stress-free boundary conditions. It has recently been pointed out, however, that the effect of boundary layers on dynamo action is of importance. We here impose rigid boundary conditions so as to resolve structures of these fields within thin boundary layers. The behaviour of the magnetic and the velocity fields is then studied for various non dimensional parameters.

A NEW MODEL OF THE GEOMAGNETIC FIELD GENERATION

Vladimir V. KUZNETSOV (Institute of Geophysics SB RAS, Koptyug av., 3, Novosibirsk 630090, Russia; e-mail: kuz@uiggm.nsc.ru)

A new model of the generation of the magnetic field on the planets and satellites is suggested. The model is based on the "hot" Earth hypothesis and the idea of galvano- magnetic amplification of initial field. The initial field is generated by daily rotation of double electric layer (DEL) that arises on the boundary of inner and outer Earth's core (F-layer). The F-layer is the region of phase transition of extra-compressed gas (substance of inner core) to liquid (substance of outer core). The change of the "condensation" to "evaporation" leads to the change of DEL polarity and, as consequence, of the geomagnetic field polarity. It is a reversal of magnetic field. The model allows to explain the generation of magnetic field on the planet bodies in the beginning of their evolution while the inner core exists yet. Current contours generating the geomagnetic field like the double cylinder located in the F-layer close to the equator plane.

ANISOTROPIC DIFFUSION AND THERMAL CONVECTION

COLLIN PHILLIPS (Mathematics Learning Centre University of Sydney NSW 2006 Australia Email: collinp@scifac.usyd.edu.au) David Ivers (School of Mathematics and Statistics University of Sydney NSW 2006 Australia)

The current linear stability model allows investigation of anisotropic turbulent diffusion. Linear stability models in general compliment fully dynamical dynamo models. The present model incorperates the momentum and heat equations, for a fluid core with no slip boundary conditions. The fluid core consisits of a basic state that is steady and axisymmetric.
The choice of representation, that being vector and tensor spherical harmonics, facilitates convenient production of the relavant spectral equations that are inaccessible using conventional methods. We utilise the close association and simple transformations to and from toroidal poloidal representations to impose solinoidal conditions. Though the transformation to toroidal poloidal conditions only occurs after the vector spherical harmonic analysis is used to produce spectral equations. The numerical code utilises the vector and tensor spherical harmonics directly in computing interaction terms and especially anisotropic diffusion.
The present model consists of themal convection (with no magnetic basic state) with anisotropic turbulent diffusion influenced by the direction of rotation and gravitational forces independently.
We outline the methods and analysis for producing the relevant spectral equations and coding directly using vector spherical harmonics and present preliminary numerical results.

CONCERNING A MODEL OF FORMATION OF TERRESTRIAL MAGNETISM

RASULOV D.KH. Lange Institute of Hydrogeology and Engineering Geology. Tashkent, Uzbekistan, E-mail: root@ariel.tashkent.su

The work gives in detail a new piezoelectric model of terrestrial magnetism which permits all the main features of geomagnetism field to be explained from the unified positions. In accordance with the model, piezoelectric textures may be formed in the Earth's crust which is oriented along a direction close to the geographic parallels. The presence of mechanical strains in Earth's crust rocks caused by an action of terrestrial gravity is to lead to an emergence of a potential difference along the piezoelectric textures. As a result, an electric current runs along these directions forming a weak quasi-stable field, which direction is to be close to that of the geographic terrestrial axis. Electric charges of the liquid core rotated in this magnetic field are affected by a force acting in the normal direction to the rotation axis which causes electric polarization of the core. Namely, this rotation of the like electric charges of the core forms the main component of the geomagnetic field.

EARTH'S MAGNETIC FIELD AND HOW IT REVERSES

Richard. Eugene D

A comparison of the Geodynamo and the geomotor is presented. Various models of the Geomotor are given and the one utilizing relativity is emphasized. A comparison is made of the two theories. Then reversals are explained on the basis of a thermostatic action utilizing heat, relativity, and the size of the spherical electron cloud with the idea that all reversals during the Cenozoic Era could be explained by this theory.

ON THE GEOMAGNETIC JERKS GENERATING PROCESSES

Anahit SIMONYAN (Institute of Geophysics & Engineering Seismology, NAS RA, Leningradian 5, Giumry, 377515 Armenia, email: iges@shirak.am)

Examination of all the geomagnetic field secular variations data temporal series obtained elsewhere by magnetic observatories allows to develop the method of representing the dynamics of the Earth's magnetic field through the jerks. Jerks on the Earth's surface mean the discontinuities of the geomagnetic field elements annual mean values second time derivatives series while first time derivatives represent the straight line segments before and after the jerks epochs for the time intervals of a few decades. The geomagnetic field and it secular variations representative spatial models were obtained including the jerks as the "quantums" of field variability. The jerks characteristic timescales and temporal intervals under consideration permit us to neglect diffusion effect while obtain the jerks originating processes in the upper layers of the Earth's liquid core. Proceeding from the frozen-flux hypothesis the jerks originating movement systems on the top of the free stream are obtained. Depending on the investigating jerk morphological data that consist of rising and/or downflowing local foci of core liquid velocity field just beneath the core-mantle boundary.

ROBUST MAXIMUM-LIKELIHOOD REGULARISED INVERSION FOR THE HISTORICAL CORE MAGNETIC FIELD

M. WALKER and A. Jackson (School of Earth Sciences, University of Leeds, Leeds, LS2 9JT, UK. Email: M.Walker@earth.leeds.ac.uk ; A.Jackson@earth.leeds.ac.uk)

Traditionally models of the geomagnetic field have been constructed under the assumption that the data are contaminated with noise originating from a Gaussian distribution. Such a distribution would originate, for example, when a number of different, independent noise sources contribute and the Central Limit Theorem (CLT) is applicable. The resulting maximum likelihood inversion for the core field results in the data being fit under the 2-norm measure of misfit; perhaps an added attraction of the method is the low computational cost. Although intuitively appealing, the fact that the crustal field overwhelms all other sources of noise suggests that the conditions for the CLT to apply are not necessarily met.
There is a mounting body of evidence suggesting that the appropriate distribution of errors is better approximated by a double exponential, or Laplace, distribution. We apply a new maximum-likelihood method for modelling magnetic field survey data under a 1-norm measure of misfit. Despite some added computational complexity, modern computer power is sufficient that computational considerations are irrelevant. The technique is applied to geomagnetic data for the last century and comparisons will be presented between models constructed under Gaussian and Laplace distributions of error.

ENVIROMT. A NEW RADIO/CONTROLLED SOURCE SYSTEM

L.B Pedersen (Department of Earth Sciences/Geophysics, Uppsala University, Villavägen 16, 752 36 Uppsala, Sweden, email: lbp@geofys.uu.se) L. Dynesius, M. Bastani and M.Gharibi (Department of Earth Sciences/Geophysics, Uppsala University, Villavägen 16, 752 36 Uppsala, Sweden, email: ld@geofys.uu.se) and U. Matzander (Metronix, Neue Knochenhauerstr 5, D-38100 Braunschweig, Germany)

The design of new electromagnetic system using radio frequencies in the band 14 kHz to 500 kHz and two perpendicular horizontal magnetic dipole sources from 1 kHz and upwards has recently been completed by Uppsala University and Metronix company.
Two horizontal electric and three magnetic components are simultaneously measured in two bands 1-25 kHz or 10-500 kHz. In the first band there are numerous VLF transmitters present starting at ca 14 kHz. In the second band, in addition to the VLF transmitters, there are more than 20 transmitters present with a rather uniform distribution of azimuths, allowing for stable estimates of the full impedance tensor and the tipper vector. If only radio frequencies are used each site can be measured in just a few seconds. The system consists of three short magnetic sensors built into one small unit and 4 small steel electrodes connected to buffer amplifiers all of which are fed into a central analogue signal conditioner before being transferred to an advanced signal processor box with AD converters, GPS synchronisation, radio-communication modem between transmitter and receiver and a new dedicated software package for data playback and visualisation, and automatic 1-D inversion.
Each of the magnetic dipole sources have maximum magnetic moments of ca 4000 Am2, powered from ordinary car batteries, whereby the maximum transmitter receiver distance exceeds 1000 meters. Thus plane wave conditions prevail down to 200 meters depth of investigation.

ON THE STABILITY OF MAGNETOTELLURIC TRANSFER FUNCTIONS AND THE RELIABILITY OF THEIR VARIANCES

Markus EISEL (GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany, email: eisel@gfz-potsdam.de) Gary D. Egbert (College of Oceanic and Atmospheric Sciences, Oregon State University, 104 Ocean. Admin. Bldg, Corvallis, OR 97331, email: egbert@oce.orst.edu)

Two years of continuous magnetotelluric (MT) time-series recordings from a two-station earthquake monitoring array were used to study the time stability of MT transfer functions (TFs), and the reliability of the estimation errors. A robust remote reference approach was used to calculate estimates of MT TFs in the band 2-3000 s for each day. No significant long

term variations could be detected, with typical deviations staying within a few percent of the long term averages. To assess reliability of the variance estimates we computed daily deviations from the median TF, divided by the respective variances. Distributions of these ratios show that the error variances are sometimes underestimated when standard (asymptotic) methods for computing error estimates are used. We also consider two variants on a jackknife approach to error bar calculation. With the first variant, the full robust TF estimation procedure is repeated using subsets of data (i.e., we omit a fixed fractions of the total set of data rather than single data entries.) This approach is very expensive in terms of computation time. With the second approach we estimate the data weights for the robust TF estimate once using all data, and then compute jackknife error bars for the weighted LS problem. We show that with this approach the error bars can be computed at essentially no cost; the result can be expressed in closed form. Both jackknife approaches yield more conservative variance estimates compared to the standard asymptotic approach. The first approach gives significantly more reliable variance estimates for periods from 10-100 s (where coherent noise contaminated TF estimates), provided the size of the omitted data fractions is large. At other periods where coherent noise does not affect the data, the smaller error bars computed by standard approaches more accurately reflect the variability in the TFs.

GA1.02/W/29-A1 0900

DC SENSITIVITY AND MT STATIC SHIFT

Klaus Spitzer (Joint Geoscientific Research Institute, Stilleweg 2, 30655 Hannover, Germany, email: klaus.spitzer@gga-hannover.de)

Magnetotelluric (MT) static shift is a non-inductive change or distortion of the MT apparent resistivity response that severely impairs the interpretation of MT data. Since MT static shift is a pure direct-current (DC) phenomenon, we can apply the DC sensitivity distribution to predict its behavior. Let us consider a four-point DC arrangement in Schlumberger configuration with current electrode spacing AB. Then negative sensitivities form two semi-spherical or bowl-shaped structures between current and potential electrodes. With the limit of AB toward infinity the semi-spheroids grow infinitely large leaving positive sensitivities only within a vertical dike structure between the potential electrodes. This arrangement represents the DC analog to the MT static shift case yielding horizontal current systems at the position of the potential electrodes or, in MT terms, of the telluric probes. Thus, the sign of static shift is due not only to the resistivity of the body but also to its location. For example, a conductive body between the telluric probes will decrease the MT apparent resistivity (positive sensitivity) whereas the same body being located aside from both probes yields an increase in apparent resistivity (negative sensitivity). 3D modelling clearly verifies this behavior. A field campaign was carried out in Unterfranken/Germany comprising MT, DC resistivity soundings, the vertical gradient method (VG) and borehole geophysics and serves as practical example. The DC resistivity data have been interpreted using 3D forward modelling to investigate the vicinity of the MT sites with respect to the static-shift problem. Finally, as a comparison undistorted results of the vertical gradient method are taken into account.

GA1.02/E/10-A1 0915

THE PHYSICS OF KEYHOLE IMAGING

Laszlo SZARKA (GGRI, H-9401 Sopron POB 5 and Universite Paris-Sud, F-91405 Orsay Cedex, Bat. 504, email: szarka@ggki.hu) and Michel Menvielle (CETP, F-94107 Saint Maur des Fosses and UPS, F-91405 Orsay Cedex, Bat. 504, email: michel.menvielle@cetp.ipsl.fr)

CSAMT analogue modelling results carried out in the Sopron modelling laboratory showed especially model-geometry connected anomalies over high-conductivity thin-sheet models, in a narrow period zone just at the end of the oscillating section of the sounding curves. Years later, full 3-D MT numerical modelling experiments confirmed the existence of such a phenomenon We call these model geometry-connected images as keyhole images (Szarka and Menvielle 1999: Geophysical Prospecting, 47, 59-71). Recently, the analogue and numerical modelling results were completed by simple two-layer analytical derivation (Szarka, Menville and Spichak 1998: The keyhole imaging. Paper presented at the Sinaia EM induction workshop). By using analytical derivation it proved to be possible to predict keyhole images: the best keyhole images appear at periods where the response to a resistivity change at a certain depth has its maximum. In this paper further numerical modelling results are presented (both for conductive and resistive targets) and the full description of this interesting phenomenon, which might be useful in some field application in the future is given.

GA1.02/W/37-A1 0930

MODELLING THE ELECTRIC FIELD AT THE SEAFLOOR DUE TO A NON-UNIFORM IONOSPHERIC CURRENT

Risto PIRJOLA and Ari Viljanen (both at Finnish Meteorological Institute, Geophysical Research Division, P. O. Box 503, FIN-00101 Helsinki, Finland, email: risto.pirjola@fmi.fi)

The estimation of geomagnetically induced currents (GIC) and voltages on submarine cables requires the knowledge of the electric field produced at the seafloor during geomagnetic disturbances. In this paper we derive relations between the seafloor electric field and the surface magnetic field in the case of a non-uniform ionospheric source. The equations thus permit the calculation of the seafloor electric field, for example, in terms of observatory magnetic data. The relations can be expressed as inverse Fourier integrals over horizontal wave numbers or as spatial convolutions. It is important to note that the transfer functions and the convolution kernels between the seafloor electric and surface magnetic fields only depend on the properties of the seawater and of the basement below the seafloor. So, after they have once been determined they are applicable to all geomagnetic disturbance events. Corresponding relations also hold true for the seafloor magnetic field and the surface magnetic field.

GA1.02/E/18-A1 0945

PRESSURE DEPENDENCE OF ELECTRICAL CONDUCTIVITY OF MANTLE OLIVINE

Thomas J. SHANKLAND (Earth and Environmental Sciences Division, MS D443,Los Alamos National Laboratory, Los Alamos, NM 87545; Email: shankland@lanl.gov), Yousheng Xu (Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany, email: yousheng.xu@uni-bayreuth.de), A. G. Duba (L201, Lawrence Livermore National Laboratory, Livermore, CA 94551; Email: alduba@llnl.gov)

We report new measurements of electrical conductivity of olivine that were made in a multi-anvil press using solid buffers (usually Mo-MoO2) to control oxygen partial pressure. The temperature range was 950-1450°C and the pressure range was 4-10 GPa. When pressure effects are interpreted as activation volumes in the Arrhenius equation, they yield values of order 0.5 ± 0.85 cm3/mole. In addition, we analysed older literature data, which produced a similar result but with larger variation. The common practice of assuming that the pressure effect on electrical conductivity of olivine in Earth's upper mantle depends weakly on pressure has rested on uncertain grounds. These new observations suggest that at upper mantle conditions (depths of 80-200 km) neglecting pressure effects on conductivity is justified. A weak pressure effect also supports the small polaron (Fe3+) model as the dominant conduction mechanism, although the mainly positive activation volumes argue for a component of lattice deformation.

GA1.02/W/31-A1 1000

MAGNETIC MAPPING AND ELECTROMAGNETIC INDUCTION IN THE EARTH

ADRIAN HITCHMAN, Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia; F.E.M. (Ted) Lilley, Research School of Earth Sciences, Australian National University, Canberra ACT 0200 Australia; Peter R. Milligan, Australian Geological Survey Organisation, GPO Box 378, Canberra ACT 2601, Australia

Time-varying magnetic fields arising from electromagnetic induction in Earth become part of the total magnetic field measured during magnetic mapping. The CICADA project is concerned with such induction effects, looking for ways to improve the resolution of the mapping and to exploit magnetic data for information on conductivity structure.
The CICADA project has four strands: *Analysis of aeromagnetic crossover misfits for conductivity information. A Fourier technique has been used to reconstruct magnetic daily variations from crossover misfits. Comparison of these and base station variations allows spatial induction patterns to be mapped using aeromagnetic survey data.
*Global Sq total-field curves. Type curves of the total-field quiet daily variation for the whole globe have been derived from an analysis by Campbell of observatory data from the International Year of the Quiet Sun. They show a pronounced latitudinal and seasonal dependence.
*Total-field magnetic amphidromes. Near a conductivity contrast, at certain main field inclinations, total-field fluctuations of period less than one hour may be undetectable with a scalar magnetometer. Such locations are called "magnetic amphidromes".
*Micropulsations and the coast effect. A line of three-component magnetometers, extending from onshore to the continental shelf, has been used to measure the coast effect at micropulsation periods. Such data provide valuable insight into the behaviour of the total field where aeromagnetic surveys are being conducted over the continental shelf, as is now common in Australia. (CICADA: Clarifying Induction Contributions to Aeromagnetic DAta)

GA1.02/E/05-A1 1015

AN AEROMAGNETIC RISK MAP OF AUSTRALIA

CHARLES BARTON (Australian Geological Survey Organisation, GPO Box 378, Canberra ACT 2601, Australia, Email: cbarton@agso.gov.au)

Base station data are used to remove time-variations of the geomagnetic field from aeromagnetic surveys. The correction suffers from spatial non-uniformity of external fields and heterogeneity of the inductive response of the Earth's crust. The latter can be mapped using magnetometer arrays. An "aeromagnetic risk factor" is developed, based on the dispersion of Parkinson induction vectors, which is a measure how accurately a base station represents the time-varying field at a remote survey point. The aeromagnetic risk factor is frequency-dependent, with short-period values being representative of shallower and generally more heterogeneous conductivity structures. An "aeromagnetic risk map" for Australia for periods of 40-60 minutes has been prepared. Such maps indicated to aeromagnetic surveyors the spatial scale over which a single base station may, or may not, be useful.

GA1.02/W/23-A1 1400

EM INDUCTION OVER A LARGE CONDUCTIVE BLOCK - A 3D NUMERICAL MODEL STUDY

A. K. Agarwal and H. W. Dosso (both at the Department of Physics and Astronomy, University of Victoria, B.C., Canada V8W 3P6, emails: numod@uvvm.uvic.ca and hdosso@uvic.ca

Electromagnetic induction in a conductive cubic block of large dimensions (150km x 150km x 150km) over a wide range of periods ranging from .1 to 15000 s and for a uniform inducing field is investigated with the aid of a staggered grid finite-difference method. The 3.6 S/m conductive block is embedded in a uniform host of conductivity .000625 S/m and 600 km depth which is underlain by a uniform layer of conductivity 3.6 S/m. Responses are computed as induction arrows which are compared with corresponding 2D responses along a profile passing through the centre of the block.
The numerical results indicate that the in-phase induction arrows over a wide range of periods always point towards high current concentrations in the conductive block, whereas the quadrature arrows are found to be oppositely directed on either side of the interface so as to point either towards or away from each other. At shorter periods, the quadrature arrows near the interface point away from each other, and at longer periods they point towards each other. The period at which the transition of the quadrature arrow reversal takes place is the characteristic period (Tc) of the model. It is known to be dependent on the model parameters. Tc can be useful in identifying the horizontal dimension of the body if the resistivity of the host is known or visa versa. Similarly, the location of the quadrature arrow sign reversal can aid in delineating a conductive - resistive interface. Further, a comparison of 3D results with the corresponding 2D results along a profile passing through the centre of the block indicates that Tc is at a lower period for 3D than for 2D, apparently due to the horizontal dimension of the block being the smaller in the 3D case. The 3D model responses at very short periods (< 5 s) along a central profile match very well with the 2D responses, but at longer periods (> 5 s) the difference increases rapidly with increasing period. Thus, the validity of a 2D assumption for a central profile over the conductive block is valid only at rather short periods.

ELECTROMAGNETIC MODELLING USING THE A-PHI FORMULATION

Eldad Haber (Dept of Earth and Ocean Sciences, University of British Columbia, Vancouver Canada, V6T- 1Z4, Email: haber@geop.ubc.ca); Uri Ascher (Dept of Computing Science, University of British Columbia, Vancouver Canada, V6T- 1Z4, Email: ascher@cs.ubc.ca); Doug Oldenburg (Dept of Earth and Ocean Sciences, University of British Columbia, Vancouver Canada, V6T- 1Z4, Email: doug@geop.ubc.ca);

Efficient modelling of quasi-static electromagnetic phenomena is a major obstacle in

recovering the earth's conductivity. There are two main difficulties in the modelling. First, the conductivity is highly discontinuous and therefore so too is the electric field. Second, Maxwell's equations in the quasi-static region tend to become singular in the case of very low frequency or very low conductivitygoal is to overcome these obstacles by re-examining Maxwell's equations in the quasi-static region. First, we examine different formulations of the equations. Although it is possible to work with either: (1) a first order system involving E and H, (2) a second order system that involves E only, (3) a second order system involving H only, or (4) a second order system that involves the potentials A and phi, we show that it is better to work with either the A-phi or the H only-systems because these choices ensure smooth variables. Second we examine the A-phi and the H systems and show that the A-phi system can be reduced to a well-posed system, even in the low frequency or zero conductivity case. This is done by transforming the system into one which resembles the Stokes problem in fluid dynamics. We show that the magnetic potential A behaves like fluid velocity and the electric potential phi behaves like the fluid's pressure. Next, we show that a reliable discretization of the system that ensures physical solutions, can be obtained by using a mixed finite element method. This requires that the divergence-free condition is used as a constraint when solving the system. Finally, we discuss the solution of the system of algebraic equations which arise from this discretization. We show that it is possible to use efficient iterative methods that were developed for the Stokes problem to solve our system in a fast and reliable manner. Out code is tested on the magnetotelluric example.

A PERTURBATION THEORY OF ELECTROMAGNETIC FIELD IN A THREE DIMENSIONAL INHOMOGENEOUS MANTLE WITH GRADUALLY LATERAL VARIATION

Ma Shi-Zhuang(Institute of Geophysics, Chinese Academy of Sciences, Beijing, 100101, China, email: szma@mail.c-geos.ac.cn)

It is one of the classical problems in Earth's electromagnetism that continuation of the observatory data of magnetic field into the conducting region. This paper built the coupling vector equations governing the poloidal, toroidal and potential fields in 3-D inhomogeneous conducting mantle. Considering the limitation on variable scale of inhomogeneities in global mantle from study of the Earth's deep interior, a perturbation theory of gradually lateral variation was presented. It is unnecessary that the 1-D spherical symmetric distribution of electric conductivity as zero-degree approximation. Serving as a example of solvability of the zero-degree approximation, it was demonstrated how the gradually lateral variation of electric conductivity effect on anti-diffusive problem of polaidal field in Earth's mantle.

3-D INVERSION OF MT AND TENSOR CSMT DATA BASED ON QUASI-LINEAR METHOD

Michael ZHDANOV and Gabor Hursan (both at the University of Utah, Department of Geology and Geophysics, Salt Lake City, UT 84112, USA, email: mzhdanov@mines.utah.edu Sheng Fang (Baker Atlas, 10201 Westheimer, Houston, TX 77042)

3-D electromagnetic (EM) inversion continues to be a challenging problem in electrical exploration. We have developed recently a new approach to the solution of this problem based on quasi-linear (QL) method of forward modelling (Zhdanov and Fang, 1996). This approach reduces the original nonlinear EM inverse problem to a set of linear inverse problems with respect to anomalous conductivity. The developed algorithm has been applied for interpretation of 3-D magnetotelluric (MT) survey conducted in the Minamikayabe area of Hokkaido, Japan, and for 3-D inversion of the tensor controlled source audio magnetotelluric (CSAMT) data collected over the Sulphur Springs thermal area, Valles Caldera.

THREE DIMENSIONAL MT MODELLING FOR TOPOGRAPHY MODELS AND HIGH RESISTIVITY CONTRAST

Elena FOMENKO (Geoelectromagnetic Research Institute RAS, Troitsk, BOX 30, Troitsk 142092, Moscow region, Russia, Email: igemi@pop.transit.ru) Toru Mogi (Department of Earth Resources Enginering, Department of Earth Resources Engineering, Graduate School of Engineering, Kyushu University 6-10-1 Hakozaki, Higashi-ku, Fukuoka, 812-8581, Japan Email: tmogi@mine.kyushu-u.ac.jp) Tatsuya Kajiwara (JMC Geothermal Endinering Co. Ltd, Takizawa, Iwate, 020-01, Japan)

We have searched 3D modelling scheme of 3D TM problems based on FEM methods (Mogi, Kajiwara,1996) and the staggered grid finite difference formulation for electrical field (Fomenko, 1998).
The comparison was made for complex magnetotelluric 3D issues such as the island effect, volcano model and topographic distorsion on the apparent resistivity and phase. These issues must deal with high conductivity contrast. We estimated that these effect is severe at some frequencies relating to the scale of the structure.
The numerical experiments show that 'natural' choice of continiuos components of E,H fields, an apppropriated choice good preconditioner of the system of linear equation and compensation of non-zero div J behavior played a principal role in obtaining solutions with high speed of accuracy and converdency. In case of absence this improvements it's problematic to obtain solution for high contrast problems with good accuracy at all.

3-D ELECTROMAGNETIC AND MAGNETIC DATA INTEGRAL INVERSION

P.S. MARTYSHKO, A.L.Rublev (Institute of Geophysics, Ural Branch of Russian Academy of Science. 620016, Ekaterinburg, Amundsen str. 100, Russia e-mail: pmart@igeoph.mplik.ru, fax:+7-3432-678872)

The interpretation of data obtained by EM methods involves considerable difficulties because in a general case the inverse problem is reduce to an operator equation of the first kind with an implicitly stipulated operator. The numerical solution of such equations requires considerable expenditures of computer time. We have obtained the new inverse problem equations of electromagnetic fields. There are the first generation equations with explicit operators. The primary field sourse can be arbitrary type. We've used representations of field functions through the values of the functions themselves and the derivatives at the boundary of the anomaly-forming object. The method for solving of 3-D nonlinear electromagnetic and magnetic inverse problem was diviced (in the cases potential and monochromatic fields). It's based on the algorithm for solving explicit equations of the 3-D inverse problem. The algorithm was successfully tested on a number of model examples. We apply the Tikhonov regularization method to 3-D EMD inversion. We do AEM and/or magnetics data inversion by two-stage interpretation method:
1) approximation of the observed data with the fields of singular sourses;
2) construction of equivalent objects with different physical parameters values.
As a result of interpretation we obtain the bodies stellate relative to some point with different values of conductivity (permeability) which generated the same (electrical or magnetic) field. We have studied the possibilities for solution uniqueness seeking on the based joint interpretation of different EMD (Airborne EM and magnetics data, charge method and so on). We have some examples with good results of interpretation.
