Abstract. The coupling between the ionised plasma and the neutral thermospheric particles plays an important role for the dynamics of the upper atmosphere. Significant progress in understanding the related processes has been achieved thanks to the availability of continuous accurate measurements of thermospheric parameters like mass density and wind by high resolution accelerometers on board the satellites CHAMP and GRACE. Here we present some examples of ionosphere-thermosphere coupling where CHAMP observations contributed considerably to their interpretation. We start with the derived properties of the thermosphere at altitudes around 400 km. A new aspect is the significant control of the geomagnetic field geometry on thermospheric features. Phenomena discussed in some depths are the equatorial mass density anomaly, the cusp-related mass density enhancement and the thermospheric response to magnetospheric substorms. Here we consider both the effect on the density and on the wind. A long predicted process is the wind-driven ionospheric F region dynamo. The high-resolution magnetic field measurements of CHAMP enabled for the first time a systematic study of that phenomenon considering longitudinal, local time, seasonal and solar flux dependences. Some open issues that require further investigations are mentioned at the end.

Keywords Ionosphere-thermosphere coupling, Low-latitude thermosphere, High-latitude thermosphere, Substorm effects, ionospheric F region dynamo.

1. Introduction

The Earth's atmosphere up to about 100 km altitude can be considered as well mixed. The relative abundance of the main constituents stays about the same as near the surface. Above 100 km the mean free path between collisions becomes increasingly larger. Therefore the constituents start to separate and decay with increasing height following their individual barometric law. The height range 100-1000 km is commonly termed thermosphere. Here the extreme ultraviolet (EUV) radiation of the sun (5~100 nm wavelength) is almost completely absorbed. This causes the temperature to rise with increasing altitude from its minimum of about 180 K to above 1000 K. The solar EUV radiation causes also a dissociation of the gas molecules. In particular, atomic oxygen is created from O₂. Because of its lighter weight and fairly large number density, atomic oxygen is the most abundant species in the height range 200 ~ 1000 km. A general introduction into the properties of the thermosphere is given, for example, by Prölls (2004).

Another effect of the high energetic solar radiation is the partial ionisation of atoms and molecules. The ionised component of the upper atmosphere is called ionosphere, and it is immersed in the thermosphere. The vertical structure of the electron density is determined by the balance between ionisation rate and recombination rate. Largest electron densities are typically found in the F region at altitudes between 250 - 300 km. Another layer forms during daytime around 115 km altitude. This so-called E region disappears during night due to the high recombination rate and the
lack of solar insulation. In the F region the recombination rate is much lower. Therefore it persists through the night.

The thermosphere and the ionosphere particles show different dynamic behaviour. The neutrals are driven by hydrodynamic forces, but the ions are controlled in addition by electrodynamic forces. Due to frequent collisions between ions and neutrals the frictional force enters the momentum equations of both species as a further term. The coupling between the ionospheric plasma and the neutral thermosphere is particularly strong in the E-layer between 100 and 120 km altitude during day time. Here the horizontal conductivity peaks, and any electric field mapped into this layer will drive currents. Since the electrical conductivity along magnetic field lines is very high, the ionospheric E and F regions are electromagnetically coupled. During day time the highly conductive E region shorts out most of the F region voltages while at night the E region behaves as an open circuit. More details about the ionospheric electrodynamics can be found, for example, in Kelley (2009).

The mass density of the thermosphere is several orders of magnitude larger than that of the ionospheric plasma. Therefore, any heat generated by the dissipation of ionospheric currents is dumped into the thermosphere, and the thermospheric temperature determines largely the ion temperature, at least up to ~400 km altitude.

In the subsequent sections we will present primarily CHAMP observations of coupling processes between ions and neutrals taking place at altitudes around 400 km. At this height range the thermosphere is largely dominated by atomic oxygen, and, in terms of the ionosphere, being generally above the F region density peak, the most abundant ion is single charged oxygen (O\(^+\)). The coupling between ions and neutrals can be considered weak at that altitude. Nevertheless, several important coupling processes are taking place there. In this article we will report about the most prominent ones.

2. CHAMP satellite measurements

The data presented here are primarily measured by the German satellite CHAMP (CHAllenging Minisatellite Payload). CHAMP was launched into a circular, near-polar (inclination: 87.2°) orbit at 456 km altitude (Reigber et al., 2002). Over its 10 years life time the orbit slowly decayed, and reentry into the atmosphere occurred on 19 September 2010. Due to the chosen inclination, the orbital plane precessed through local time at a rate of 1 hour per 11 day. It thus took CHAMP 131 days to sample all local times on ascending and descending orbital arcs. When considering a time period of 5 years the local time distribution of CHAMP readings is evenly distributed over all seasons. For that reason a 5-year interval is most suitable for a statistical study.

A schematic picture of the CHAMP satellite is shown in Figure 1. The spacecraft is 3-axes stabilised, pointing with the boom into flight direction. The scientific payload consists among others of a scalar magnetometer at the boom tip. This absolute instrument is used for magnetic calibration purposes. A fluxgate magnetometer is mounted at the centre of the boom, together with a pair of star cameras for precise altitude determination. Readings of the vector magnetometer are employed for the determination of ionospheric currents. A planar Langmuir probe (PLP) faces into the ram direction. From its readings the electron density and the electron temperature can be deduced. Of particular interest for the results presented here is the accelerometer accommodated at the satellite’s center of gravity. At this position it senses only the non-gravitational forces acting on the spacecraft. The measurement principle is based on a proof-mass of about 100g that is kept floating in the center of a vacuum cage by electrostatic forces. The acceleration acting on the spacecraft body is deduced from the restoring forces in the three spatial directions that are required to keep the proof-mass in the center.

From the air drag experienced by the satellite the thermospheric mass density and wind can be deduced.
The basis equation is

$$a = -\frac{1}{2} \rho \frac{C_d}{m} A_{\text{eff}} v^2$$

(1)

where $a$ is the measured acceleration, $\rho$ is the mass density, $m$ is the satellite mass, $A_{\text{eff}}$ denotes the effective cross-section area in ram direction and $v$ the velocity of the satellite. $C_d$ is the drag coefficient vector with different values for along-track and cross-track directions.

Eqn. (1) can be solved for the mass density, $\rho$, since the other quantities are known or measured. Further details about the interpretation of accelerometer data are given by Doornbos et al. (2010).

For the estimation of the thermospheric winds we make use of the measured acceleration components. Under the assumption that the experienced acceleration, $a$, is aligned with the velocity, $v$, with respect to the air rest frame we may write for the vector components:

$$\frac{a_y}{a_x} = \frac{v_y}{v_x}$$

(2)

where the $x$ component is aligned with the spacecraft along-track axis and $y$ with the cross-track axis. Vertical wind contributions are ignored because they are much weaker than the horizontal ones. Since CHAMP had a polar orbit, the zonal wind velocity, $u$, can be derived by

$$u = v_x \frac{a_x}{a_x} - v_{\text{cor}}$$

(3)

where $v_x$ is the orbital velocity ($7.6 \text{ km/s}$) and $v_{\text{cor}}$ is the corotation velocity of the atmosphere (~490 km/s at the equator). The approach actually used for deriving the zonal wind is more sophisticated and is described by Doornbos et al. (2010).

3. Gross features of thermospheric mass density

Before looking into the coupling between ionosphere and thermosphere we present gross features of the quiet time thermosphere. CHAMP crosses all latitudes on its orbit and covers all local times within 4 months. Thanks to the long and homogeneous set of accelerometer measurements the climatology of the mass density at an altitude of 400 km was compiled. Since the CHAMP orbit decays slowly, the actual density readings, $\rho(h)$, have been normalised to a common altitude of 400 km ($\rho(400\text{km})$). For this purpose we made use of collocated mass density predictions of the MSIS model.

$$\rho(400\text{km}) = \rho(h) \frac{\text{MSIS}(400\text{km})}{\text{MSIS}(h)}$$

This approach is regarded justified since the height change of CHAMP during the studied periods was less than one scale height (~60km).

Based on these density data important features were identified by Lui et al. (2005). A quantitative description of the low-latitude thermospheric density and its variation with local time and season was given later by Müller et al. (2009). They also looked into the response to changes in solar EUV flux and magnetic activity. One of their conclusions is that the effects of the four controlling parameters considered in the study, local time, season, solar flux, and magnetic activity, on the thermospheric density can be treated as a linear combination of the different influences. Non-linear coupling was not identified as an important process.

In a statistical survey of the thermospheric mass density, Lui et al. (2005) determined among others the mean diurnal variation. Opposed to previous studies, they binned the density readings by magnetic latitude rather than geographic latitude. As can be seen in Figure 2, largest densities are observed about 1.5 hours after noon. Peak values, however, do not appear at the subsolar point, but at latitudes some 25° north and south of the magnetic equator. This is an unexpected phenomenon.
For comparison, the thermospheric density distribution as predicted by the MSIS model (Hedin, 1991) is shown below. Although gross features are well reflected by the model, there is no sign of a bifurcation at day time hours. Liu et al. (2007a) had a closer look at the so-called equatorial mass density anomaly (EMA). They find that, especially during equinox seasons, the two bands of enhanced density follow reasonably well magnetic latitudes, as can be seen in Figure 3. In addition there is some longitudinal structure visible. This can be related to tidal signatures, as was shown later by Lui et al. (2009b), but this topic will not be addressed here. During solstice seasons the EMA becomes asymmetric, favouring the summer hemisphere (Liu et al., 2007a). There have been attempts to link the EMA with the well-known equatorial ionisation anomaly (EIA). A possible mechanism for causing the density bulges at low latitudes is chemical heating. Following the suggestions of Fuller-Rowell et al. (1997), oxygen ions, O\(^+\), are lifted up over the magnetic equator by the ion fountain effect, then diffuse down along field lines into the northern and southern hemisphere. At E region altitude, charge exchange, in particular between O\(^+\) and O\(^+\)_2, takes place. The difference in ionisation energy (1.6 eV per nucleus) is emitted, thus heats and may lift the atmosphere at footprint latitudes of the EIA fluxtubes. However, there are also other processes discussed. A final verification of the EMA mechanism is still pending. In any case, the equatorial mass density anomaly is a product of ionosphere-thermosphere coupling. Plasma is the medium to communicate the magnetic geometry to the neutral gas.

4. Gross features of thermospheric winds

As mentioned in the earlier sections, CHAMP measurements provide also information on thermospheric winds. For these studies altitude changes of the orbit have not been taken into account since it is known that the wind above 300km depends little on altitude (Prölss, 2004). A first global survey of CHAMP low-latitude zonal wind was presented by Liu et al. (2006). They determined the diurnal variation of wind speed and its dependence on solar flux level and magnetic activity. Previously known features could be confirmed: westward wind at the equator at day time and eastward winds during evening and night hours. In a follow-on study Liu et al. (2009a) investigated the zonal wind distribution within the latitude range ±60° of magnetic latitude. As can be seen in Figure 4, highest wind speeds are observed at the equator. The reversals of wind direction do not take place simultaneously at all latitudes. The switch from westward to eastward in the afternoon occurs about an hour later at the equator than at 60° latitude. An even larger time difference of up to 7 hours is found in the early morning between equator and 60° latitude for the direction change from eastward to westward. The observed latitude dependence of the zonal wind direction reversal on local time can be explained in part by the influence of the Coriolis force. If an air parcel is moved from the equator to the pole, it is deflected eastward. This situation, valid on the day side, causes the earlier eastward turning at high latitudes around noon. Conversely, air moving from the poles to the equator, as happens on the night side, experiences a westward deflection. Since wind speeds are larger on the night side than on the day side, the Coriolis effect here causes a larger delay between high and low latitude reversals.

From Figure 4 it is obvious that highest eastward wind speeds of about 150 m/s are observed at the night time magnetic equator. In order to investigate this situation further Lui et al. (2009a) have looked at the longitude distribution of the zonal wind velocity. As can be seen in Figure 5, there is a jet stream of fast zonal wind along the magnetic equator at all longitudes. Liu et al. (2009a) have explained this high-speed channel by the reduced ion air drag within the equatorial ionisation trough. In that sense the wind distribution controlled by the geomagnetic field geometry is another form of ionosphere-thermosphere coupling.

When integrating the zonal wind velocity over all longitudes, as shown in Figure 4, we obtain the net zonal motion of the air at given latitudes. From the right frame of Figure 4 we see that the air rotates faster than the planet at low latitude and slower at high latitude. For an outside observer the
Earth's upper atmosphere exhibits a differential rotation velocity, fastest at the equator and progressively slower towards the poles. The excess rotation rate at the equator is 8% according to Figure 4.

An even stronger interaction between ions and neutrals is observed at high magnetic latitudes. The wind distribution in the polar region, as observed by CHAMP, was first studied by Lühr et al. (2007). A similar study based on DE-2 satellite data was presented by Thayer et al. (1987). Due to the short DE-2 mission duration and sparse sampling, detailed features could not be resolved. A common result of both studies is the strong day-to-night wind over the polar cap with speeds in excess of 600 m/s. In this region hydrodynamic forces and plasma drifts are well aligned. From comparison with the low-latitude evening terminator region we can expect velocities up to 150 m/s due to neutral forcing (see Fig. 4), such as the pressure gradient. A much larger effect has to come from the cross-polar cap potential difference which drives the plasma into the anti-sunward direction at speeds of more than 1 km/s. The plasma drift velocity, \( v \), at CHAMP altitude is described by \( v = E x B / B^2 \). For a typical polar cap electric field strength of \( E = 50 \) mV/m and an ambient magnetic field, \( B = 50000 \) nT, we obtain a plasma velocity, \( v = 1 \) km/s. Plasma transfers momentum to the neutral particles by collisions. The relevant momentum equation can be written as

\[
\rho \frac{du}{dt} = -\text{grad}P + \rho v_{i,n} (v - u)
\]

where \( \rho \) is the mass density, \( u \) is the wind velocity, \( P \) is the thermal pressure and \( v_{i,n} \) is the ion/neutral collision frequency. This equation tells us that the acceleration of wind speed by the plasma is proportional to the collision frequency and to the velocity difference between ions and neutrals. Due to the large inertia of the thermosphere the wind speed will respond to changes in plasma drift with a time delay of tens of minutes.

The average polar region wind distribution for the four months around June solstice 2003 is shown in Figure 6. At both hemispheres we observe similar distributions. Signatures are clearer and winds are stronger in the northern (summer) hemisphere. This can be attributed to the higher plasma and neutral densities during that season, giving rise to a higher collision frequency and thus causing a closer coupling between ions and neutrals. There is a clear asymmetry between the dawn and dusk sides. Lühr et al. (2007) report fast winds towards the night time sector on the dawn side, but stagnant flow on the dusk side. There are two effects contributing to this difference. One is the plasma flow along the auroral oval streaming generally sunward. This moves in opposite direction to the prevailing thermospheric wind. The other effect is caused by a combined action of Coriolis and centrifugal forces. For an explanation of the fast day-to-night winds on the dawn side, Lühr et al. (2007) refer to the arguments of Fuller-Rowell and Rees (1984) who state that particles starting at noon and moving westward experience an equatorward centrifugal force, but at the same time a poleward Coriolis force. The velocity at which the two forces cancel each other depends on the polar distance, \( \theta \)

\[
\sin \theta = v/985 \quad [\text{m/s}]
\]

At a latitude of 60° (\( \theta = 30° \)) we obtain \( v = 498 \) m/s for the critical velocity. This value is close to the wind speed observed on the dawn side (cf. Fig. 6). Obviously, many air particles move along the stable paths and the counter-streaming plasma has little effect. On the dusk side the Coriolis and centrifugal forces act into the same direction deflecting the particles into an anti-cyclonic spiral motion. Such a signature can be seen in Figure 6 near 70° of magnetic latitude at 18:00 local time. The additional effect of a sunward plasma flow along the auroral oval causes wind stagnation on the afternoon side.

Within the night sector the equatorward wind is deflected westward, as expected from the action of the Coriolis force. This observation is consistent with our interpretation of the latitude dependent shift in local time, where the zonal wind switches direction, as evident from Figure 4.

The effect of the high-latitude plasma drift pattern on thermospheric winds was investigated in more details by Förster et al. (2008). The authors clearly show that the wind direction over the polar regions depends on the interplanetary magnetic field (IMF) components \( B_y \) and \( B_z \). Their
results provide further evidence for the close control of the plasma dynamics on the thermospheric wind. Over the northern hemisphere polar cap highest wind speeds are observed for a combination of negative IMF $B_y$ and $B_z$ components. In the southern hemisphere wind speeds maximise for positive IMF $B_y$ and negative $B_z$. The clockwise wind vortex on the dusk side increases in the northern hemisphere when IMF $B_y$ is positive. The opposite $B_y$ polarity causes the vortex to grow in the south. This behaviour is consistent with the response of the plasma vortex to IMF conditions. Interestingly, on the dawn side the wind velocity shows little dependence on IMF orientation. Obviously, the coupling between ions and neutrals is less efficient here. For a dedicated investigation of the interaction between neutral air and plasma in the F region, it would be desirable to measure wind and ion drift by the same spacecraft. ESA's upcoming constellation mission “Swarm” will provide this capability; it carries both an accelerometer and an ion driftmeter on each of the three spacecraft.

5. The cusp-related mass density anomaly

In section 3 we had presented the average thermospheric mass density at low and mid latitudes for altitudes around 400 km. Here we focus on local phenomena at high magnetic latitudes. A surprising observation, made already early in the CHAMP mission, was the appearance of rather localized large peaks in air drag. As an example, acceleration measurements over the first 8 orbits on 25 September 2000 are shown in Figure 7. Clearly visible are the harmonic variations of air drag over an orbit. Near the orbital maxima there are large small-scale spikes in deceleration. All these peaks tend to appear at magnetic latitudes near 75° and within the time sector around 10:30 of magnetic local time (MLT). This confinement in local occurrence suggests a relation to the ionospheric cusp. Lühr et al. (2004) were the first to look into this phenomenon in some detail. They related the deduced local mass density enhancement to concurrent peaks in ionospheric current observations. During the prominent event shown in Figure 8 the air density almost doubles in the cusp region with respect to the background. Collocated with the density peak intense field-aligned currents (FACs) are observed. A particularly outstanding feature is the strong burst of kilometre-scale FACs. Also the Hall current in the electrojet region is enhanced. Both FAC and electrojet intensities are deduced from the CHAMP high-resolution magnetic field measurements. The approach applied for deriving these currents is described by Wang et al. (2005) and Ritter et al. (2004) for the FAC and electrojet, respectively. After CHAMP has crossed the polar cap we find on the same pass comparably strong Hall currents in the evening auroral region, but they are not accompanied by a density anomaly. Lühr et al. (2004) provided additional evidence that intense small-scale FACs play an important role for the formation of cusp-related density anomalies.

A more extended study of this density phenomenon was performed by Schlegel et al. (2005), but no conclusive explanations for a generation mechanism could be offered. Demars and Schunk (2007) made an attempt to reproduce the density anomaly by means of their high-resolution thermosphere model. For achieving a local doubling of the mass density near the cusp, as reported by Lühr et al. (2004), they had to increase the heating in the E region by an unrealistic factor of greater than 100.

Motivated by these open issues Rentz and Lühr (2008) performed a systematic study of the cusp-related density anomaly, based on CHAMP data from the years 2002-2005. An anomaly is defined as an enhancement above the large-scale background density. It is quantified either as an absolute increase above background or as a relative enhancement. The region scanned comprises the magnetic local time sector 08 to 16 MLT and the latitude range of 60° to 80° of magnetic latitude in both hemispheres. The peak value of density enhancement from each overflight was sorted into the appropriate equal-area bin of a latitude-by-local-time grid. Figure 9 shows the resulting average amplitude distribution on a dial plot separately for every year. Density anomalies cluster around the nominal cusp location in all cases. The amplitudes get smaller each year and decrease by a factor of 4 from 2002 to 2005. This is accompanied by a reduction of solar EUV flux. The mean F10.7 index
declines from 181 sfu in 2002 to 91 sfu in 2005. This suggests a significant dependence of the
density anomaly’s magnitude on solar activity. Similar results, as shown for the northern
hemisphere, are observed in the south, but there the amplitudes are smaller by a factor of 1.7 on
average.

In the quest for the mechanism that causes the mass density enhancement near the cusp Rentz
and Lühr (2008) correlated the anomalies with solar flux and solar wind parameters. The solar wind
input is characterised by the merging electric field, $E_m$, as defined by Kan and Lee (1979)

$$E_m = v_{SW} \sqrt{B_y^2 + B_z^2} \sin^2 \left( \frac{\theta}{2} \right)$$

(6)

where $B_y$ and $B_z$ are the IMF components, $v_{SW}$ is the solar wind speed, and $\theta$ is the IMF clock angle
the average of F10.7 over 81 days. Figure 10 shows the dependence of the anomaly amplitude on
P10.7 and $E_m$. From the top two frames we may conclude that a combination of high solar flux with
strong solar wind input favours the formation of large density peaks. For this reason we find
anomalies with appreciable amplitude only in the upper right corner. The reduced amplitude of the
anomalies in the southern hemisphere, as quantified above, is clearly visible in this figure.

Beside the absolute amplitude, also the relative amplitude of the anomaly with respect to the
background density is shown in Figure 10 (lower frames). In that case the dependence on solar EUV
is largely reduced but not fully removed. In any case, it demonstrates the dominant role of the solar
wind input for the formation of the anomalies.

A prime question that remains after all is, what causes the confinement of the anomalies to
the ionospheric cusp region? For part of the answer we can refer to the association with the intense
bursts of small-scale FACs as shown by Lühr et al. (2004). It had been reported by Neubert and
Christensen (2003) and later by Rother et al. (2007) that there exists a clear occurrence maximum of
kilometre-scale FACs in the polar cusp region. With respect to the model results obtained by Demars
and Schunk (2007), however, it was questionable whether the amount of Joule heating in the E
region caused by small-scale FACs would be sufficient to fuel the observed amount of air up-
wellling.

Rentz and Lühr (2008) suggested that particle precipitation may also play an important role
for the formation of the density anomaly. In order to test the hypothesis we may have a look at the
important quantities. The effective amount of Joule heating can be expressed as function of altitude

$$j \cdot E = \sigma_p(h) E^2 = \sigma_p(h) (E_{DC} + E_{AC})^2$$

(7)

where $j$ is the local current density, $E$ is the electric field and $E_{DC}$, and $E_{AC}$ are the large- and small-

scale parts of the electric field, $\sigma_p(h)$ is the height-dependent Pedersen conductivity. The E-field
deeps only weakly on altitude because the almost vertical magnetic field lines can be considered
as equipotential lines. For a given electric field the Pedersen conductivity determines the amount of
Joule heating and the affected altitude range. For assessing the effect of precipitation on the
conductivity we make use of the CTIP model (Millward et al., 1999), since there are no particle
measurements from CHAMP. It is known that the cusp is characterised by high fluxes of soft
particle precipitation. Typical energies for particles have been used, Maxwellian distributions
peaking at 50 eV for electrons and 500 eV for ions. Geophysical conditions were chosen as those on
14 December 2002. CTIP runs were compared for precipitation switched on and off. Figure 11
presents results of the two runs. Height profiles of the Pedersen conductivity show a clear response
to the precipitating particles. For altitudes between 130 and 400 km the conductivity is significantly
enhanced by precipitation. When looking at the relative increase of conductivity (plotted in the right
frame), which is proportional to the ratio of the Joule heating rate with and without precipitation, we
find the largest effects up to a factor of 9 above 150 km altitude, i.e. in the F1 region. This uplift of the conductive and current-carrying layer is caused by high fluxes of low energetic particles which is a typical feature of the cusp. Particle precipitation in the cusp is primarily caused by reconnection at the dayside magnetopause. The strength of the merging electric field, $E_m$, is commonly seen as an indicator of an enhanced reconnection rate. In this respect $E_m$ seems to indicate a two-fold effect on the strength of the cusp-related density anomalies: (1) reconnection on the dayside controls the flux of precipitating soft particles, (2) merging enhances the convection electric field which is partly mapped into the cusp region. It has been noticed earlier from Freja and FAST satellite data that high fluxes of cusp-type soft precipitation are commonly accompanied by intense small-scale FACs. Waterman et al. (2009) provided observational evidence for this by comparing DMSP particle precipitation measurements with FAC estimates from Ørsted and CHAMP. Another particular feature is the strong conductivity enhancement above 150 km of altitude. This causes a large fraction of currents to flow in the F1 region. In this altitude range the thermospheric density is about two orders of magnitude lower than in the E region at 110 km. This means, a given amount of Joule heating will cause a much larger temperature enhancement in the F1-layer than in the E-layer.

By summarizing the observations made in the context of mass density anomalies we may offer a suggestion why prominent density peaks occur preferably in association with the ionospheric cusp. The intense precipitation of low energy particles is regarded as the key process for determining the location of the anomaly. Some researchers even claim that the energy deposited by the incident particles may already account for the major part of heating (Clemmons et al., 2008). Soft precipitation occurs frequently in the cusp region. The largely enhanced conductivity in the F1 region due to precipitation places the heating region to 150 km and higher. At this altitude predominantly molecules are heated and subsequently uplifted. Crowley et al. (2008) presented observational evidence for a reduced O/N$_2$ ratio in the cusp/cleft region during enhanced magnetic activity. This increased abundance of heavier particles in the upper thermosphere adds to the density anomaly detected by CHAMP. Our suggested mechanism is also consistent with the strong dependence of the anomaly amplitude on the merging electric field. The merging rate controls both the precipitating particle flux and the cross-polar cap potential. A verification of this chain of arguments by physics-based numerical modelling would be highly desirable.

6. Substorm effects on the thermosphere

In their early paper Liu et al. (2005) reported about a mass density anomaly observed by CHAMP at auroral latitudes in the time sector before midnight. The authors found that the anomaly intensifies during magnetically active periods. From that dependence they suggested a relation between the enhanced air density and substorm processes. In a dedicated statistical study Ritter et al. (2010) investigated the thermospheric response to the substorm onset. CHAMP mass density and wind measurements were investigated for a large number of substorms. The survey was performed using onsets from the catalogue published by Frey and Mende (2006), containing more than 4000 entries. Events were selected based on the criteria that CHAMP passed the onset location sufficiently close in space and time. By stacking the results of many substorm events significant structures in mass density and wind could be deduced.

In order to determine the spatial and temporal evolution of substorm-related thermospheric effects CHAMP data were binned according to certain criteria. Figure 12 shows a local time dial plot with a schematic illustration of the auroral oval. The substorm onset location is marked by a yellow/orange star. There are three local time bins defined, each one is 30° in longitude wide (2 h in LT). When CHAMP passed the actual onset location to the west (0°-30° in longitude) data are sorted into bin 1, when it passed to the east (0°-30° in longitude) data went into bin 2 and further east (30°-60° in longitude) into bin 3. For tracking the temporal evolution of the disturbance the satellite pass
before the substorm is taken as reference and is used for comparison with the passes subsequent to
the onset. The orbital period of CHAMP is about 93 minutes.

Figure 13 shows the mean thermospheric density response to a substorm. Presented are
observations of bin 2, around midnight. The left frames contain variations at middle latitudes, and on
the right side the high-latitude response is shown. Substorms have a significant effect on the
thermosphere during magnetically active periods, as can be seen in the top panels ($K_p \geq 4$).
Conversely, for substorms during quiet times ($K_p \leq 2$), we hardly see any difference between the
before-substorm curve (black) and the later passes. The amount of energy accumulated in the
magnetospheric tail and released into the thermosphere during quiet-time isolated events is
obviously too small. For that reason we focus in the subsequent paragraphs on active periods. Figure
14 shows mass density changes with respect to the before-substorm measurements. Plotted are mean
latitude profiles derived from subsequent orbits. Measurements of the three consecutive passes are
taken on average 45 min, 2.4 h and 4 h after the onset. Results of all three local time bins are
presented. An outstanding feature is the mass density bulge appearing at the magnetic equator 4 h
after the onset. Density changes are largest in bin 2, around midnight. First effects are observed at
high latitudes between 70° and 80° of magnetic latitude (red curves). During the second pass (blue
curve) the density enhancement has already expanded to mid latitudes, both from the northern and
southern auroral regions. By the time of the third pass (green curves), about 4 hours after onset, the
substorm-related density enhancements from both hemispheres reach the equator and pile up there.
All these effects are largest in the time sector around midnight (bin 2). Here the density bulge at the
equator surmounts the background density by 20%. At locations to the west of the onset (bin 1) the
same density features are observed, but with smaller amplitude. The apparent minor density bulge of
the red curve at the equator in bin 1 is a remnant of a substorm taking place about 3 hours earlier.
More details of this study can be found in Ritter et al. (2010). Interestingly, in the post-midnight
sector (bin 3) only marginal substorm-related thermospheric variations are recorded. The amplitudes
are in the range of uncertainties ($\pm 0.1 \times 10^{-12} \text{ kg/m}^3$). This asymmetry between pre- and post-midnight
effects supports the notion of the widely accepted current wedge model (e.g. Clauer and McPherron,
1974; Ritter and Lühr, 2008) according to which most of the energy injected from the tail is
deposited in the vicinity of the upward directed field-aligned current region in the pre-midnight
sector.

The density enhancement caused by the substorm in the auroral region propagates as
travelling atmospheric disturbance (TAD) equatorward. Ritter et al. (2010) have deduced a mean
propagation speed of 650 m/s from their observations. Furthermore they report a westward
deflection of the travel path. This can largely be explained by the Coriolis force acting on the air
parcel which moves equatorward, but an additional westward velocity component is needed for the
full explanation of the observations. From these results we see that auroral phenomena like
substorms can affect the thermosphere at low and mid latitude significantly.

Substorms are expected to have also an influence on thermospheric winds. In order to check
that, Ritter et al. (2010) had a look at zonal winds which are detectable by CHAMP. The same
procedure as used for the density study was applied to the cross-track wind component. Figure 15
shows the obtained average zonal wind distribution observed in association with substorms. In
general, there is little difference between the various passes before and after the onset both during
magnetically active periods (top frames) and quiet periods (bottom frames). This suggests that
substorms do not influence the zonal wind on the night side significantly. However, we have no
information about effects on the meridional wind. Based on simulation results Fujiwara and Miyoshi
(2006) predict a strong equatorward meridional wind surge around midnight which is related to the
equatorward TAD initiated by the substorm. For zonal winds their model also predicts only small
effects.

For both cases of high and low magnetic activity we find peak eastward zonal wind speeds at
the magnetic equator and lower velocities at higher latitudes. This signature is consistent with the
global zonal wind distribution shown in Figure 4. Interestingly, peak wind velocities are higher
during quiet times. This observation confirms the prediction of the DWM07 model that there is a westward directed disturbance wind during active periods at low and mid latitude on the night side (Emmert et al., 2008). The disturbance wind amounts to 20 m/s at the equator and increases monotonically to 50 m/s at 50° of magnetic latitude. At high latitudes, Ritter et al. (2010) report a reduction of the westward wind to almost stagnation around 65° of magnetic latitude during high magnetic activity. In order to find an explanation for the wind speed reduction we estimated the electrojet strength in this region from CHAMP magnetic field data. Ritter et al. (2004) described and validated in a systematic study their approach for determining source-free currents (largely identical with the auroral electrojet) from CHAMP total magnetic field recordings. We applied this technique to magnetic field data from the same set of CHAMP passes as used in connection with our substorms study. Figure 16 shows the latitudinal distribution of the electrojet current density as derived from a superposed epoch analysis applied to many substorms. Again magnetically active and quiet periods were considered separately. Also the colours of the curves mark the same succession of orbits after onset. In both frames we find negative (westward) electrojet currents at latitudes where the westward wind is diminished. Since the plasma drifts in the opposite direction as the electrojet current, we can imply eastward flowing plasma in the latitude range of electrojet. This can explain neatly the retarding effect on the westward wind by ion friction through eastward drifting plasma.

When looking at the evolution of the electrojet strength over the course of a substorm we find a persistent westward electrojet before and well after the substorm. This seems to be driven by the prevailing convection electric field. An outstanding feature can be observed at the first orbit (~ 45 min) after the onset (red curve). There we find a current strength increase on average by a factor of 1.5, which is attributed to the substorm-related current wedge (see Ritter and Lühr, 2009). Interestingly, this additional current does not seem to have an influence on the zonal wind. This observation implies that there is no enhancement of the electric field (plasma drift) by the substorm, just an increase in conductivity. The highly conductive channel appears a few degrees further poleward of the prevailing electrojet. This interesting behaviour of the substorm electrojet justifies further investigations including concurrent plasma drift measurements.

7. The equatorial F region dynamo

In the previous sections we presented examples for thermospheric signatures caused by plasma processes. Here we show a case of an ionospheric process driven by the thermosphere. The concept of an F region dynamo was presented already several decades ago by Rishbeth (1971). He suggested a wind-driven dynamo in the low-latitude ionospheric F region. Zonal wind blowing across the geomagnetic field will cause a charge separation by interaction with the plasma. This sets up a polarisation electric field in the meridional plane. The strength of the E-field, $E$, driven by the F region dynamo depends on the ratio between the conductance in the F and E regions. According to Kelley (2009) it can be expressed as

$$E = \frac{\Sigma_P^F}{\Sigma_P^{EN} + \Sigma_P^{ES} + \Sigma_P^F} \cdot u \times B$$

where $\Sigma_P^{EN}$ and $\Sigma_P^{ES}$ are E region height-integrated Pedersen conductivities at the northern and southern ionospheric footprints, $\Sigma_P^F$ is the fluxtube-integrated conductivity in the F region, $u$ is the wind velocity, and $B$ is the ambient magnetic field. The F region electric field drives toroidal current systems in both hemispheres. Figure 17 shows schematically the important elements of the F region dynamo in the evening sector.

First observational evidence of the F region dynamo was presented by Maeda et al. (1982) based on Magsat data. Since that satellite was in orbit only for a few months and sampled only the
dawn/dusk sector, many issues were left unresolved. New opportunities for studying this phenomenon arose with the CHAMP mission lasting for almost one solar cycle. The diurnal variation of the F region dynamo current strength was first presented by Lühr and Maus (2006). They found downward currents in the F region which peak around noon and upward currents in the evening that are largest between 18 and 19 local time. This notion is consistent with prevailing westward zonal winds during daytime and eastward winds in the evening and night time hours (see section 4).

A detailed statistical study based on CHAMP data for determining the climatological characteristics of the F region dynamo was conducted by Park et al. (2010a). The authors sorted the data by various parameters and thus could determine the dependence of the current strength on local time, season, longitude and solar flux. Figure 18 shows the local time variation of the sheet current density generated by the F region dynamo. Downward vertical currents are denoted positive. The diurnal variations are determined separately for each season. During post-midnight and morning hours no clear current signal could be deduced from the magnetic field measurements. Consistent with the results of Lühr and Maus (2006) Park et al. (2010a) find downward (positive) currents in all seasons around noon and upward (negative) current densities around evening hours. In the vicinity of the current reversal our automatic processing does not work properly. Therefore, the unreliable results in this area have been omitted in Figure 18. Nevertheless, a zero crossing of the current between 15 and 16 LT can be found for all seasons. This local time is consistent with the reversal in zonal wind direction from westward to eastward (see Fig. 4). Smallest current densities are attained around June solstice, while during equinox and December solstice months the diurnal variations are comparable and amplitudes are about twice as large as in June.

The vertical current in the F region is diverted and flows along field lines into the E regions of both hemispheres. For the closure currents, \( J_P \), in the E-layer we obtain

\[
J_P = \Sigma_E E
\]

(9)

where \( E \) in this case is the sum of E and F region electric fields. When inserting the electric field from Equation (8) into Equation (9) and assuming that the conductance, \( \Sigma_E \), is the same in the two E regions and that the conductance in the E region is much larger than that in the F region, which is reasonable during day time, we obtain

\[
J_P = \frac{1}{2} \Sigma_E \left[ uB_z \right]^F - \Sigma_E \left[ uB_z \right]^E
\]

(10)

Here the terms in brackets with superscript F denote the zonal wind velocity and the field strength in the equatorial F region, whereas in the brackets with superscript E we consider the zonal wind and vertical magnetic field at the E region footprint of the fluxtube. Equation (10) reveals that the sheet current density in the E region depends on the zonal winds in the E and F regions. Around noon the zonal winds at the two layers have, according to the wind model HWM07, opposite directions, and the product (\( uB_z \)) is about 5 times larger in the F region than in the E-layer. Thus, \( J_P \) is the sum of two almost equally strong contributions from both layers. However, the vertical F region dynamo current, \( J_Z \), is less influenced due to the small E region electric field contribution.

\[
J_Z \approx \Sigma_E \left[ uB_z \right]^F - \left[ uB_z \right]^E
\]

(11)

From Equation (11) we can see that the current of the F region dynamo is strongly controlled by the fluxtube-integrated conductivity in the F region. This quantity is highly dependent on the electron and neutral particle density. For the interpretation of the current strength minimum around June solstice one has to look into the electron density (Lui et al., 2007b) and neutral density (Müller et al., 2008). Both exhibit their annual minimum during that season. The reported density depletions are sufficient to explain the June depression of the F region dynamo currents.

A detailed investigation of the longitudinal variation of the F region dynamo current was performed by Park et al. (2010a). Extracted from that study we show the longitude dependence of the noon-time F region dynamo currents in Figure 19, separately for the seasons. Quite obvious are again the small amplitudes at times around June solstice. During equinoxes there is a remarkable
longitudinal variation of the current strength. Values vary between 2 and 15 mA/m. Rather obvious is a four-peaked longitudinal pattern. This is indicative of forcing by non-migrating tides. We will not go into the details of that topic, but refer to Park et al. (2010a) who discussed the tidal aspect in some depth. During the months around December solstice the current intensity varies not much with longitude. A wavenumber-2 structure seems to dominate. During all seasons an outstanding current feature is observed around 300°E longitude. We relate this prominent peak in F region dynamo current to the South Atlantic Anomaly (SAA). Takeda (1996) predicted that in a region of low ambient magnetic field the F region is lifted higher up. As a consequence, it populates a longer fluxtubes and the field-aligned integrated Pedersen conductivity become larger. The resulting positive effect on the vertical current density (cf. Eq. (11)) is expected to surmount that of the reduced polarisation field, $\mathbf{u} \times \mathbf{B}$. Our observations are in support of Takeda’s (1996) results.

Quite different longitudinal variations were observed during evening hours. In this local time sector several features of the noon-time recordings are missing. From Figure 20 it can be deduced that the current distribution is less structured. There is no outstanding current density peak near the SAA (around 300° longitude). Also the wavenumber-4 longitudinal pattern has disappeared. In particular, during equinoxes there is only little variation with longitude. For June solstice months we observe very week F region dynamo currents over the longitude sector 300° – 108°E. In other regions they attain appreciable values, peaking around 230°E of longitude. Similarly, during December solstice months we find a large-scale variation with minimum around 150°E and maximum at 320°E of longitude. The observed phase difference of the dominating wavenumber-1 longitudinal variation between the two solstices is, according to Park et al. (2010a), 115°E in longitude. This large-scale variation of the vertical F region current density can be attributed to the combined effects of the longitude-dependent displacement of the dip-equator from the geographical equator and the seasonal variation of upper atmospheric conditions.

In general, we can state that the F region dynamo currents around noon reflect many features of the E region dynamics, e.g. wavenumber-4 longitudinal pattern and SAA enhancement. All these do not appear in the recordings from the evening hours’ F region dynamo. This confirms the strong coupling between E and F region during day time and the disconnection of the regions at sunset. Further studies are required to resolve all the different longitudinal variations of the F region dynamo.

Another influence that has been investigated by Park et al. (2010a) is the dependence on the solar flux index, F10.7. According to Equation (11) the F region dynamo current is directly proportional to the conductance in the F region. The conductance depends both on electron density and neutral particle density. These two quantities increase with the solar flux at F region heights, as has been shown for the neutral density, e.g. by Müller et al. (2009) and for the electron density in the equatorial ionisation anomaly, e.g. by Stolle et al. (2008). Figure 21 presents the dependence of the F region dynamo current density on the solar flux level, as observed by CHAMP, separately for data taken around noon and during evening hours. For both time sectors we find a clear linear relation. Interestingly, the fitted regression lines have practically the same slopes. The noon values, however, are consistently higher by about 1mA/m. Such an amplitude difference is also evident in Figure 18. The similarity in slope around noon and dusk suggest that the same mechanisms cause the F region dynamo currents to increase in response to higher solar flux. As mentioned before, a more conductive F region is our preferred candidate.

It has been suggested for quite some time that the F region dynamo in the dusk sector might be the main driver for the peak in vertical plasma drift around sunset. Park at al. (2010b) were the first to provide observational evidence, based in CHAMP data, for the close relationship between the F region dynamo current strength and the peak value of the vertical plasma drift during the pre-reversal enhancement (PRE). They also show that the azimuthal conductivity gradient of the E-layer along the terminator is an important factor in this relationship. Since the peak plasma drift during PRE plays a crucial role for initiating ionospheric instabilities during pre-midnight hours, a better
understanding of the dusk-sector current generator is of great interest. Further studies on the relation between F region dynamo and PRE are thus highly recommended.

8. Conclusion and Outlook

The previous sections gave an idea of the large variety of processes coupling the ionosphere with the thermosphere. The German satellite, CHAMP, with its continuous measurements over almost one solar cycle helped to advance our understanding of many phenomena. In the past, progress in research was often hampered by the lack of sufficient observations of thermospheric quantities. This has changed drastically since satellites like CHAMP and GRACE carry sensitive accelerometers for recording the air drag. Only now it has become clear that thermospheric density distribution is significantly controlled by the shape of the geomagnetic field. Examples for that are found at low latitudes, e.g. the equatorial mass density anomaly, and at high latitudes, e.g. the cusp-related density enhancement. Both these features are not reproduced by any of the thermospheric models. Since these are systematic features, their consideration in models is highly recommended.

Ionospheric processes at auroral latitudes have been shown to have strong effects on the thermospheric dynamics. This connection is known qualitatively since the early days of satellite missions. Only now, statistically significant quantitative relations between plasma dynamics and thermospheric response have been deduced. An example presented here is the thermospheric wind at polar regions. It is driven strongly by plasma convection, but shows also a clear response to Coriolis force and centrifugal force. Therefore, plasma convection and polar region wind show rather different patterns. Also in this case, empirical models provide only a rather poor representation of wind patterns at high latitudes. Another example is the thermospheric disturbance caused by substorms. CHAMP measurements revealed that air parcels lifted up at auroral latitudes propagate as density bulges equatorward and cause large transient density enhancements at low latitude. Zonal winds are only marginally influenced by substorms.

The equatorial F region dynamo is presented, as an example of a ionospheric process driven by the thermosphere. Here again, CHAMP measurements provide the first comprehensive overview of its properties. Features of the F region dynamo in the noon sector reflect many properties of the E region dynamics. This is indicative of a close connection between E and F regions during that time of the day. Conversely, a decoupling of the two regions is deduced from the F region dynamo current features in the dusk sector. On the other hand, we found a close relation between the F region current strength in that sector with the vertical plasma drift velocity during the pre-reversal enhancement (PRE). This result suggests that the size of the PRE, which plays an important role for post-sunset ionospheric instabilities, is controlled by a wind-driven dynamo. In particular, this coupling process between neutral particles and plasma calls for further detailed investigations.

ESA’s upcoming constellation mission Swarm, consisting of 3 CHAMP-like spacecraft, is well-equipped to advance the studies of ionosphere-thermosphere coupling. With its instrumentation package involving accelerometer, ion driftmeter and magnetometers it will record the ion and neutral dynamics simultaneously. The foreseen orbit configuration of the constellation enables the employment of spatial gradients in the data interpretation. The launch of Swarm is scheduled for July 2012.

Acknowledgements The CHAMP mission was sponsored by the Space Agency of the German Aerospace Center (DLR) through funds of the Federal Ministry of Economics and Technology, following a decision of the German Federal Parliament (grant code 50EE0944). The data retrieval and operation of the CHAMP satellite was performed by the German Space Operations Center (GSOC).
